## Abstract

Mass Transport of Condensed Species in Aerodynamic Fallout Glass from a Near-Surface Nuclear Test

by

David Gabriel Weisz

Doctor of Philosophy in Engineering – Nuclear Engineering

University of California, Berkeley

Professor Karl van Bibber, Chair

In a near-surface nuclear explosion, vaporized device materials are incorporated into molten soil and other carrier materials, forming glassy fallout upon quenching. Mechanisms by which device materials mix with carrier materials have been proposed, however, the specific mechanisms and physical conditions by which soil and other carrier materials interact in the fireball, as well as the subsequent incorporation of device materials with carrier materials, are not well constrained. A surface deposition layer was observed preserved at interfaces where two aerodynamic fallout glasses agglomerated and fused. Eleven such boundaries were studied using spatially resolved analyses to better understand the vaporization and condensation behavior of species in the fireball. Using nano-scale secondary ion mass spectrometry (NanoSIMS), we identified higher concentrations of uranium from the device in 7 of the interface layers, as well as isotopic enrichment ( $>75\%$   $^{235}\text{U}$ ) in 9 of the interface layers. Major element analysis of the interfaces revealed the deposition layer to be chemically enriched in Fe-, Ca- and Na-bearing species and depleted in Ti- and Al-bearing species. The concentration profiles of the enriched species at the interface are characteristic of diffusion. Three of the uranium concentration profiles were fit with a modified Gaussian function, representative of 1-D diffusion from a planar source, to determine time and temperature parameters of mass transport. By using a historical model of fireball temperature to simulate the cooling rate at the interface, the temperature of deposition was estimated to be  $\sim 2200$  K, with  $1\sigma$  uncertainties in excess of 140 K. The presence of Na-species in the layers at this estimated temperature of deposition is indicative of an oxygen rich fireball. The notable depletion of Al-species, a refractory oxide that is highly abundant in the soil, together with the enrichment of Ca-, Fe-, and  $^{235}\text{U}$ -species, suggests an anthropogenic source of the enriched species, together with a continuous chemical fractionation process as these species condensed.

This dissertation is dedicated to the memory of Dr. Ian D. Hutcheon and of Professor Stanley G. Prussin

Their passion and knowledge truly set the bar for scientific excellence. Their friendship and mentorship will be deeply missed.

## Acknowledgments

First I would like to thank my late advisors Stanley Prussin and Ian Hutcheon. Both pillars of their respective fields, Stan and Ian were like minded in their idealism for the scientific process – they taught me that no work is worth doing unless done properly. Even in the face of grave illness, they remained dedicated to their work and their students to the very end. I will be forever grateful for their mentorship.

I would next like to thank my current technical advisor, Kim Knight. Despite her already enormous work load, she took on the responsibilities of advising me. She held me to the same standards that Stan and Ian would have expected, and I am sure they would have immense pride seeing her fill this role. I would also like to thank my current academic advisor, Karl van Bibber, for his support through this process; his encouragement during a time of uncertainty was integral to the completion of this work. I would like to thank my other committee members Rick Norman and Michael Nacht for their time and insight.

Without the numerous collaborators at Lawrence Livermore National Laboratory, this work would have been impossible. Rick Ryerson provided critical guidance in both the planning and execution of diffusion couple experiments. Brett Isselhardt spent hours editing this dissertation and still more hours sitting through meetings and discussion regarding this work. Ben Jacobsen spent months helping me put this work in publishable form, and came in on weekends to help me collect NanoSIMS data. Naomi Marks endured much harassment showing me how to operate the EPMA. Jenny Matzel and Peter Weber provided technical guidance and discussion, particularly regarding the NanoSIMS. Christy and Erick Ramon, Gary Eppich, Josh Wimpenny, and many others in the Nuclear and Chemical Sciences group at LLNL, provided invaluable support.

The other members of Stan's research group – Laurence Lewis, Patricia Shuster, Eva Uribe, Araina Hansen, and Brian Quiter – dedicated much time and effort helping me get through this process during our weekly group meetings. My officemates at LLNL Marc Fitzgerald and Laurence both entertained endless, and oftentimes questionable, discussion regarding this work.

Lastly, I would not be here without the support of my friends and family. I would like to thank my parents and my brother, who encouraged my scientific curiosity from the beginning. I also thank my children, Aria and Aiden, for being my very favorite diversions. Most of all, I would like to thank my loving wife Jess, whose support over the years it took to get to this point is so appreciated.

# Chapter 1

## Introduction

### 1.1 Studying glassy fallout debris to understand post-detonation fallout formation

The hazardous effects of nuclear weapons have been apparent since the Trinity test in 1945, which marked the beginning of the Atomic Era. The immediate destructive effects of a nuclear explosion manifest as a shockwave, thermal radiation, and nuclear radiation in the form of gamma rays and neutrons [1]. In addition to these initial effects, the production of radioactive fallout is of critical concern to the exposed population and emergency response personnel, and further forms a record for post-detonation nuclear forensics [2]. In the intervening decades, the arms race between the United States and the Soviet Union resulted in the development and testing of sophisticated weapon designs and delivery systems, as well as the proliferation of nuclear weapons technology to countries around the world. Today, the threat posed by nuclear weapons still exists, whether it is an exchange between potential regional rivals [3], or a smuggled nuclear device by non-state actors into a major city [4].

Radioactivity in a post-detonation environment is primarily a result of the short-lived products from the fissioning of nuclear fuel (usually as either  $^{235}\text{U}$  or  $^{239}\text{Pu}$ ), although neutron activation products also have an effect [1]. Many of these products, which are in the vapor phase immediately post-detonation, can incorporate into carriers, such as water, molten soil, or other nearby materials, forming fallout which is then dispersed based on size and local weather conditions. For example, when a nuclear bomb is detonated in a near-surface explosion, materials from structures and nearby surfaces (environmental debris) are swept up into the ensuing fireball and can interact with vaporized device material. As the fireball rises, the entrained environmental debris, can melt, incorporate bomb debris, then quench, producing micron- to mm and greater sized fallout glasses of various morphologies [1, 5, 6]. Fallout glass morphologies depend on the emplacement of the device and the local geology. For example, in near-surface shots in silicate soil, observed fallout objects included large irregular objects of partially melted soil (mm-scale and larger) as well as smaller, spherical glassy objects (sub-mm to mm-scale). Higher radioactivity associated with the glassy regions

(rather than unmelted regions) indicates that radionuclides must have mixed into molten carrier material, which then quenched quickly, without significant recrystallization [7, 8, 9]. Aerodynamic glass objects consisting of multiple agglomerated spheroidal glasses have been observed in numerous near-surface testing environments [7]. These objects, which formed in the fireball and quenched prior to hitting the ground, would have had the highest probability of interaction and incorporation of vaporized device material.

Fallout has been a subject of study over several decades to understand how radionuclides are incorporated into fallout, and determine how radionuclides would be distributed over a geographic area following a nuclear event [6, 10, 11, 12]. Understanding how radionuclides are distributed around ground zero is essential to public safety and strategic deployment of emergency personnel in the event of a nuclear detonation [2]. As the dose-rate to emergency personnel dictates where and for how long they can be deployed following a nuclear explosion, predictive dispersion modeling coupled with real-time radiation measurements is necessary to determine the radiation field. Further, predictive dispersion modeling is used to dictate the potential evacuation of down-wind population centers [13].

To determine the hazard from fallout in terms of radiation dose, dispersion codes [14] incorporate historical fallout formation models explaining the variation in chemical behavior of radionuclides observed in fallout from aboveground tests [15, 16]. Such types of codes are currently in use by the Interagency Modeling and Atmospheric Assessment Center (IMAAC) to model nuclear incidents (*e.g.*, the detonation of an improvised nuclear device) [17]. While models for how radionuclides interact with carrier materials differ, there is consensus that fission products, unfissioned actinides, and vaporized inert materials are incorporated into molten carriers via some combination of condensation, convective mixing, and agglomeration [15, 18, 19] (Figure 1.1). These models capture a general picture of fallout formation, but the processes controlling how environmental debris and device material interact in the vapor phase and combine with carrier materials remain relatively unexplored. The physical and chemical processes through which device material and environmental debris interact to form fallout glass are not well constrained, yet are essential for advancing the understanding of chemistry of fallout formation. Because of these issues, if a nuclear explosion were to occur in an urban environment, fallout formation models used to inform dispersion models may be inaccurate, as these models are based on observations from above ground nuclear testing in non-urban environments [15, 16]. It is possible that the tons of structural material incorporated into the fireball would interact with vaporized fission products and device materials in ways not observed in previous testing environments, which would subsequently affect the resultant prediction of fallout formation and dispersion. Any inaccuracies in the predicted radiation hazard may hamper the efforts of emergency responders, and further endanger lives in an already chaotic environment.

Understanding how device materials incorporate into fallout is also integral to post-detonation nuclear forensic analysis, as these materials preserve a record of device signatures that have been altered by the physical and chemical processes of fallout formation [20]. The setting in which a detonation occurs, such as height of burst and geology, can have an effect on the interdependent processes that control how device materials interact with the environ-

ment, and are subsequently interpreted. In the event of a nuclear detonation by an unknown perpetrator in a metropolitan area, decision makers handling post-event response will require answers expeditiously. Interpreting signatures for the purposes of attribution after they have been altered in a nuclear explosion is complicated and time consuming [2], and is reliant on an understanding of the chemical processes (*e.g.*, fractionation) that occurred post-detonation [20]. Inaccurate assumptions regarding chemistry in the fireball could potentially muddle or delay the attribution process. However, by studying the chemical variation observed in fallout glasses, we can gain critical insight into fallout formation chemistry, which can better inform these types of nuclear forensic analyses particularly if faced with nuclear explosions in untested environments.

Historically, chemical distributions of actinides were explored via autoradiography, a technique used to spatially determine the distribution of gamma and beta-emitters in samples characterized shortly after formation. The autoradiographs revealed patterns of radionuclide incorporation which were used to develop fallout formation models [15, 16]. For example, studies commonly reported a relative increase in the radionuclide activity at the surface of fallout objects, which suggested a fractionation sequence based on condensation temperature, wherein more refractory (higher vaporization temperature) species condensed early, while the more volatile species condensed later, at cooler fireball temperatures [6, 12]. Autoradiography, however, cannot determine the identity of these radionuclides, and the spatial resolution of this technique is typically limited to 10's of microns.

While many of the high activity species observed in these original studies have decayed away in the intervening decades, historical fallout still retains a record of the chemical interactions that control fallout formation. These interactions can be revealed through the study of unfissioned actinides as well as major element compositional variation, including investigation of surface layers preserved in fallout today. By using modern, spatially resolved analytical techniques (*e.g.*, nano-scale secondary ion mass spectrometry (NanoSIMS)), the species, such as residual actinides, that are preserved in these surface layers of glassy fallout can be observed, and subsequently interpreted through the lens of historical fallout formation models (as shown in Lewis et al. (2015)).

In this study, it is observed for the first time that a surface deposition layer is preserved at the interfaces between fused molten objects, where vaporized species deposited on the surface of either object prior to collision and quenching. This thesis investigates the interfaces of agglomerated glassy fallout objects from a near-surface, uranium-fueled test, in order to test formation models and further investigate the chemical processes that control the incorporation of device materials into glassy fallout objects. A combination of qualitative (scanning electron microscopy), semi-quantitative (energy dispersive X-ray spectroscopy), and quantitative analytical techniques (electron probe microanalysis and NanoSIMS) is used to characterize the compositional variation of major elements and uranium isotopes at these interfaces. Preserved interfaces in agglomerated fallout glasses appear to retain a record of the interaction of device material and environmental debris as a distinctive chemical layer that was originally deposited on the surface of fallout objects prior to agglomeration. Additionally, a record of diffusive mass transport from these interfaces into the agglomerated

objects is preserved as distinct concentration profiles. Here, these observations are used to estimate thermal and temporal conditions applying a model of one-dimensional planar diffusion and yield-dependent fireball cooling curves. This thesis uses the unique relationships at agglomerate interfaces to characterize the vapor component in the fireball, interpret how key chemical species interacted with molten environmental debris to form fallout glasses, and deduce the time and temperature conditions over which these species diffuse into agglomerated objects.

Figure 1.1: This diagram illustrates the interaction of the fireball with environmental debris and the subsequent condensation process onto carrier materials. According to the Miller model [15], refractory species will distribute volumetrically in molten carriers, while more volatile species will accumulate on the surface of already frozen carriers. In this study, it is hypothesized that a deposition layer on the surface of molten carriers agglomerated onto larger host objects prior to quenching is preserved at the interface of where the objects fused together. This interface is the main object of study for this thesis.

## 1.2 Historical Models of Fallout Formation

In order to understand how fallout forms and how fission products and device material incorporate into fallout, it is necessary to understand the progression of a nuclear explosion to the subsequent fireball of bomb vapor that is produced, and then cools. When a nuclear weapon detonates, the initial energies produce temperatures on order  $10^7$  K, vaporizing the device. At approximately 1 microsecond, these materials radiate heat as soft X-rays (a few eV), which are absorbed by the surrounding air [1]. The volume of air that absorbs this energy is highly dependent on yield and initial temperature conditions (Figure 1.2) [21]. As this parcel increases in temperature, it becomes increasingly transparent to the emitted radiation, while the cooler air surrounding it is opaque. The hot air reradiates in the visible spectrum, leading to the rapid, isotropic heating of the surrounding air, resulting in a luminous fireball [22]. The fireball rapidly expands within a millisecond, leading to an adiabatic decrease in average temperature of the fireball. The fireball, which is much less dense than the surrounding air, quickly rises, and continues to expand and cool as it incorporates more air [1, 21].

In the case of an air-burst, where the fireball does not interact with the ground, macroscale fallout is not formed. This is because in the absence of carrier materials, fallout is formed as micron-scale (and smaller) condensates, which distribute over thousands of kilometers [1]. In contrast, in a near-surface nuclear explosion, environmental material and debris from structures may be incorporated into the fireball, the extent of which is controlled by the yield and height of burst. The reflection of the blast wave and rising fireball off the surface of the earth brings soil or structural materials into the fireball, which can melt and/or vaporize depending on the fireball temperature. For example, in a surface-burst, it is estimated that approximately 5000 tons of soil are displaced per kiloton of yield, about 25 tons are vaporized [23]. As vaporized materials in the fireball cool, they may condense onto the surface of molten carrier materials – about 200 tons of soil are melted per kiloton of yield in a surface-burst. When the molten materials mixed with the bomb vapor quench (either when the fireball is cool enough, or if they are ballistically ejected from the fireball), they encapsulate the incorporated fission products and/or other vaporized device and environmental materials, that condensed onto carrier surfaces and diffused or otherwise mixed into these molten precursors. The materials that fall to the surface over the first 24 hours are known as 'local' fallout, and can range in size from a few microns to a few cm, distributing geographically based on size [24, 25].

Analyses of fallout and melt products, and theories on fallout glass formation, first emerged following the detonation of the Trinity device. In 1948, Ross made observations of the glass, known as trinitite, that formed as a result of that test. While his analysis was limited to the optical properties of the glass, he inferred details about formation temperature (much greater than  $1470$  °C), as well as the potential addition of anthropogenic copper to the glass while molten [5]. This information, along with the geographic spread of radioactivity following detonation, provided the first evidence of the extent to which device materials and radioactive fission products interacted with, and dispersed through, the environment

Figure 1.2: The required size of a spherical parcel of air that would be necessary to absorb the amount of X-ray energy initially produced from the given yield for a range of initial temperature conditions (adapted from [21])

post-detonation.

One of the first mathematical approaches to the formation of fallout, published in 1956 by Stewart, described the mechanisms of condensation and coagulation [26]. In this model, the nucleation of condensates formed from the cooling vapor depends on the saturation vapor pressure of metal or metal-oxide species in the fireball, as well as the potential cooling rate and thermal variation within the fireball. These calculations provide a prediction of the size distribution of particles expected to result from either a near-surface explosion or an air-burst. The model is also based, in part, on empirical observations of fireball temperature and estimates of vaporization of materials in the fireball (*i.e.*,  $\sim 100$  tons of  $\text{SiO}_2$  for a surface burst). The study predicts an average particle size of less than 1 micron assuming a pure condensation process, but acknowledges that non-vaporized materials could effect the particle size distribution, and that more information is required to derive a comprehensive formation model. This information was acquired in a series of subsequent studies, including determination of the particle size distribution [27], spatial distribution of radionuclides within individual fallout objects [10], and the gross radioactivity of fallout objects [28, 29].

The environment and height of burst of the detonation have an effect on key parameters of fallout formation models, including the size distribution, the degree of chemical fractionation, and morphology of the subsequent fallout [27]. As reported by Heft, surface-bursts and sub-surface bursts (Figure 1.3A) produce glassy particles in sizes ranging from tens to thousands

of microns. In the Heft study, chemical fractionation of radionuclides in these particles is approximated as a linear relationship between the ratio of a given radionuclide to refractory species, and the ratio of specified volatile and refractory species. Fallout formation in tower shots displays a similar pattern of fractionation to surface bursts, but also includes metallic spheres up to a few hundred microns in diameter, presumably the result of molten tower components. Air bursts are observed to produce metal oxide particles from the sub-micron size up to 20 microns in diameter. The Heft study thus categorized fallout into two broad particle populations: one that is comprised of environmental debris that was melted (or partially melted), and another that is comprised of metal oxide spheres that formed from a condensation and/or agglomeration process. The observation of sub-micron particle sizes from air-bursts is in line with the Stewart model of condensation ( $\sim 1$  micron) [26]; however, the largest particles ( $>10$  microns) are not explainable by that model, and were asserted to be a result of the agglomeration of material that was not completely vaporized.

Further studies exploring fallout found that different types of particulates had different radionuclide compositions [28, 29]. Fallout from a high-yield test in the Eniwetok Proving Grounds was characterized by two classes of environmental debris-based fallout: the 'altered' fallout, which comprised partially or wholly melted coral particulates, or 'unaltered' particulates [28]. The primary difference in the associated radionuclide composition was that the 'altered' particles were measured to have 100-fold higher fissions/g than the 'unaltered' particles, and appeared to be depleted in the more volatile radionuclides. This observation suggests that these volatile species may have condensed at later times late, thus the 'altered' molten particles incorporated disproportionately more of the less volatile radionuclides. This finding was not observed in the Small Boy test, however, a lower-yield near-surface test, where these two sample populations showed comparable radionuclide fractionation patterns [29]. In that event, the spheroidal, or 'altered', particles were shown to have higher specific activities. In Figure 1.3B for example, a fallout object from an unidentified moderate yield, near-surface shot with a silicate glass core is shown, with an exterior layer having high radioactivity [12]. The surface is coated with iron oxide-rich glass which, with the activity distribution, is consistent with a condensed layer incorporating into the interior of the object via diffusive mass transport.

Another study from an unidentified test in the Eniwetok Proving Grounds characterized three types of fallout, with varying amounts of tower material and environmental material [10, 12]. The composition of the first type of fallout was a combination of calcium carbonate, calcium hydroxide, and iron oxide. In this fallout, radioactivity is primarily associated with iron oxide rich regions, as observed by autoradiography, and was thought to have resulted from vapor phase condensation of fission products and tower components. The second type of fallout was characterized as sub-mm black spheroids of mixed iron oxides, that were homogeneous in their radioactivity distributions. The third type of fallout from this test was found in the form of unaltered coral grains that had approximately 10 micron radioactive black spheroids fused to the surface. These black spheroids are interpreted to be the result of vapor condensation of fission products that collided with other vapor condensed particles, such as the iron support structure. While the observed chemistry in fallout from various

testing environments differed, the empirically derived size and activity relationships from these studies form the basis for general fallout formation codes that are relied upon today [14].

Figure 1.3: (A) A graph of the size distribution of fallout from an unidentified test. The 'early cloud' peak indicates the fallout size distribution from air filter samples collected early in the cloud, while the 'local fallout' peak indicates the size distribution from glassy samples collected proximate to ground zero (adapted from [27]). (B) Thin section and autoradiograph (left and right, respectively) from a tower shot at the Nevada Test Site [12]. The activity is seen deposited around the outside of the fallout object, and appears to have mixed inward.

Fallout formation and distribution models by Miller [15], Freiling [30], and Norman [31] were developed using observations from nuclear testing, and were based on both physico-chemical principles and empirical relationships determined from tests. These models explored how fallout formed in a wide range of environments, including details such as how the local geology, height of burst, incorporation of structures (*e.g.*, support tower), and yield, affects the formation of fallout and the resultant distribution of fission products (and other radionuclides).

In the 1960's, a more comprehensive set of models of fallout formation were published by Miller, for the first time combining both condensation theory and empirical relationships of fireball parameters derived from nuclear testing [7, 12, 15, 32]. Miller's models, specified for near-surface explosions, provide a mathematical treatment to fractionation, condensation thermodynamics, and the effect of carrier size. One key component of his model involves the invocation of a two-stage condensation sequence. In the first stage, refractory materials condense onto the surface of liquid-state carrier materials. Some of these larger carriers fall out of the fireball early, proximate to ground zero, and contain comparatively little in the way of volatile radioisotopes. During the second stage, after the fireball has cooled, the more volatile species condense onto the surfaces of particles that have quenched (Figure 1.1A). Some of these particles constitute 'global' fallout, or fallout particulates that travel thousands of kilometers away from ground zero.

At its root, the Miller model bases fractionation of vaporized species in the fireball on their vapor pressures, as determined by Raoult's law (1),

$$P_{v1} = N_1 P \quad (1.1)$$

where  $P_{v1}$  is the vapor pressure of the species of interest,  $N_1$  is the mole fraction in the vapor phase, and  $P$  is total pressure of the vapor. This model also makes use of empirical scaling equations (2) and (3), as determined by fireball light output,

$$W = 0.65 \rho_0 (2R)^5 / t^2 \quad (1.2)$$

$$H = 3.75 W^{0.51} t_*^{-1.45} e^{-9e^{-2.73t_*}} e^{-93-12Wt_*} \quad (1.3)$$

where  $W$  is total weapon yield in kt,  $H$  is the power output (kilotons/second),  $\rho_0$  is the air density,  $R$  is the radius of the main shock front, and  $t_*$  is the ratio of time to the time of the final maximum (based on light output).

Freiling expanded upon the approach of Miller [16, 18, 30, 33], incorporating physical principles such as gas-phase diffusion of species in the fireball, condensation onto carriers, diffusion within carriers, as well as re-evaporation of deposited species into a model based on fluid dynamics and equilibrium thermodynamics (Figure 1.4A). In Freiling's model, the incorporation of radionuclides is ruled by the continuous, temperature-dependent competition between each of these processes as given by

$$J_n = J_v \times \alpha_c - J_c \times \alpha_e \quad (1.4)$$

where  $J_n$  is the total inward flux of a given radionuclide,  $J_v$  is the flux from condensation of a vaporized radionuclide species,  $\alpha_c$  is the probability that a vapor-phase radionuclide sticks to the surface,  $J_c$  is the flux of a radionuclide species within a molten carrier, and  $\alpha_e$  is the probability that a radionuclide species within a molten carrier escapes back into the vapor phase.

The notable addition of diffusion and re-evaporation of species is of particular interest, as this formulation addresses the competition between the amount of radionuclide addition versus radionuclide loss in carriers. Furthermore, the effect of heat transfer in a cooling fireball affects the rate of diffusion, which is based on the Arrhenius relationship

$$D = D_0 e^{-E_a/RT} \quad (1.5)$$

where  $D$  is the diffusivity of the species of interest,  $D_0$  is the pre-exponential constant,  $E_a$  is the activation energy of diffusion,  $R$  is the gas constant, and  $T$  is the instant temperature. This was taken into account in Freiling's model by integrating over the change of temperature over time [16].

Another early publication [31] disputed the model presented by Miller, particularly what was perceived as a simplification of the condensation and diffusion processes as a "go/no-go"

model of two stages based on the physical state of the carrier material. This study, by Norman and Winchell, instead proposed a continuous condensation/diffusion process that occurs throughout a carrier's residence time in the fireball, even below the freezing temperature of the carrier material – in this particular study, a silicate. While acknowledging the effect the changing temperature has on diffusivity, this study presented the diffusivity of radionuclides of interest at 1450 °C in a molten silicate, characterizing radioantimony as a function of SiO<sub>2</sub> content. Most pertinent to this thesis, concentration gradients measured by electron probe microanalysis were characteristic of diffusion of Pb and Fe from the surface to interior of a fallout object, supporting a model of condensation, diffusion, and thermodynamic radionuclide absorption onto the surfaces of fallout objects (Figure 1.4B).

After above-ground testing effectively ended in 1963 with the Limited Test Ban Treaty [1], computational models became a primary resource for understanding fallout aerial distribution and dispersion. By the 1970's, the study of fallout formation became dominated by the development of computational fallout dispersion models. For example, the details from earlier formation models were used in the development of a computational model known as the Defense Land Fallout Interpretive Code (DELFIIC). The DELFIIC model [14] incorporates variables of atmospheric conditions, particulate diffusion through a gaseous medium, fireball evolution, activity distribution in particles, assumptions of the chemical properties of entrained materials, and the height of burst to predict the aerial distribution of fallout and radioactivity after a nuclear explosion. Of interest to fallout formation, DELFIIC uses a generalized version of the model Freiling established for activity incorporation for different particle-size distributions [14, 34, 35]. More specifically, the DELFIIC model calculates the activity distribution in fallout based on the size of the particle (the volume of fission products potentially incorporated), the volatility of species in a fission mass chain (assuming oxide form), and the particle-size distribution.

Today, there are several well-known particle dispersion and distribution models in addition to DELFIIC, including the Hazard Prediction and Assessment Capability (HPAC) [36, 37] and the Hybrid Single-Particle Lagrangian Integrated Trajectory Model (HYSPLIT) [38, 39, 40]. The HPAC model, developed by the Defense Threat Reduction Agency, is a dispersion and plume model for weapons of mass destruction, including but not limited to nuclear explosions and radiological releases [36, 37]. HYSPLIT is a plume and deposition model for a general pollutant or dispersant [38]. Given the broader application of these two models (*e.g.*, chemical and biological agent dispersion), neither HPAC nor HYSPLIT directly account for incorporation of radionuclides into a liquid phase carrier.

In all of these models, which combine mathematical treatments with empirical relations derived from test data, the understanding of how radionuclides and residual actinides incorporate into carrier materials is largely based on empirical relationships derived from a few early atmospheric tests. Further, the physicochemical parameters that are incorporated into computational models utilize experimentally derived chemical properties of materials (*i.e.*, the vaporization properties of radionuclides and carrier materials which control fractionation [34, 14]), which may be carrier-material dependent and/or dramatically variable in different fireball conditions. Two parameters that are not adequately addressed in fallout formation

models, but are critical to understanding formation chemistry, are 1) condensation sequence and speciation of vaporized species and 2) the mechanism of mixing of species into carrier materials after condensation. More specifically, the presence of oxidizing or reducing environments may affect the speciation of vaporizing or condensing materials [41], which affects temperature-dependent fractionation. Finally, the rate at which material volumetrically incorporates into molten hosts will affect the rate of re-evaporation of condensed species, which is essential for determining the amounts of various species present in molten hosts. The rate of bomb vapor incorporation into molten carrier material is controlled by diffusion and mechanical mixing, is dictated by the diffusivity of species in the molten carriers as well as the viscosity of the molten carrier materials, both of which are temperature dependent [11, 42]. Clearly, further study is required to address these parameters to establish a more comprehensive model of fallout formation.

Figure 1.4: (A) The effect of condensation, diffusion within the carrier, and re-evaporation from the carrier given in Equation 1.4 (derived from [18]). (b) Concentration profiles in fallout from the Norman and Winchell study (after Figure 18 in [31]), illustrating the diffusion behavior of Pb (top line) and Fe (bottom line).

### 1.3 Contemporary Fallout Research

Over the past decade, there has been renewed interest in fallout research. In contrast to Cold War era research focused on the distribution and dispersion of radioactive fallout particulates, these studies are typically motivated by renewed interest in interpreting details and signatures of a device having a potentially unknown origin [43, 44, 45, 46]. For example, a study of trinitite (fallout formed in the Trinity explosion) published in 2006 measured several activation products and fission products via gamma spectroscopy in the glass, from which device characteristics were hypothesized [43]. These studies show copper and iron inclusions, as well as variable lead isotopic compositions, which the authors suggest are indicative of device components, such as wiring and the tamper [44, 45]. Such studies have motivated further interest in improving the understanding of mixing relationships between device materials and soil using modern analytical techniques including scanning electron microscopy, X-ray spectroscopy, mass spectrometry [47, 48, 49, 50, 51, 52, 53].

Several recent studies of trinitite have focused on formation, specifically in terms of how the device material mixed with local soil [46, 51, 50]. One model of trinitite glass formation was put forth by Belloni, based on gamma spectroscopy and autoradiography. This model suggested that as the fireball cooled, vaporized sand, fission products, activation products, and non-fissioned actinides mixed together and coalesced, into droplets. These droplets then rained down onto the molten surface of sand on the ground, forming the observed high-activity top layer. This model states that still more sand was incorporated into the fireball due to the subsequent vacuum and afterwinds, followed by the instantaneous freezing of entrained material at approximately 10 seconds after the explosion was initiated, as cold air infiltrated the fireball [46], thus increasing the inventory of trinitite. However, this accounting of the formation of trinitite contradicts early formation theories put forth by Stewart and Heft, where primary condensates either deposit on the surface of entrained molten soil, or disperse as 'global' fallout [12, 26, 27], and would instead explain trinitite formation wholly by the gravitational settling of entrained soil onto a molten layer of soil on the ground.

Other work, using autoradiography, electron probe microanalysis (EPMA) and laser ablation inductively-coupled plasma mass spectrometry (LA-ICP-MS), identify the distribution of actinides, major elements, and trace elements in trinitite to deduce how the device material mixed with soil [50, 51]. Through such analyses, a series of correlations between soil-based and anthropogenic species were established using bivariate plots and three-isotope plots of analyzed species, as well as multivariate statistical techniques [50, 51], to explain the incorporation of device materials into molten soil. For example, one study used a series of bivariate plots of major element oxides against FeO to differentiate minerals found at the Trinity test site from potential anthropogenic species, and Principal Component Analysis (PCA) including trace elements and actinides to make determinations of alleged anthropogenic end-members (*i.e.*, device associated materials) [51]. However, the model proposed in that study is based on condensation temperatures derived from a solar system composition gas condensation process [41], which is markedly different than the environment of a nuclear fireball, and would have a notable effect on the speciation of condensing materials. While

these studies indicate that device-related material mixed with molten soil, and propose techniques for nuclear forensic analysis, such recent studies do little to address the deficiencies in historical fallout formation models.

Recent work analyzing fallout from other nuclear tests focus on determining formation conditions and how device materials incorporated into glassy fallout [54, 55, 56]. The characterization of stable noble gasses has confirmed that historical fallout preserves a record of the relative volatilities of some fission products, though the distribution was not spatially determined in this study [54]. By looking at the stable xenon isotope ratios preserved in aerodynamic fallout glass, this study was able to estimate the surface closure time of selected fallout samples from a near-surface test, as well as characterize the volatility of the xenon isotope precursors in the fireball as they incorporated into the carrier materials. These parameters suggest a residence time of the characterized fallout in the fireball of <3 seconds, under potentially reducing conditions. These parameters can be used to, in part, address the oxidation state and subsequent speciation of materials interacting with carriers lacking in historical formation models.

In another publication, bulk chemical and isotopic data from a uranium-fueled test were acquired, indicating two-component mixing of unfissioned fuel with molten soil in a population of mm-scale fallout debris [55]. *In situ* secondary ion mass spectrometry (SIMS) analyses of samples from the same test reveal some degree of isotopic enrichment of uranium (residual nuclear fuel) throughout the volume of such fallout glasses [56]. Together, these analyses characterize the degree of heterogeneity observed in actinide distributions between fallout objects and within individual fallout objects (the  $^{235}\text{U}/^{238}\text{U}$  ratio ranges from 0.02 to 11.84 [56]). When interpreted in the context of fallout formation models such as the Miller's, the presence of device uranium in the fallout samples is expected, as refractory materials were theorized to condense first and mix volumetrically into molten carriers. However, the observed heterogeneity in uranium isotopic composition through the samples is indicative of a more complex physicochemical mixing processes between host objects and a vapor phase containing an unfissioned fuel component, and point away from simple fractionation models proposed by historical fallout studies.

Thus, despite new research into glassy fallout formation and signature incorporation, current models still do not adequately describe formation chemistry, particularly the processes of condensation and diffusion that are important to how vaporized species interact with carriers. Further, recent studies focused on constraining fallout formation parameters illustrate that the approaches taken by historical fallout formation models may be oversimplified, and that the parameters that control fractionation, condensation, and incorporation of vaporized species into carrier materials used in fallout dispersion models are still inadequate. By determining the composition of the surfaces of glassy fallout objects, this thesis seeks to reveal key details of chemical fractionation, condensation/deposition, and incorporation, and provide a test of the validity of historical fallout formation models.

## 1.4 Samples

### Sample isolation and selection

To understand the chemical and isotopic variation on the surfaces of fallout objects, agglomerated fallout objects having multiple adhered spherules on the surfaces were selected. It was hypothesized that at the interfaces where glassy objects have fused together, a surface layer would be best preserved and protected from any subsequent effects of weathering or other alteration. In this thesis, observations at the interfaces of agglomerated fallout samples are used to test established formation models, identify short their comings, and suggest alternative formation sequences. Additionally, this study seeks to estimate the time and temperature of mass transport from composition profiles at these interfaces, further constraining fallout formation conditions. In order to explore these interfaces, agglomerated fallout glass samples from a uranium-fueled, near-surface nuclear test were selected, provided from the same anonymous event studied by Eppich et al. (2014) and Lewis et al. (2015) [55, 56].

Figure 1.5: Aerodynamic fallout glass and soil grains. The fallout glass is seen as mm-scale, black, spherical objects.

The Eppich et al. (2014) study characterizes the typical samples from this test to be opaque and greenish-black, with no observable crystallinity and often containing visible vesicles. As seen in Figure 1.5, the aerodynamic fallout glasses from this event are often black, highly symmetric glasses of approximately mm-scale. For this study, aerodynamic fallout glasses from this test were separated by sieve size (down to 0.30 mm mesh size), and were shown to have a range of aerodynamic morphologies. The sizes of these objects range from sub-mm to cm-scale, while the shapes range from nearly perfectly spherical to irregular rounded objects (*e.g.*, Figure 1.6). Five samples of agglomerated fallout glasses from a region close to ground zero were acquired for this study. The samples were specifically chosen for their preservation of secondary objects fused to the host glass surfaces. All samples

were mm-sized, highly symmetric, aerodynamic glassy objects with multiple adhered smaller spheroids.

Figure 1.6: Examples of glassy fallout objects. (A) A larger spheroidal glassy object, approximately 3 mm in diameter. The irregular white line at the center of the object is the reflection of the optical microscope light. (B) A large aerodynamic glassy fallout object having smaller glassy objects agglomerated onto it. (C) A secondary electron image (showing sample topography, explained in detail in Chapter 2) of fallout glass from the smallest sampled sieve size, showing a much smaller (approximately 20 micron) sphere attached to its surface.

## Sample Descriptions

In sample A, tens of secondary objects ranging in size from 5 to 500 microns can be observed fused to the larger host object (Figure 1.7). In the other 4 samples selected for this study, fewer than five secondary objects (100 micron-scale) were observed fused to each larger host sample (Figure 1.8). On sample B, several sub-mm scale spheroidal objects are seen fused to the surface, with the central two also fused to each other. This sample is approximately 0.4 cm long, although it appears to have fractured on both ends. Sample C shows a tapered and curved fallout object with at least 6 secondary objects agglomerated onto the surface. The agglomerated spherules labeled C1 and C2 are adjacent to one another, and the agglomerated object labeled C3 is isolated and more fully incorporated into the larger host object. Sample D shows a larger, oblong host having two spheroidal objects, adjacent to one another, fused to the surface. The two fused peripheral objects are approximately the same size, each between 200 and 300 microns in diameter. Sample E shows an oblong host object having a number of objects agglomerated to its surface. The agglomerated objects where interfaces were studied are labeled E1 and E2, where E1 is largely independent from the rest of the host object, while E2 is fully incorporated into the host and does not appear as an agglomerated object in optical imaging.

A collection of local soil proximate to the test ground zero was also collected to study the likely protolith to the aerodynamic glassy fallout. The soil at this test site was a combination of fine grained sand and small pebbles [55], which were separated by size fraction and picked

Figure 1.7: Optical and secondary electron image of Sample A. (A) Optical image of Sample A, which is an agglomeration of numerous sub-mm-scale spheroids. (B) Secondary electron image of Sample A, coated in iridium, showing the topography of the sample surface.

clean of remnant fallout glass. These soil samples were selected from the size 12 sieve separation (approximately 1.68 mm), and grains were typically between 1 and 2 mm in size. Approximately 50 of these soil grains (of the same size fraction shown in Figure 1.5,  $\sim 1$  mm) were randomly selected and mounted in a 1-inch (2.54 cm) epoxy puck.

Figure 1.8: Optical images of Samples B-E. The top left frame shows sample B, where attached objects B1, B2, and B3 are labeled. Object B2 is fully incorporated into B3, and cannot be seen optically. The top right frame shows sample C, with fused objects C1, C2, and C3 labeled. The bottom left frame shows sample D, with attached objects D1 and D2 labeled. The bottom right frame shows sample E, with attached objects E1 and E2 labeled. Object E2 is fully incorporated into larger sample E, and cannot be distinguished by optical microscopy.

## 1.5 Thesis Outline

All prepared samples were characterized using multiple analytical techniques (as discussed in Chapter 2), including scanning electron microscopy (SEM) and electron probe microanalysis (EPMA) on both fallout and environmental debris samples, and NanoSIMS (nanoscale secondary ion mass spectrometry) on fallout samples.

The following Chapter (2) summarizes all analytical techniques used, including scanning electron microscopy, energy dispersive and wavelength dispersive X-ray spectroscopy, and nano-scale secondary ion mass spectrometry. The summary includes the basic theory behind instrument operation, as well as the conditions and operating parameters used to conduct the

analyses for each instrument. This chapter also includes a description of sample preparation for fallout and soil samples.

In Chapters 3 and 4, the results of the analytical techniques are presented. More specifically, the results of qualitative and semi-quantitative techniques (*i.e.*, scanning electron microscopy, energy dispersive X-ray spectroscopy, and X-ray mapping) are presented in Chapter 3, while the results of quantitative analytical techniques (*i.e.*, wavelength dispersive X-ray spectroscopy and nano-scale secondary ion mass spectrometry) are given in Chapter 4. Also in Chapter 4, the results of the analytical techniques are interpreted in terms of the compositions that are observed at the interfaces, and applied to models of vaporization and condensation processes of device materials and environmental materials in the fireball. In Chapter 5, a model of diffusive mass transport from the deposition layer into glassy fallout is defined and applied to observed profiles of compositional variation in selected fallout samples.

In Chapter 6, the limitations of current literature values used in the diffusive mass transport models are discussed, and preliminary results of diffusion studies conducted in manufactured materials similar to those of the studied fallout glasses are shown. Finally, in Chapter 7, summarized conclusions are given, along with discussion of promising avenues of future research to refine fallout formation modeling in terms of condensation and diffusion incorporation parameters. The full dataset for each analytical technique is provided in the appendices.

## Chapter 2

# Analytical Methods: Theory and Application

To characterize the compositional variation at the interfaces of agglomerated fallout glasses, a series of analytical techniques is applied, including scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDS), electron probe microanalysis (EPMA), and nano-scale secondary ion mass spectrometry (NanoSIMS). Each of these techniques is used to make a unique measurement in the samples: SEM utilized both backscatter and secondary electron modes to qualitatively understand compositional variation, as well as topography of intact samples and polished sample surfaces. EDS and EPMA qualitatively and quantitatively characterized major element compositional variation across sample interfaces, and NanoSIMS was used to characterize uranium isotopic variation across interfaces, in combination with select isotopes of Si, Fe, and Ca. Table 2.1 provides a list of the samples and the analytical techniques applied to each one.

### Sample preparation

In order to apply the above surface characterization techniques, all samples had to be polished flat. To achieve this, individual fallout glasses (and soil grains) were embedded in epoxy mounts, cured, and polished flat through a sequence of polishing grits, until a 1 micron surface roughness was achieved. Selected polished fallout glasses (sample B, C, and D) are shown in Figure 2.1. Polishing reduces the effects of surface topography, which can locally change the penetration depth of an incident beam, and result in image artifacts not representative of the sample composition. As the samples are non-conductive fallout glasses (or soil grains), a 5 nm conductive carbon coating was applied to their surfaces, to reduce the effects of localized charge buildup, which can distort the resultant images.

Table 2.1: Analytical techniques applied to fallout and soil samples

Sample ID	Optical	SEM	EDS	EPMA	NanoSIMS	Diameter (major axis)
A1	x	x	x		x	144 $\mu m$
B1	x	x		x	x	398 $\mu m$
B2		x		x	x	50 $\mu m$
B3	x	x	x	x	x	560 $\mu m$
C1	x	x	x	x	x	142 $\mu m$
C2	x	x	x	x	x	138 $\mu m$
C3	x	x	x	x		90 $\mu m$
D1	x	x	x		x	165 $\mu m$
D2	x	x		x	x	173 $\mu m$
E1	x	x	x	x	x	157 $\mu m$
E2		x	x	x		86 $\mu m$
Soil	x		x			

Figure 2.1: Optical image of polished, flat Samples B, C, and D, with attached objects indicated by yellow arrows. The scale is the same across all images. Large vesicles, ranging in size from  $\sim 10$ - $100$  microns, can be observed in all of these samples.

## 2.1 Scanning Electron Microscopy

### Introduction

Scanning electron microscopy has been used for over 70 years as a technique for micron and sub-micron scale imaging [57, 58]. The basic principle of operation of the scanning electron microscopy relies on the irradiation of a sample surface by a focused electron beam that is rastered over a surface. This irradiation results in electron interactions within the sample,

producing detectable signals in the form of secondary electrons, backscattered electrons, and X-rays, which can be detected, and used to characterize sample topography and composition [58].

For this study, an FEI Inspect-F Scanning Electron Microscope was used to acquire secondary-electron images (SE) and backscatter electron (BSE) images. SE images were acquired to observe topographical features on the intact sample prior to polishing, while BSE images were used to characterize the compositional variations in all the fallout samples and interfaces. The mineral compositions and characteristic heterogeneity of the local soil was also characterized through BSE imaging of polished grain mounts.

Figure 2.2: General schematic of a FEI Inspect-F SEM, the scanning electron microscope setup used for the analyses in this study, including secondary electron detector, backscatter electron detector, and energy dispersive X-ray detector.

## The Scanning Electron Microscope

A basic schematic of a scanning electron microscopy is given in Figure 2.2. The incident electron beam source, or the electron gun, is used to generate electrons and is typically thermionically emitted from a tungsten filament [57]. For the SEM used in this study, electrons are generating using a field emission gun. In this type of electron source, a high voltage is applied to the tip of a tungsten needle approximately 100 nm in diameter. This produces a field in excess of 10 V/nm, lowering the potential barrier for electron emission. The advantage of a field emission source is that it increases electron emission (up to 1000× compared to conventional tungsten filaments) and decreases energy spread of emitted electrons, which improves resolution. However, this source requires high vacuum to prevent gas deposition at the tip, which would detrimentally affect electron emission [58]. The potential difference between the source and the anode determines both the field strength for electron emission as well as the accelerating voltage of the electrons to the sample. The accelerating voltage applied in these analyses were 5 kV and 15 kV for SE and BSE images, respectively.

The initial electron beam exiting the anode is defocused. In the case of a field emission source, a demagnification of over 100x is required to produce a small probe size (approximately 1 nm) (*ibid.*). In order to produce a small probe size, a series of electromagnetic lenses is necessary to focus the incident beam. These lenses, known as condensing lenses, are made of iron cylinders filled with wire windings, that focus the beam as determined geometrically by

$$m = p/q \tag{2.1}$$

where  $m$  is demagnification,  $p$  is the distance to the lens midpoint from the source, and  $q$  is the distance from the lens midpoint to the image (*ibid.*).

Scanning coils raster the beam across the sample surface via the Lorentz force. The beam is moved sequentially across the sample in two dimensions as the current in the scanning coils changes continuously over time. The beam location (*i.e.*, the current in the coils) corresponds to a specific location on the sample, so the detected signal emitted by the sample (*i.e.*, backscatter electrons, secondary electrons, or X-rays) after the beam interacts can be displayed digitally as either an electron micrograph or a compositional X-ray map (further described below).

## Secondary Electron Detection

Secondary electrons originate in the sample itself, as outer shell electrons with low binding energy. Electrons from the incident beam that inelastically scatter in the sample strip these outer shell electrons as they travel into the sample. The probability of escape decreases exponentially with depth

$$p \approx e^{-z/\lambda} \tag{2.2}$$

where  $z$  is depth into the sample,  $\lambda$  is the mean free path [58]. Due to their very low energies, only electrons at the very surface (a depth of  $<10$  nm) will be emitted. More than 90% of emitted secondary electrons have energies less than 10 eV. This makes SE detection ideal for surface characterization, as illustrated in Figure 2.3. In this image, variation in surface topography for intact sample A is illustrated.

Figure 2.3: Example of a SE micrograph, shown for sample A. This image shows micron-scale topographical features that are difficult to resolve with optical microscopy.

The most common type of secondary electron detector, the Everhart-Thornley detector (used in this study), comprises a scintillator and a Faraday cage having a low positive voltage. This low voltage attracts the low energy secondary electrons emitted from the surface of the sample, liberated by the incident beam, while backscatter electrons are virtually unaffected [59]. The only backscatter electrons that are detected are those that impinge directly onto the detector, thus, the secondary electron detector is situated away from regions of high backscatter emission to minimize this effect.

## Backscatter Electron Detection

When the electron beam interacts with the sample, the incident electrons also elastically scatter in the sample. These electrons have a probability of leaving the sample after multiple scattering events; the electrons that escape the sample are known as backscattered electrons. This process is dependent on atomic number and electron energy by

$$Q = 1.62 \times 10^{-20} (Z^2/E^2) \cot^2(\phi_0/2) \quad (2.3)$$

where  $Q$  is the cross-section of elastic scattering above the threshold angle for backscatter ( $\phi_0$ ),  $Z$  is the atomic number of the sample atom, and  $E$  is the incident electron energy [58]. The dependence of the probability of backscatter on sample atomic number allows for relative compositional variations (based on average  $Z$ ) to be characterized through changes in the relative intensity of backscatter electrons detected. This is exemplified in Figure 2.4, which is a BSE micrograph of object D2. In this image, the brightness corresponds to BSE electron density, which is in turn related to average atomic number, as dictated by equation 2.2.

For BSE imaging, samples were prepared by polishing flat, and coated with conductive carbon. As the backscatter electrons can be emitted from depths of up to 1 micron from the sample surface, the samples were prepared by polishing flat to 1-micron surface roughness.

Figure 2.4: Example of a BSE micrograph, shown for object D2, illustrating composition as contrast variation, with brighter areas corresponding to higher average atomic number.

Backscatter electrons are emitted by the sample in a distribution approximately following the form of

$$\eta(\phi) = \eta_n \cos(\phi) \quad (2.4)$$

where  $\eta$  is the fraction of electrons emitted at angle  $\phi$  from the sample, and  $\eta_n$  is the number of backscatter electrons emitted back towards the incident beam [57]. Because of this emission distribution, the backscatter electron detector is a ring-shaped, solid-state silicon diode situated above the sample (and around the incident beam).

## Energy Dispersive X-ray Spectroscopy

As the incident beam interacts with the sample material, electrons can be inelastically scattered by an inner shell electron in a sample atom. This process ejects inner shell electrons or excite them into a higher energy level, leaving the atom in an excited state. The hole in the inner shell is rapidly filled by de-excitation of an electron in a higher energy level into the lower energy level, along with the release of energy in the form of a characteristic X-ray, as illustrated in Figure 2.5. The energy release of these X-rays is based on the starting energy level of the electron that is moving into the hole, as well as the energy level of the inner shell where the hole is. The emitted photon energy  $E$  is given by

$$E = RZ^2 \left( \frac{1}{n_l^2} - \frac{1}{n_u^2} \right) \quad (2.5)$$

where  $R$  is the Rydberg constant (13.6 eV),  $Z$  is the atomic number,  $n_l$  is the lower energy level, and  $n_u$  is the upper energy level [57]. These characteristic X-ray energies are representative of the atoms from which they are emitted; thus, the detection of these X-ray energies can be used to characterize the composition of the sample material. In energy dispersive X-ray spectroscopy (EDS), these characteristic X-rays are detected in a single crystal semiconductor diode. The EDS detector in the SEM used in this study was an AMETEK EDAX Apollo XL silicon drift detector, which is advantageous in that it does not require liquid nitrogen cooling, accepts high input count rates, and is capable of a larger detector area relative to older EDS detector technologies. The energy resolution for this detector is on order 100-200 eV, depending on the X-ray energy and count rate conditions. However, X-ray production and detection has several complicating factors, including continuum X-ray production, the path of incident electron penetration scattering in the sample, X-ray absorption within the sample, as well as X-ray fluorescence effects, each of which are described below.

As incident electrons penetrate into a sample, they undergo Coulombic deceleration as they interact with the fields of charge carriers in the sample. This deceleration results in incident electron energy loss in the form of X-ray emission known as Bremsstrahlung. Because deceleration events may cause an electron to lose any amount of energy up to its initial energy, a continuum of X-ray energies are emitted, which are detected along with the characteristic X-rays. Therefore, in order to determine the composition from X-ray emissions, the characteristic X-ray peaks have to be distinguishable from this background of

Bremsstrahlung. This can be achieved using an incident electron energy that is sufficiently high in comparison to the excitation energy of the atom of interest. As incident electron energy increases, the depth of penetration and scattering into the sample increase. Not only does this cause a degradation in spatial resolution, but it also increases the absorption of produced X-rays in the sample [58]. Thus, a balance between spatial resolution and X-ray production must be determined for individual sample analyses.

The production of X-rays in the sample does not only depend on the initial electron beam energy, but also the electron density of the material. This X-ray production range is given by the empirically determined Anderson-Hasler range equation

$$R = \frac{0.064}{\rho} (E_0^{1.68} - E_c^{1.68}) \quad (2.6)$$

where  $\rho$  is the material density,  $E_0$  is the incident electron energy, and  $E_c$  is the excitation energy for a specified element and energy level [60]. For a given electron beam energy, the interaction volume varies depending on the characteristic X-ray of interest. In this thesis, a 15 keV incident electron beam was used; thus, the range of Al  $K_\alpha$  X-rays was 2.2 microns, while the range of Fe  $K_\alpha$  X-rays was 1.7 microns.

As X-rays are produced, they interact within the sample and may be absorbed, such that the total number of emitted X-rays are attenuated by the sample itself. The intensity of emitted X-rays in comparison to the initial intensity of produced X-rays also depends on the depth at which they were produced and the density of the sample through the relationship

$$I = I_0 e^{-\mu x} \quad (2.7)$$

where  $I$  is the emitted X-ray intensity,  $I_0$  is the initial intensity,  $x$  is the path length of the X-ray through the sample, and  $\mu$  is attenuation coefficient of the X-ray for a specific energy and material. Given the above equation, the effect of X-ray absorbance in the sample is highly dependent on the depth of X-ray production, the material in which it is produced, and the energy of the X-ray.

Finally, the effect of secondary fluorescence has to be taken into account when using emitted X-ray energies to determine sample composition. This secondary fluorescence effect is present when characteristic X-rays from one element has a have enough energy to excite an inner shell electron of other elements in the sample to a higher energy level, which de-excites by emitting its own characteristic X-ray. This effect can cause an overestimate of the amount of the other elements in the sample, if not corrected for. This is well illustrated in samples with Ni and Fe, where the Ni  $K_\alpha$  X-rays are strongly absorbed by Fe in the sample and re-emitted as Fe  $K_\alpha$  X-rays, which not only decreases the observable signal from Ni, but erroneously increases the signal from Fe.

In compositional analysis by EDS, the above effects are accounted for using what is known as the ZAF correction, encompassing sample atomic number (Z), X-ray absorption (A), and X-ray fluorescence (F) [58]. The correction can be applied either using standards or without standards. When standards are used to determine the ZAF correction, matrix effects, X-ray

absorption, and X-ray fluorescence are accounted for by comparing the measured spectrum in the unknown sample with a spectrum from a known material using the same operating procedures. In standards-based ZAF, mathematical models are combined with empirical test data for scattering, absorption, and ionization potential, which are then used to define the correction factor for a species of interest (*ibid.*). In standardless ZAF, models of X-ray production and propagation are used in combination with a library of experimentally acquired values on pure-element standards [61]. In both cases, the correction is applied iteratively, based on an initial guess of element concentrations.

Figure 2.5: Illustration of the de-excitation of an atom as a higher energy level electron (blue) moves into an inner-shell hole (white), with emission of a characteristic X-ray (purple)

In this study, a standardless ZAF correction was applied to X-ray spectra acquired by EDS to determine compositional variation for Si, Al, Fe, Mg, Ti, Na, K, Ca, and O, as EDS was used for rapid and semi-quantitative understanding of composition across the interfaces. The ZAF correction was determined using the TEAM EDS software suite (by EDAX, Inc.). In Figure 2.6, an X-ray spectrum of an EDS spot taken on a Sample A is given, along with the composition as determined by standardless ZAF correction (Table 2.2). Here, a standardless ZAF correction was applied to counts from specific characteristic X-ray peaks

(*e.g.*, Al  $K_{\alpha}$  X-ray peak) to determine composition. The uncertainties are based on counting statistics and peak convolution.

Figure 2.6: X-ray spectrum from an EDS spot taken on Sample A. Iridium peaks are due to the conductive iridium coating.

Table 2.2: ZAF correction from the TEAM EDS Software Suite (EDAX, Inc.), showing composition by element weight percent as determined by the spectrum in Figure 2.6.

Element	Weight (%)	Error (%)
O $K_{\alpha}$	39.37%	7.52%
Al $K_{\alpha}$	8.00%	3.59%
Si $K_{\alpha}$	36.96%	3.27%
Ir $M_{\alpha}$	4.57%	2.21%
K $K_{\alpha}$	2.97%	2.81%
Ca $K_{\alpha}$	2.23%	2.85%
Fe $K_{\alpha}$	5.91%	2.73%

As seen from the X-ray spectrum, the ZAF correction can be complicated by several factors, including (1) when the signal of the characteristic X-ray of the element of interest is too low in comparison to the continuum X-rays, or (2) if the elements in the sample produce characteristic X-ray peaks that cannot be resolved (*i.e.*, too close in energy) [58]. For example, in Figure 2.6, several peaks can be seen that have very low signal to background ratio (*e.g.*,  $Mg_{K_{\alpha}}$ ).

As can be seen in Figure 2.7, an EDS spectrum taken at another spot on the same sample identified a phosphorus  $K_{\alpha}$  (2.01 KeV) X-ray peak, where an iridium  $M_{\alpha}$  (1.99 KeV) X-ray peak was in Figure 2.6, such that it measured 1.39 wt.% phosphorus, but did not detect iridium. As the sample was initially iridium coated for conductivity, the peak is misidentified as phosphorus and the ZAF correction is improperly applied. The assertion that this peak is misidentified is further supported by the measured X-ray intensities, as the predicted phosphorus  $K_{\alpha}/M_{\alpha}$  intensity ratio is  $\sim 100$  [62], compared with a measured value of  $\sim 7$ . To avoid this specific issue, the samples were coated with carbon, which does not interfere with peak identification for species of interest. However, low signal-to-background ratios still affected some peak identification in this study, and spectra were reviewed manually prior to acceptance.

Figure 2.7: X-ray spectrum from an EDS spot taken on a second location on Sample A. A phosphorus peak is incorrectly identified where the iridium M X-ray peak is seen in Figure 2.4, with which it completely overlaps.

Thus, in this study, energy dispersive X-ray spectroscopy was used as a semi-quantitative analysis method to rapidly characterize compositional variation across the interfaces. The EDS data was used to understand general variations of each species of interest in terms of their change in X-ray counts, and thus did not quantify the data in terms of element concentrations. Profiles across the diameter of attached objects and the interfaces where the fused onto the host objects were acquired as a series of 1 micron diameter analysis spots, spaced approximately 1 micron apart, with elemental variation reported as total X-ray counts per spot for each element. A total of 7 interfaces were characterized in this way (see Table

2.1). This is exemplified for object C3, where the Fe variation is shown across the attached object and its respective interface, in Figure 2.8.

Figure 2.8: The left frame shows the BSE image of object C3, with the red line showing the traverse along which EDS spot analyses were taken. The right frame shows the variation of Fe  $K_{\alpha}$  X-ray counts acquired per spot across object C3 and its corresponding interface, exemplifying qualitative EDS sample analysis. The error bars represent the  $1\sigma$  uncertainty, which is based solely on counting statistics.

## 2.2 Electron Probe Microanalysis

To quantitatively determine sample compositions, an electron probe microanalyzer (EPMA) was utilized. As the incident electron beam, optics, and electron detection techniques are, in principal, the same as an SEM, an EPMA is capable of acquiring backscatter and secondary electron micrographs in the same manner [57]. While X-rays are also generated in the same way (electron interactions in the sample, see Section 2.1), the X-ray detection technique that was used via EPMA for this study was wavelength dispersive X-ray spectroscopy (WDS), rather than EDS. Compositional maps of major elements (Si, Al, Fe, Ca, K, Mg, Mn, Ti, and Na) and quantitative analyses of major elements (Si, Al, Fe, Ca, K, Na, Mg, Mn, and Ti, as oxides) were acquired using WDS for both soil samples and fallout samples.

In WDS, diffraction crystals are used to select specific wavelengths from the X-rays emitted by the sample and reflect them into a detector. This crystal-detector system improves energy resolutions 10-fold over typical EDS detectors, and allows for quantitative analysis of species present in concentrations down to 0.1 weight % [58]. The EPMA used for this study, a JEOL JXA-8200 electron microprobe, has 5 wavelength-dispersive spectrometers, each having a different crystal configuration. In WDS, the crystal diverts X-rays following Bragg's law:

$$n\lambda = 2d\sin(\theta) \quad (2.8)$$

where  $n$  is an integer,  $\lambda$  is the wavelength of the incident X-ray,  $d$  is the lattice spacing of the crystal, and  $\theta$  is the scattering angle. Bragg's law of diffraction of X-rays from a crystal, such as those used in WDS detectors, is given in Equation 2.8, where the incident X-ray beam shown going to the lower level in the lattice travels a path  $2d\sin\theta$  longer than the beam incident on the top level of the lattice (see Figure 2.9).

Figure 2.9: The incident and scattering angle are identical for two incident X-ray beams on a lattice, with levels spaced  $d$  apart, illustrating Bragg's law of diffraction.

The diffraction crystals used in WDS detectors are manufactured having a curvature, such that all incident X-rays are scattered at the same angle. This is because in a perfectly flat diffraction crystal, the incident X-rays emitted from the sample would impinge on the diffraction crystal at different angles and subsequently be scattered at different angles, dramatically reducing X-ray collection efficiency. Individual detectors and diffraction crystals are bound to a circle that is defined by the radius of curvature of the diffraction crystal, which is known as a Rowland circle [57].

As no single crystal is capable of diffracting all X-ray wavelengths of interest to a detector bound by the Rowland circle, WDS detectors are typically equipped with several crystals having varying lattice spacings. This EPMA instrument is equipped with multiple detectors, each of which are bound by distinct Rowland circles offset by angle or radius, as exemplified in Figure 2.10 [58, 57]. Having this system of multiple detectors, each having multiple diffraction crystals, the EPMA was capable of quantitatively analyzing multiple elements in a single sample simultaneously across the spectral range of potential X-ray emissions. The diffraction crystals used in this study were thallium acid phthalate (TAP), pentanerythritol (PET), and lithium fluoride (LIF). The detected major elements, their corresponding detection energies, and crystal energy detection ranges [63] are given in Table 2.3.

In the WDS spectrometers used in this study, the detectors used were gas proportional counters. In these gas proportional counters, the fill gas is xenon and P10 (which is a

Figure 2.10: Example of two detector-crystal pairs bound to individual Rowland circles, each of which is specific to an individual X-ray wavelength (shown in blue and red) [57].

combination of 10 % methane and 90 % argon). The X-rays incident on these detectors pass through a window into the gas, creating electron-ion pairs by photoelectric interaction. These electrons are collected by a positively charged tungsten wire, which generates a measurable pulse [58]. The applied potential is on order 1 kV in these detectors, which is sufficient to generate a discrete discharge pulse from each collected ion pair. Thus, the number of ion-pairs, and the pulse generated, is proportional to the energy of the incident X-ray.

In addition to using WDS for X-ray detection, the other distinct feature of the EPMA used in this study (in comparison to the EDS) is the incorporation of standards, with which the EPMA calibrated all spectrometers for each analysis. For standards-based analyses, mineral standards were selected to most closely match the suspected composition of the sample (which was estimated using EDS). In samples such as fallout, which comprise multiple oxide species, there was not a single standard containing all the elements of interest. In this case, several standards were used to calibrate each characteristic X-ray wavelength to be used for compositional quantification. For quantitative standardization, mineral stan-

Table 2.3: EPMA crystal settings and detected X-ray energies for major elements

Element	Crystal	Energy Range (KeV)	$E_{K\alpha}$ (KeV)
Al	TAP	0.521 - 1.695	1.486
Na	TAP	0.521 - 1.695	1.041
Mg	TAP	0.521 - 1.695	1.254
K	PET	1.535 - 4.994	3.314
Si	PET	1.535 - 4.994	1.739
Ca	PET	1.535 - 4.994	3.692
Ti	PET	1.535 - 4.994	4.511
Mn	LIF	3.332 - 15.330	5.899
Fe	LIF	3.332 - 15.330	6.404

dards comprising the oxide species of interest were analyzed using the same spectrometer and goniometer crystal settings used in sample analysis. The standards were K-Feldspar ( $\text{KAlSi}_3\text{O}_8$ ) for  $\text{K}_2\text{O}$ ,  $\text{Al}_2\text{O}_3$  and Si; hematite ( $\text{Fe}_2\text{O}_3$ ) for FeO; spessartine ( $\text{Mn}_3^{2+}\text{Al}_2(\text{SiO}_4)_3$ ) for MnO; rutile ( $\text{TiO}_2$ ) for  $\text{TiO}_2$ ; diopside ( $\text{MgCaSi}_2\text{O}_6$ ) for CaO; albite ( $\text{NaAlSi}_3\text{O}_8$ ) for  $\text{Na}_2\text{O}$ ; and magnesium oxide ( $\text{MgO}$ ) for MgO. The composition was quantified applying a standard-based ZAF correction, which was calculated by comparing the measured spectra to the standard spectra, with individual elements calibrated corresponding their specified standard. For this study, the ZAF correction program used for quantitative EPMA was *CITZAF*, developed by the National Institute of Standards and Technology [64].

Quantitative composition profiles of major elements (presented here as the oxides  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ , FeO, CaO,  $\text{K}_2\text{O}$ ,  $\text{Na}_2\text{O}$ , MgO, MnO,  $\text{TiO}_2$ ) were acquired via WDS in traverses across the diameter of each analyzed fallout spherule along a path normal to the interface between fused objects, as well as across the interface into the larger host objects. The traverses consisted of 1 micron diameter analysis spots spaced 1.5 microns apart, with a total of 9 interfaces characterized this way, exemplified in Figure 2.11 for FeO variation in sample C1. Each spot was acquired with an accelerating voltage of 15 kV and a current of 10 nA. Quantitative analyses were collected as element weight percent totals and converted to their corresponding oxide species using stoichiometric oxide conversion. In order to avoid topographical edge effects near the boundary between the sample material and the epoxy, only points more than 3 microns away from the edge were considered.

Spot analyses in fallout samples were categorized regarding their proximity to the interface. Spots with local concentration maxima or minima observed co-located with the relatively high-Z interface region identified by BSE images are designated as 'interface points', while all points not co-located with the high-Z interface are designated 'interior points', for the purposes of data discussion. Individual spot analyses were also acquired by WDS on the soil grain mounts in order to characterize the composition of the constituent phases of the soil material.

Figure 2.11: The left frame shows the BSE image of object C1, with the red line showing the traverse along which EPMA spot analyses were acquired. The right frame exemplifies the results of EPMA spot analyses along the red line, showing the variation of FeO across object C1 and its corresponding interface in weight %, with the interface points highlighted in yellow. The error bars show  $1\sigma$  uncertainty determined by counting statistics and the applied CITZAF correction. The traverse of EDS spot analyses can be seen as a gray line immediately adjacent to the red arrow.

Qualitative compositional maps were also acquired via WDS in the areas around the interfaces where the smaller objects were fused to the large host object in each sample. A total of 10 interface areas were characterized this way for Si, Al, Fe, Ca, K, Mg, Mn, Ti, and Na. This is exemplified for sample D (Figure 2.12), where the Ca WDS map shows the elemental variation, reflective of what is also seen in backscatter. The maps of K, Mg, Mn, and Ti are not reported, as variation in these elements is not observable. This is due to the very low count rate for Mn (found to be  $\sim 1$  cps in spot analyses). For Mg and Ti, the signal-to-noise ratio was found to be very low, approaching  $\sim 1$  in most cases. The maps of K do not show variation, despite high count rates found in spot analyses ( $>900$  cps) and very high signal-to-noise ( $>40$ ); however, this could indicate that there is either minimal variation in K in these samples (which is not the case, see section 4.1), or that the analysis time was not sufficient to resolve compositional variation. The characterization of K and Na, two volatile elements, is explored in the next section.

Figure 2.12: The left frame shows the BSE image of Sample D, where contrast variation represents change in average atomic number. The right frame exemplifies the results of WDS mapping, showing the variation of Ca across the mapped region of Sample D. As seen in this image, the variation in contrast often corresponds to variation in a particular element, in this case Ca.

## Volatilization of Sodium and Potassium

As shown in the EPMA analyses on the fallout samples (Section 4.1), the  $\text{Na}_2\text{O}$  and  $\text{K}_2\text{O}$  concentration appears to have a high degree of uncertainty in comparison to the other measured major elements, given its concentration in the samples, and in comparison to the EDS analyses (see Section 3.4). This uncertainty may have been an effect of volatilization of  $\text{Na}_2\text{O}$ , as well as  $\text{K}_2\text{O}$ , due to electron beam interaction with the glass matrix of the samples. This effect is a well known phenomenon in electron probe microanalysis, and is attributed to a localized rise in temperature at the analysis site [65]. This change in temperature is dependent on the beam conditions, and can be calculated as follows

$$\Delta T = 1.14 \frac{VI}{kd} \quad (2.9)$$

where  $\Delta T$  is the change in temperature in Celsius,  $V$  is the accelerating voltage in kV,  $I$  is the current in  $\mu\text{A}$ ,  $k$  is the thermal conductivity, and  $d$  is the spot size in microns. As suggested by Equation 2.9, the localized change in temperature increases as the spot size decreases. The study by Siivola [65] demonstrated that this volatilization effect was most profound in the alkali metals Na, K, and Cs, and was particularly apparent for Na in all of the analyzed samples (which included crystalline and amorphous samples).

In order to study the effect of alkali volatilization in the fallout samples due to electron

probe beam interactions, a series of analyses were acquired on Lake County obsidian glass, which has a composition very similar to the fallout glass that was the subject of study for this thesis [66] (further detailed in Chapter 6). A series of 10 WDS analyses were acquired for each of 5 different spot sizes, ranging from the focused probe diameter up to a 20 microns spot size, under otherwise identical conditions. The average concentration for  $\text{Na}_2\text{O}$  from 10 spots is plotted for each probe diameter, as well as the standard deviation, in Figure 2.13A. As seen in the plot, there is approximately a 15% relative depletion from the highest to the lowest probe diameter, with measured concentration systematically decreasing as the probe diameter is increasingly focused. This trend was not observed in the  $\text{K}_2\text{O}$  concentration (Figure 2.13B), consistent with the study by Siivola [65], which found that Na generally volatilizes more readily. Thus, the EPMA measurements of  $\text{Na}_2\text{O}$  made on the fallout samples may be depleted, or incorporate a degree of uncertainty in each individual measurement of more than 15%. While it is unclear to what extent this effect is present in the EDS analyses, the smaller relative variation of the spot analyses acquired by semi-quantitative EDS (rather than EPMA) suggests that these data may be more reliable for illustrating relative compositional variation of Na in the fallout samples.

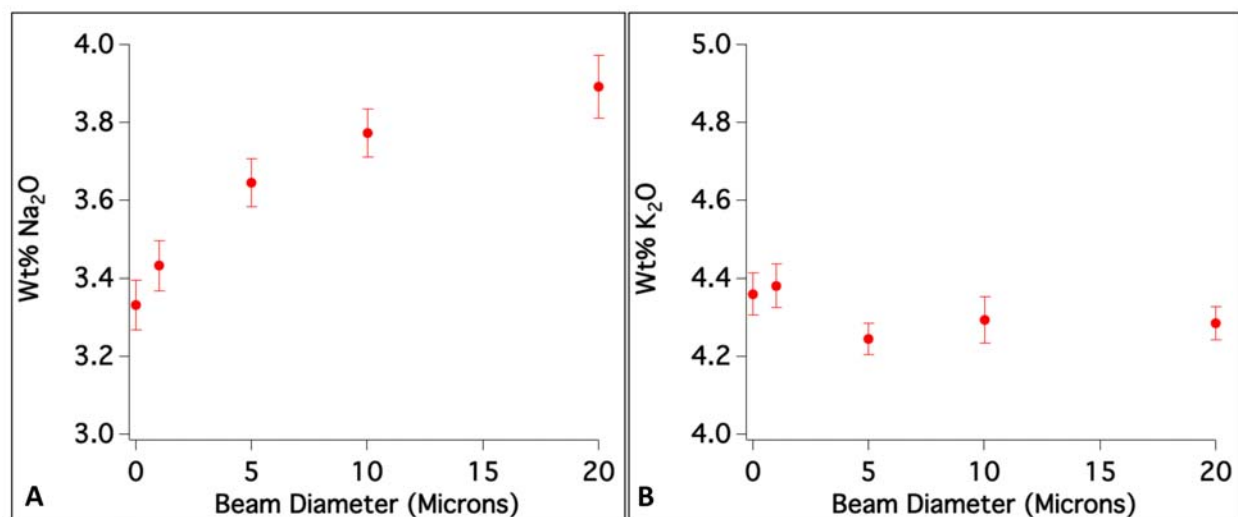

Figure 2.13: Na and K concentration in Lake County Obsidian as a function of EPMA beam size. (A) EPMA analyses for  $\text{Na}_2\text{O}$  on homogenized Lake County obsidian glass for spot sizes ranging from 20 microns down to the focused probe diameter ( $\ll 1$  micron), showing a systematic decrease in concentration with increasing probe diameter. (B) EPMA analyses for  $\text{K}_2\text{O}$  using the same parameters, showing no discernible volatilization trend.

## 2.3 Nano-scale Secondary Ion Mass Spectrometry

Secondary ion mass spectrometry (SIMS) is a mass spectrometric technique used for acquiring spatially resolved analyses in a sample to determine isotopic composition of a species. SIMS is ideal in that a wide range of isotopes can be separated and analyzed, it is capable of measuring species in trace amounts, and has very high lateral spatial resolution [67]. In this study, a Cameca NanoSIMS 50, which is capable of sub-micron lateral spatial resolution, was used to measure secondary ions of  $^{30}\text{Si}^+$ ,  $^{54}\text{Fe}^+$ ,  $^{44}\text{Ca}^+$ ,  $^{235}\text{U}^+$ ,  $^{238}\text{U}^+$ ,  $^{235}\text{U}^{16}\text{O}^+$ , and  $^{238}\text{U}^{16}\text{O}^+$  across agglomerate interfaces, with a spot size of 750 nm.

In secondary ion mass spectrometry, a primary beam of ions is used to sputter material from the surface of a sample, some of which are emitted in the form of secondary ions (Figure 2.14a). SIMS instruments fundamentally comprise of a primary ion source, a primary column through which the primary beam travels and is focused on the sample, a secondary column through which the sputtered secondary ions are directed, a mass spectrometer where the ions are separated by mass and charge, and a detector (or series of detectors) to measure species of interest (Figure 2.14b).

Figure 2.14: (a) illustration of primary ion beam sputtering ions and neutral species from the surface of a sample. (b) general schematic of a double-focusing SIMS instrument.

The primary ion beam can be one of numerous species, and the ions used are dependent on the sample and analytical conditions, including ion yield for the species of interest, resolution, sample conductivity, and other factors. Commonly,  $\text{O}_2^+$ ,  $\text{Cs}^+$ , and  $\text{O}^-$  are used, with each species more favorable for particular analytes and sample conditions [68]. For instance, in samples where positive ions are of interest, oxygen primary ions produce a secondary ion yield enhancement, whereas cesium primary ions enhance yields of secondary negative ions. In non-conductive samples, using a negative primary ion beam is favorable to reduce charge localization effects, which can negatively affect ion yields and/or deflect the incident beam [68].

For this study, as uranium was the species of interest in the sample, an oxygen primary beam was utilized. More specifically, an  $\text{O}^-$  primary beam was used to charging effects on

the non-conductive glassy fallout samples. For oxygen ions, the most commonly used ion generation source is a duoplasmatron. However, in this study, we used a Hyperion II ion source, which has superior brightness to duoplasmatron sources [69]. The Hyperion II is an inductively coupled plasma ion source, where a tunable RF power source is coupled to a number of induction coils around a chamber. This in turn supplies energy to oxygen (or another gas) in the chamber and ionizes it. An ion beam is extracted via an aperture in the anode and accelerated down the primary column [70]. The sample is held at a voltage opposite of the anode, which attracts primary ions to the surface and repels secondary ions. The primary beam is subsequently shaped by a series of electrostatic condenser lenses known as einzel lenses, which comprises three cylindrical electrodes designed to focus the ion beam onto the sample.

As secondary ions are sputtered from the surface of the sample, they are accelerated down the secondary column through an aperture in a grounded metallic plate known as the immersion lens. In the NanoSIMS instrument, the primary and secondary ion beams are coaxial, which allows the immersion lens to be as close to the sample as possible, which increases the efficiency of secondary ion collection. In the secondary column, another series of electrostatic lenses and deflectors are used to direct the secondary ion into the mass spectrometry system [67]. This system is a double focusing mass spectrometer, comprising both an electrostatic analyzer (ESA) and a magnetic sector. The electrostatic analyzer is comprised of two curved plates held at different potentials [71]. This works to improve mass resolution by narrowing the spread of ion energies following

$$R = \frac{2V}{E} \quad (2.10)$$

where  $R$  is the radius of curvature of the deflection of the secondary beam,  $V$  is the potential between the two plates, and  $E$  is the energy of the secondary ion.

Upon exiting the ESA, the focused secondary ion beam is directed into the magnetic sector, which separates the ions by mass following Lorentz law

$$R = \frac{mv}{qB} \quad (2.11)$$

where  $m$  is ion mass,  $v$  is velocity,  $q$  is charge, and  $B$  is the applied magnetic field. This separates the incident ions in the secondary beam by their mass onto different radial trajectories. These ions are then directed towards the detection system.

In the NanoSIMS instrument, there are two types of detectors used to measure ions: a faraday cup or an electron multiplier. In a faraday cup, ions are collected in a metal cup producing a deposited charge. The current from this deposited charge is converted to voltage by measuring the signal across a resistor. This voltage signal can be used to calibrate the number of counts per second detected on the faraday cup. A faraday cup is particularly useful for measuring very high count rates ( $>1 \times 10^6$  cps) [67].

In this study, electron multipliers were used as the ion detectors. In an electron multiplier, a conversion electrode produces electrons upon collision of the secondary ions. These

electrons are accelerated onto acceleration electrodes known as dynodes, each of which produce multiple electrons for every electron impact. Thus, for each detected ion, up to  $10^9$  electrons are generated, with the number of electrons and the subsequent current produced a function of the impact energy and acceleration voltage of the ions [67]. This type of detector has much higher sensitivity than the faraday cup detector, but cannot accommodate high count rates (the maximum count rate in this study was for  $^{30}\text{Si}$  at  $\sim 100000$  cps). The NanoSIMS instrument has 5 electron multipliers, which can be moved to detect magnetically separated ions on different radial trajectories (as dictated by equation 2.11) without having to change the B-field in the magnetic sector. Secondary ions of  $^{30}\text{Si}^+$ ,  $^{54}\text{Fe}^+$ ,  $^{44}\text{Ca}^+$ ,  $^{235}\text{U}^+$ , and  $^{235}\text{U}^{16}\text{O}^+$  were collected simultaneously, at a magnetic field of 3791 mT. The secondary ions  $^{238}\text{U}^+$  and  $^{238}\text{U}^{16}\text{O}^+$  were collected simultaneously, at a magnetic field of 3815 mT.

In order to acquire quantitative measurements using secondary ion mass spectrometry, a constant concentration of primary ions must be present in the surface, as changes in the sample matrix can affect ion yields [72]. This steady state, known as sputtering equilibrium, was determined in these analyses by looking at the yield of  $^{235}\text{U}$  in each measurement cycle, and removing those cycles that fell below the steady state count rate (exemplified in Figure 2.15). Sample analyses were acquired as secondary ion images of  $20 \times 20 \mu\text{m}^2$  areas (*e.g.*, Figure 2.16a), with each image constructed from a series of 75-100 cycles of  $256 \times 256$  pixel rasters (except Sample A1, which was constructed from a  $10 \times 10 \mu\text{m}^2$ ,  $128 \times 128$  pixel raster).

To quantify the variation of  $^{54}\text{Fe}$ ,  $^{44}\text{Ca}$ , and  $^{235}\text{U}$  across the interface on fallout samples, the ion images were normalized to  $^{30}\text{Si}$ , which was found to be relatively constant ( $<10\%$  variation in the image). This is exemplified in Figure 2.16, where the  $^{30}\text{Si}$  ion image is shown at the interface of object C1 (Figure 2.16a), as well as the variation across the interface (Figure 2.16b).

Thus, isotope ratio images of  $^{54}\text{Fe}/^{30}\text{Si}$  (except Sample A1, which used  $^{56}\text{Fe}/^{30}\text{Si}$ ),  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ , and  $^{235}\text{U}/^{238}\text{U}$  were then generated from the ion images, wherein the ratio image is an intensity map of an isotope ratio at each interface. Isotope ratio images were constructed using L'Image software [73]. Each ratio image was smoothed using a 9-pixel smoothing function (which approximated the NanoSIMS spot size used in this study, 750 nm). This is exemplified in Figure 2.17, where the ratio image of  $^{235}\text{U}/^{30}\text{Si}$  at the interface of object D2 is shown (Figure 2.17a) as well as its relative position in BSE imaging (Figure 2.17b).

In order to construct isotope ratio profiles, a 15-pixel wide line was drawn normal to and across the interface between the two fused objects in each isotope image. The width of the line was selected to minimize the uncertainties in regions where count rates were low, while still accurately representing the variation of the isotope ratio across the interface. The  $1\sigma$  measurement uncertainties for isotope ratios derived from the profiles (as determined from counting statistics) were  $<1\%$  for  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{54}\text{Fe}/^{30}\text{Si}$ , and  $^{56}\text{Fe}/^{30}\text{Si}$ ,  $<5\%$  for  $^{235}\text{U}/^{30}\text{Si}$ , and  $<10\%$  for  $^{235}\text{U}/^{238}\text{U}$  (the full data set is given in Appendix C).

Figure 2.15: Sputtering equilibrium determined for NanoSIMS analysis of object C1, based on counts/cycle of  $^{235}\text{U}$ . The blue line represents the average of the last 30 cycles, and was used as a determination of equilibrium counts/cycle, and the black line indicates where equilibrium was acquired at cycle 15. Uncertainties are  $1\sigma$ .

Figure 2.16: (A) Ion image acquired by NanoSIMS of  $^{30}\text{Si}$  at the interface of object C1, where variation is shown as an intensity map (the color bar is in total counts per pixel), with red and yellow depicting the highest intensity and blue and black depicting the lowest intensity. The white arrow indicates the path of the traverse shown in (B), from object C1, across the interface, and into the larger host object. (b) Plot of counts of  $^{30}\text{Si}$  along the white arrow shown in (a), which has an average value of  $20463 \pm 483$  counts (representing a 2.4% standard deviation). The variation in Si does not exceed 10% for any interface.

Figure 2.17: The left frame shows a BSE image of sample D, showing the relative position of the ratio image. The right frame shows the isotope ratio image of  $^{235}\text{U}/^{30}\text{Si}$  at the interface of Object D2 and Sample D.

## Analyses of Standards

Due to the the variable ionization properties of different species in different matrices, quantitative analysis by SIMS is only possible with the use of standards. Quantitative determination of concentration requires the use of relative sensitivity factors (RSF) as determined from standards. These relative sensitivity factors are acquired for species of interest in a specific matrix, and concentration can be determined following

$$\frac{I_R}{C_R} = RSF_E \frac{I_E}{C_E}, \quad (2.12)$$

where  $I_R$  and  $I_E$  are the secondary ion intensities of the reference element and element of interest, respectively,  $C_R$  and  $C_E$  are the concentrations of the reference element and element of interest, respectively, and  $RSF_E$  is the relative sensitivity factor for the species of interest. The RSF values are typically derived from calibrated standards [68].

The standards used in this study included both a matrix-matched glass standard (to measure concentration and uranium isotope ratio), as well as a  $U_3O_8$  standard (as a second measurement of isotope ratio, for comparison). The  $^{235}U$ -enriched glass standard was created at LLNL by fusing 5% by weight of the CRM U100  $U_3O_8$  standard into a matrix of approximately 32%  $SiO_2$ , 37%  $Al_2O_3$ , and 31%  $CaO$ . The RSF was determined for the ratio of  $(^{235}U + ^{238}U) / ^{30}Si$  to be  $0.07 \pm 0.04$ . This value is comparable to the RSF ratio of  $U/Si$  of 0.12 in a silicon matrix, as determined by Wilson using an oxygen primary beam [74]. The uncertainty on the measured RSF ratio was attributed to compositional heterogeneity in the glass. The absolute concentration of uranium in these samples was determined by

$$C_U = A \cdot C_{^{30}Si} \cdot RSF_{U/Si} \left(1 + \frac{1}{B}\right), \quad (2.13)$$

where  $A$  is the  $^{235}U/^{30}Si$  ratio,  $B$  is the  $^{235}U/^{238}U$  ratio, and  $C_{^{30}Si}$  is the concentration of  $^{30}Si$  determined by EPMA (and the natural abundance of  $^{30}Si$ ).

Measurements on standards were conducted to calibrate the  $^{235}U/^{238}U$  values. This calibration takes into account the instrumental mass fractionation of uranium isotopes over the course of the analyses, and were conducted on both a matrix-matched glass standard (U100) and a  $U_3O_8$  particle standard (U200) as described above [75, 76]. The U100 analyses were acquired as ion images ( $12 \times 12 \mu m^2$ ). Analyses on the U200 particle standard were acquired as  $10 \times 10 \mu m^2$ ,  $64 \times 64$  pixel rasters, not measured as ion images, but instead as ion sum totals.

As seen in Figure 2.18, the isotope ratios images of  $^{54}Fe/^{30}Si$ ,  $^{44}Ca/^{30}Si$ ,  $^{235}U/^{30}Si$ ,  $^{235}U/^{238}U$  are presented for the U100 glass standard (the same isotope ratio images presented for fallout samples). From the images, it is clear that there is compositional heterogeneity in the sample for Fe, Ca, and U, which have maximum variations of >300%, 140%, 240%, and 180% respectively. This heterogeneity is likely due to the manufacturing process of the glass standards (which were produced in house at LLNL [77]). The ratio image of  $^{235}U/^{238}U$  does, however, show a relative homogeneity in comparison to the other isotope ratio images.

As only the relative chemical variation of Fe, Ca, and U was necessary for the study, and the  $^{235}\text{U}/^{238}\text{U}$  ratio image indicates isotopic homogeneity, the U100 glass standard was found to be appropriate for  $^{235}\text{U}/^{238}\text{U}$  calibration.

In order to minimize potential edge effects, the edge of the rasters were excluded by using a region central to the ion image. This is shown in Figure 2.19, where there is a clear region of high signal intensity around the periphery of the image, which is likely an analytical artifact. These edge effects are likely due to crater formation from sputtering via the incident beam, which can affect sample topography (see Figure 2.20, which shows the crater formed from ion imaging by the NanoSIMS in SE imaging). To avoid this effect, a region of interest was acquired for each ion image, defined as a  $10\times 10$  micron box in the center of each image to avoid edge artifacts (Figure 2.19). The counts of  $^{235}\text{U}$  and  $^{238}\text{U}$  within this box were summed, and used to acquire the  $^{235}\text{U}/^{238}\text{U}$  ratio for each U100 standard analysis, which are presented in Table 2.4.

Also shown in Figure 2.18 (rightmost image) is the relative error image. In this image, the yellow region represents regions of high relative error, and the black/blue regions represent regions of low relative error as calculated by

$$\delta R = \frac{\sigma R}{R} \quad (2.14)$$

where  $\delta R$  is the relative error,  $\sigma R$  is the uncertainty on the ratio at a given pixel, and  $R$  is the ratio of interest (in this case  $^{44}\text{Ca}/^{30}\text{Si}$ ). As seen in the relative error image, the region of interest (white box) was chosen to avoid the region of highest relative error (at the top) and mitigates the influence of edge effects.

In Table 2.4, the results from both the U100 and U200 standard analyses are presented, as well as their certified reference values. The measurements for both standards shows a minimal degree of isotopic variation between each analysis, regardless of whether they were acquired as ion images (in the case of U100) or simply as rasters (in the case of U200). The deviations from the certified value for each analysis are also presented. As indicated in Table 2.4, there is little deviation from the certified  $^{235}\text{U}/^{238}\text{U}$  value in any single measurement for either U100 glass or U200 (as a particle), illustrative of the accuracy and precision of the uranium isotope ratio measurements acquired in this study. The average deviation was 1.5%. As shown in Table 2.4, the U100-doped glass has a  $^{235}\text{U}/^{238}\text{U}$  ratio of  $0.1136 \pm 0.0001$  (measured at LLNL by ICP-MS), and 20%  $^{235}\text{U}$  enriched  $\text{U}_3\text{O}_8$  particle standard (CRM U200, certified  $^{235}\text{U}/^{238}\text{U}$  ratio =  $0.2512 \pm 0.0003$ ) was also used. The glass and  $\text{U}_3\text{O}_8$  particle standards yielded measured percent deviations from the certified  $^{235}\text{U}/^{238}\text{U}$  ratios of 1.5% and 2.5%, respectively.

Even with the use of calibrated standards, interferences can produce inaccurate results in SIMS (and mass spectrometry, generally). These interferences come in the form of molecular species that have masses close to that of the species of interest, isotopes of different elements having the same mass number, or even other isotopes of the same element if the mass number is sufficiently high. The interferences of interest for this study were  $^{208}\text{Pb}^{27}\text{Al}$ , which interferes with  $^{235}\text{U}$  measurements, and  $^{29}\text{Si}^1\text{H}$ , which interferes with  $^{30}\text{Si}$  measurements. These

interferences were resolved by using the above described double-focusing mass spectrometer in combination with a physical barrier in the form of a slit. Wider slits allow a wider range of ion masses through, while narrow slits have higher mass resolving power, which comes at the cost of signal intensity. Mass resolving power, a factor that is often used to ensure that interferences are satisfactorily resolved, can be calculated by

$$R = \frac{M}{\delta M} \quad (2.15)$$

where  $R$  is the required mass resolving power,  $M$  is the mass of the species of interest, and  $\delta M$  is the mass difference between the species of interest and the potential interference mass. For this study, a mass resolving power ( $M/\delta M$ ) of 4000 was used, which was sufficient to resolve both  $^{208}\text{Pb}^{27}\text{Al}$  (required  $M/\delta M = 2741$ ) and  $^{29}\text{Si}^1\text{H}$  (required  $M/\delta M = 2841$ ).

Figure 2.18: Isotope ratio images for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$  acquired from one analysis raster ( $12 \times 12 \mu\text{m}^2$ ) on the U100 glass standard (pixel size is  $\sim 90 \text{ nm}$ ). The color bar shows the value of each isotope ratio at each pixel.

Figure 2.19: The left image shows the isotope ratio image ( $12 \times 12 \mu\text{m}^2$ ) of  $^{44}\text{Ca}/^{30}\text{Si}$  from Figure 2.18 (same color scale, pixel size  $\sim 90 \text{ nm}$ ). The middle frame shows the isotope ratio image of  $^{44}\text{Ca}/^{30}\text{Si}$  from Figure 2.18, with the region of interest used for standard analysis shown as a white box ( $10 \times 10 \mu\text{m}^2$ ) in the center of the image. The right frame shows the relative error image, where yellow represents regions of high relative error, and the black represent regions of low relative error. The color scale here represents the value of the  $1\sigma$  uncertainty on the  $^{44}\text{Ca}/^{30}\text{Si}$  ratio at each pixel.

Table 2.4: Summary of standard analysis results for  $^{235}\text{U}/^{238}\text{U}$  ratio acquired from both the U100 and U200 standards. Uncertainties are  $1\sigma$  on both the isotope ratios and the % deviation.

Sample ID	$^{235}\text{U}/^{238}\text{U}$	% Deviation
U100	$0.1167 \pm 0.0016$	$2.18 \pm 0.67$
U100	$0.1148 \pm 0.0015$	$0.53 \pm 0.66$
U100	$0.1145 \pm 0.0023$	$0.29 \pm 1.56$
U100	$0.1153 \pm 0.0002$	$0.99 \pm 0.10$
U100	$0.1158 \pm 0.0003$	$1.46 \pm 0.13$
U200	$0.2428 \pm 0.0031$	$3.37 \pm 0.62$
U200	$0.2479 \pm 0.0030$	$1.34 \pm 0.60$
U200	$0.2464 \pm 0.0032$	$1.93 \pm 0.64$
U100 reference value	$0.1142 \pm 0.0001$ [75]	
U200 reference value	$0.2513 \pm 0.0003$ [76]	

Figure 2.20: SE image of a NanoSIMS crater on Sample B3, the borders of which can give rise to edge effects which can locally affect ion image intensities, as shown in Figure 2.19. The bright, saturated regions are where the primary ion beam sputtered away the conductive carbon coating, causing sample charging.

## Chapter 3

# Qualitative Compositional Analysis

### 3.1 Backscatter Electron Imaging

After polishing the samples to expose their interiors and interfaces, samples were imaged in backscatter electron imaging (Table 2.1). This imaging shows the spatial distribution of average atomic number variation across the sample and the interface, and is used to qualitatively characterize the composition. In backscatter electron imaging, the interface in every sample appears as a bright, white boundary, separating the attached spherule from the larger host object, indicating higher average atomic number.

In Sample A, the interface appears diffuse, and is approximately 10 microns at its widest point (Figure 3.1). The edge of object A1 where the sample meets the epoxy also appears bright in backscatter electron imaging, and looks continuous with the interface. However, it is unclear if the brightness along the edge is due to an actual higher atomic number feature, or if it is simply an edge effect. The effect of charging is most obvious in the large central crack, where irregular regions of high brightness are present. Cracking in these samples is very common after polishing, as the glasses are likely under high internal stress due to rapid quenching, as well as the expansion of the epoxy as it cures. Also seen in Figure 3.1 is what appears to be another interface that extends to the bottom righthand side of the image. This is likely another agglomerated object that fully incorporated into the larger host object, a feature that is commonly found throughout the sample set.

Figure 3.1: Backscatter electron micrograph of object A1 on Sample A, with the interface indicated by the red arrow. The effects of charging is apparent around the perimeter of Object A1 as bright white regions, which are also seen around the large central crack.

In Figure 3.2, the backscatter micrograph of Sample B shows the interface of where the two attached spherules are fused (interface B1), as well as the interface of where the one of these spherules is attached to the larger host object (interface B3). Next to and intersecting interface B1, there is another interface (interface B2), which outlines an object that is fully incorporated into the larger object central to Figure 3.2. The contrast variation within this sample shows a number of interesting features present in the sample. First, there appear to be several compositionally distinct agglomerated objects around the perimeter of the large central object (which is fused at interface B3), that have fully incorporated into B3. Additionally, there is considerable compositional banding across the object, which is indicative of flow while the carrier was still molten. There are also several voids of varying size (micron-scale to tens of microns in diameter), which appear as black circles in the body of the sample. These voids are likely the result of degassing of the molten material. Finally, diffuse, dark regions (*i.e.*, low average atomic number) are present throughout this sample and the sample set as a whole, and are indicative of relict (incompletely melted/mixed) minerals in the carrier, presumably from the original mineral/soil host object.

Figure 3.2: Backscatter electron image showing objects B1, B2, and B3, with each object and interface indicated by a corresponding red arrow. Flow banding is evident throughout the objects, particularly in Object B3, which features relict mineral grains and numerous small voids.

The backscatter electron image of Sample C (Figure 3.3) is shown inverted relative to its corresponding optical image (see Figure 1.8), with the agglomerated objects of interest at the top of the image. The entire sample is shown in the backscatter image. The contrast variation in the image shows what appears to be a heterogeneous host, with relatively homogeneous spheroidal objects fused to its surface (sample heterogeneity is further discussed in Section 3.2). In the larger host object, there appear to be numerous relict minerals of distinct composition, observable as regions of varying brightness. As with the previous Sample B, there are a number of voids, as well as evidence of flow banding. The fused objects themselves show little relative compositional variation under the contrast and brightness conditions provided in this backscatter image. Further, each agglomerated object (from left to right) shows an increasing degree of incorporation into the larger host object.

Figure 3.3: Backscatter electron image of Sample C, with Objects C1, C2 and C3 (and their interfaces) indicated by red arrows. Objects C1, C2, and C3 appear relatively homogeneous in comparison to the larger Sample C, which has numerous relict minerals and several large interior voids (as well as many smaller voids).

The backscatter image of Sample D (Figure 3.4) shows that the large object and the smaller fused objects are compositionally heterogeneous. There is obvious compositional banding, indicative of liquid phase flow, that continues from the large object into either of the smaller fused objects shown in the electron micrograph. The object on the left (Object D1) hosts a large void within its volume, which appears to be deformed directionally against the host, and appears to have chipped and cracked where the surface of the object meets with the epoxy. Such defects in the surface of Object D1 may be the result of environmental exposure effects or, more likely, a result of polishing. The righthand object (D2) hosts an apparent relict mineral grain, which can be seen as a diffuse, dark bleb. Interestingly, the flow banding in Object D2 appears to follow the contours of the relict grain, suggesting flow as a result of rotation of the relict grain within the volume of the object while molten.

Figure 3.4: Backscatter electron image of Sample D, with Objects D1 and D2 (and their interfaces) indicated in red. The larger Sample D appears to host both lower and higher relative atomic number relict mineral, as well as several obvious voids. Object D1 hosts a large central void, while Object D2 hosts a lower atomic number relict mineral.

Upon polishing, the interfaces of Object E1 and included Object E2 were exposed, as shown in backscatter electron imaging (Figure 3.5), and found to be approximately coplanar. The most striking feature shown here is the very large (approximately 1 mm in diameter) central void in the host. The exposed region to the top-right of the host that appears detached from the rest of the sample is the large spherical object that is barely fused to the surface. It appears detached by virtue of where it fused to the host; it would require further polishing to reveal the interface of this object (it is not coplanar with E1 and E2). The attached Objects E1 and E2 do not appear to have the level of heterogeneity illustrated by the rest of the host sample, although Object E2 does have two relict mineral

grains embedded in its volume.

Figure 3.5: Backscatter electron image of Sample E, with Objects E1 and E2 (and their interfaces) indicated by red arrows. While Object E1 is spheroidal and fused to the surface, Object E2 is flattened and almost fully incorporated into the larger host. The larger host object of Sample E appears relatively heterogeneous, and hosts a mm-scale central void. A third object (top right), which appears detached, is indeed fused to Sample E, but the interface is not co-planar with the other objects and is therefore not visible in this image.

The backscatter electron images of soil (exemplified in Figure 3.6) reveal that individual soil grains consist of numerous mineral compositions of varying sizes. The observed grains are consistent with previous analyses of soil from this test [55] in that they were characteristic of granitic and rhyolitic clasts, containing porous and microcrystalline features. As seen in the electron micrograph (Figure 3.6), there are a range of mineral compositions from relatively high average atomic number (an iron rich mineral, later identified by EPMA as ilmenite in Chapter 4) to relatively low atomic number (an  $\text{SiO}_2$  rich mineral, later identified by EPMA as quartz in Chapter 4) within a single soil grain. The black regions are epoxy which, within the sample, highlights the microcrystalline structures characteristic of clay

minerals, which predominate. As has been shown, the fallout is comprised of molten and partially homogenized soil grains such as those shown in Figure 3.6, and is commonly found to host relict mineral grains, which are likely the result of larger minerals in the soil that did not have time to fully diffuse or otherwise mix into the rest of the melt prior to quenching.

Figure 3.6: Backscatter electron image of a soil grain, illustrating the general heterogeneity of the soil. Key minerals were later identified (by EPMA, see Chapter 4), on the basis of composition.

## 3.2 Relative heterogeneity and morphology of fused glassy objects

Sample heterogeneity was characterized by examining the contrast variation in backscatter electron imaging between the larger host object (Samples A, B, C, D, and E) and select agglomerated objects (Objects A1, B1, B2, B3, C1, D1, D2, and E1). The degree of heterogeneity represented by the relative grayscale intensities does not translate from image to image, as the brightness and contrast was not kept consistent between the images, but instead maximized to highlight local compositional variation. However, the difference in contrast variation within images of single samples can be used as a qualitative metric for understanding the extent of mixing and homogenization within the analyzed fallout glasses.

The relative brightness distributions of each object was determined in *ImageJ* image processing software by acquiring a histogram of gray-scale intensity (256 intensities) for all pixels in each object, from BSE images. The brightness and intensity of objects within a single image were normalized to accentuate the contrast variation such that objects would be comparable within each BSE image. Voids and epoxy, which had the lowest relative brightness of any feature, were excluded by thresholding.

### Contrast Variation Plots

Figure 3.7: Left, backscatter electron image of part of Sample A from which contrast variation was measured. Right, histograms of Object A1 as well as Sample A are plotted, normalized to maximum frequency. The histogram of relative brightness of Object A1 reveals relative homogeneity in comparison to Sample A.

In Figure 3.7, the contrast variation shows the relative heterogeneity between the smaller fused object (A1) and the host (Sample A). As seen in Figure 3.7 (right frame), the primary peak of the host object has a slightly larger spread in contrast than the smaller fused object (A1). Further, the larger host object has a secondary peak at a relative brightness of 0.3. Based on the contrast variation, the larger object shows a slightly greater degree of heterogeneity at relatively lower  $Z$  when compared to the smaller fused Object A1.

In Figure 3.8, the contrast variation was acquired for Sample B, in the same manner as described for Sample A, above. The BSE image shown in Figure 3.8 (left frame) shows attached Objects B1, B2, and B3 (B2 is fully integrated into B3, see Figure 3.2). As shown in Figure 3.8 (right frame), the host object shows a range of contrast variation that is substantially broader than either attached Objects B1 or B2 and B3, which are combined into a single contrast variation curve. However, this could be due to a systematic decrease in brightness from the right side of the object to the left side of the object, as can be seen

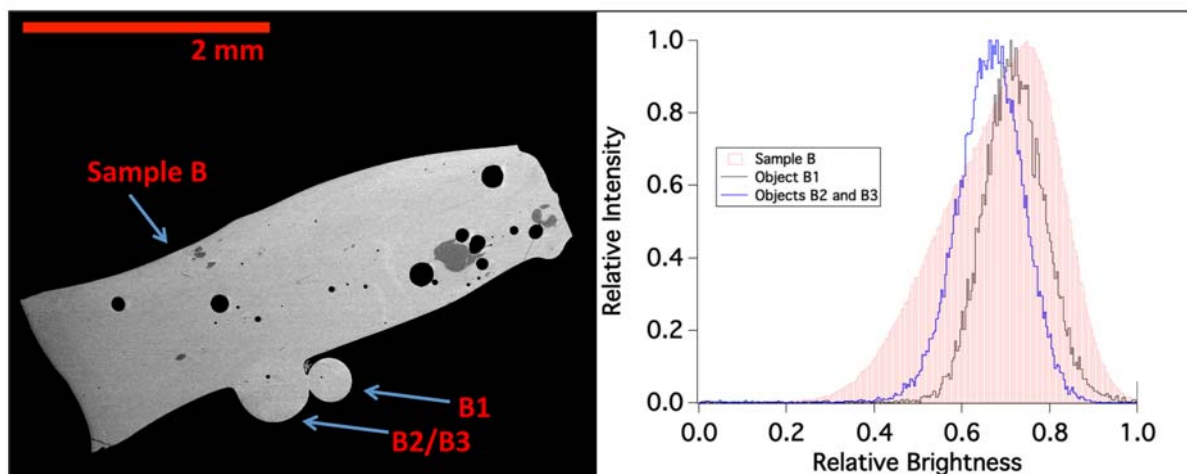

Figure 3.8: Left, backscatter electron image of the entirety of Sample B, including attached objects B1, B2, and B3. Right, histograms of the relative brightness for B1, and B2/B3 together, as well as the larger host object are plotted, showing similar relative heterogeneity in Objects B1, B2, and B3. The width of the relative brightness histogram of Sample B may be due to misalignment of the sample during analysis.

in the BSE image (Figure 3.8, left frame). The systematic variation observed may be due to misalignment of the sample during analysis. The attached objects, while offset from one another in terms of their relative brightness variation, have approximately the same peak width, indicating similar degrees of compositional heterogeneity at these boundaries.

In Sample C, the large object is host to a numerous relict mineral grains, as apparent in BSE imaging (Figure 3.9, left frame). The smaller adhered objects are generally homogeneous when compared to the larger host object, as exemplified by the contrast variation plots of both the adhered Object C1 along with the larger host object, as shown in Figure 3.9 (right frame). The contrast variation plot for Sample C shows a convolution of two peaks in relative brightness (one at approximately 0.55, and another at approximately 0.62 relative brightness). The contrast variation of attached Object C1 has a single quasi-Gaussian brightness distribution, with a peak at approximately 0.6 relative brightness. The distribution of Object C1 is notably narrower than the extent of the distribution of the larger host object, indicating that C1 is relatively more homogeneous.

In Sample D, BSE imaging (Figure 3.10, left frame) of this fallout object shows visible heterogeneity in the form of numerous relict mineral grains. The smaller adhered Objects D1 and D2 display a degree of visible heterogeneity that was not obvious in Object C1. Flow banding can be seen extending from the larger host into the interior of Object D2. The resultant heterogeneity of all of these objects is shown in Figure 3.10 (right frame). In this figure, the normalized contrast variation for all of the objects gives a brightness distribution that is approximately the same for both attached Objects D1 and D2, as well

Figure 3.9: Left, backscatter electron image of the entirety of Sample C, including attached Objects C1, C2, and C3. Right, histograms of the relative brightness for C1 as well as the larger Sample C are plotted, showing the relative homogeneity of Object C1 compared with Sample C.

as the larger host object. There is a slight offset in brightness between each of the objects, potentially indicating a gross compositional difference. However, given the similarity in width of each of the relative brightness distributions, it can be ascertained that a similar degree of heterogeneity is present not only between the smaller Objects D1 and D2, but also of the larger host.

In Sample E, BSE imaging (Figure 3.11, left frame) depicts a largely heterogeneous host object with a mm-scale central void. Object E1 is adhered to the surface, while Object E2 is shown integrated into the body of the host object. The large host shows compositional flow banding as well as multiple relict mineral grains. The contrast variation of object E1 as well as the larger host object is shown in Figure 3.11 (right frame). In this plot, the relative brightness distribution of the host object appears as a convolution of at least two peaks, similar to that of the larger host object in Sample C. The slight intensity increase near the origin is likely due to voids, which were unable to be excluded from the measurement based on size. The relative brightness distribution of the smaller fused Object E1 is substantially narrower than the host, indicating a much higher degree of homogeneity. The single-peak distribution is in approximately the same location as the higher-maximum second peak of the larger host.

## Summary

Backscatter electron images of polished fallout samples show a range of morphological and compositional characteristics in mm-scale host objects and smaller, adhered fallout spherules. The 5 larger (mm-scale) host objects, to which the smaller objects are attached, commonly

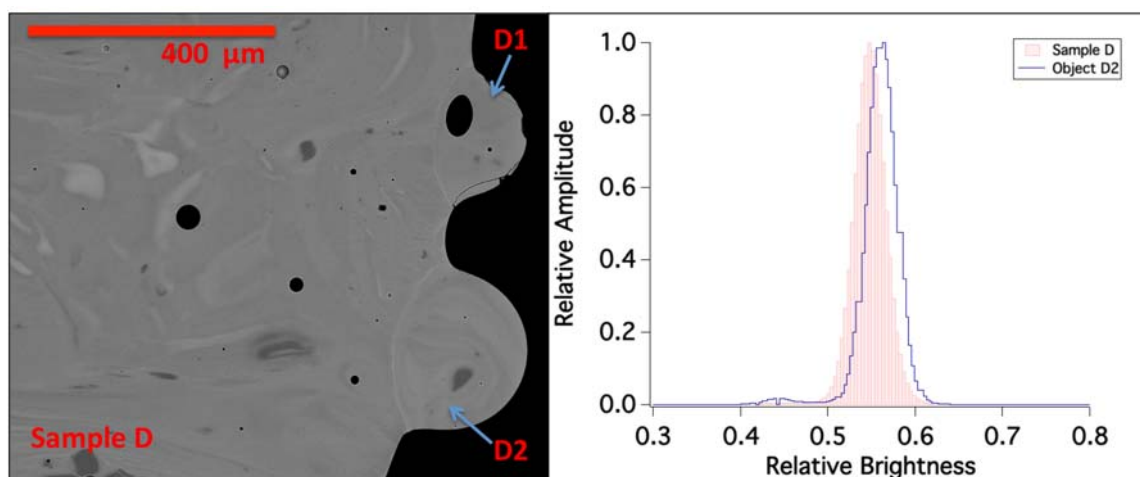

Figure 3.10: Left, backscatter electron image of Sample D, including attached Objects D1 and D2. Right, histograms of the relative brightness for D1 and D2, as well as the larger host object, are plotted, showing the same relative heterogeneity between D1, D2 and larger Sample D.

have large vesicles (up to 1 mm in diameter), as well as inclusions of what appear to be relict soil grains with diffuse boundaries based on major element composition (*e.g.*, Object D2). The internal composition of the small, attached, glassy objects ranges from relatively chemically homogeneous (Objects C1-3, E1) to distinctly heterogeneous (Objects B3, D1, and D2). Vesicles (seen as dark black circles or ovals) were most commonly observed in the samples showing the greatest degree of heterogeneity in major element composition. Small patches, approximately tens of microns in diameter (*e.g.*, Sample D2), were identified by EDS, as nearly pure  $\text{SiO}_2$  in composition and were commonly observed throughout the sample suite.

The extent to which the smaller objects have been incorporated into larger objects varies. For example, Objects C1 and C2 are two fused objects that have retained a highly spherical geometry, with the ratio of major and minor axes being 1.07 in both cases. Object C3, on the other hand, appears flattened against the host object, having a ratio of major to minor axis of 1.44, with the major axis measured at the widest point of the sample. This is further exemplified in objects B1-3, where multiple stages of incorporation appear to be preserved; Object B3 has a flattened interface and has merged into the larger host, while Object B1 has only slightly merged with the central object. Between these two agglomerates, Object B2 is a smaller (50 micron) object that is sandwiched between B1 and B3, and appears to have merged fully into the surface of B3.

As described in section 3.1, the distinct feature present in all samples, and of particular relevance to this study, is seen at the interfaces of where the small glassy spheres (<1 mm) are attached to the larger objects. These interfaces appear as a thin bright boundary line, and

Figure 3.11: Left, backscatter electron image of the entirety of Sample E, including attached Objects E1 and E2 (which appears fully integrated into the larger host object). Right, histograms of the relative brightness for E1 as well as the larger host object are plotted, showing the relative homogeneity of Object E1 compared with larger Sample E.

are regions of relatively higher average atomic number ( $Z$ ) than the surrounding material. Despite the range of morphologies and compositional variation observed in the agglomerated glassy fallout presented in this study, this high  $Z$  boundary feature is observed at every interface where the objects have fused together, and has not been previously documented in the fallout literature.

### 3.3 X-ray Mapping

#### Sample Maps

At the interface where Object A1 is attached to the larger host, energy dispersive X-ray spectroscopy was used to acquire maps for Al, Ca, Fe, and Na (Figure 3.12). This was the only sample in which electron probe microanalysis was not used to acquire maps, as the sample was damaged before this technique could be employed. In the EDS map for Al, there is a consistent depletion at the interface, with relatively higher concentration in attached object A1, and even higher concentration in the larger host. Both Ca and Fe are enriched at the interface and the edge of the sample, though this is most evident for Fe. The regions of enrichment of Fe, in particular, spatially correspond to the regions of Al depletion. In the EDS map of Na, the smaller attached object appears volumetrically enriched with Na relative to the larger host, and there is enrichment of Na at the interface or the edge.

In Figure 3.13, X-ray maps of Objects B1, B2, and B3 are shown for Al, Ca, Fe, and Na, as acquired by EPMA. These maps show a similar pattern of Al depletion co-located

Figure 3.12: Qualitative compositional map of Object A1 (see Figure 3.1 for BSE image) acquired by energy dispersive X-ray spectroscopy for aluminum, calcium, iron, sodium. There is depletion of Al at the interface, with relative enrichments of Ca and Fe. Attached Object A1 appears relatively more enriched in Na in comparison to larger Sample A.

with Fe and Ca enrichment. This is most evident at the interface of where attached object B1 is fused to B2 and B3, although this pattern is observed at all interfaces on this sample. Both the Al and Ca maps show evidence of compositional flow banding, and the Ca map shows evidence of agglomeration of multiple objects. The Na map shows enrichment of Na around the surface of object B3 where it meets the epoxy (shown in black). The interface of where object B1 meets objects B2 and B3 shows enrichment of Na, though enrichment is not immediately apparent at any of the other interfaces on this object, as observable in X-ray mapping.

The EPMA map for Objects C1 and C2 show differing patterns of compositional variation (Figure 3.14). While both Objects show enrichment of Fe and depletion of Al at their respective interfaces, the Ca and Na maps of objects C1 and C2 show distinct differences. Object C2 shows relatively higher volumetric Ca enrichment than object C1. Further, while

Figure 3.13: Qualitative compositional map of Objects B1, B2, and B3 (see Figure 3.2 for BSE image), acquired by wavelength dispersive X-ray spectroscopy for aluminum, calcium, iron, sodium. The interfaces of attached objects are depleted in Al and enriched in both Ca and Fe, relative to the interior composition of either the attached objects or the host sample. The edge of the attached objects adjacent to the epoxy are discontinuously enriched in Na.

both Objects C1 and C2 show enrichment of Ca around their edges and interfaces, C2 shows a distinct double ring feature, wherein a ring of high Ca enrichment encircles a ring of low enrichment around the surface of the object and at the interface. In the Na X-ray map, object C1 appears to be volumetrically more enriched in Na than C2. In Object C1, the Na variation appears diffuse, having a higher relative Na concentration at the edge and interface than its interior. In C2, however, the Na map indicates that Na did not appreciably penetrate into the volume of the object from the exterior. The EPMA map of Object C3 (Figure 3.15) shows a similar pattern of Al, Ca, and Fe composition to that seen in Object C1, although the composition at the edge of the object is difficult to discern due to chipping of the sample (likely due to polishing). As was observed in Object C1, the Na map of Object C3 shows a higher volumetric Na concentration, relative to a diffuse pattern of Na

compositional variation from the exterior to the interior of the object.

Figure 3.14: Qualitative compositional map acquired of Objects C1 (right) and C2 (left, see Figure 3.3 for BSE image), by wavelength dispersive X-ray spectroscopy for aluminum, calcium, iron, sodium. Object C1 has an interface depleted in aluminum and enriched in Ca and Fe. Object C2 has an interface depleted in Al and enriched in Fe; however, the interface exhibits a unique double ring feature in the Ca compositional map that extends through the interface all the way around the object. Larger Sample C is enriched in Na at the edge close to the epoxy and both attached objects.

In Figure 3.16, EPMA maps reveal the compositional variation for both Objects D1 and D2, as well as the adjacent region of the larger object of Sample D, for Al, Ca, Fe, and Na. At the interfaces of D1 and D2, the maps of Al, Ca, and Fe show the same relative depletion and enrichment patterns observed in the previous samples. The interface of object D2 shows a distinct enrichment of Na, which is not obvious, and may be absent, at the interface of Object D1. The Ca map is illustrative of the heterogeneity of the large host object in Sample D, as well as in the smaller attached Objects D1 and D2, where compositional banding and relict mineral inclusions are present. In the Na map, the larger object shows a higher relative

Figure 3.15: Qualitative compositional map acquired of Object C3 (see Figure 3.3 for BSE image) by wavelength dispersive X-ray spectroscopy for aluminum, calcium, iron, sodium. The interface of Object C3 is depleted in Al and enriched in both Ca and Fe. The Na compositional map indicates chemical enrichment of Na around the edge of attached Object C3.

concentration of Na at the surface of the sample where it meets the epoxy compared to its interior.

The EPMA X-ray maps in Figure 3.17 show the compositional variation of Al, Ca, Fe, and Na in Object E1. The edge and interface composition shown in the X-ray maps for this object are exemplary of the pattern of enrichment of Ca, Fe, and Na shown in other samples, as well as the distinct depletion of Al at the interface. The Na map shows a diffuse, continuous layer of Na all the way around the surface of Object E1, as well as at the interface (as further shown in Figure 3.26). In Figure 3.18, the EPMA X-ray maps are shown for Object E2. This object, which is fully integrated into the larger host, is most clearly outlined in the Na X-ray map (upper right side). As with the previous samples, there is a distinct depletion of Al, and relative enrichment of Ca and Fe, at the interface. As with

Figure 3.16: Qualitative compositional map acquired of Objects D1 (left) and D2 (right, see Figure 3.4 for BSE image) by wavelength dispersive X-ray spectroscopy for aluminum, calcium, iron, sodium. The Al compositional map shows depletion of Al at the interfaces of both attached objects. The interface is enriched in Ca, Fe, and Na, as shown in their corresponding compositional maps. The Ca map suggests distinct heterogeneity within larger Sample D in comparison to Objects D1 and D2.

E1, the Na map shows a continuous, diffuse, layer of Na all the way around the object and at the interface. In the Ca map, another smaller object adjacent to E2 is present, and also fully incorporated into the larger host.

## Summary

X-ray intensity maps show that the high Z interfaces observed in the BSE images are part of a continuous layer that surrounds the smaller, attached objects, and is enriched in Ca and Fe and depleted in Al relative to the average composition of the interiors of the smaller objects. The edges of objects adjacent to epoxy also are enriched in Ca and Fe relative to the interiors. Although this enrichment at the sample edges could result from an artifact due

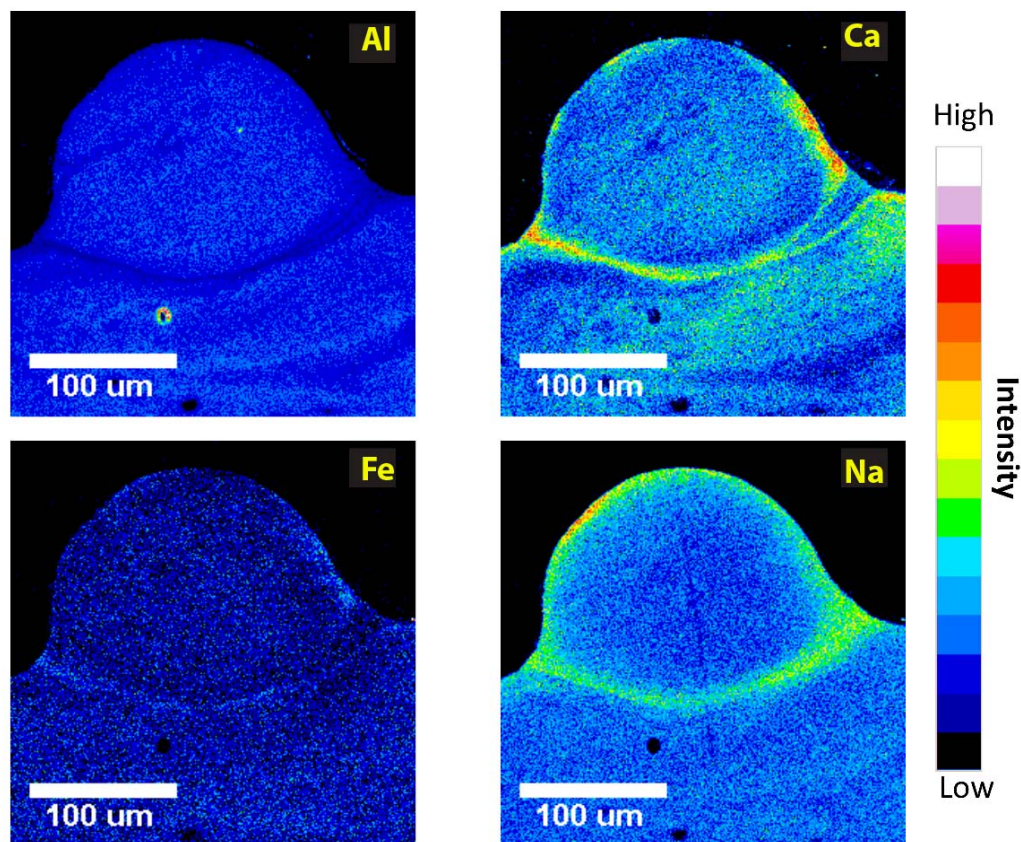

Figure 3.17: Qualitative compositional map acquired of Object E1 (see Figure 3.5 for BSE image) by wavelength dispersive X-ray spectroscopy for aluminum, calcium, iron, sodium. The interface of Object E1 is depleted in Al and enriched in Fe and Ca. The Na compositional map shows a diffuse Na layer all the way around the attached object.

to topographical edge effects, the continuity of this feature along agglomeration boundaries away from edges is strong evidence that the feature is intrinsic to the adhered objects. Sample C2 in particular shows a continuous, uniformly thick layer of Ca around the entire object, and is adjacent a region depleted in Ca. In 9 of the studied objects, the interface and exterior edge of the adhered objects is also enriched in Na, appearing as a thicker, more diffuse region when compared to the areas of Ca and Fe enrichment. Objects with observable enrichment in Na at the interface and/or outer edge (as seen in X-ray intensity maps and EDS traverses) include A1, B1, B2, C1, C2, C3, D2, E1 and E2.

Figure 3.18: Qualitative compositional map acquired of Object E2 (see Figure 3.5 for BSE image) by wavelength dispersive X-ray spectroscopy for aluminum, calcium, iron, sodium. The interface of Object E2 is relatively depleted in Al and enriched in Ca and Fe. The Na compositional map indicates that, like Object E1, there is a diffuse Na layer all the way around the object.

## 3.4 Semi-quantitative Compositional Variation

### EDS Spot Analyses

For selected samples and interfaces (see Table 2.1), energy dispersive X-ray spectroscopy was utilized to acquire a series of one-micron spot analyses across the interfaces of attached objects to rapidly capture compositional variation for major elements. The output of these spot analyses were in total X-ray counts for each major element of interest, including Al, Si, Fe, Ca, Mg, Na, and K, which provided a metric for semi-quantitative, relative compositional variation between samples (see Appendix A).

In Figure 3.19, a backscatter electron image of Object A1 is shown in the upper frame, with the location and direction of the spot analyses shown by the red arrow. The major

element variation as X-ray counts for Al, Ca, Fe, and Na are shown in the right hand frames. The output for each EDS analyzed interface is presented in the same format below. For Object A1, approximately 40 spots were acquired across the interface into the larger host object. As seen in the major element plots, the patterns observed in the qualitative EDS maps for Object A1 match with the semi-quantitative compositional variation for these major elements. The corresponding depletion of Al for A1 was found to be approximately 30%, and the corresponding enrichments for Ca, Fe, and Na were approximately 50%. The major element plots also show the difference in composition between the attached objects and the large host object in each sample. Here, for example, the Al and Ca content is notably higher (22% and 9%, respectively) in Sample A compared to Object A1, while the Fe content is approximately the same between the two. The Na content, on the other hand, is shown to be slightly lower (approximately 14%) in Sample A.

From Object B3, 32 spot analyses were acquired by EDS across the interface into Sample B (red arrow, Figure 3.20). At the interface of Object B3, the compositional variation trends in Al, Ca, and Fe (right frames, Figure 3.20) are consistent with the results of EPMA maps, and conform to the pattern observed in other samples. The variation in Na, however, does not show a discernible enrichment at the interface. Unlike Sample A, Sample B has a lower Al and Ca content than the attached Object B3 (2% and 13%, respectively), while Fe content is still approximately the same between the two (<1% difference). Again, the variation in Na at the interface and on either side of it does not yield any discernible pattern of enrichment or depletion.

In Sample C, spot analyses were acquired by EDS across the major diameters of attached Objects C1, C2, and C3 and through their respective interfaces into Sample C (Figures 3.21-3.23). These analyses revealed major element variation at the edge as well as at the interface. In Object C1 (Figure 3.21), the Al, Ca, and Fe major element plots show the characteristic depletion and enrichment at the interface (located at 200 microns, Figure 3.21) observed in other samples, with 45% relative depletion of Al, and relative enrichments of 19% and 45% for Ca and Fe, respectively. Further, the major element variation at the edge (located at 0 microns, Figure 3.21), show the same pattern as at the interface for Al, Ca, and Fe, wherein there is a depletion of Al (21%) and a enrichment of Fe and Ca (8% and 4%, respectively), though not to the same extent as observed at the interface. The Na variation in this sample shows an enrichment at both the edge and the interface, with a gradient of decreasing concentration towards the interior of the object, as observed in EPMA mapping (Figure 3.14). The sharp rise in Ca in the interior of the object observed in the major element plot (Figure 3.21) is also apparent in the EPMA map (Figure 3.14).

Object C2 (Figure 3.22) shows major element variation that is distinct from all of the other samples for Fe and Ca. The double-ring structure shown for Ca in the EPMA map (Figure 3.14) is also evident from the spot analyses at the interface (see Ca plot, 200 microns, Figure 3.22), where a 34% depletion in Ca is adjacent to a 47% enrichment. In the semi-quantitative EDS plots, there is a depletion of Ca followed by a narrow region of enrichment; this pattern is also observed for Fe at the interface. While evident in EPMA mapping at the edge, this feature was not observed in the semi-quantitative EDS spot analyses at the edge

(at 0 microns, Figure 3.22), likely due to its proximity to the epoxy. For Al, Ca, Fe, and Na, the composition within the interior of the object is relatively homogeneous in comparison to the other measured samples.

In Figure 3.23, the major element variation is shown for Object C3. The interface where Object C3 is fused to Sample C (at approximately 95 microns, Figure 3.23) shows the characteristic enrichment of Fe and Ca, and depletion of Al, as seen at the other interfaces (with the exception of Object C2). Of particular interest, the degree of enrichment of Ca and Fe (and depletion of Al) at the edge of the sample (at 0 microns, Figure 3.23) is similar to what is observed at the interface. The Na plot also shows an enrichment at both the edge and the interface, though the edge appears to be substantially more enriched (20% relatively more enriched than the interface). The observed drop at the very edge in all the plots (at 0 microns, Figure 3.23) is likely due to spot overlap on the epoxy.

Sample D1 (Figure 3.24) shows the greatest degree of variation for the plotted major elements. It is unclear to what extent the proximity of the spots to the large central void in the object affected the analyses (due to topographical variation). However, the interface (at 175 microns, Figure 3.24), shows a depletion in Al. There is also a sharp local maximum for both Ca and Fe at the interface. The spots at the edge are difficult to interpret, and may be affected by potential chipping or cracking at the very edge of Object D1 (at 0 microns, Figure 3.24). The Na plot does show a very distinct enrichment at the edge (35% relative to the interior), with a slight but distinguishable enrichment at the interface. Unique to this sample, approximately 100 EDS analyses were taken within Sample D. The degree of compositional variation for Al, Ca, and Fe within the large host is comparable to that observed within attached object D1, although the larger host is relatively depleted in Na (12%, relative to the interior of the attached object).

Finally, Object E1 (Figure 3.25) shows the characteristic patterns enrichments and depletions of the major elements that were established in almost all of the samples. The degree of depletion of Al (30%), and enrichment of Ca and Na (35% and 70%, respectively), at the edge is almost identical to what is observed at the interface. The variation observed within the sample itself is relatively minimal (% standard deviations of 3%, 4%, 5%, and 8%, for Al, Ca, Fe, and Na, respectively), with larger fluctuations attributable to spots taken on cracks within the sample.

Given the chemical similarities of Na and K (as alkali metals, they have very similar bonding, ionization, oxidation properties, and mineral sources), it was expected that the variation of K will reflect the variation in Na. The patterns of K measured by EDS, though not shown in the above plots (see Appendix A), were observed to be comparable to Na in 5 of the measured objects. This is exemplified in Figure 3.26, where the K and Na variation across object E1 are plotted together, and the patterns of variation are almost identical.

Other measured elements included Mg, Ti, and Si. Due to the low count rates (*i.e.*, low concentrations of <1 wt.% element) of Mg and Ti, the semi-quantitative analyses of these elements did not reveal obvious patterns of variation that could be distinguished from the uncertainty on the individual measurements. The EDS spot analyses reveal a Si variation of less than 10% of the maximum value for every measured interface, with no discernible

pattern of enrichment or depletion at the interface. The entire EDS data set is given in Appendix A.

## Summary

A total of 7 interfaces were characterized for compositional variation via EDS spot analyses (see Table 2.1). Compositional variation was determined as a series of EDS spot analyses along traverses from within adhered objects into the host samples. At every interface characterized by EDS spot analyses, there is a relative increase in Fe and Ca (up to 50% relative enrichment) at the interface compared to within the attached objects and samples themselves. All of the interfaces characterized by EDS also present a relative depletion of Al (up to 45% relative depletion), which also spatially correspond to enrichments of Ca and Fe. In 6 of the 7 interfaces, there was also an enrichment of Na (up to 70% relative enrichment) that spatially corresponds to Fe and Ca. This consistent and distinct pattern of enrichment and depletion at the interfaces is associated with the same pattern of enrichment and depletion present at the edges in 5 of the objects, although these edges are more difficult to characterize using EDS spot analyses due to edge effects. These observations are indicative of a distinct chemical layer around the adhered spheroidal glassy objects, which is further characterized for quantitative major element composition in the following Chapter (4).

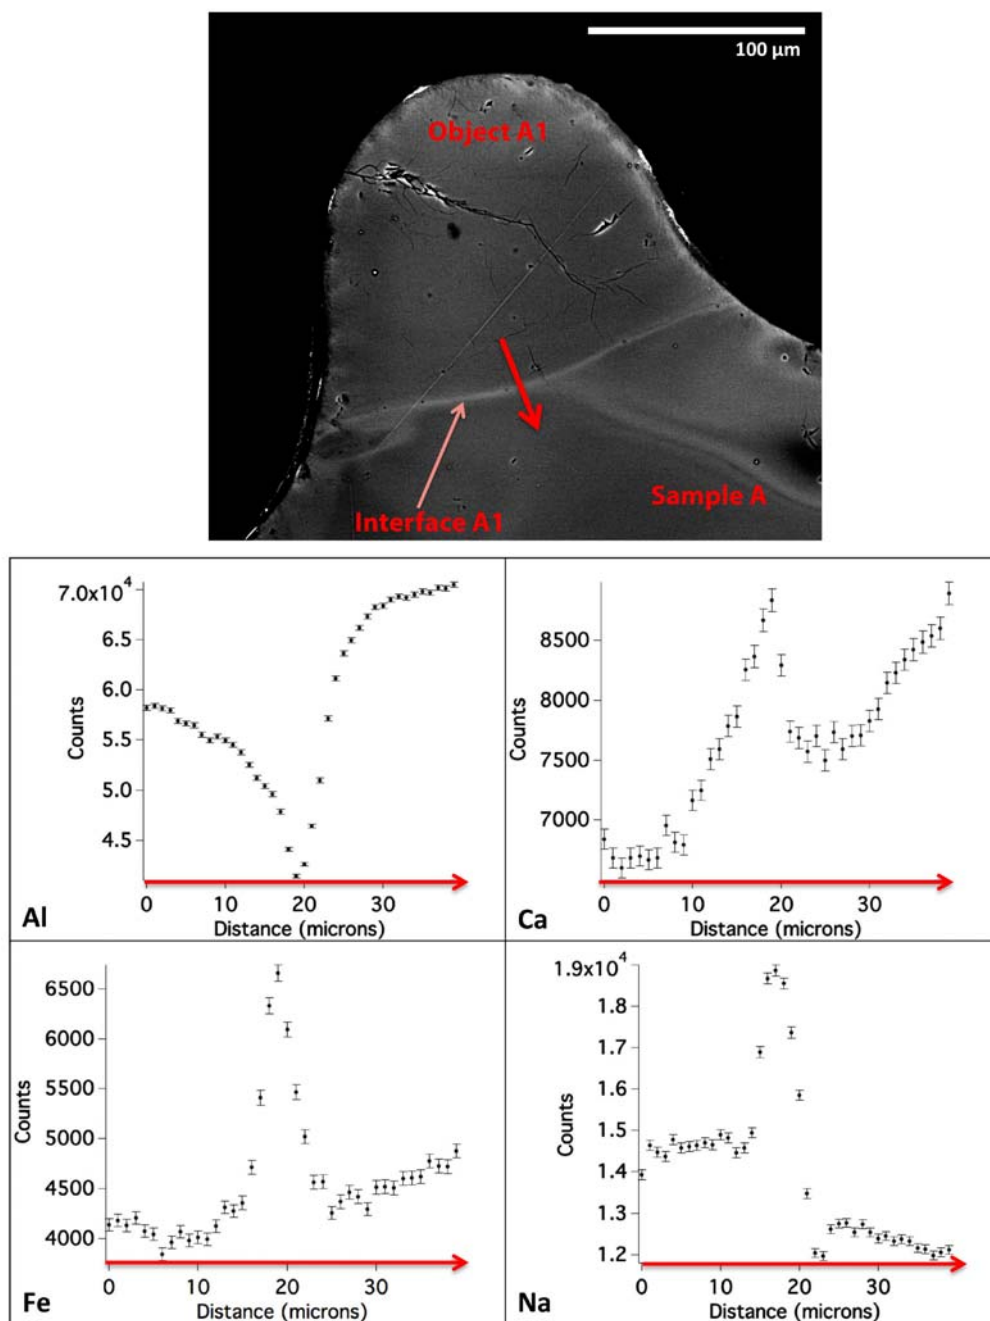

Figure 3.19: EDS spot analyses along the red line across the interface of Object A1 for aluminum, calcium, iron, and sodium. The variation of Al indicates a depletion at the interface relative to the interior regions on either side, while the variation of Ca, Fe, and Na indicates relative enrichment of each of these species at the interface.

Figure 3.20: EDS spot analyses along a line across the interface of Object B3 for aluminum, calcium, iron, and sodium. The variation of Al indicates a depletion at the interface relative to the interior regions on either side of it, while the variation of Ca and Fe indicates relative enrichment of each of these species at the interface. The variation of Na across the interface does not correspond, spatially, with any other observed enrichment or depletion.

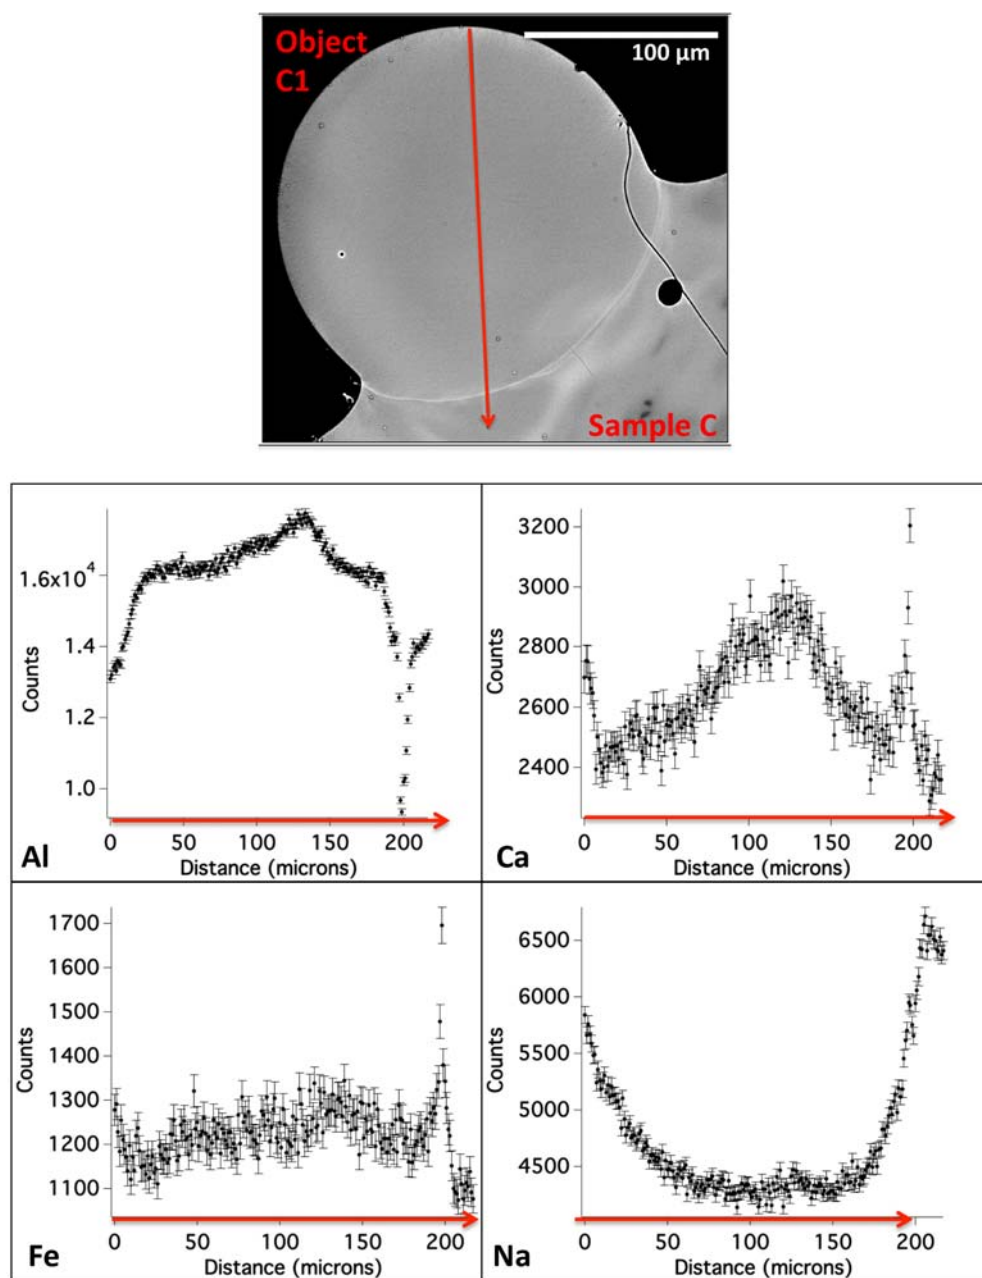

Figure 3.21: EDS spot analyses along a line from the edge of Object C1 across the interface into the larger object for aluminum, calcium, iron, sodium. In these plots, the edge is noted as 0 microns, and the interface is located at approximately 200 microns from the edge. The edge and the interface are both depleted in Al, and enriched in Ca, Fe, and Na, relative to the interior of the attached object and Sample C.

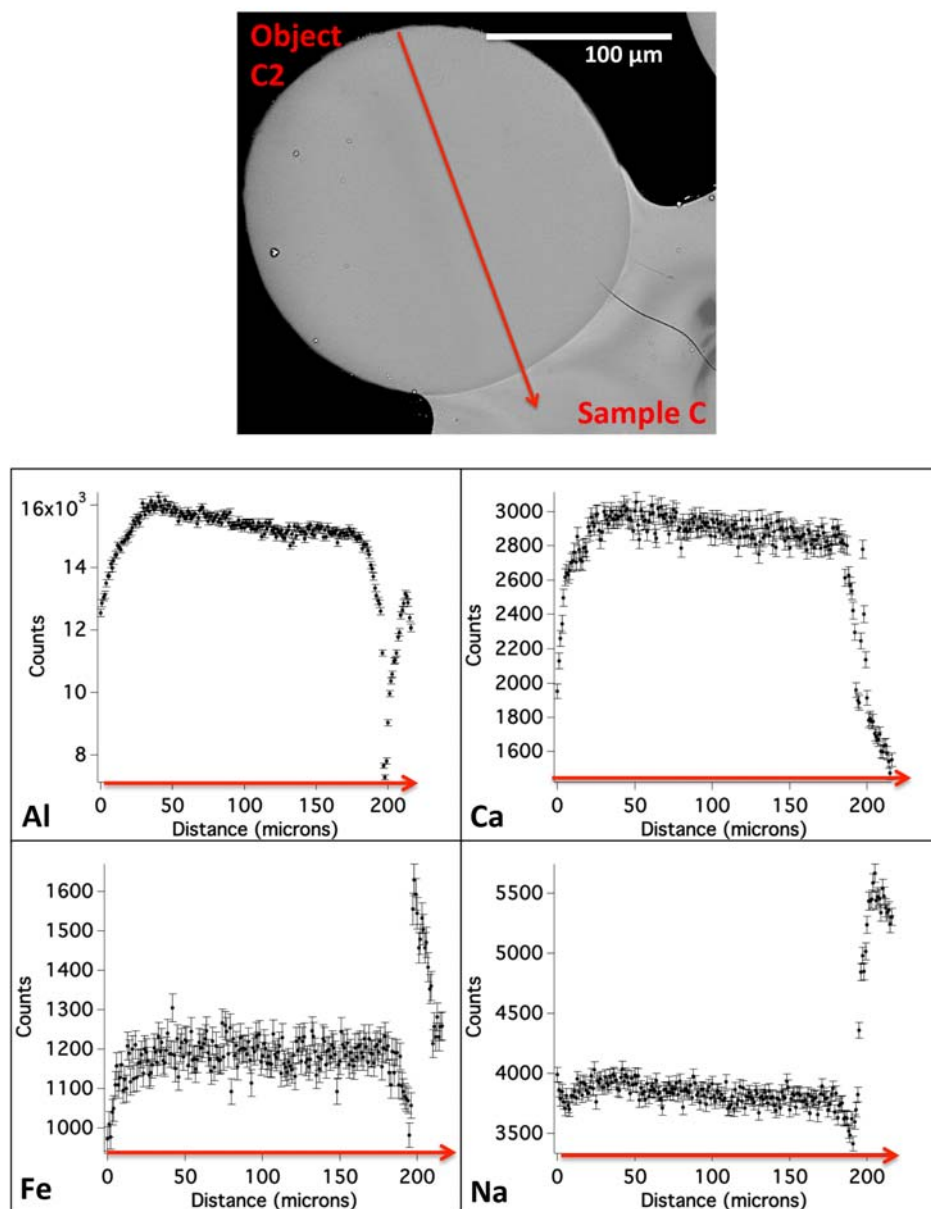

Figure 3.22: EDS spot analyses along a line from the edge of Object C2 across the interface into Sample C for aluminum, calcium, iron, sodium. The edge is noted as 0 microns, and the interface is located at approximately 200 microns from the edge. The edge and the interface are both depleted in Al. The edge is depleted in Fe and Ca, while the interface shows a region of relative depletion compared to the interior of Object C2, adjacent to a region of relative enrichment of both Fe and Ca. It is unclear if Na is enriched at the interface, or if the increase in Na is due to a higher Na concentration in Sample C.

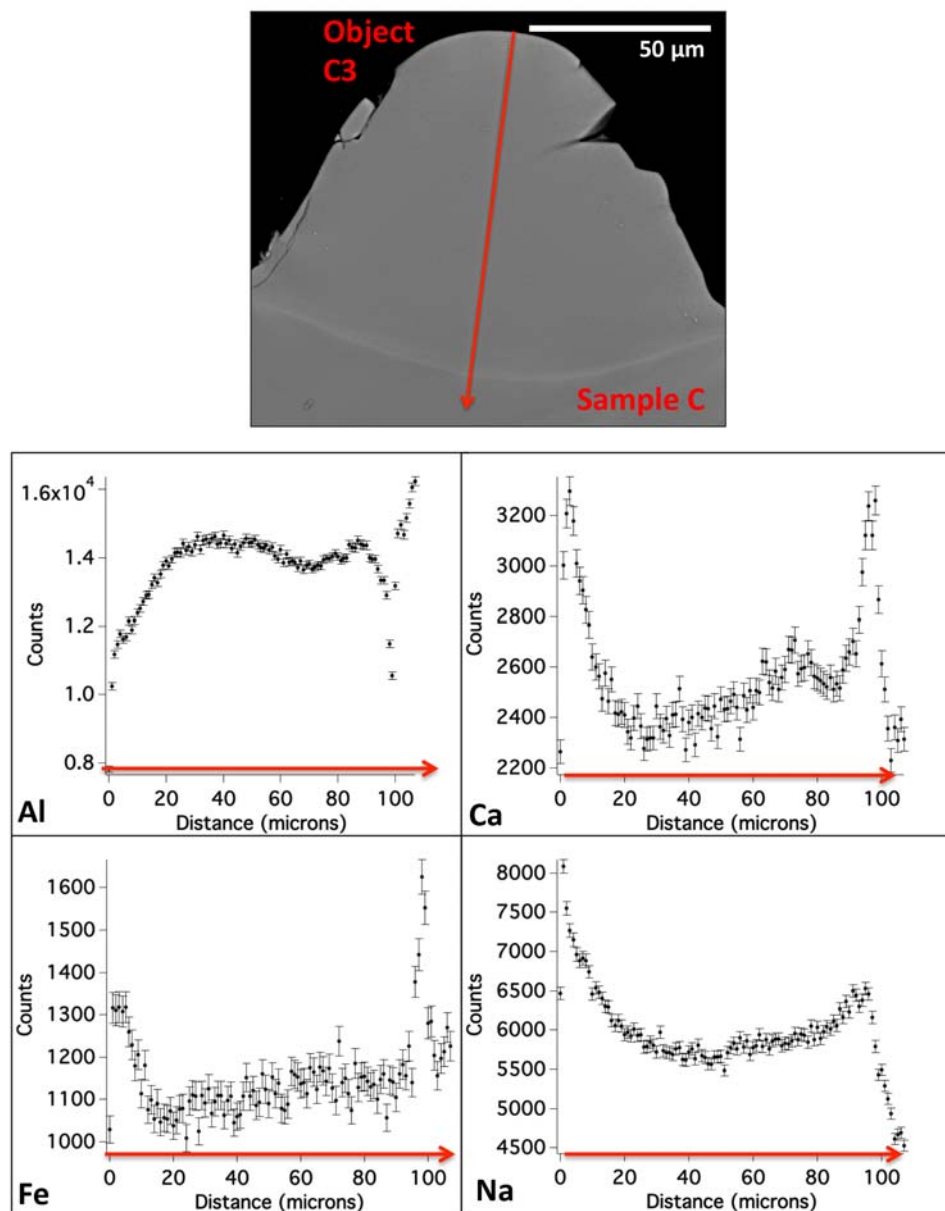

Figure 3.23: EDS spot analyses along a line from the edge of Object C3 across the interface into Sample C for aluminum, calcium, iron, sodium. The edge is noted as 0 microns, and the interface is located at approximately 95 microns from the edge. The edge and interface are relatively depleted in Al, and enriched in Ca, Fe, and Na, compared with the interior of Object C3.

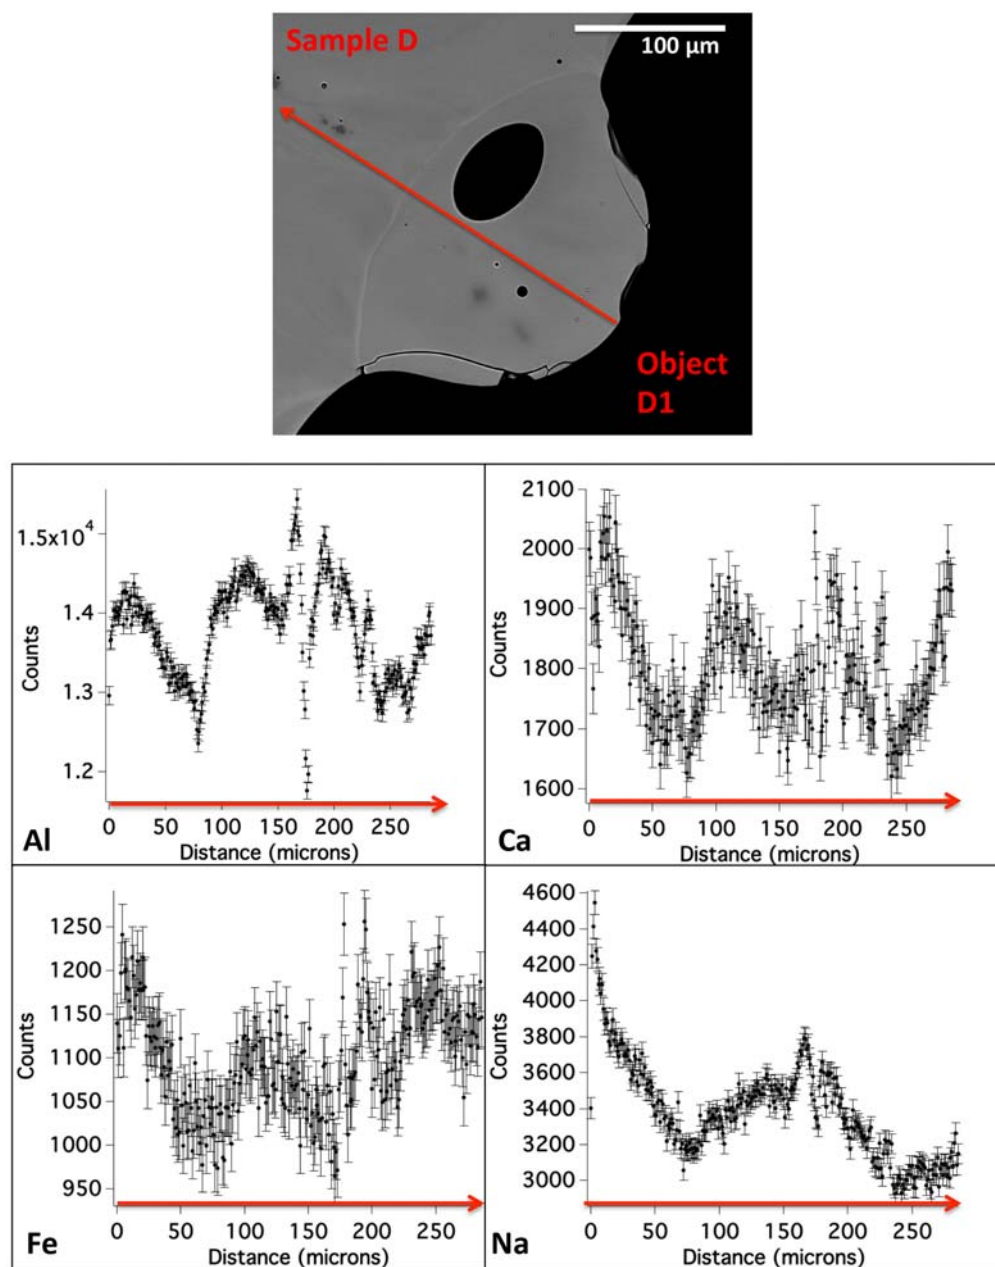

Figure 3.24: EDS spot analyses along a line from the edge of Object D1 across the interface into Sample D for aluminum, calcium, iron, sodium. The edge is noted as 0 microns, and the interface is located at approximately 175 microns from the edge. The heterogeneity of Object D1 is shown by the variation in each species. Despite this variation, there is a distinct depletion of Al at the interface relative to the interior composition of Object D2, and a corresponding relative enrichment of Ca, Fe, and Na.

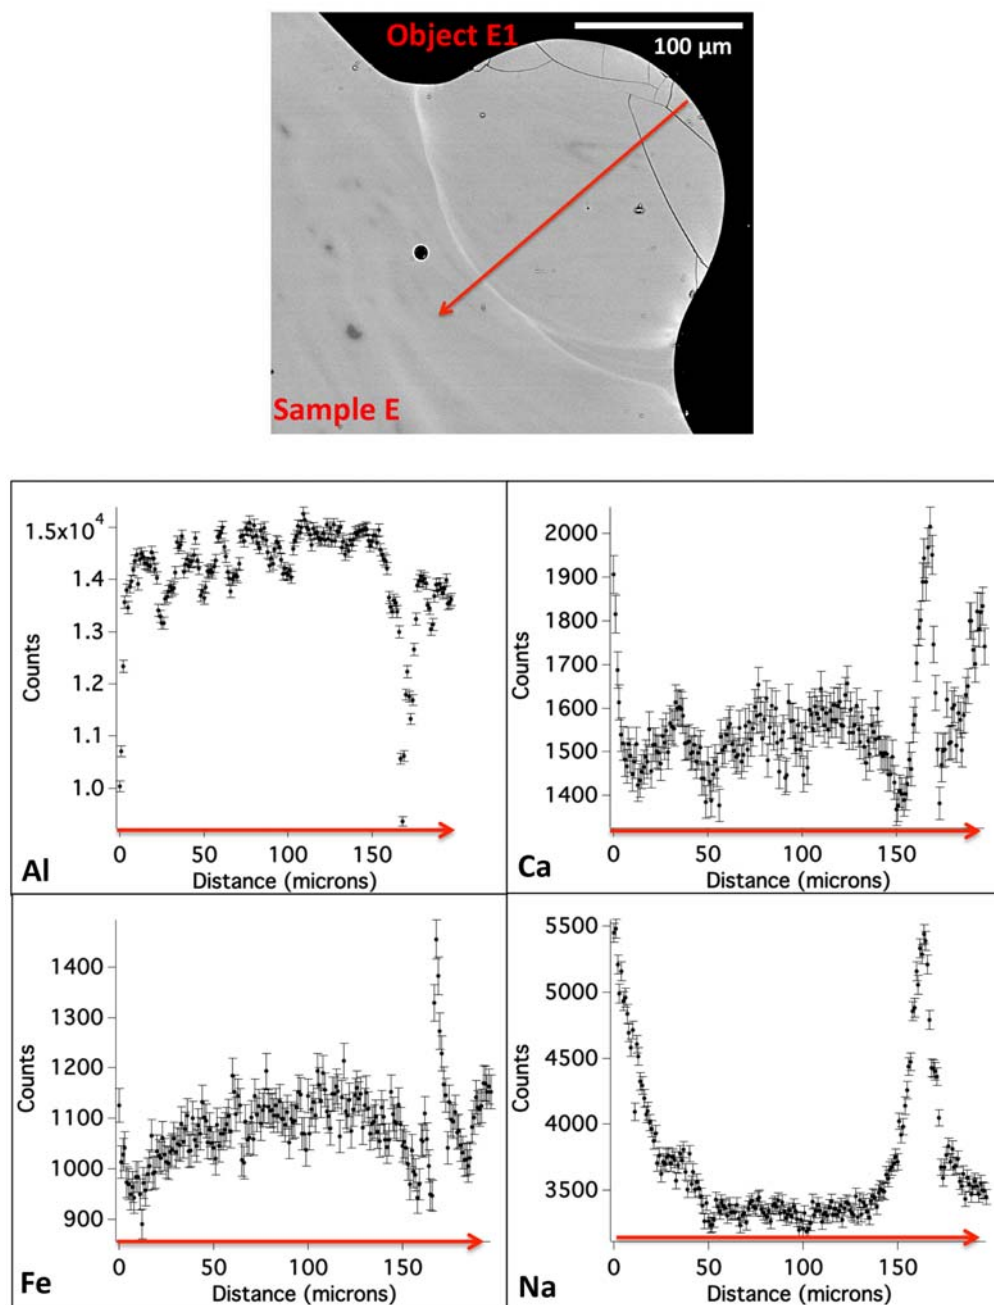

Figure 3.25: EDS spot analyses along a line from the edge of Object E1 across the interface into Sample E for aluminum, calcium, iron, sodium. The edge is noted as 0 microns, and the interface is located at approximately 170 microns from the edge. The edge and interface are relatively depleted in Al, and relatively enriched in Ca, Fe, and Na, compared with the interior of Object E1.

Figure 3.26: EDS spot analyses across object E1 for Na and K, showing relative enrichment of both Na and K at the edge and interface and the similarity of these patterns between these two elements.

## Chapter 4

# Quantitative Compositional Analysis

To quantitatively understand the variation of species within agglomerated fallout objects and at the interfaces where they fused onto the surfaces of larger hosts, quantitative analytical techniques are used, including electron probe microanalysis (EPMA) and nano-scale secondary ion mass spectrometry (NanoSIMS). Specifically, EPMA is used to measure the major element variation through agglomerated fallout objects and across their interfaces, as well as measure the major element composition of selected soil samples, which served as the carrier precursors to the fallout objects in this test. In order to understand the contribution of device uranium to the agglomerate interface layer, NanoSIMS is used to measure  $^{235}\text{U}$  and  $^{238}\text{U}$  variation, and estimate the uranium concentration at the interfaces.

### 4.1 EPMA Analyses

Electron probe microanalysis (EPMA) was used to acquire wavelength dispersive x-ray spectroscopy (WDS) analyses across selected attached objects (See Table 2.1) and their interfaces to quantitatively assess the compositional variation of major elements. The analyses were acquired as a series of 1 micron spots spaced 1 micron apart, following the analytical conditions set forth in Section 2.2. The WDS analyses were acquired for Si, K, Mn, Al, Fe, Ca, Na, Mg, and Ti, and the results are presented in stoichiometrically oxide corrected form for  $\text{Al}_2\text{O}_3$ ,  $\text{FeO}$ ,  $\text{CaO}$ ,  $\text{Na}_2\text{O}$ ,  $\text{MgO}$ , and  $\text{TiO}_2$  (unlike element X-ray counts, as given in the EDS spot analyses, Figures 3.19-3.26). As these species are likely present as oxides in these samples, the WDS data are presented in oxide form, although the precise speciation is unknown. Further, as discussed in Section 2.2, the values for  $\text{Na}_2\text{O}$  may be underestimated by up to 15%, due to beam volatilization effects. The edges and interfaces of agglomerated objects were compared to the average interior composition (Figure 4.1) of the objects to determine the extent of compositional variation in the deposition layer shown in Chapter 3. For the purposes of comparison, the edges are defined as regions of chemical enrichment or depletion within 10 microns from the edge of an agglomerated object adjacent to the epoxy, and the interfaces are defined as regions of chemical enrichment or depletion 5-10 microns

wide where agglomerated objects fused to the surface of larger hosts. The interior average composition (as shown in Figure 4.1), is defined as the average value of all data points within agglomerated objects, excluding points defined as edge or interface points.

The average major element oxide composition of the interiors of agglomerated fallout objects exhibit a different compositional range than the values found in mm-scale objects [55, 56]. For example, the average  $\text{Al}_2\text{O}_3$  and  $\text{SiO}_2$  concentrations range from 12.78 - 16.96 wt.% and 68.15 - 74.92 wt.% respectively (Figure 4.1, top left), while the values acquired by Lewis et al. (2015) have respective ranges of 13.5 - 14.6 wt.% and 71.4 - 72.4 wt.%. The average MgO and  $\text{TiO}_2$  concentrations range from 0.46 - 0.91 wt.% and 0.23 - 0.46 wt.% respectively (Figure 4.1, bottom left), while the values acquired by Lewis et al. (2015) have respective ranges of 0.4 - 0.6 wt.% and 0.2 - 0.3 wt.%. The average  $\text{Na}_2\text{O}$  concentrations in the agglomerated objects (ranging from 1.05 - 2.29 wt.%, Figure 4.1, bottom right), fall below the range found by Eppich et al. (2014) and Lewis et al. (2015), which are 3.0 - 3.6 wt.% and 3.0 - 3.7 wt.%, respectively. However, the average  $\text{K}_2\text{O}$  concentrations (3.44 - 5.78 wt.%) are similar to those found by Eppich et al. (2014) and Lewis et al. (2015), (3.9 - 5.5 wt.%, and 3.5 - 4.9 wt.%, respectively). The average CaO and FeO concentrations (1.19 - 2.49% and 2.13 - 3.52% respectively, Figure 4.1, top right) have approximately the same ranges of both Lewis et al. (2015) and Eppich et al. (2014).

In the following section, the Si data are not presented, as the Si content across the interfaces and the samples themselves is not highly variable (<2.9% standard deviation for the entire dataset). The K data are also not presented, given their similarity to the Na data (as shown by EDS, Figure 3.26). Finally, the Mn data are not plotted, as the count rate was very low ( $\sim 1$  cps), and often indistinguishable from background ( $\sim 2$  cps).

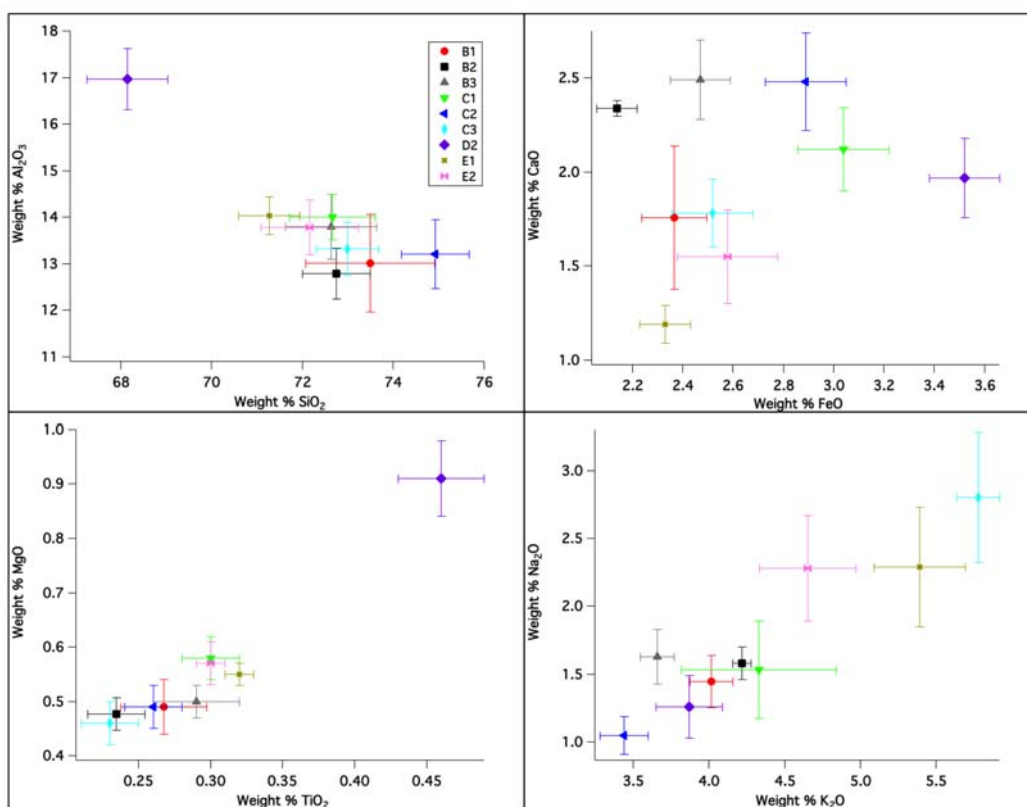

Figure 4.1: Average major element oxide composition of the interiors of agglomerated fallout objects B1, B2, B3, C1, C2, C3, D2, E1, and E2, with  $1\sigma$  uncertainties. The top left plot shows the average  $\text{Al}_2\text{O}_3$  and  $\text{SiO}_2$  concentrations (ranging from 12.78 - 16.96 wt.% and 68.15 - 74.92 wt.% respectively), the top right plot shows the average  $\text{CaO}$  and  $\text{FeO}$  concentrations (ranging from 1.19 - 2.49 wt.% and 2.13 - 3.52 wt.% respectively), the bottom left plot shows the average  $\text{MgO}$  and  $\text{TiO}_2$  concentrations (ranging from 0.46 - 0.91 wt.% and 0.23 - 0.46 wt.% respectively), and the bottom right plot shows the average  $\text{Na}_2\text{O}$  and  $\text{K}_2\text{O}$  concentrations (ranging from 1.05 - 2.29 wt.% and 3.44 - 5.78 wt.% respectively). In the top left and bottom right plots, Object D2 can be seen apart from the concentration cluster of the other objects, indicating similar concentrations in the rest of the objects for these species.

## Trends and characterization of major element relationships at agglomerate interfaces

The spot analyses across Objects B1 and B2 were taken along a single joined traverse, as they were both agglomerated onto Object B3, which is fused to Sample B (Figure 3.2). The spot analyses for Object B1 and its interface are presented in Figure 4.2, where the interface points are highlighted in blue. The interface is 4.5 microns wide, as characterized by the  $\text{FeO}$

variation (extending from within Object B1 across the interface into Object B2). This plot shows a local maxima for CaO, MgO, and FeO at the interface, which are 74%, 44%, and 32% enriched, respectively, relative to their average interior compositions ( $1.76 \pm 0.38\%$ ,  $0.49 \pm 0.05\%$ , and  $2.37 \pm 0.13\%$  by weight, respectively). There is also a local minima of  $\text{Al}_2\text{O}_3$  at the interface ( $11.62 \pm 0.06\%$  by weight, relative to the average interior concentration of  $13.02 \pm 1.05\%$ ), although it is difficult to distinguish from the variation of  $\text{Al}_2\text{O}_3$  through the object itself (which spans a relative range of  $\sim 40\%$ ). The  $\text{Na}_2\text{O}$  plot shows an increase at the interface, although it is not clear if this illustrates an enrichment at the interface, or simply a higher relative  $\text{Na}_2\text{O}$  content in Object B2. The  $\text{TiO}_2$  content at this interface is difficult to distinguish from the variation through the sample itself. This could be due to the low concentration  $\text{TiO}_2$  ( $\sim 0.25$  weight %) in these fallout samples, which approaches the limit of detection by EPMA.

The spot analyses for Object B2 traverse the diameter of the entire object ( $\sim 50$  microns). This dataset is a continuation of the dataset given for Object B1, where the data at 200 microns in Figure 4.2 corresponds to the data at 0 microns in Figure 4.3, also shown in the BSE image of Figures 4.2 and 4.3. The major element composition in the interior of Object B2 is more homogeneous than in Object B1, which corresponds to what is observed qualitatively in BSE; this is most apparent for  $\text{Al}_2\text{O}_3$  and CaO (Figure 4.3). The concentration of  $\text{Al}_2\text{O}_3$  at the interface is  $11.27 \pm 0.07\%$  by weight, representing a 12% depletion relative to the average composition of  $12.79 \pm 0.54\%$  by weight in Figure 4.1. Again, the FeO, MgO, and CaO plots show increased concentration at the interface ( $2.55 \pm 0.08\%$ ,  $0.55 \pm 0.01\%$ ,  $2.90 \pm 0.03$  by weight, respectively) relative to the interior concentrations of these species ( $2.14 \pm 0.08\%$ ,  $0.48 \pm 0.03$ , and  $2.34 \pm 0.04\%$  by weight, respectively). The interface, as characterized by the FeO variation, is 3 microns wide. The  $\text{TiO}_2$  plot shows a depletion of 24% at the interface relative to the interior concentration ( $0.23 \pm 0.02\%$  by weight). Object B2 does not show an observable pattern of enrichment or depletion in  $\text{Na}_2\text{O}$  through the object, or at the interface itself. However, there is greater than 20% relative variation in  $\text{Na}_2\text{O}$  within the interior of the sample from spot to spot, which is indicative of Na heterogeneity in the sample.

In Object B3, spot analyses were acquired across the interface (Figure 4.4), and approximately 60 microns into the large host object of sample B. As shown in the BSE image, there is significant chemical heterogeneity. The major element composition at the interface follows a similar pattern as seen in objects B1 and B2, where local minima are observed co-located for  $\text{Al}_2\text{O}_3$  and  $\text{TiO}_2$ , and local maxima are observed co-located for CaO, FeO, and MgO. The interface is 6 microns wide, as measured by the FeO variation. Again, there is  $>20\%$  spot to spot variation in the  $\text{Na}_2\text{O}$  analyses. There is relative depletion of  $\text{Al}_2\text{O}_3$  at the interface ( $12.67 \pm 0.07\%$  by weight) relative to the average interior composition ( $13.80 \pm 0.70\%$  by weight). There is also an observed relative depletion of  $\text{TiO}_2$  at the interface ( $0.25 \pm 0.01\%$  by weight) in comparison to its average interior concentration ( $0.29 \pm 0.03\%$  by weight), although this depletion falls within the range of the observed spot-to-spot variation in the interior concentration dataset (which spans a relative range of 17%). These local minima of  $\text{Al}_2\text{O}_3$  and  $\text{TiO}_2$  at the interface are co-located with enrichments in CaO, MgO,

and FeO concentration (29%, 33%, and 32%, respectively), relative to the average interior concentrations ( $2.49 \pm 0.21\%$ ,  $0.50 \pm 0.03\%$ , and  $2.47 \pm 0.12\%$  by weight, respectively).

Object C1 illustrates a pattern of enrichment and depletion of the major elements typically observed in most samples for this study (Figure 4.5). The spot analyses were acquired from the outer edge of the object, through its major diameter, and across the interface, capturing the major element variation at the edge and the interface. The composition of the interior points is homogeneous for  $\text{Al}_2\text{O}_3$ , FeO, MgO, and  $\text{Na}_2\text{O}$  (Figure 4.1). There is depletion of  $\text{Al}_2\text{O}_3$  concentration at the outer edge of the object, and a depletion at the interface ( $5.37 \pm 0.05\%$  by weight, compared to  $14.00 \pm 0.49\%$  by weight at the interface). While it is difficult to distinguish a depletion of  $\text{TiO}_2$  at the edge within the measurement uncertainties,  $\text{TiO}_2$  shows strong depletion at the interface ( $0.19 \pm 0.02\%$  by weight compared to  $0.30 \pm 0.02$ ). The compositional variation of CaO, MgO, and FeO at the edge and the interface show enrichment in both places, co-located with the depletion of  $\text{Al}_2\text{O}_3$ . The enrichments of CaO, MgO, and FeO are significant also at the interface, with enrichments of 54%, 12%, and 41%, respectively, relative to their interior concentrations of  $2.12 \pm 0.22\%$ ,  $0.58 \pm 0.04\%$ , and  $3.04 \pm 0.18\%$  by weight. The interface, as measured by the FeO variation, is 9 microns wide. There is also enrichment of  $\text{Na}_2\text{O}$  at the interface ( $2.24 \pm 0.04\%$  by weight, compared to  $1.53 \pm 0.36\%$  by weight at the interface).

In attached object C2, there is a unique pattern of compositional variation at both the edge and the interface (Figure 4.6) where the object is fused to the large host of Sample C. The interior points for all the major elements show minimal variation in comparison to the other samples (Figures 4.1 and 4.6). This observation of homogeneity is in line with the qualitative results of X-ray mapping, which also show relative homogeneity in Al, Ca, Fe, and Na concentrations (Figure 3.14). At the edge and the interface, there is a depletion of  $\text{Al}_2\text{O}_3$  and  $\text{TiO}_2$ . Specifically, the  $\text{Al}_2\text{O}_3$  concentration at the interface is  $7.05 \pm 0.06\%$  by weight, compared to  $13.21 \pm 0.74\%$  by weight on the interior of the object, while the  $\text{TiO}_2$  concentration at the interface is  $0.15 \pm 0.02\%$  by weight, compared to an average concentration of  $0.26 \pm 0.02\%$  by weight on the interior of the object. Unlike all of the other analyzed interfaces, there is also a depletion of MgO at the edge and the interface (29% relative to the average interior concentration). The CaO, FeO, and  $\text{Na}_2\text{O}$  composition at the edge and the interface show an unusual pattern of enrichment and depletion. This is most visible at the interface, where there is a relative depletion of  $\sim 60\%$  and  $\sim 30\%$  in CaO and FeO concentration, respectively, compared to the interior average concentrations ( $2.48 \pm 0.26\%$  and  $2.89 \pm 0.16\%$ , respectively) immediately followed by a relative enrichment of CaO and FeO ( $\sim 50\%$  and  $\sim 100\%$ , respectively, compared to the aforementioned region of relative depletion) moving from the interior of the object, across the interface into the large host object. The  $\text{Na}_2\text{O}$  plot shows the inverse pattern: a relative enrichment ( $\sim 100\%$ ) followed by a relative depletion ( $\sim 50\%$ ) at the interface. The interface, as characterized by the FeO variation, is 9 microns wide. At the edge, there is relative depletion of CaO and FeO ( $\sim 50\%$  and  $\sim 30\%$ , respectively), which is not discernible in the X-ray map (Figure 3.14). The X-ray map shows that the enrichment pattern observed at the interface (particularly for CaO) continues all the way around the object as concentric rings of enrichment and

depletion. The absence of this pattern at the edge of the plot of the spot analyses (Figure 4.5) is likely due to the elimination of the points at the very edge which overlapped with the epoxy.

Object C3 shows the more typical pattern of chemical variation at its edge and interface for  $\text{Al}_2\text{O}_3$ ,  $\text{CaO}$ ,  $\text{MgO}$ , and  $\text{FeO}$  (Figure 4.7). There is a depletion of  $\text{Al}_2\text{O}_3$  at the interface ( $9.19 \pm 0.12$  wt.% in comparison to an average interior concentration of  $13.32 \pm 0.57$  wt.%), followed by an increase in concentration in the host sample C ( $>18$  wt.%). The  $\text{CaO}$ ,  $\text{MgO}$ , and  $\text{FeO}$  composition at the edge and interface indicates an enrichment of each species, with relative enrichments of 57%, 30%, and 55%, respectively, at the interface (relative to interior average concentrations of  $1.78 \pm 0.18$  wt.%,  $0.46 \pm 0.04$  wt.%, and  $2.52 \pm 0.16$  wt.%, respectively). There is no observable depletion of  $\text{TiO}_2$  at the interface, although there is a slight depletion at the edge (17% relative to the interior). The  $\text{Na}_2\text{O}$  composition across the object does not show any discernible variation, with the exception of a relative decrease in concentration of 31% in host Sample C. The interface, as characterized by the  $\text{FeO}$  concentration variation, is 7.5 microns wide.

Compositional flow structures within object D2 and the large host object (Figure 4.8), are reflected in the major element concentration plots. Despite the extent of the compositional variation observed in Object D2 ( $>50\%$  relative variation for the  $\text{Al}_2\text{O}_3$ ,  $\text{CaO}$ ,  $\text{MgO}$ , and  $\text{TiO}_2$  and datasets) a discernible compositional change at the interface outside of this variation is captured in the data, reflecting the depletion of  $\text{Al}_2\text{O}_3$  ( $12.57 \pm 0.14$  wt%, compared to an average interior concentration of  $16.96 \pm 0.66$  wt.%) and enrichment of  $\text{CaO}$  ( $2.21 \pm 0.04$  wt.% compared to an interior concentration of  $1.97 \pm 0.21$  wt.%) and  $\text{FeO}$  ( $4.24 \pm 0.13$  wt.% compared to an interior concentration of  $3.52 \pm 0.14$  wt.%) at the interface. The interface, as characterized by the  $\text{FeO}$  concentration variation, is 9 microns wide. The  $\text{MgO}$  concentration variation does not reflect an enrichment at the interface due to the variation within the sample itself; there is a concentration of  $0.82 \pm 0.03$  wt.% at the interface, compared to the average interior concentration of  $0.91 \pm 0.07$  wt.%. There is a decrease in  $\text{TiO}_2$  concentration at the interface, however, there is no observable local minima. It is difficult to distinguish a unique  $\text{TiO}_2$  concentration at the interface from the change in concentration between object D2 and the large host object of Sample D due to the uncertainties on each spot analysis. There is no distinguishable  $\text{Na}_2\text{O}$  variation at the interface relative to the  $\text{Na}_2\text{O}$  concentration on either side of it.

Perhaps the most illustrative example of the major element enrichment and depletion trends that appear to be characteristic of interfaces is preserved in object E1 (Figure 4.9). The interface where object E1 is fused to the larger host of sample E shows relative depletions of  $\text{Al}_2\text{O}_3$  and  $\text{TiO}_2$ , as well as relative enrichments of  $\text{CaO}$ ,  $\text{MgO}$ ,  $\text{FeO}$ , and  $\text{Na}_2\text{O}$ . The depletions of  $\text{Al}_2\text{O}_3$  and  $\text{TiO}_2$  are 42% and 32%, respectively, relative to the respective average interior concentrations of  $13.78 \pm 0.59$  wt.% and  $0.30 \pm 0.01$  wt.%. The relative enrichments of  $\text{MgO}$  and  $\text{FeO}$  were both 55% compared to their respective average interior concentrations of  $0.57 \pm 0.04$  wt.% and  $2.58 \pm 0.20$  wt.%. The relative enrichment of  $\text{CaO}$  is 199% compared to the average interior concentration of  $1.19 \pm 0.10$  wt.%. The interface, as characterized by the  $\text{FeO}$  concentration variation, is 7.5 microns wide.

The interface where object E2 is fused to the larger host object E shows the same trend of depletion and enrichment for all of the major elements observed in Samples A, B, C, and D, with the exception of  $\text{TiO}_2$ , which does not show a clear pattern of enrichment or depletion at the interface (Figure 4.10). There is a depletion of  $\text{Al}_2\text{O}_3$  ( $11.39 \pm 0.06$  wt.%, compared to an average interior concentration of  $13.78 \pm 0.59$  wt.%) and enrichments of  $\text{CaO}$  ( $3.11 \pm 0.03$  wt.% compared to an average interior concentration of  $1.55 \pm 0.25$  wt.%),  $\text{MgO}$  ( $0.93 \pm 0.02$  wt.% compared to an average interior concentration of  $0.57 \pm 0.04$  wt.%), and  $\text{FeO}$  ( $3.71 \pm 0.11$  wt.% compared to an average interior concentration of  $2.58 \pm 0.20$  wt.%). There is also an enrichment of  $\text{Na}_2\text{O}$  at the interface ( $3.02 \pm 0.04$  wt.% compared to an average interior concentration of  $2.28 \pm 0.39$  wt.%), observable in the X-ray map of Na for object E2 (see Figure 3.18), where a layer of relatively higher Na concentration surrounds the entire object. The peak width for interface E2 (as defined by the FeO variation) is 12 microns, is the widest of all of the measured interfaces.

Figure 4.2: EPMA spot analyses across Object B1 (see Figure 3.2 for the full BSE image) showing variation of Al, Ca, Fe, Mg, Na, and Ti oxide concentrations. The location of the analyses is shown in the BSE image as a red-dashed line, along which a series of 1 micron spot analyses were acquired. The interface points, defined by the FeO local maximum, are shaded in blue, and is 4.5 microns wide. Local maxima for CaO, MgO, and FeO at the interface, show enrichment of 74%, 44%, and 32% enriched, respectively, relative to their average interior compositions. Na<sub>2</sub>O is increased at the interface, although it is offset by 3 microns. There is ~40% relative variation through the interior of the object, and a local minima of Al<sub>2</sub>O<sub>3</sub> at the interface is apparent. The TiO<sub>2</sub> does not show any trend at the interface.

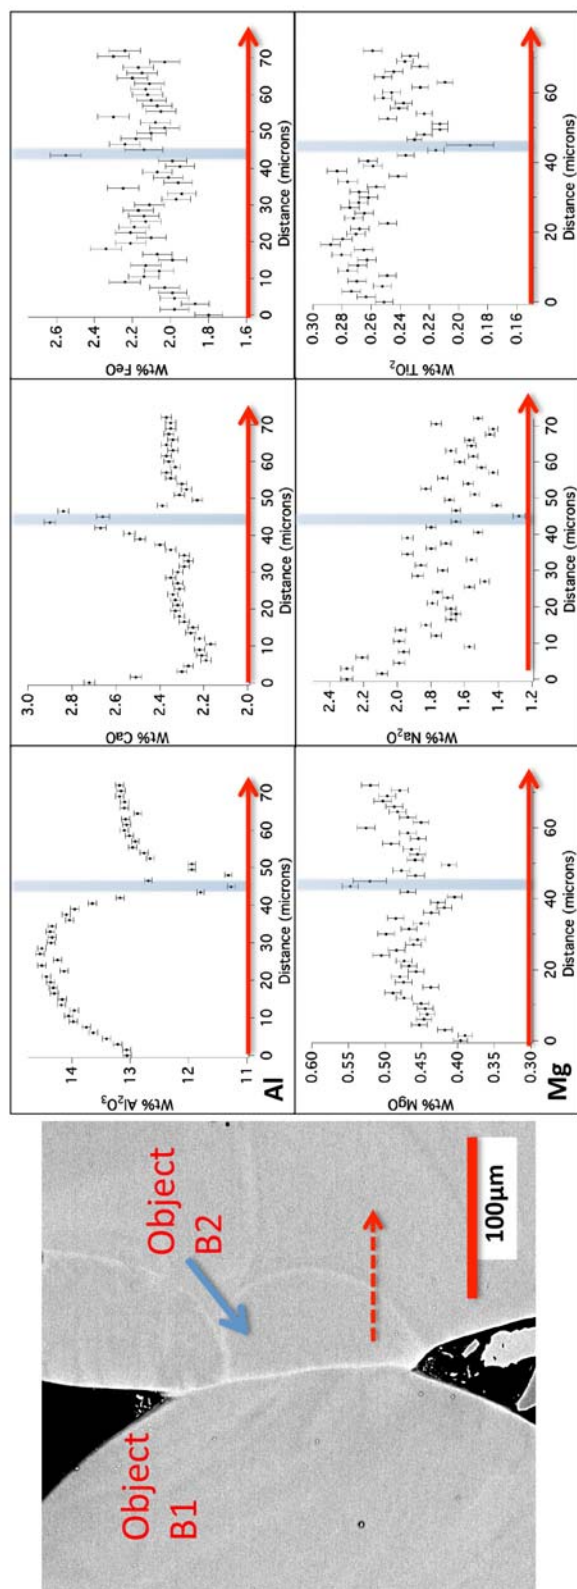

Figure 4.3: EPMA spot analyses across object B2 (along the same traverse shown in Figure 4.1) showing variation of Al, Ca, Fe, Mg, Na, and Ti oxide concentrations. The location of the analyses is shown in the BSE image as a red-dashed line, along which a series of 1 micron spot analyses were acquired. The interface points, defined by the FeO local maximum, are shaded in blue, and is 3 microns wide. This dataset is a continuation of the dataset given for Object B1, where the data at 200 microns in Figure 4.2 correspond to the data at 0 microns in Figure 4.3. The Al<sub>2</sub>O<sub>3</sub> plot reveals a depletion at the interface, while the FeO, MgO, and CaO plots show a co-location of increased concentration at the interface relative to the interior concentrations of these species. The TiO<sub>2</sub> plot shows a depletion of 24% at the interface relative to the interior concentration. There is no observable pattern of enrichment or depletion in Na<sub>2</sub>O through the object, or at the interface itself.

Figure 4.4: EPMA spot analyses across object B3 showing variation of Al, Ca, Fe, Mg, Na, and Ti oxide concentrations. The location of the analyses is shown in the BSE image as a red-dashed line, along which a series of 1 micron spot analyses were acquired. The interface points, defined by the FeO local maximum, are shaded in blue, and is 6 microns wide. Local minima are observed for  $Al_2O_3$  and  $TiO_2$ , and local maxima are observed for CaO, FeO, and MgO at the interface.  $Na_2O$  does not show an obvious trend of enrichment or depletion at the interface.

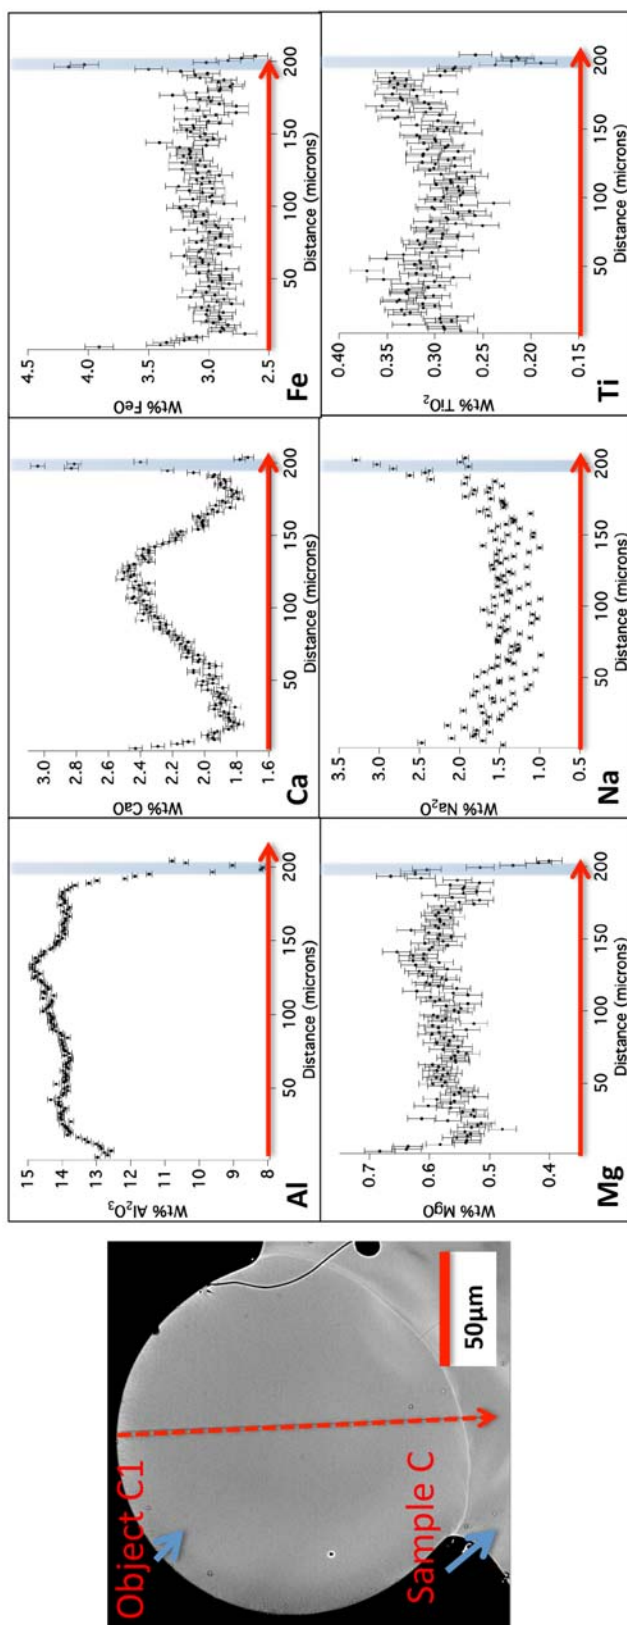

Figure 4.5: EPMA spot analyses across object C1 showing variation of Al, Ca, Fe, Mg, Na, and Ti oxide concentrations. The location of the analyses is shown in the BSE image as a red-dashed line, along which a series of 1 micron spot analyses were acquired. The interface points, defined by the FeO local maximum, are shaded in blue, and is 9 microns wide.  $\text{Al}_2\text{O}_3$  and  $\text{TiO}_2$  are depleted at the interface, while CaO, FeO, MgO, and  $\text{Na}_2\text{O}$  are enriched relative to the interior concentrations. The  $\text{Na}_2\text{O}$  and MgO maxima are 3 microns offset from the FeO maxima.

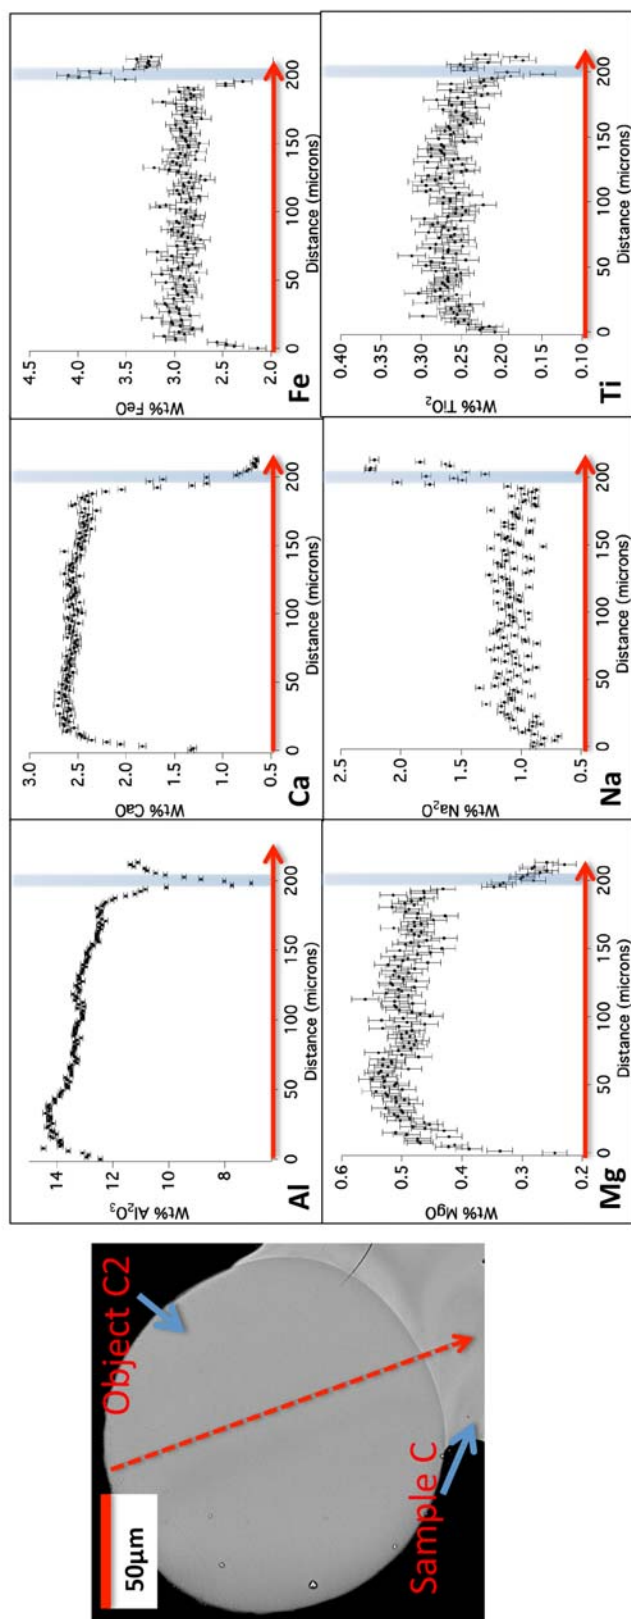

Figure 4.6: EPMA spot analyses across object C2 showing variation of Al, Ca, Fe, Mg, Na, and Ti oxide concentrations. The location of the analyses is shown in the BSE image as a red-dashed line, along which a series of 1 micron spot analyses were acquired. The interface points, defined by the FeO local maximum, are shaded in blue, and is 9 microns wide. The interior points for all the major elements show a relatively homogeneous composition. There is a unique pattern of compositional variation at both the edge and the interface in CaO, FeO, and Na<sub>2</sub>O. This is most visible at the interface, where there is a relative depletion of CaO and FeO concentration immediately followed by a relative enrichment of CaO and FeO, and an inverse pattern in Na<sub>2</sub>O. At the edge, EPMA data show relative depletion of CaO and FeO, and X-ray mapping shows that this enrichment pattern (particularly for CaO) continues all the way around the object as concentric rings (Figure 3.14).

Figure 4.7: EPMA spot analyses across object C3 showing variation of Al, Ca, Fe, Mg, Na, and Ti oxide concentrations. The location of the analyses is shown in the BSE image as a red-dashed line, along which a series of 1 micron spot analyses were acquired. The interface points, defined by the FeO local maximum, are shaded in blue, and is 7.5 microns wide. This object shows the more typical pattern of chemical variation at its edge and interface for  $Al_2O_3$ ,  $CaO$ ,  $MgO$ , and FeO. There is a depletion of  $Al_2O_3$  at the interface in comparison to its average interior concentration, followed by an increase in concentration in host sample C. The  $CaO$ ,  $MgO$ , and FeO composition at the edge and interface indicate enrichment of each species relative to the interior. There is no observable depletion of  $TiO_2$  at the interface. The  $Na_2O$  composition across the object or interface does not show any discernible variation, and there is a relative depletion of  $Na_2O$  in the larger host of Sample C.

Figure 4.8: EPMA spot analyses across object D2 showing variation of Al, Ca, Fe, Mg, Na, and Ti oxide concentrations. The location of the analyses is shown in the BSE image as a red-dashed line, along which a series of 1 micron spot analyses were acquired. The interface points, defined by the FeO local maximum, are shaded in blue, and is 9 microns wide. As seen in the BSE image, there are visible compositional flow structures within object D2 which are reflected in the major element concentration plots. There is a depletion of  $\text{Al}_2\text{O}_3$  and  $\text{TiO}_2$  at the interface, and a corresponding enrichment of CaO, FeO, and MgO relative to the values on either side of the interface. There is no distinguishable  $\text{Na}_2\text{O}$  variation at the interface relative to the  $\text{Na}_2\text{O}$  concentration on either side of it.

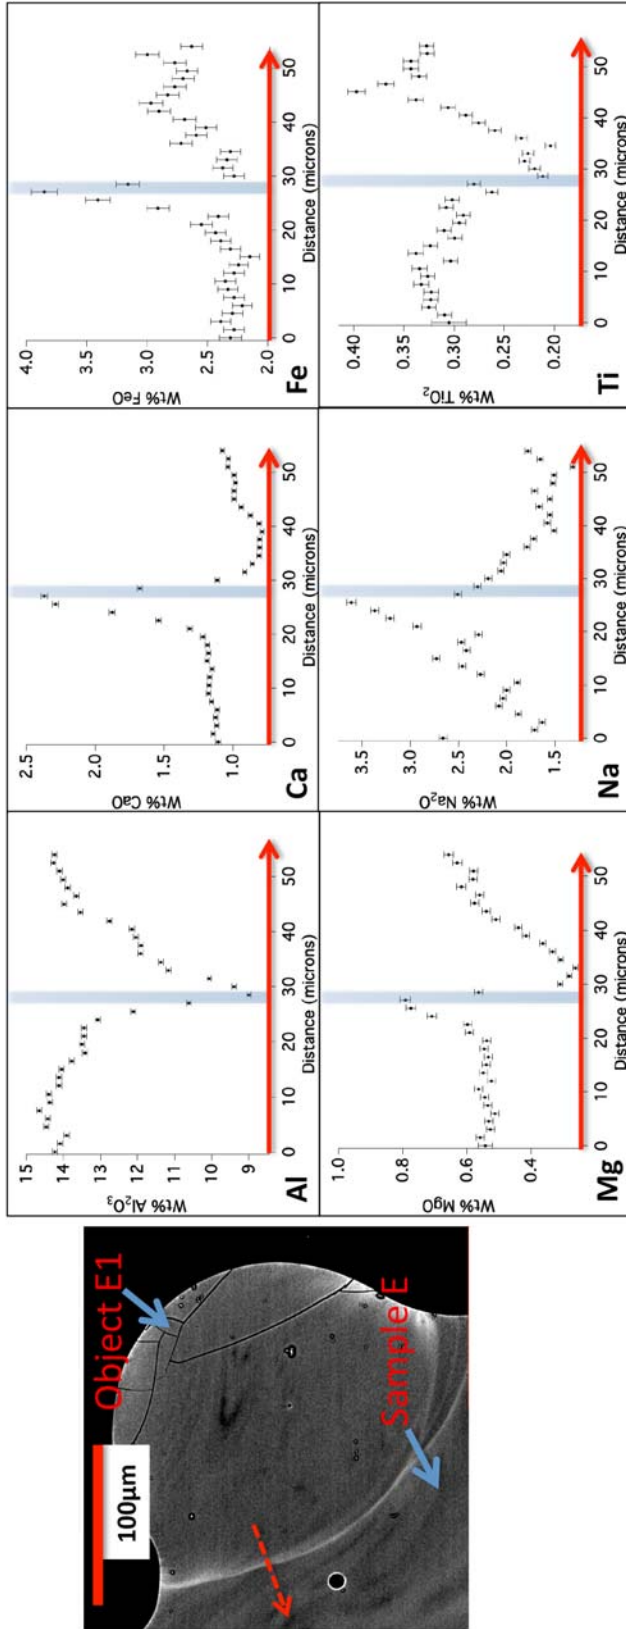

Figure 4.9: EPMA spot analyses across object E1 showing variation of Al, Ca, Fe, Mg, Na, and Ti oxide concentrations. The location of the analyses is shown in the BSE image as a red-dashed line, along which a series of 1 micron spot analyses were acquired. The interface points, defined by the FeO local maximum, are shaded in blue, and is 7.5 microns wide. The interface where object E1 is fused to the larger host of sample E shows relative depletions of  $\text{Al}_2\text{O}_3$  and  $\text{TiO}_2$ , as well as relative enrichments of CaO, MgO, FeO, and  $\text{Na}_2\text{O}$ . The relative enrichment of CaO is the largest relative increase of any interface (199%) compared to the average interior concentration.

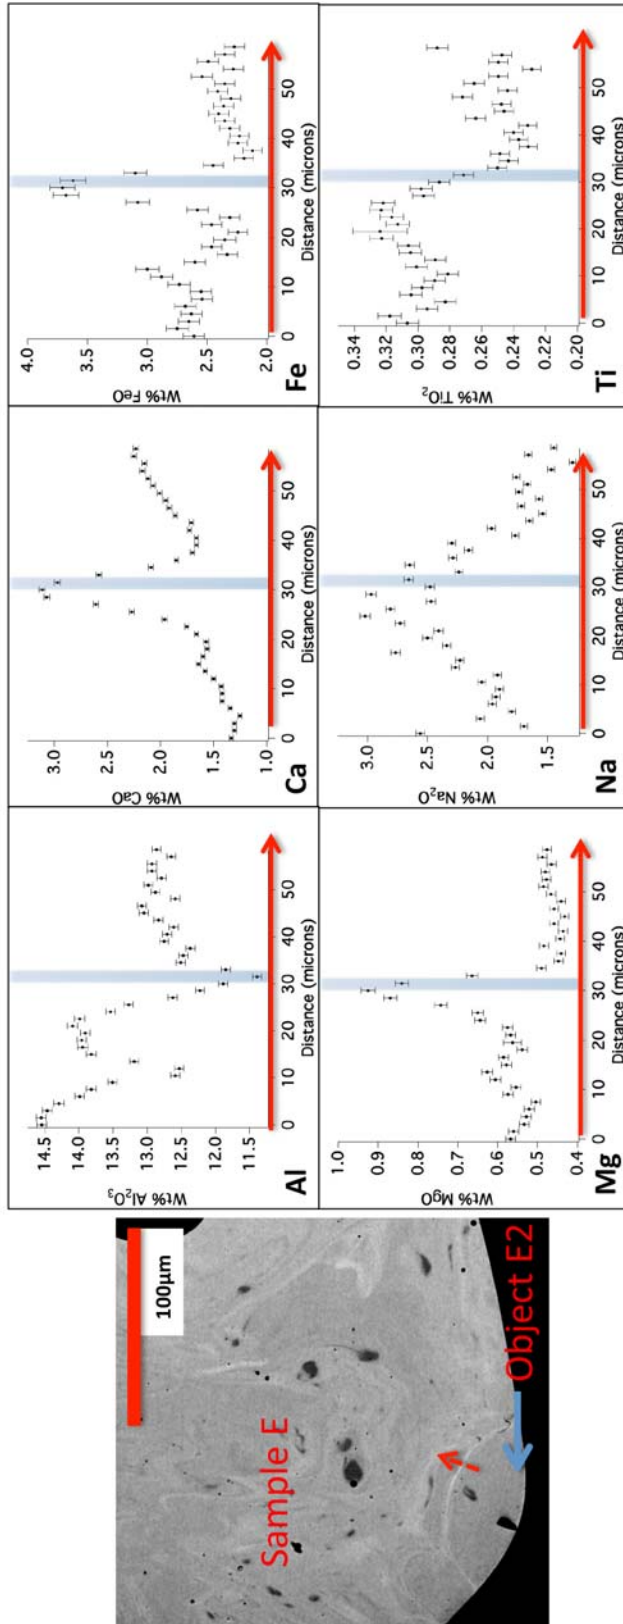

Figure 4.10: EPMA spot analyses across object E2 showing variation of Al, Ca, Fe, Mg, Na, and Ti oxide concentrations. The location of the analyses is shown in the BSE image as a red-dashed line, along which a series of 1 micron spot analyses were acquired. The interface points, defined by the FeO local maximum, are shaded in blue, and is 12 microns wide, which is the widest of all of the measured interfaces. There is a depletion of  $\text{Al}_2\text{O}_3$  at the interface, and a corresponding enrichment of CaO, FeO, and MgO relative to the values on either side of the interface.  $\text{TiO}_2$  does not show a clear pattern of enrichment or depletion at the interface. There is also an enrichment of  $\text{Na}_2\text{O}$  at the interface, which appears diffuse and is offset from the FeO maxima by 4.5 microns (also observable in the X-ray map of Na for object E2, see Figure 3.18).

## Summary of quantitative major element fallout glass analyses

The major element traverses show a chemical enrichment of Fe and Ca observed at every interface, along with a corresponding depletion of Al and Ti, relative to the interiors of agglomerated objects. While the interface values do not show a pattern of enrichment or depletion in comparison to the interface values for SiO<sub>2</sub> (Figure 4.11, top left), all of the interface values (ranging from 5.37 - 12.67 wt.%) are depleted in Al<sub>2</sub>O<sub>3</sub> relative to their respective average values (ranging from 12.78 - 16.96 wt.%). All of the interface values for CaO (ranging from 2.55 - 4.49 wt.%) and FeO (ranging from 1.76 - 3.11 wt.%, Figure 4.11, top right) are enriched compared to their interior average values (ranging from 1.19 - 2.49 wt.% and 2.13 - 3.52 wt.% respectively), with the exception of B2 and C2. The TiO<sub>2</sub> concentration at the interface (ranging from 0.15-0.29 wt.%) is depleted relative to the interior average (ranging from 0.46 - 0.91 wt.%, Figure 4.11, bottom left) in all the objects except B1 and B3. Neither the K<sub>2</sub>O nor the Na<sub>2</sub>O concentrations show a discernible pattern of enrichment or depletion at the interface relative to the interior averages (Figure 4.11, bottom right).

The compositional and spatial data for 9 measured interfaces are presented in Table 4.1. Localized enrichments of Fe, Ca, and Mg (converted to oxides) are observed at all 9 measured interfaces (Table 4.1). As the concentration of each measured element varies considerably on either side of the interface, nominal values are described here as the average value of three points on either side of the peak for each oxide of interest, exemplifying the increase in concentration of these species due to a deposition layer. Both Fe and Ca interface enrichments are observed to be ~50% relative to their corresponding nominal values observed on either side of each interface. A corresponding depletion at the interface of Al and Ti is also observed at all 9 interfaces measured with EPMA, with both elements depleted ~20% relative to the nominal values on either side of the minima for each interface (Table 4.1). Six of the 9 interfaces are shown to have a relative enrichment of Na<sub>2</sub>O compared to the nominal values on either side of the interface (Table 4.1). A schematic characterizing this observed trend in compositional variation at the outer edges and interfaces of agglomerated fallout objects is given in Figure 4.12.

Table 4.1: Summary of WDS analyses at interfaces characterizing the relative enrichment and depletion in comparison to nominal values on either side of the interface. The uncertainties on the maxima/minima are the  $1\sigma$  uncertainties on the measurement. The  $\text{Na}_2\text{O}$  data may be underestimated due to the volatilization effect described in Section 2.2. The uncertainties on the nominal values are the  $1\sigma$  standard deviation of 6 spot analyses on either side of the interface.

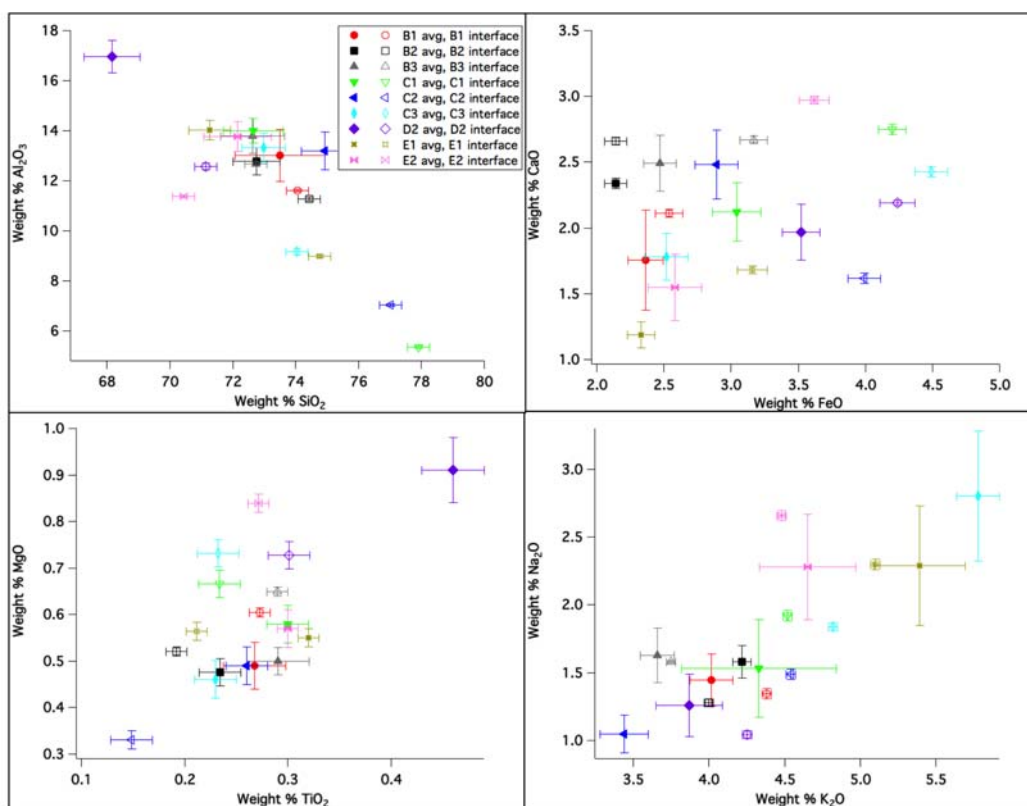

Figure 4.11: Average major element oxide composition of the interiors of agglomerated fallout objects B1, B2, B3, C1, C2, C3, D2, E1, and E2, with their corresponding interface values ( $1\sigma$  uncertainties). While the interface values do not show a pattern of enrichment or depletion in comparison to the interface values for  $\text{SiO}_2$  (top left), all of the interface values are depleted in  $\text{Al}_2\text{O}_3$  relative to their respective average values. All of the interface values for  $\text{CaO}$  and  $\text{FeO}$  (top right) are enriched compared to their interior average values, with the exception of B2 and C2. The  $\text{MgO}$  concentration (bottom left) at the interface is enriched relative to the interior average value in all objects except C2 and D2, while the  $\text{TiO}_2$  concentration at the interface is depleted relative to the interior average in all the objects except B1 and B3. Neither the  $\text{K}_2\text{O}$  nor the  $\text{Na}_2\text{O}$  concentrations show a discernible pattern of enrichment or depletion at the interface relative to the interior averages.

Figure 4.12: Diagram of the most commonly observed compositional variation observed at the edges and interfaces of agglomerated fallout objects.

## Quantitative major element soil analyses

Quantitative compositional analyses of soil were acquired by EPMA on polished grains from soil acquired proximate to ground zero. These analyses provide a general understanding of the composition of the soil, which served as the carrier material precursor for fallout glass from this test. While these analyses do not provide a comprehensive mineralogical survey of the soil, they do provide a context through which to understand the possible combinations of mineral compositions that combined to form the dominant glass compositions in the resultant fallout. To a first order, the contribution from non-soil sources to major element concentrations in these glasses is considered negligible. Qualitatively, backscatter electron imaging (*e.g.*, Figure 3.6) reveals that the soil is primarily comprised of fine-grained granitic and rhyolitic clasts (<1 mm). The mineralogy is dominated by clay, as well as roughly equal amounts of feldspar minerals and quartz, with lesser amounts of pyroxene and ilmenite. All spot analyses made on the darkest regions (Figure 3.6) revealed a >98% SiO<sub>2</sub> composition, and were compositionally consistent with quartz.

A series of 18 WDS spot analyses were acquired on suspected feldspar minerals observed in the soil, which are presented in Table 4.2. The major element composition reveals a range of compositions, which were then used to determine the fraction of feldspar components contributing to each analysis, presented in Table 4.3, (illustrated in Figure 4.13), where representative analyses are shown on corresponding minerals in BSE imaging. The feldspar component mole fractions show that the feldspar minerals observed in the soil include plagioclase and alkali feldspars. These compositions were plotted as a ternary diagram in Figure 4.14, with the designated feldspar mineral ranges superimposed on the plotted data. From this plot, it is clear that the analyzed feldspar minerals fall predominantly in the ranges defined for andesine and sanidine (Figure 4.13). As shown in Figure 4.14, the sanidine compositions have roughly equal concentrations of Na and K, and the andesine concentrations have a Ca:Na ratio of ~2:3. This is similar the concentrations of these species observed in the soil analyses of Eppich et al. (2014) from the same test [55], indicating that these feldspar minerals may be the dominant contributors of Na, K, and Ca to the soil, which served as the carrier materials precursors for the fallout objects in this study. Further, the analyzed feldspar minerals have high concentrations of Al<sub>2</sub>O<sub>3</sub> (>17%, Table 4.2), and are one of the predominant sources of Al in the soil (which serves as a carrier for glassy fallout), which has a concentration of ~10 wt % Al<sub>2</sub>O<sub>3</sub> [55].

Figure 4.13: Three representative soil analyses on feldspar minerals from a soil grain acquired proximate to ground zero of this test, as shown in BSE imaging. These spots correspond to feldspar analyses #4, 6, and 18 in Tables 4.2 and 4.3, corresponding to andesine (spots 4 and 6) and sanidine (spot 18) as shown in Figure 4.14. Also shown in this figure is a representative pyroxene, corresponding to pyroxene analysis #1 in Table 4.4, characterized as clinoenstatite in Figure 4.15.

Table 4.2: Major element composition of feldspar minerals in soil samples proximate to ground zero acquired by EPMA spot analyses. Uncertainties are  $1\sigma$ .

Figure 4.14: Ternary diagram of feldspar components, with EPMA spot analyses of feldspar minerals in selected soil samples overlaid based on their component mole fraction. The analyzed feldspar minerals fall predominantly in the ranges defined for andesine and sanidine. The sanidine compositions have roughly equal concentrations of Na and K, and the andesine concentrations have a Ca:Na ratio of  $\sim 2:3$ .

To a lesser extent, various minerals of relatively higher average atomic number were also observed in backscatter imaging of the soil samples (approximately 10% of the observed non-clay minerals). EPMA spot analyses of the brightest regions acquired by WDS identified most of these minerals as ilmenite ( $\text{FeTiO}_3$ , see Figure 3.6), with a composition approximately equal parts FeO and  $\text{TiO}_2$  (42% and 48% by weight, respectively, with approximately 1% of both MgO and MnO). Other high-Z minerals were identified as pyroxene of various composition (Table 4.4). The major element analyses were used to determine the pyroxene component fractions of each of the 3 analyses. The components fractions show that the pyroxene minerals observed in the soil include at least two distinct pyroxene compositions. These component fractions were plotted as a ternary diagram in Figure 4.14, with the designated pyroxene mineral ranges superimposed on the plotted data. From this plot, it is clear that the analyzed pyroxene minerals fall in the range defined for clinoenstatite ( $\text{Mg}_2\text{Si}_2\text{O}_6$ ) and diopside ( $\text{CaMgSi}_2\text{O}_6$ ) (Figure 4.15), and are the predominant source of Mg observed in the soil samples. Further, diopside (along with andesine, Table 4.2) may also serve as a significant source of Ca in these fallout glasses (which have a Ca concentration ranging from 1.19 - 2.49 wt.%, Figure 4.1), although it was relatively rare. The clay minerals which predominate the soil samples were also characterized by EPMA. However, the effect of volatilization on clay minerals makes data acquisition by EPMA difficult, often producing major element sum totals <96%. A total of 6 spot analyses on clay minerals (*e.g.*, Analysis #5, Figure 4.13) were acquired with adequate sum totals (>96%), and are presented in Table 4.6. These minerals have significant  $\text{SiO}_2$  ( $77.26 \pm 6.66$  wt.%),  $\text{Al}_2\text{O}_3$  ( $11.81 \pm 3.08$  wt.%),  $\text{K}_2\text{O}$  ( $4.76 \pm 0.98$  wt.%),  $\text{Na}_2\text{O}$  ( $4.02 \pm 0.91$  wt.%), and FeO ( $1.94 \pm 0.86$  wt.%) concentrations, and likely serve as a significant source of these species in the fallout glasses, which have similar concentrations of these species (Figure 4.1).

Although data was not acquired on all of the observed minerals, there is assuredly a broader range of pyroxene, ilmenite, and feldspar compositions in the soil than represented by the above dataset. Other less common minerals, such as zircons, were also rarely observed; these were only cursorily analyzed in real-time by EDS, and quantitative data were not acquired.

Figure 4.15: Ternary diagram of pyroxene components, with EPMA spot analyses of pyroxene minerals in selected soil samples overlaid based on their component mole fraction, showing a predominance of Mg-rich pyroxenes.

In Figure 4.16, the  $\text{Al}_2\text{O}_3$  data is plotted against the  $\text{SiO}_2$  data for the feldspar analyses, clay analyses, as well as the analyses acquired by EPMA within the attached glassy fallout objects and their interfaces. In this figure, the data closest to the local maximum at the interfaces of each agglomerated fallout object is represented by red hexagons, the analyses acquired within the attached objects is shown as gray triangles, the feldspar analyses are shown as black diamonds, and the clay analyses are shown as blue triangles. The black line is a linear fit of the feldspar data with a pure quartz (100%  $\text{SiO}_2$ ) data point, which approximates a first order mixing relationship between the measured feldspar and observed quartz in the soil data. The clay data fall into the same compositional region as the analyses on the interiors of attached glassy fallout objects, and 4 of the 6 data points fall along the line representing simple mixing between quartz and feldspar. This indicates that the major element (*i.e.*, Si, Al) composition of the attached objects can be described, to a first order, as a mixture between these major soil components (*i.e.*, clay, feldspar minerals, and quartz). The dashed gray line represents a linear fit of the interface data points, showing a similar relationship between  $\text{Al}_2\text{O}_3$  and  $\text{SiO}_2$ , but offset from the composition of both soil and the interiors of the agglomerated fallout objects. This is indicative of the contribution of another component that significantly altered the major element composition of the interface.

Figure 4.16: The  $\text{Al}_2\text{O}_3$  vs.  $\text{SiO}_2$  data for feldspar, clay and fallout glasses. The interface data is shown as red hexagons (representing points at the interface proximate to the local maxima/minima), and the interior data is shown as gray triangles. Feldspar analyses are shown as black diamonds, all uncertainties are given as  $1\sigma$ . Blue triangles represent the EPMA analyses acquired on clay-dominated regions in the soil (See Figure 4.13). The black line is a linear fit of the feldspar data with a pure quartz (100%  $\text{SiO}_2$ ) data point, and the dashed gray line represents a linear fit of the interface data points of the glassy agglomerated fallout. The data points interior to attached fallout objects as well as the clay compositions are bound by these two lines. This shows that the major element (*i.e.*, Al, Si) composition of the attached objects can be described as a mixture between major soil components (clay, feldspar minerals, and quartz). The interface data points show a similar relationship between  $\text{Al}_2\text{O}_3$  and  $\text{SiO}_2$ , but offset from the composition of both soil and the interiors of the agglomerated fallout objects. This is indicative of the contribution of another component that significantly altered the major element composition of the interface.

## 4.2 NanoSIMS Analyses

Nano-scale secondary ion mass spectrometry (NanoSIMS) was used to determine the relative variation of uranium isotopes ( $^{235}\text{U}$  and  $^{238}\text{U}$ ) across selected interfaces (specified in Table 2.1) where the attached glassy objects were fused to the larger fallout samples. NanoSIMS is better suited for these samples given its ability to measure the relative variation of individual uranium isotopes ( $^{235}\text{U}$  and  $^{238}\text{U}$  in this study), high lateral spatial resolution (sub-micron scale, compared to micron-scale for EPMA), and its superior detection limit of trace species (the detection limit for U in EPMA is  $>40$  ppm in the most ideal case, versus sub-ppm for NanoSIMS [80]). To determine the spatial relationship between of uranium isotope variation at the interface, and the local enrichment and depletion trends of major elements (as presented in Section 4.1), isotopes of Ca ( $^{44}\text{Ca}$ ) and Fe ( $^{54}\text{Fe}$  or  $^{56}\text{Fe}$ ) were also acquired by NanoSIMS at the same locations.

To address condensation and deposition of vaporized species onto agglomerated fallout objects, determining the absolute concentration of species across the interface was not necessary. The relative compositional variation, however, may be illustrative of how carriers incorporate species to form fallout. This was exemplified by Lewis et al. (2015), where the relative variation in isotope ratio of  $^{235}\text{U}/^{238}\text{U}$  was used to understand the relative variation of uranium concentration within fallout objects [56]. Here, the relative variation of uranium concentration was determined by normalizing the uranium isotopic measurements to  $^{30}\text{Si}$ , as Si content was shown to be relatively invariable across the interfaces (never exceeding 10% relative variation, see Section 2.3). Ion images and the data plots (presented in Figures 4.17 - 4.26) show the relative compositional variation of Fe, Ca, and U as isotope ratios of  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ , and  $^{235}\text{U}/^{30}\text{Si}$  (with the exception of object A1, which uses  $^{56}\text{Fe}/^{30}\text{Si}$ ). To assess the degree of isotopic enrichment of uranium at these interfaces, ion images and data plots for  $^{235}\text{U}/^{238}\text{U}$  are also presented for each analyzed interface. These values were calibrated using uranium doped glass and uranium oxide particle standards (detailed in 'Analyses of Standards', Section 2.3), and the maximum concentration of uranium was estimated at each interface using the calculated RSF (see Section 2.3, Equation 2.12).

The NanoSIMS ion image data acquired at the interface of object A1 (Figure 4.17) and the larger host object show the expected pattern of Fe and Ca chemical enrichment, as observed in the EDS analyses. This is seen clearly in the isotope ratio images of  $^{56}\text{Fe}/^{30}\text{Si}$  and  $^{44}\text{Ca}/^{30}\text{Si}$ , where higher isotope ratios are shown in orange and yellow, and lower isotope ratios are shown in blue and black. The relative variation is illustrated (right hand side) as traverses across the interface following the white arrow in the upper-left isotope ratio image. In these plots, the  $^{56}\text{Fe}/^{30}\text{Si}$  and  $^{44}\text{Ca}/^{30}\text{Si}$  peaks (relative enrichments of 61% and 11%, respectively) are co-located (within 1.5 microns, at 5.7 microns in the plots). The width of the interface, as characterized by the width of the base of the  $^{56}\text{Fe}/^{30}\text{Si}$  peak, is  $\sim 7$  microns. Unique to object A1, the compositional variation of U (as represented by  $^{235}\text{U}/^{30}\text{Si}$ ) shows a region of relative depletion co-located with the enrichments of Fe and Ca at the interface. There is a local maximum of  $^{235}\text{U}/^{30}\text{Si}$  adjacent to this region of depletion, seen at approximately 3.6 microns; however, it is difficult to distinguish this local maximum from

compositional variation around the interface. The BSE image (far left, Figure 4.17), with the  $^{235}\text{U}/^{30}\text{Si}$  isotope ratio image superimposed on it, shows that the region of depletion is indeed co-located with interface. As seen in the  $^{235}\text{U}/^{238}\text{U}$  data plot (Figure 4.17), the uranium at the interface, and on either side of it, is predominantly  $^{235}\text{U}$ . The  $^{235}\text{U}/^{238}\text{U}$  isotope ratio exceeds 7 across the isotope ratio image, and reaches a ratio as high as  $9.58 \pm 0.34$ , which corresponds to an isotopic enrichment of  $90.5 \pm 0.3\%$ . While the lowest  $^{235}\text{U}/^{238}\text{U}$  point ( $7.13 \pm 0.30$ ) corresponds to the region of depletion in the  $^{235}\text{U}/^{30}\text{Si}$  ( $0.000121 \pm 0.000003$  at 5.7 microns), the isotopic variation of uranium ( $^{235}\text{U}/^{238}\text{U}$  ratio) does not correspond to the uranium concentration (as represented by  $^{235}\text{U}/^{30}\text{Si}$ ). All isotope ratios on either side of the interface are roughly the same in both Object A1 and host Sample A.

As was observed in Object A1, the isotope ratio data for Object B1 (Figure 4.18) shows a pattern of relative  $^{54}\text{Fe}/^{30}\text{Si}$  and  $^{44}\text{Ca}/^{30}\text{Si}$  enrichment (100% and 93%, respectively), which is also observed in the EPMA data (Figure 4.2) across the interface of where object B1 fuses to the larger Sample B. For this object, and all of the subsequent NanoSIMS analyses for this thesis,  $^{54}\text{Fe}$  was measured rather than  $^{56}\text{Fe}$  (as was measured in Object A1). The width of the interface as characterized by the width of the base of the  $^{54}\text{Fe}/^{30}\text{Si}$  peak is  $\sim 7$  microns, compared with 4.5 microns, as measured by EPMA. The data calculated as a traverse across the acquired isotope ratio image of the interface (Figure 4.18) along the white arrow, show that the enrichment of Fe and Ca are co-located. At this interface, the uranium compositional variation (as represented by the  $^{235}\text{U}/^{30}\text{Si}$  ratio) shows a distinct enrichment that is co-located with the Fe and Ca enrichment. Contrary to what is shown in object A1, the BSE image with the  $^{235}\text{U}/^{30}\text{Si}$  ratio image superimposed on it shows that the region of uranium enrichment is approximately continuous with the bright, diffuse interface region shown in BSE (see Figure 3.2). The  $^{235}\text{U}/^{238}\text{U}$  image and plot show a distinct isotopic enrichment in object B1 relative to the object to which it is attached (a ratio of  $6.30 \pm 1.23$  compared with a ratio of  $4.12 \pm 0.36$ ). In both cases, the average isotopic enrichment away from the boundary is very high ( $>80\%$  in both objects). As seen in Object A1, there is no observable increase of isotope ratio at the interface, where the  $^{235}\text{U}/^{30}\text{Si}$  maxima ( $2.02 \pm 0.05 \times 10^{-4}$ , corresponding to a uranium concentration of  $36 \pm 21$  ppm by weight, calculated as shown in Section 2.3) is located.

The ion image data acquired for object B2 shows another unique pattern (with this data set) of chemical and isotopic variation in uranium (Figure 4.19). The  $^{54}\text{Fe}/^{30}\text{Si}$  and  $^{44}\text{Ca}/^{30}\text{Si}$  ratio images and plots show peak enrichment (22% and 45%, respectively, relative to the values on either side of the interface) co-located with the interface (as observed in the EPMA analyses), with a width of  $\sim 7$  microns, compared with 3 microns as determined by EPMA, which is attributable to the spatial uncertainties in the EPMA spot analyses ( $\pm 1.5$  microns) or, more likely, spatial variations in interface width. There is no relative enrichment of uranium concentration at the interface. There is, however, an increase in uranium concentration and uranium isotopic enrichment in the object to which B2 is fused (Object B3) relative to Object B2 itself. Also, there is a gradient of decreasing concentration from Object B3 to Object B2 (Figure 4.19) rather than a local minimum or maximum (as seen in objects A1 and B1, respectively). Of further note, the  $^{235}\text{U}/^{238}\text{U}$  variation across

the interface appears to closely mirror the  $^{235}\text{U}/^{30}\text{Si}$  variation. The  $^{235}\text{U}/^{238}\text{U}$  ratio within Object B2 is on average  $4.36 \pm 0.52$  (which corresponds with what was observed in Object B1, Figure 4.18), while in the larger object to which it is fused, the  $^{235}\text{U}/^{238}\text{U}$  is  $6.20 \pm 0.20$  ( $86.1 \pm 0.4\%$  enriched in  $^{235}\text{U}$ ).

The ion image data acquired for object B3 (Figure 4.20) shows relative enrichment of Fe, Ca, and U at the interface (as seen in the ratio images and plots of  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ). While the  $^{54}\text{Fe}/^{30}\text{Si}$  variation shows the same pattern of local enrichment at the interface that has been observed in the previous samples (a distinct maximum above an approximately constant baseline, in this case 33%, with a width of  $\sim 6$  microns), this is not the case for  $^{44}\text{Ca}/^{30}\text{Si}$  variation. Despite an enrichment of  $^{44}\text{Ca}/^{30}\text{Si}$  at the interface, Object B3 has a substantially lower  $^{44}\text{Ca}/^{30}\text{Si}$  ratio than Sample B (36% lower  $^{44}\text{Ca}/^{30}\text{Si}$  ratio relative to Sample B), making a local maximum difficult to distinguish. As seen in the EPMA plot (Figure 4.5) at the same interface, there is significant variation in Ca concentration (17% standard deviation), and the BSE image (Figure 4.2) shows a high degree of chemical heterogeneity, generally. This heterogeneity in both Sample B and Object B3 is also reflected in the image and plot of  $^{235}\text{U}/^{30}\text{Si}$  (26% standard deviation). While there is a distinct region of enrichment seen at the interface, it is adjacent to two regions of relative depletion of  $^{235}\text{U}/^{30}\text{Si}$  ratio within both object B3 and the large host object. Further, the local maximum of  $^{235}\text{U}/^{30}\text{Si}$  near the interface ( $0.75 \pm 0.03 \times 10^{-4}$ , corresponding to a uranium concentration of  $14 \pm 8$  ppm by weight) is offset from the local maximum of  $^{54}\text{Fe}/^{30}\text{Si}$  by 3.8 microns. The local maximum of  $^{235}\text{U}/^{238}\text{U}$  is approximately co-located with the  $^{235}\text{U}/^{30}\text{Si}$  near the interface ( $4.17 \pm 0.35$ ). Object B3 has an average  $^{235}\text{U}/^{238}\text{U}$  ratio of  $3.23 \pm 0.83$ , consistent with what was observed in Object B2 (Figure 4.19).

The ion image data of object C1 show the characteristic relative enrichments of Fe, Ca, and U (as seen in the ratio images and plots of  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ , Figure 4.21) observed at most of the analyzed interfaces. The ratio images and the data plots show that the peaks of  $^{54}\text{Fe}/^{30}\text{Si}$  ( $0.1910 \pm 0.0001$ , a relative enrichment of 72%, with a width of  $\sim 7$  microns),  $^{44}\text{Ca}/^{30}\text{Si}$  ( $0.1251 \pm 0.0001$ ), and  $^{235}\text{U}/^{30}\text{Si}$  ( $9.43 \pm 0.09 \times 10^{-4}$ , corresponding to a uranium concentration of  $154 \pm 88$  ppm by weight) are the global maxima for each image, and are co-located (at 8.6 microns, Figure 4.21). The  $^{235}\text{U}/^{238}\text{U}$  image captures an isotopic enrichment of uranium at the interface ( $7.73 \pm 0.15$ ), and the  $^{235}\text{U}/^{238}\text{U}$  plot shows that this enrichment is co-located with the  $^{235}\text{U}/^{30}\text{Si}$  peak, indicating a relationship between isotopic enrichment and concentration, spatially, which have been previously reported by Eppich et al. (2014) and Lewis et al. (2015), but in contrast to other objects (like A1 and C2, see below). While host Sample C has a similar  $^{235}\text{U}/^{30}\text{Si}$  ratio as Object C1, the  $^{54}\text{Fe}/^{30}\text{Si}$  and  $^{44}\text{Ca}/^{30}\text{Si}$  ratios are slightly depleted relative to Object C1 (23% and 30% relative depletion, respectively).

The isotope ratios for  $^{54}\text{Fe}/^{30}\text{Si}$  and  $^{44}\text{Ca}/^{30}\text{Si}$  in Object C2 (Figure 4.22) show a pattern of enrichment and depletion as observed in the X-ray maps (Figure 3.14) and the WDS dataset (Figure 4.5) for Fe and Ca. The pattern of variation in the isotope ratio images of  $^{54}\text{Fe}/^{30}\text{Si}$  and  $^{44}\text{Ca}/^{30}\text{Si}$  consists of a region of depletion (24% and 53% relative depletion for  $^{54}\text{Fe}/^{30}\text{Si}$  and  $^{44}\text{Ca}/^{30}\text{Si}$ , respectively, to the interior values) adjacent to a region of relative

enrichment at the interface (225% and 246% relative to the local minima for  $^{54}\text{Fe}/^{30}\text{Si}$  and  $^{44}\text{Ca}/^{30}\text{Si}$ , respectively). There is a gradual decrease in relative concentration for both Fe and Ca moving away from the interface into the large host object of Sample C, suggestive of a diffusive boundary. This same pattern is observed in the plot of  $^{235}\text{U}/^{30}\text{Si}$ , where a distinct maximum at the interface ( $4.50 \pm 0.05 \times 10^{-4}$ , corresponding to a uranium concentration of  $82 \pm 47$  ppm by weight) is co-located with the relative enrichment of  $^{54}\text{Fe}/^{30}\text{Si}$  and  $^{44}\text{Ca}/^{30}\text{Si}$  ratios. Because of the substantially lower  $^{235}\text{U}/^{30}\text{Si}$  ratio within attached object C2, it is difficult to distinguish if a region of relative depletion at the interface (at 4.5 microns) exists. The data acquired from the traverse across the interface (along the white arrow), do not yield an observable pattern of  $^{235}\text{U}/^{238}\text{Si}$  ratio variation ( $6.52 \pm 1.04$  in Object C2, and  $6.81 \pm 0.21$  in Sample C adjacent to the interface), contrary to what was observed in Object C1, and what has been described in previous studies [55, 56]. Of further note, the regions of high  $^{235}\text{U}/^{30}\text{Si}$  in the ion image (seen superimposed on the BSE image in Figure 4.22) are continuous with the wide, bright region on the BSE image (which was found by EPMA to be enriched in Fe and Ca, Figure 4.6), forming a continuation of the boundary of agglomerated Object C2.

The ion image data acquired for object D1 (Figure 4.23) reveals relative enrichments of  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ , and  $^{235}\text{U}/^{30}\text{Si}$  co-located at the interface (30%, 44%, and 28%, respectively). The width of the interface, as characterized by the width of the base of the  $^{54}\text{Fe}/^{30}\text{Si}$  peak, is  $\sim 8$  microns. Unique to this interface, and most clearly seen in the upper-right of the  $^{44}\text{Ca}/^{30}\text{Si}$  ratio image, there appears to be a discontinuity at the interface. In this region, the average number of counts per pixel increases by 17%, 8%, and 37% for  $^{30}\text{Si}$ ,  $^{54}\text{Fe}$ , and  $^{235}\text{U}$  relative to the regions on either side of the interface, while exhibiting a relative decrease of 55% in  $^{44}\text{Ca}$ . In BSE imaging (Figure 4.24), this region is seen as a dark bleb at the interface, indicating lower average atomic number. The increase in  $^{30}\text{Si}$  indicates that this region is a  $\text{SiO}_2$  inclusion, that accumulated Fe and  $^{235}\text{U}$  as a result of being located at the interface between Object D1 and Sample D. Uranium concentration could not be calculated, as Si concentration was not acquired by EPMA for this interface.

In object D2 (Figure 4.25), there is relative enrichment of  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ , and  $^{235}\text{U}/^{30}\text{Si}$  co-located at the interface (55%, 86%, and 219%, respectively, compared with the regions on either side of the interface). The width of the interface as characterized by the width of the base of the  $^{54}\text{Fe}/^{30}\text{Si}$  peak is  $\sim 5$  microns. The acquired ion images appear to overlap another region of relatively higher atomic number, as shown in the BSE image. In the ion image, this second region can be seen as an area at the bottom, with high  $^{54}\text{Fe}/^{30}\text{Si}$  and  $^{235}\text{U}/^{30}\text{Si}$  ratios of similar value to the central interface ( $7.5 \times 10^{-2}$  and  $1.2 \times 10^{-4}$ , respectively). The local  $^{235}\text{U}/^{238}\text{U}$  maximum ( $5.74 \pm 0.18$ ) is co-located with the local maximum of  $^{235}\text{U}/^{30}\text{Si}$  (at  $\sim 11$  microns), which corresponds to a uranium concentration of  $29 \pm 17$  ppm by weight.

The ion image data acquired for object E1 (Figure 4.26) show enrichment for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ , and  $^{235}\text{U}/^{238}\text{U}$  that are approximately co-located (at 9.0 microns, Figure 4.26), although the  $^{235}\text{U}/^{30}\text{Si}$  ratio maximum is slightly shifted (at 7.2 microns). At this interface, as also seen in the EPMA spot analyses (Figure 4.8), the region of relative enrich-

ment is substantially wider ( $>12$  microns) than in the other measured interfaces (between 5 and 10 microns in width). As seen in most of the measured interfaces, the  $^{235}\text{U}/^{238}\text{U}$  ratio data plot shows a local maximum ( $8.91 \pm 0.30$ ) at approximately the same place as the local maximum for  $^{235}\text{U}/^{30}\text{Si}$  ( $3.13 \pm 0.03 \times 10^{-4}$ ), corresponding to a uranium concentration of  $50 \pm 29$  ppm by weight.

Figure 4.17: In the top frames, a BSE image showing the location of ion image acquisition at the interface of object A1, as well as the isotope ratio images for  $^{56}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , are shown. The black squares in the BSE image are locations of NanoSIMS analysis craters not acquired as images. In the bottom frames, isotope ratio variations along the white arrow across the interface (shown in the  $^{56}\text{Fe}/^{30}\text{Si}$  ratio image) for  $^{56}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$  are shown, with the location of the local  $^{56}\text{Fe}/^{30}\text{Si}$  maximum indicated by the blue line in each frame. There are enrichments of both  $^{56}\text{Fe}/^{30}\text{Si}$  and  $^{44}\text{Ca}/^{30}\text{Si}$ , co-located (within 1.5 microns) with a depletion of  $^{235}\text{U}/^{30}\text{Si}$  at the interface relative to the regions adjacent to the interface. The  $^{235}\text{U}/^{238}\text{U}$  ratio does not show a discernible pattern, but indicates a high isotopic enrichment ( $>87\%$   $^{235}\text{U}$ ). The uncertainties in the lower panels are  $1\sigma$ .

Figure 4.18: In the top frames, a BSE image showing the location of ion image acquisition at the interface of object B1, as well as the isotope ratio images for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , are shown. In the bottom frames, isotope ratio variations along the white arrow across the interface (shown in the  $^{54}\text{Fe}/^{30}\text{Si}$  ratio image) for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$  are shown, with the location of the local  $^{54}\text{Fe}/^{30}\text{Si}$  maximum indicated by the blue line in each frame. The white squares seen in the BSE image show where the coating has been sputtered away during NanoSIMS analysis: the white square on the right is where the ion images of object B2 were made (Figure 4.19), the white square at the top is simply where the coating was sputtered away when searching for the interface with the instrument. There are enrichments of  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ , and  $^{235}\text{U}/^{30}\text{Si}$  precisely co-located at the interface. The  $^{235}\text{U}/^{238}\text{U}$  ratio variation does not show a discernible pattern at the interface, but increases in Object B1, relative to Object B2. The uncertainties in the lower panels are  $1\sigma$ .

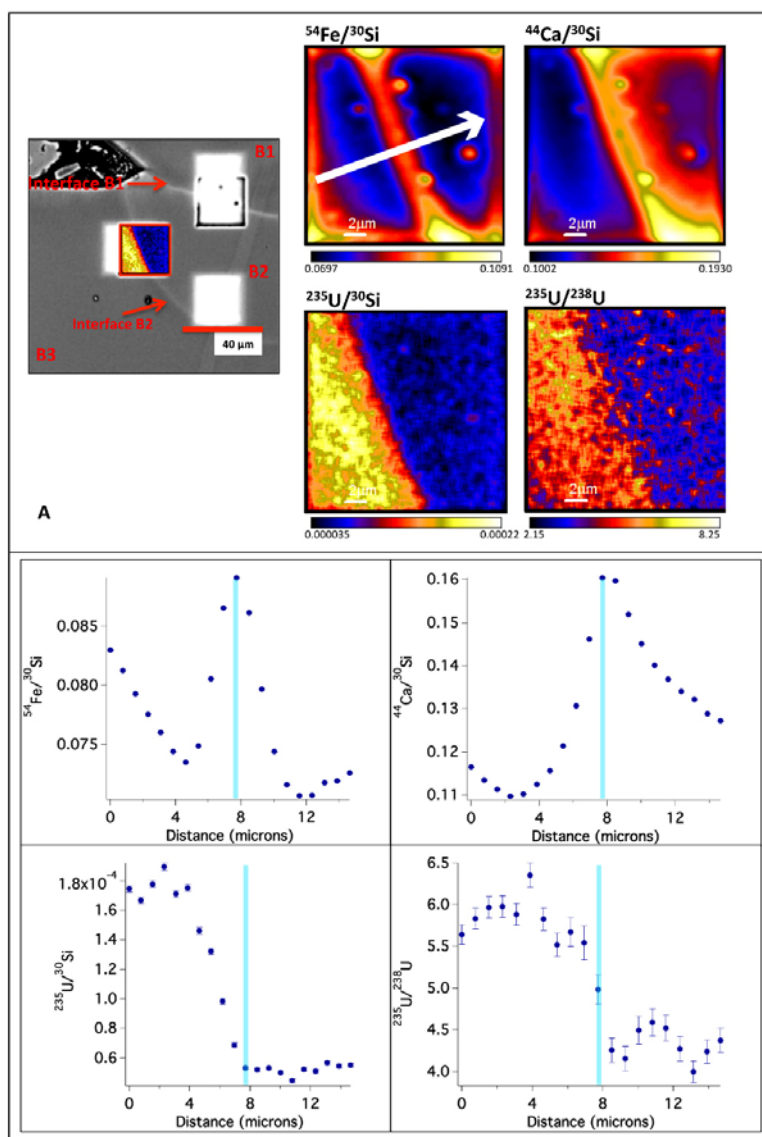

Figure 4.19: In the top frames, a BSE image showing the location of ion image acquisition at the interface of object B2, as well as the isotope ratio images for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , are presented. In the bottom frames, the isotope ratio variations along the white arrow across the interface (shown in the  $^{54}\text{Fe}/^{30}\text{Si}$  ratio image) for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , are presented, with the location of the local  $^{54}\text{Fe}/^{30}\text{Si}$  maximum indicated by the blue line in each frame. While there is relative enrichment of  $^{54}\text{Fe}/^{30}\text{Si}$  and  $^{44}\text{Ca}/^{30}\text{Si}$  ratio at the interface, this pattern is not observed for the  $^{235}\text{U}/^{30}\text{Si}$  ratio. Instead, there is a gradient of decreasing concentration from Object B3 to Object B2, which is also observed in the  $^{235}\text{U}/^{238}\text{U}$  ratio variation. The uncertainties in the lower panels are  $1\sigma$ .

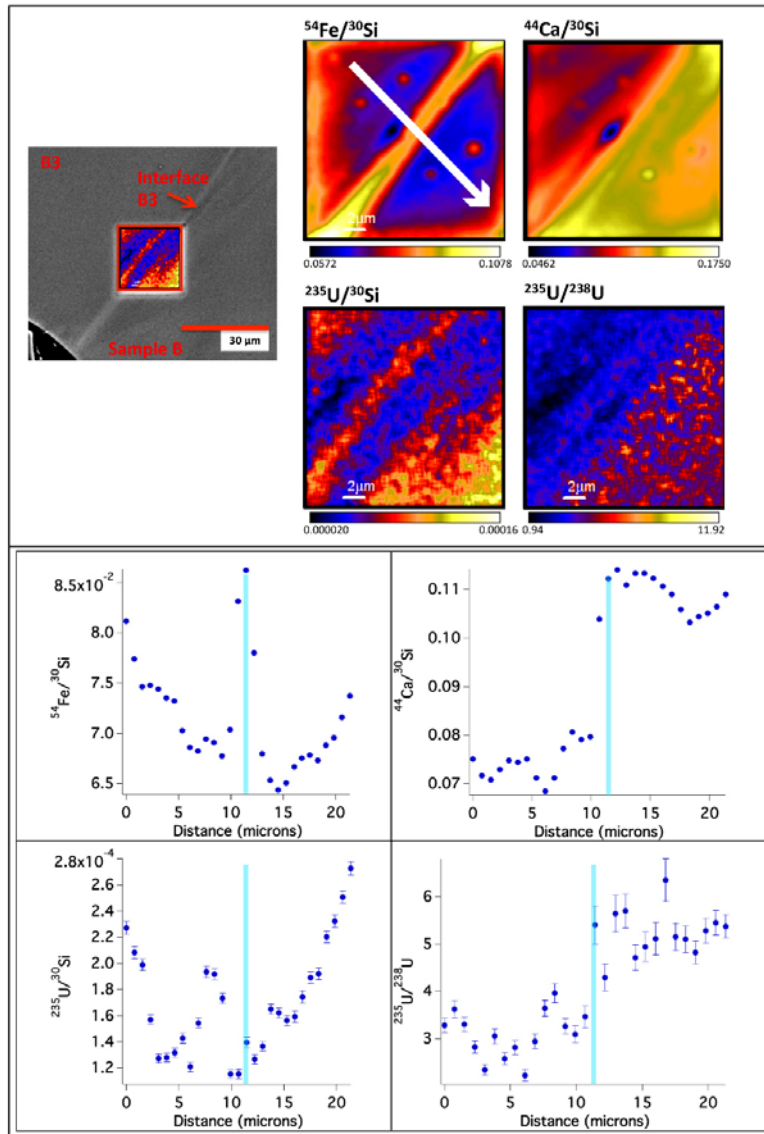

Figure 4.20: In the top frames, a BSE image showing the location of ion image acquisition at the interface of object B3, as well as the isotope ratio images for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , are presented. In the bottom frames, the isotope ratio variations along the white arrow across the interface (shown in the  $^{54}\text{Fe}/^{30}\text{Si}$  ratio image) for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , are shown, with the location of the local  $^{54}\text{Fe}/^{30}\text{Si}$  maximum indicated by the blue line in each frame. The  $^{54}\text{Fe}/^{30}\text{Si}$  variation reveals local enrichment at the interface. There is an enrichment of  $^{44}\text{Ca}/^{30}\text{Si}$  at the interface, however, Object B3 has a substantially higher  $^{44}\text{Ca}/^{30}\text{Si}$  ratio than Sample B, making a local maximum difficult to distinguish. There is a region of enrichment of  $^{235}\text{U}/^{30}\text{Si}$  ratio seen at the interface, adjacent to two regions of relative depletion. The uncertainties in the lower panels are  $1\sigma$ .

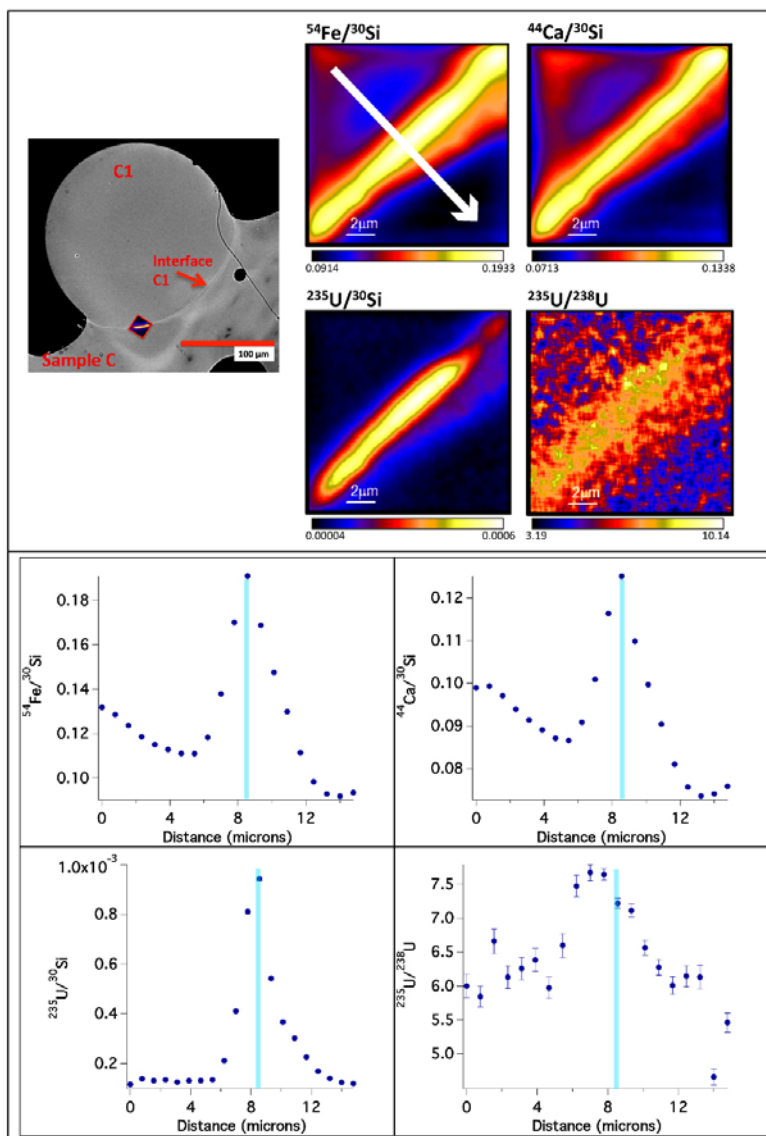

Figure 4.21: In the top frames, a BSE image showing the location of ion image acquisition at the interface of object C1, as well as the isotope ratio images for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , are presented. In the bottom frames, the isotope ratio variations along the white arrow across the interface (shown in the  $^{54}\text{Fe}/^{30}\text{Si}$  ratio image) for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , are presented, with the location of the local  $^{54}\text{Fe}/^{30}\text{Si}$  maximum indicated by the blue line in each frame. There are characteristic relative enrichments of  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ . The  $^{235}\text{U}/^{238}\text{U}$  plot shows relative enrichment that is co-located (within 1.5 microns) with the  $^{235}\text{U}/^{30}\text{Si}$  maxima. The uncertainties in the lower panels are 1  $\sigma$ .

Figure 4.22: In the top frames, a BSE image showing the location of ion image acquisition at the interface of object C2, as well as the isotope ratio images for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , are presented. In the bottom frames, the isotope ratio variations along the white arrow across the interface (shown in the  $^{54}\text{Fe}/^{30}\text{Si}$  ratio image) for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , are presented, with the location of the local  $^{54}\text{Fe}/^{30}\text{Si}$  maximum indicated by the blue line in each frame. The isotope ratio images of  $^{54}\text{Fe}/^{30}\text{Si}$  and  $^{44}\text{Ca}/^{30}\text{Si}$  show of a region of depletion adjacent to a region of relative enrichment at the interface. There is a decrease in relative concentration for both Fe and Ca moving away from the interface into the large host object of Sample C, suggestive of diffusion. The data acquired from the traverse across the interface (along the white arrow), do not yield an observable pattern of  $^{235}\text{U}/^{30}\text{Si}$  ratio variation. The uncertainties in the lower panels are  $1\sigma$ .

Figure 4.23: In the top frames, a BSE image showing the location of ion image acquisition at the interface of object D1, as well as the isotope ratio images for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , are shown. In the bottom frames, the isotope ratio variations along the white arrow across the interface (shown in the  $^{54}\text{Fe}/^{30}\text{Si}$  ratio image) for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , are shown, with the location of the local  $^{54}\text{Fe}/^{30}\text{Si}$  maximum indicated by the blue line in each frame. Unique to this interface, and most clearly seen as a region of depletion in the upper-right of the  $^{44}\text{Ca}/^{30}\text{Si}$  ratio image, there is a discontinuity at the interface. This feature is characterized in more detail in Figure 4.24. The uncertainties in the lower frames are  $1\sigma$ .

Figure 4.24: The discontinuity in the  $^{44}\text{Ca}/^{30}\text{Si}$  seen in Figure 4.22 is shown in BSE imaging, which is seen as a dark bleb (yellow arrow) indicating relatively lower average atomic number (but not a void). This region corresponds to a 20% increase in  $^{30}\text{Si}$  counts, indicating that this region is likely an  $\text{SiO}_2$  inclusion. In this region, the average number of counts per pixel increases by 17%, 8%, and 37% for  $^{30}\text{Si}$ ,  $^{54}\text{Fe}$ , and  $^{235}\text{U}$  relative to the regions on either side of the interface. The increase in  $^{30}\text{Si}$  indicates that this region is a  $\text{SiO}_2$  inclusion, that accumulated Fe and  $^{235}\text{U}$  as a result of being located at the interface between Object D1 and Sample D.

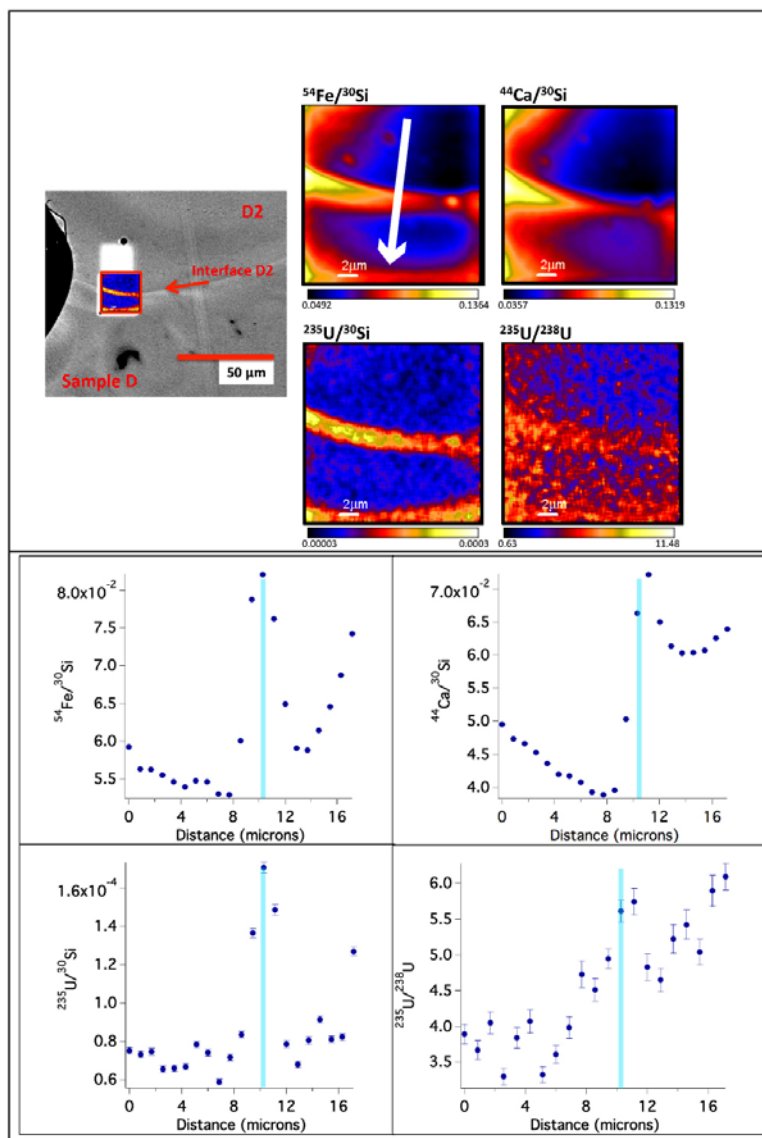

Figure 4.25: In the top frames, a BSE image showing the location of ion image acquisition at the interface of object D2, as well as the isotope ratio images for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , are presented. In the bottom frames, the isotope ratio variations along the white arrow across the interface (shown in the  $^{54}\text{Fe}/^{30}\text{Si}$  ratio image) for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , are presented, with the location of the local  $^{54}\text{Fe}/^{30}\text{Si}$  maximum indicated by the blue line in each frame. There is relative enrichment of  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ , and  $^{235}\text{U}/^{30}\text{Si}$  co-located (within 1.5 microns) at the interface. The local  $^{235}\text{U}/^{238}\text{U}$  maximum is co-located with the local maximum of  $^{235}\text{U}/^{30}\text{Si}$ . The uncertainties in the lower panels are  $1\sigma$ .

Figure 4.26: In the top frames, a BSE image showing the location of ion image acquisition at the interface of object E1, as well as the isotope ratio images for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , are presented. In the bottom frames, the isotope ratio variations along the white arrow across the interface (shown in the  $^{54}\text{Fe}/^{30}\text{Si}$  ratio image) for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , are presented, with the location of the local  $^{54}\text{Fe}/^{30}\text{Si}$  maximum indicated by the blue line in each frame. There is enrichment of  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ , and  $^{235}\text{U}/^{238}\text{U}$  approximately co-located at the interface. The local maximum of  $^{235}\text{U}/^{238}\text{U}$  ratio is approximately co-located (within 1.5 microns) with the local maximum for  $^{235}\text{U}/^{30}\text{Si}$ . The uncertainties in the lower panels are  $1\sigma$ .

## Summary

The isotope ratio images of  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{238}\text{U}$ , and the ratio variation profiles acquired from them, show a relative enrichment of  $^{54}\text{Fe}/^{30}\text{Si}$  and  $^{44}\text{Ca}/^{30}\text{Si}$  ratio at the interface (relative to the regions on either side of the interface) for all 9 of the analyzed interfaces (Table 4.7). This is consistent with what is observed by EPMA at these interfaces (with the exception of Interface A1 and D1, which were not analyzed with EPMA). The  $^{235}\text{U}/^{30}\text{Si}$  ratio was used to understand the variation of uranium concentration across the interface (assuming Si is relatively invariable, as previously supported in Section 4.1). The  $^{235}\text{U}/^{30}\text{Si}$  ratio is relatively enriched at the interface in 7 of the 9 analyzed interfaces, with the exception of A1 and B2 (Table 4.7). The relative increase in  $^{235}\text{U}/^{30}\text{Si}$  ratio at interfaces, in comparison to the regions on either side of the interface, varied between the analyzed interfaces from a minimum relative enrichment at Interface D1 of 28% to a maximum relative enrichment of 900% at Interface C1. At only 5 of these interfaces, the increase in  $^{235}\text{U}/^{30}\text{Si}$  ratio spatially corresponds to an increase in the  $^{235}\text{U}/^{238}\text{U}$  ratio (Interfaces B3, C1, D1, D2, and E1). At all all of the measured interfaces, there was an enrichment in  $^{235}\text{U}/^{238}\text{U}$  ratio relative to natural (0.0073). The minimum measured  $^{235}\text{U}/^{238}\text{U}$  ratio was  $2.21 \pm 0.12$  (corresponding to an enrichment of  $68.8 \pm 1.1\%$ , at Interface D3) and the maximum measured ratio was  $9.73 \pm 0.43$  (corresponding to an enrichment of  $90.7 \pm 0.4\%$ , at Interface A1, Table 4.7).

In previous studies [55, 56], the absolute concentration of uranium was also measured within fallout glasses from this test. In the Eppich et al. (2014) study, which measured uranium concentration via bulk dissolution mass spectrometry, the concentration of uranium was reported to be between 14.7 and 32.9 ppm, whereas soil from the test site was found to have a measured uranium concentration from 2.7 to 4.3 ppm. In the Lewis et al. (2015) study, which estimated uranium concentration from SIMS spots taken within similar glassy objects, the uranium concentration was found to range from 3.5 to 19.4 ppm across objects. In this study, however, the interface U concentrations (calculated as described in Section 2.3) were considerably higher: the minimum measured concentration at an interface was  $14 \pm 8$  ppm (Interface B3), and the highest concentration was found to be  $154 \pm 88$  ppm (Interface C1, Table 4.7). Given the high  $^{235}\text{U}/^{238}\text{U}$  ratios at every interface (>80% enriched in  $^{235}\text{U}$ ), this constitutes a higher contribution of device material at these surfaces of these objects prior to agglomeration than has ever been previously reported. However, unlike the studies by Eppich et al. (2014) and Lewis et al. (2015), the  $^{235}\text{U}/^{238}\text{U}$  isotope ratio does not exhibit an obvious correlation with uranium concentration in this data set (Figure 4.27). This could be the effect of heterogeneous mixing of uranium from vaporized soil with uranium from the device.

Figure 4.27: The  $^{235}\text{U}/^{238}\text{U}$  ratio as derived from the NanoSIMS ion image traverses is plotted against uranium concentration calculated from the  $^{235}\text{U}/^{30}\text{Si}$  ratio for the entire NanoSIMS ion image traverse data set (Interfaces A1 and D1 are excluded, as the uranium concentration could not be calculated, as the Si concentration was not determined via EPMA). As seen here, there is no correlation between the uranium isotope ratio and concentration. This may be due to heterogeneity in vaporized uranium components (*i.e.*, from the soil and device) in the fireball.

Table 4.7: NanoSIMS analyses at the interface for  $^{54}\text{Fe}/^{30}\text{Si}$ ,  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{235}\text{U}/^{30}\text{Si}$ , and  $^{235}\text{U}/^{238}\text{U}$ , along with the calculated U concentration at the interface. Uncertainties are  $1\sigma$ .

Interface	$^{44}\text{Ca}/^{30}\text{Si}$		$^{54}\text{Fe}/^{30}\text{Si}$		$^{235}\text{U}/^{30}\text{Si}$		$^{235}\text{U}/^{238}\text{U}$	U conc (ppm)

\*A1 actually used the  $^{56}\text{Fe}/^{30}\text{Si}$  ratio

\*\*A1 and D1 did not have EPMA data for  $\text{SiO}_2$  so concentration could not be calculated

†B2 did not have a local maximum at the interface for  $^{235}\text{U}/^{30}\text{Si}$ , so the global maximum was used

### 4.3 Interpreting qualitative and quantitative observations

The results of each analytical technique yield observations of distinct chemical and/or isotopic variation at the interface of where small, glassy fallout objects are fused to the surface of larger host objects, as well as the outer edge of these objects, compared to the interiors of agglomerated fallout objects. The compositional variation at the edge follows the same general compositional pattern as what is observed at the interfaces, and shown to be continuous in X-ray mapping. Clearly, the distinct compositional region at the interface is a layer that is continuous around the surface of at least the attached objects. This layer must have deposited in the fireball while the carrier was still molten, and likely constitutes a late-stage deposition, as it is preserved where two glassy objects are fused together. The composition of this deposited layer provides insight into the environment in which species vaporized post-detonation, how these materials may have interacted in the vapor phase, and how they condensed and mixed into molten carrier materials.

#### Thermal histories preserved in agglomerated fallout glasses and their implications

The bulk composition of fallout glass is compositionally similar to local environmental materials [55] (see also, Figure 4.16); however, at the sub-mm-scale, fallout glasses reveal significant compositional heterogeneities (*e.g.*, Figure 3.4). Larger (mm-scale) host objects preserve evidence of mechanical mixing (such as flow banding, Figure 3.4), variable degrees of vesiculation (*e.g.*, Figure 3.5), eccentric (non-spherical) shapes (*e.g.*, Figure 3.3), and inclusion of vitrified relict grains (in these samples, typically SiO<sub>2</sub> with diffuse boundaries, *e.g.*, Figure 3.4). Among the studied population of agglomerated objects examined here, several are quite homogeneous in average chemical composition compared to their larger hosts (Figures 3.7-3.11, and 4.1). This observation suggests that these smaller objects were not only molten long enough to acquire a spherical shape through surface tension, but also heated to sufficient temperature long enough to allow for relative homogenization of multi-mineralic soil grains through advection and diffusion.

There also exists varying degrees of homogeneity between the small adhered objects in this sample set. For example, Object D2 is the among the most compositionally heterogeneous in the sample set, while sample C1 is relatively homogeneous (Figure 4.28). As shown in Figure 4.28, D2 and C1 are approximately the same size ( $\sim 250$  and  $\sim 200$  microns in diameter, respectively). While a comparable level of homogeneity would be expected assuming identical starting composition and temperature history, C1 is compositionally homogeneous in major elements, while D2 is not (relative to their respective host objects). Further, Sample D2 shows evidence of relict quartz, and has preserved compositional flow banding, suggesting internal advection or mechanical mixing. The difference in the degree of chemical heterogeneity between the two objects indicates that these individual objects have

distinct thermal histories. That is, they were exposed to variable degrees of heating and/or a variable duration of heating.

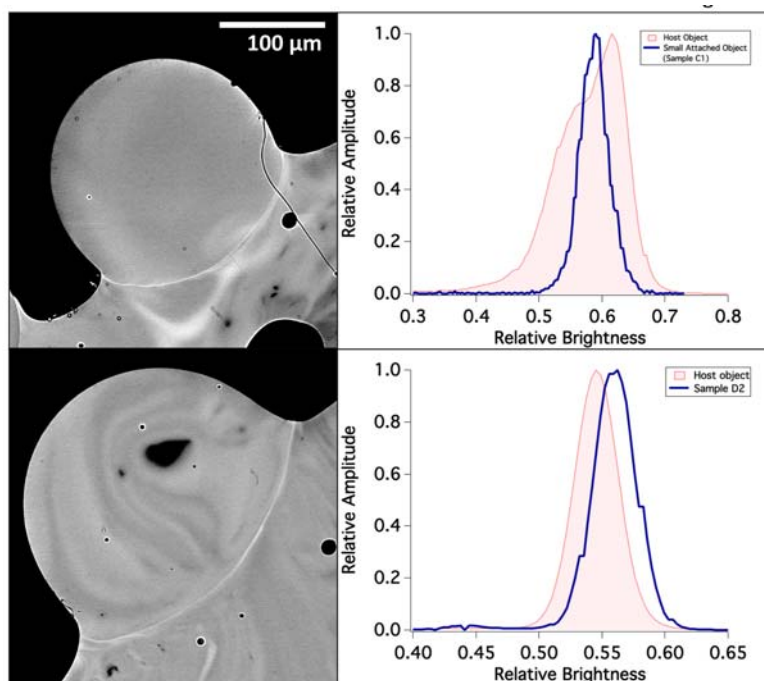

Figure 4.28: BSE images of C1 and D2 along with their contrast variation plots, juxtaposed to show the range in heterogeneity in similarly-sized agglomerated objects.

The degree of deformation and coalescence of small objects after collision with larger objects is also indicative of a variable record of the thermal history of glassy fallout agglomerates. In Objects C1-3 for instance (Figure 3.3), C1 and C2 experienced little deformation from sphericity upon collision with the larger object, while C3 has coalesced with the larger object. In sample C2, the larger host object appears to wrap around the exterior of the smaller object to some extent (see Figure 3.14, Na X-ray map). This suggests that the smaller object was more viscous than the host object, though surface tension and collisional velocity also affect the outcomes of liquid droplet collisions [81]. While droplet interaction parameters were not quantified in this study, viscosity increases more than 1000-fold for glass compositions similar to fallout from 2000K to 1500K [42], and the degree of deformation and coalescence may reflect the thermal dissimilarity between objects.

The timescales at which surface closure to mass transfer occurs in glasses of these compositions ( $\sim 1500$  K) has been quantified by Cassata et al. (2014) in mm-scale objects to be from  $<0.1$  to 2.9 seconds, a range that is attributed to both thermal variation in the fireball and the trajectory of entrained material through the fireball [54]. Thus, as the collisions between agglomerated objects occurred in the fireball, the range of thermal histories experienced by similarly-sized fallout objects also indicates thermal heterogeneity in the fireball

and/or a difference in duration of heating for individual objects. In either or both cases, the presence of a deposition layer at every observed interface suggests that condensation processes, or deposition of condensates onto the surfaces of molten carrier materials, occurs over a range of times and/or temperatures, during which the molten environmental debris is entrained in the fireball. Further, given the diffusive nature of the composition profiles, the deposition at the interface was likely continuous (*i.e.*, not a result of re-entrainment).

## Interpreting enrichments of device material at interfaces

Using NanoSIMS to probe the interfaces of agglomerated fallout glasses, an increase in  $^{235}\text{U}$  was observed relative to the interior of these objects. The ubiquitous presence of enriched levels of  $^{235}\text{U}$  (Table 4.7) in these fallout glasses confirms that there is significant mixing of device material with environmental debris during formation, as seen in previous studies of larger objects [55, 56]. The bulk uranium concentration in aerodynamic fallout glasses from this test calculated by previous studies indicates that condensation of device material and subsequent deposition onto molten carriers occurred early enough to mix (by advection, diffusion, or both) into the interior of the carrier. However, the substantial increase in concentration of uranium (Table 4.7) at the interfaces of agglomerated fallout glasses indicates that this deposition was, in fact, highly favored immediately prior to quenching of carrier materials. Historical autoradiography studies also show that the mixture of device material into fallout is indeed not a uniform process - in particular, an enrichment of active beta emitters (such as  $^{90}\text{Sr}$  and other fission products) has been observed as a surface layer on fallout objects [8, 10]. While we can no longer directly characterize high-activity nuclide distributions in these aged materials due to their decay, this historically observed feature is likely the same surface layer preserved at the interface of agglomerated objects.

It is expected that a fraction of other local material proximate to the device (such as soil and structures) would have also been vaporized in the initial explosion, and is probably the source of the other observed chemical enrichments in the interface layers. In these analyses, local enrichments of  $^{235}\text{U}$  are correlated with increased iron and calcium concentration at 7 of 9 interfaces (as shown by the isotope ratios in Figures 4.17 - 4.26), suggesting that these species co-condensed, and were deposited together. This is exemplified in Figure 4.29, which shows the peak-normalized variation of  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{54}\text{Fe}/^{30}\text{Si}$ , and  $^{235}\text{U}/^{30}\text{Si}$  at the interface of Object C1. This figure illustrates the precise co-location of  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{54}\text{Fe}/^{30}\text{Si}$ , and  $^{235}\text{U}/^{30}\text{Si}$  enrichments at the interface which is observed in most samples. These patterns of enrichments are likely the result of Fe and Ca from the soil or anthropogenic components vaporizing together with the device, and subsequently forming either a direct condensate from the vapor state or depositing onto the carrier materials as a condensed species. In the case of object C1 (and other interfaces exhibiting the co-location of enriched species), these species were likely well mixed in the vapor phase prior to condensation, and co-deposited onto the surface of the object prior to its fusing to the host with no significant re-evaporation of any of the deposited species.

Figure 4.29: Peak-normalized variation of  $^{44}\text{Ca}/^{30}\text{Si}$ ,  $^{54}\text{Fe}/^{30}\text{Si}$ , and  $^{235}\text{U}/^{30}\text{Si}$  at the interface of object C1 plotted together to show co-location of local maxima.

#### 4.4 Interpreting chemical variation at the interface

In Figure 4.30, the comparison of the interface values with the average object compositions reveal that the observed concentration enrichments and depletions cannot be explained by compositional variation of the host objects. This is exemplified by the major element oxide plot of CaO vs.  $\text{Al}_2\text{O}_3$  (Figure 4.30A); the interior data points vary by approximately 10 wt.% in  $\text{Al}_2\text{O}_3$  and 2 wt.% in CaO, however, the interface data points are all lower in  $\text{Al}_2\text{O}_3$  composition. While some interface data points do fall within the compositional range of the interior points, they are still depleted in Al when compared to the interior data points of their corresponding host object (Table 4.6). The Ca content of interface data points is also generally enriched compared to interior points; however, samples C2 and E1 appear to have a lower concentration of Ca at the agglomerate interface. When compared to the corresponding interior points, however, the interface of sample E1 is still substantially enriched in Ca (41% enriched, Figure 4.11). In the plot of FeO vs.  $\text{TiO}_2$  (Figure 4.30B), the interface data points show a clear trend of enrichment in Fe relative (by as much as 55%) to the interior points of the corresponding host samples, with the exception of samples B1 and B2. In 6 of the 9

measured interfaces, there is evidence of Ti depletion relative to the interior data points by  $>25\%$ .

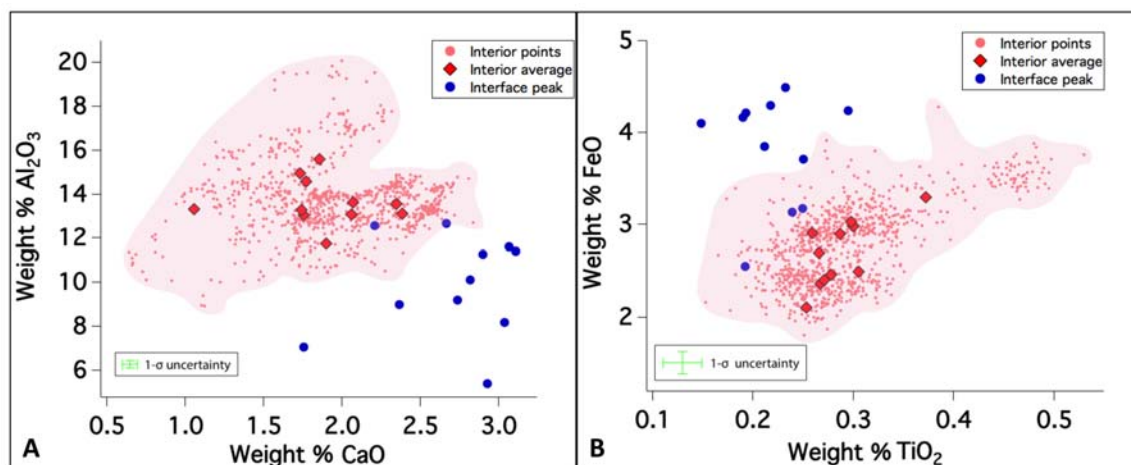

Figure 4.30: (A) Major element oxide plot of CaO vs. Al<sub>2</sub>O<sub>3</sub> taken from quantitative WDS data from across the agglomerated spheroidal glassy objects, and across the interface where they fused to larger objects. The interior data represent 903 data points taken in the interior of the spheroidal objects; the gray shaded region shows the compositional range of the dataset. The interface points, indicated in blue, represent data points taken at the Al<sub>2</sub>O<sub>3</sub> trough of relative Al depletion in concentration (the same spatial location of the local FeO maxima at each interface). The interface data points are depleted in Al<sub>2</sub>O<sub>3</sub> for all samples, and the CaO content at the interface is enriched in 8 of the 9 samples. (B) Major element oxide plot of FeO vs TiO<sub>2</sub> from the same dataset, with the shaded region depicting the range of the interior dataset. Here, FeO is observed to be enriched at the interface with a corresponding depletion of TiO<sub>2</sub> for 6 of the 9 sample interfaces.

Al<sub>2</sub>O<sub>3</sub> and TiO<sub>2</sub> are relatively refractory oxides which are abundant in the soil material from which such fallout is derived. Given the similarity in boiling points of FeO, TiO<sub>2</sub>, CaO, and Al<sub>2</sub>O<sub>3</sub> (2785K, 3273K, 3100K, and 3250K respectively [82, 83, 84, 85]) and the occurrence of FeO with TiO<sub>2</sub> and CaO with Al<sub>2</sub>O<sub>3</sub> in major mineral phases (*i.e.*, ilmenite and andesine, respectively, see Section 4.1), it might be expected that these species would enter the vapor phase together, and condense proportionally onto molten hosts. However, it was observed that the agglomerate interface layers are consistently depleted in Al and Ti, alongside relative enrichment of Fe and Ca (Figure 4.30).

Recent studies of fallout debris from the Trinity test (trinitite) identify unusual chemical and isotopic enrichments as signatures from the support structure, unfissioned fuel, and non-fuel device components [44, 51, 52, 53]. Thus, one possible explanation of the fractionation of Al from Ca may be that the Ca enrichments observed at the interface reflect the role of an anthropogenic source. This source could be a support structure, such as common

cement (having >60% CaO), proximate to the device prior to detonation, rather than simple derivation from local soil material (which is  $\sim 1.5$  wt% CaO [55]). While  $\text{Al}_2\text{O}_3$  is also a common constituent of concrete aggregates, the relative aluminum content of potential anthropogenic structures can vary considerably, and for this anonymous event, is unknown. The excess Fe-bearing species observed at the interfaces in these samples would also support an origin from vaporization of a substantial Fe-bearing component (*i.e.*, steel) possibly in the form of associated structural materials. The observed pattern of enrichments and depletions may therefore result from contributions of proximate structural materials, creating an apparent fractionation of aluminum-bearing species from the iron, calcium, and uranium-bearing species.

Another possible explanation for the observation of depletion of Al and Ti at the interfaces, however, is that Al and Ti did not enter the vapor phase with Fe and Ca as might be expected based on their boiling points and co-occurrences in their respective common mineral phases (Al, Ca in andesine and Fe, Ti in ilmenite), and thus, were not available for interaction with molten hosts in the fireball. While boiling point data gives a general metric for relative volatility, it may in this case be a poor proxy for estimating vaporization behavior, as it is typically calculated for pure compounds. It is possible that Fe and Ca (as well as the other locally enriched species) could disproportionately enter the vapor phase relative to Al and Ti in multicomponent carriers. This interpretation is complicated, however, by the observation that CaO is approximately as refractory as  $\text{Al}_2\text{O}_3$  in a molten silicate system similar to that which is found in the fallout samples [86]. However, fractionation between these species may instead be dictated by the condensation behavior of these species in the fireball, which is dependent on speciation of vaporized constituents. The speciation in the vapor phase depends on the oxygen fugacity of the environment and the interactions between vaporized constituents. For example, condensation temperatures for Ca, Ti, and Al are calculated by Lodders et al. (2003) [41] to be within  $\sim 100$  K of each other. However, these values are calculated for elements condensing out of a solar composition gas in equilibrium rather than for fireball conditions, which is dramatically different.

The study by Lamoreaux et al. (1987), which presents vapor pressure data for major element oxides, exemplifies the effect environment can have on vapor phase constituents [87]. For example, in that study, Ca is shown to have the highest vapor pressure of any Ca-species between 1300K and 2200K in reducing environments. In oxygen-rich environments, on the other hand, CaO has the highest vapor pressure, and is over 5 orders of magnitude lower than Ca in the reducing environment over the same temperature range. Further, compared to any Al-species in oxygen-rich environments, the CaO vapor pressure is roughly 2 orders of magnitude higher in vapor pressure, while Al-species in reducing environments have the same vapor pressure as Ca. The effect of speciation is further complicated in oxygen-rich environments for Al-species in that AlO has a higher vapor pressure in one temperature regime ( $>2000$  K), and Al has a higher vapor pressure in another ( $<2000$  K). Based on this data, changes in oxygen fugacity will change the proportions of how species vaporize, and changes in temperature can change the speciation of vapor phase constituents, which will affect the rate and temperature of condensation. Although the data in this thesis are

reported as oxides (for EPMA data) and ions (for NanoSIMS), the speciation of the deposited constituents is unknown.

## Continuous fractionation and fireball heterogeneity

Historical models of fallout formation argue that refractory species (including uranium) are expected to condense early and distribute volumetrically into molten host materials, while more volatile species are expected to condense later and deposit on the surface of already solidified hosts [15, 18, 88]. In a silicate system of composition similar to that of the fallout objects,  $\text{Al}_2\text{O}_3$  and  $\text{CaO}$  would be considered the most refractory species, while  $\text{K}_2\text{O}$ ,  $\text{SiO}_2$ , and  $\text{Na}_2\text{O}$  are the most volatile [86]. Thus, if the condensation was dictated by the relative volatility of individual vaporized species, one would expect to see a distinct separation of refractory oxides from volatile oxides. Consequently, this would lead to a higher relative concentration of refractory species (*e.g.*, Ca and Al from the environmental debris,  $^{235}\text{U}$  from the device) volumetrically distributed inside of the glassy fallout objects, and a post-quenching surface-deposited layer of volatile species (*e.g.*,  $\text{Na}_2\text{O}$ ,  $\text{K}_2\text{O}$  from the environmental debris). Instead, as observed at these interfaces, both refractory (Fe, Ca, and  $^{235}\text{U}$ ) and volatile species (Na) are observed to be co-located at the interfaces in more than half of the observed samples, while there is a notable depletion of Al in all the interfaces.

The presence of a layer enriched in both refractory and volatile species deposited onto molten soils that have already encountered and incorporated a device-material bearing vapor phase does not fit well into a two-stage interaction model such as that proposed by Miller (1960) [15]. Two possible explanations can account for the presence of such a layer: 1) The presence of a continuous condensation and mixing process based on the volatility of species and the cooling of the fireball that resulted in the deposition of a condensation layer on cooling fallout objects, and/or 2) molten fallout interacting with a compositionally and thermally heterogeneous fireball. Norman and Winchell (1966) [31] first proposed a model of continuous condensation and diffusion to explain the incorporation of fission products, in contrast with the model of Miller (1960) where refractory species would condense early and mix volumetrically, while volatile species would deposit onto an already frozen particle without being appreciably incorporated into the object. However, continuous profiles of condensed species were not observed at *every* interface in our study. As shown in the  $^{235}\text{U}/^{30}\text{Si}$  ion ratio images of the agglomerate interfaces of samples A1 and B3 (Figures 4.17 and 4.20, respectively), as well as the qualitative EPMA map of the Ca distribution in sample C2 (Figure 3.14), continuous concentration profiles of every species are not present in all samples. This observation is exemplified in Figure 4.20, where the  $^{235}\text{U}/^{30}\text{Si}$  isotope ratio image shows a distinct layer of  $^{235}\text{U}$  at the interface between two objects. Two zones of relative  $^{235}\text{U}$  depletion can be seen on either side of the interface, one of which hosts a local maxima for  $^{54}\text{Fe}/^{30}\text{Si}$ , separating it from the higher  $^{235}\text{U}/^{30}\text{Si}$  ratio in the two objects (Figure 4.20, top left and bottom right).

The presence of a relatively high  $^{235}\text{U}/^{30}\text{Si}$  region adjacent to a relatively low  $^{235}\text{U}/^{30}\text{Si}$  (but high  $^{54}\text{Fe}/^{30}\text{Si}$ ) region can only be explained by a discontinuous evaporation and con-

densation process. For example, if the molten carrier objects passed through a vapor in the fireball having a negligible uranium concentration (*i.e.*, not well-mixed with device material) but significant iron concentration, the partial pressure of U would then favor an evaporative process, resulting U loss from the environmental host material, but permitting significant deposition of Fe. Subsequently, if debris then passed through a vapor having high uranium concentration (*i.e.*, well-mixed with vaporized device material), the partial pressure of U would favor a condensation process, depositing a layer of higher relative  $^{235}\text{U}$ . If the trajectory of the fallout debris brought it through a relatively cooler region of the fireball that was more concentrated in volatile species, it is possible that these species could also condense onto and diffuse into a still-molten fallout object. Given the variation in relative enrichment and depletion of species observed at the interfaces, this study suggests that a combination of these processes is likely to be occurring.

The scenarios that describe the pattern of chemical variation at the interface are summarized in Figure 4.31. As illustrated in Figure 4.31A, the presence of both volatile and refractory species at the interface is suggestive of a semi-continuous process of condensation, deposition, and mixing. This continuous process would also account for the potential chemical fractionation caused by unexpected speciation due to chemical interactions within the fireball environment. The range of chemical behaviors observed at the interface, such as the relative enrichment of volatile species only at selected interfaces, also suggests a heterogeneous temperature distribution and/or unmixed vaporized species in the fireball. Further, as illustrated in Figure 4.31B, the depletion of refractory Al and Ti oxides at the interface co-located with similarly refractory Ca oxide could suggest the presence of a non-soil source, such as anthropogenic structural material. Given the observed patterns of compositional variation described above, it seems likely that all of these processes are occurring to some extent. To further understand speciation in the fireball, constraints on the time and temperature of deposition of the observed layer at agglomerated interfaces were derived (see Chapter 5).

Figure 4.31: (A) A semi-continuous fractionation process describes the presence of volatile and refractory species co-located at interfaces. (B) The depletion of Al and Ti, and enrichment of Ca, Fe, and  $^{235}\text{U}$ , suggests the presence of a non-soil derived vapor source.

## Chapter 5

# Diffusive mass transport in agglomerates from a deposition layer

### 5.1 Introduction

The conditions and chemical processes through which device material and soil interact to form glassy fallout objects are not well understood, particularly the effects of fireball temperature and composition on speciation and condensation. However, these details are critical to our understanding of the distribution of radionuclides post-detonation, and improving sample interpretation for nuclear forensic analysis. One goal of this study was to constrain the time scales and temperature ranges that control mass transport in aerodynamic fallout glasses by studying and modeling the compositional variation profiles at the interfaces of agglomerated glassy objects. By constraining these parameters, the temperature of deposition of species onto agglomerated fallout objects can also be constrained, and then be used to interpret speciation of vaporized constituents in the fireball. As previously shown, the interfaces between the small objects and the larger host objects are consistently enriched in iron, calcium, magnesium, and uranium. The quasi-Gaussian concentration profiles of these elements suggest chemical diffusion, from which time and temperature parameters can be derived.

In this study, a model of diffusive mass transport was applied to the observed uranium concentration variation (as  $^{235}\text{U}/^{30}\text{Si}$  isotope ratio profiles) in the observed deposition layer found at the interfaces of agglomerated fallout objects. This chapter describes the relationship of fireball cooling rates (modeled yields ranged from 0.1 kt to 10 kt), soil residence time, and temperature, on the diffusion of  $^{235}\text{U}$  in a deposited layer from the surface of aerodynamic fallout objects. By applying a one-dimensional planar diffusion model to observed  $^{235}\text{U}/^{30}\text{Si}$  profiles at the interfaces where two fallout objects have fused, one can estimate the cooling time and temperature range over which diffusion occurs post-deposition.

## 5.2 Model

### Diffusive mass transport from a planar source

In the case of a thin layer of condensed species deposited on the surface of a molten soil host that subsequently fuses with a larger molten object the deposited layer is expected to diffuse into both objects, assuming that there is a chemical potential gradient between the layer and the molten objects. In the idealized case that the layer comprises a single species, is infinitesimally thin, and is between two homogeneous objects of equal composition, we expect a concentration distribution to evolve from the layer between two objects of equal temperature over time, following the form of Equation 5.1

$$C(x, t) = C_0 e^{-\frac{x^2}{4Dt}}, \quad (5.1)$$

where  $C$  is concentration,  $C_0$  is the initial concentration of the species in the layer,  $D$  is the diffusivity,  $t$  is time, and  $x$  is the dimension of diffusion [89].

Equation 5.1 is derived from Fick's second law of diffusion, which describes diffusive flux of a species through a medium. In this model, Fick's second law is applied to a system of a dilute, planar source diffusing into a liquid-phase medium (*i.e.*, molten soil). However, in order to apply Fick's second law of diffusion to a model of planar diffusion from a deposition layer in molten carrier material for the purposes of fallout formation modeling, a basic understanding of binary diffusion must be established (illustrated in Figure 5.1).

Fick's second law can be derived [90] from the change in mass of a species through a volume

$$\Delta M = m_1 - m_2, \quad (5.2)$$

where  $\Delta M$  is the change in mass of the diffusing species,  $m_1$  is the mass of the species entering the volume, and  $m_2$  is the mass of the species exiting the volume. This equation can be rewritten as

$$V \frac{\Delta M}{V} = A \frac{m_1}{A} - A \frac{m_2}{A}, \quad (5.3)$$

where  $V$  is volume, and  $A$  is the cross sectional area of the volume through which the species is diffusing to derive a relationship between change in concentration and fluence of the species. By substituting concentration ( $C = \frac{\Delta M}{V}$ ) and fluence ( $\phi = \frac{m}{A}$ ), this equation becomes

$$V \Delta C = A \phi_1 - A \phi_2, \quad (5.4)$$

where  $\Delta C$  represents the change in concentration of the species through the volume. As diffusivity is a time-dependent process, both sides of the equation are divided by  $\Delta t$ , giving

$$V \frac{\Delta C}{\Delta t} = A \frac{\phi_1}{\Delta t} - A \frac{\phi_2}{\Delta t} = A(J_1 - J_2), \quad (5.5)$$

where  $J$  is the flux of the species through cross sectional area  $A$ . Dividing both sides by  $V$ , and considering  $J_2 = J_1 + \Delta J$ , where  $\Delta J$  is the change in flux over the volume,

$$\frac{\Delta C}{\Delta t} = \frac{A}{V}(J_1 - (J_1 + \Delta J)). \quad (5.6)$$

As the concentration and flux through the volume change instantaneously with time, then for one-dimensional diffusion the above equation is better represented as

$$\frac{\delta C}{\delta t} = \frac{A}{V}(J_1 - (J_1 + \frac{\delta J}{\delta x} \Delta x)), \quad (5.7)$$

where  $\Delta x$  represents the length of the volume in the direction of diffusion, following the relationship  $\Delta x = \frac{V}{A}$ . Thus, the above equation can be rewritten as

$$\frac{\delta C}{\delta t} = \frac{1}{\Delta x}(J_1 - (J_1 + \frac{\delta J}{\delta x} \Delta x)), \quad (5.8)$$

which reduces to

$$\frac{\delta C}{\delta t} = -\frac{\delta J}{\delta x}. \quad (5.9)$$

Figure 5.1: Mass transport between two semi-infinite volumes of different concentration, illustrative of one dimensional diffusive mass transport in a diffusion couple.

When studying diffusive mass transport of a species between regions of varying concentrations, one can consider the probabilistic transfer of mass between two adjacent, semi-infinite volumes (*i.e.*, a diffusion couple). This is illustrated in Figure 5.1; the left-hand volume ( $V_1$ ) has a concentration  $C_1$ , and a species with mass  $m_1$  has equal probability of moving towards  $V_1$  or  $V_2$ . This process is the same for species in  $V_2$  (which has concentration  $C_2$ ); these species, having mass  $m_2$ , have equal probability of moving towards  $V_2$  and  $V_1$ . Using these definitions,

$$m_{1 \rightarrow 2} = 0.5 \cdot C_1 \cdot A \cdot \Delta x, \quad (5.10)$$

and

$$m_{2 \rightarrow 1} = 0.5 \cdot C_2 \cdot A \cdot \Delta x, \quad (5.11)$$

where  $m_{1 \rightarrow 2}$  is the mass moving from  $V_1$  to  $V_2$ , and  $m_{2 \rightarrow 1}$  is the mass moving from  $V_2$  to  $V_1$ . In this case,  $\Delta x$  represents the distance of the concentration gradient ( $\frac{\delta C}{\delta x}$ ) between the two volumes. Thus, the total mass transferred between  $V_1$  and  $V_2$  is still  $\Delta M$ , given as

$$\Delta M = m_{1 \rightarrow 2} - m_{2 \rightarrow 1} = 0.5 \cdot A \cdot \Delta x (C_1 - C_2). \quad (5.12)$$

Again, as diffusive mass transport is a time-dependent process, the above equation is rewritten as

$$\frac{\Delta M}{\Delta t} = \frac{0.5 \cdot A \cdot \Delta x (C_1 - C_2)}{\Delta t}, \quad (5.13)$$

which represents the change in total mass transferred between the two volumes over time in the diffusion couple shown in Figure 5.1.

The difference in concentration between  $V_1$  and  $V_2$  can be represented as

$$C_2 = C_1 + \frac{\delta C}{\delta x} \cdot \Delta x, \quad (5.14)$$

which simply states that the concentration in  $V_2$  is equal to the concentration in  $V_1$  plus the concentration gradient induced by the mass transfer between the two halves of the diffusion couple.

Thus, equation 5.13 can be rewritten as

$$\frac{\Delta M}{\Delta t \cdot A} = \frac{0.5 \cdot \Delta x (C_1 - (C_1 + \frac{\delta C}{\delta x} \cdot \Delta x))}{\Delta t}, \quad (5.15)$$

where diffusive flux between the two halves of the diffusion couple is represented by

$$J = \frac{\Delta M}{\Delta t \cdot A}. \quad (5.16)$$

Equation 5.15 can simply be reduced to

$$J = -\frac{0.5 \cdot (\Delta x)^2}{\Delta t} \frac{\delta C}{\delta x} = -D \frac{\delta C}{\delta x} \quad (5.17)$$

where  $\frac{0.5 \cdot (\Delta x)^2}{\Delta t}$  is defined as a coefficient,  $D$ , known as the diffusivity.

Combining equations 5.9 and 5.17, we arrive at Fick's second law

$$\frac{\delta C}{\delta t} = D \frac{\delta^2 C}{\delta x^2}, \quad (5.18)$$

which states that the time-dependent change in concentration is equal to the rate of change of the concentration gradient in one dimension, given a proportionality constant  $D$  (*i.e.*, the diffusivity). Thus, using this equation, the functional form of a concentration profile can be determined for 1-dimension mass transport problems, such as the above described planar diffusion model [91].

Assuming the deposition layer is infinitesimally thin in comparison to the carrier objects, we can represent the deposition layer as a delta function. This is illustrated in Figure 5.2, where the deposition layer at Interface D2 is shown to be very thin (<5 microns) in comparison to either Object D2 or Sample D (also shown in Figure 3.4).

Figure 5.2: Top, BSE image of the interface between Sample D and Object D2. The interface region is very thin (<5 microns) in comparison to the larger objects. Bottom, schematic of mass transport from an infinitesimal planar source (red) through a volume (blue) having cross sectional area  $A$ , which was used to model deposition layers as shown at Interface D2 (above).

The initial concentration of the layer is given as

$$C(x) = M\delta(x) \quad (5.19)$$

where  $M$  is the mass of the diffusant. The variables that control mass transport can be organized into dimensionless parameters via the Buckingham Pi theorem [91]:

$$\pi_1 = \frac{C}{M/A\sqrt{Dt}}, \quad (5.20)$$

and

$$\pi_2 = \frac{x}{\sqrt{Dt}}, \quad (5.21)$$

such that, through dimensional analysis,  $\pi_1$  is equal to some function of  $\pi_2$ :

$$\pi_1 = f(\pi_2), \quad (5.22)$$

where  $A$  is the cross sectional area,  $D$  is the diffusivity,  $t$  is time, and  $x$  is the direction of diffusion.

Equation 5.22 can be reorganized to present concentration as a function of time and distance,

$$C(x, t) = \frac{M}{A\sqrt{Dt}} f\left(\frac{x}{\sqrt{Dt}}\right). \quad (5.23)$$

Using a series of substitution steps, Equation 5.23 can be combined with Equation 5.18 to determine the functional form of  $f$ , from which we arrive at the equation representing a concentration distribution from diffusion of a planar source

$$C(x, t) = \frac{M}{A\sqrt{4\pi Dt}} e^{\left(\frac{-x^2}{4Dt}\right)}, \quad (5.24)$$

which is identical to Equation 5.1, where the pre-exponential fraction can be defined as  $C_0$ . In the idealized case described above, one would expect the concentration distribution of the diffusing species to spread in a Gaussian shape from a delta function over time, as shown in Figure 5.3.

Thus, when considering a deposited layer of material at the interface of agglomerated glassy fallout objects, concentration profiles should approximate a Gaussian distribution from the interface, particularly if the still-molten material did not have considerable pre-existing concentration or thermal gradients prior to deposition and agglomeration (addressed in Section 5.3). In such a scenario, the concentration profile of a species of interest can be fit by a Gaussian distribution,

$$G = \frac{A}{\sigma\sqrt{2\pi}} e^{-\frac{(x-\mu)^2}{2\sigma^2}}, \quad (5.25)$$

where  $A$  is the amplitude of the peak,  $\sigma$  is the standard deviation of the distribution, and  $\mu$  is the average. In non-linear least squares regression analysis, each of these variables are fitting parameters and are determined from the fit. Using Equation 5.25 to fit the

Figure 5.3: Model of a concentration distribution from 1-dimensional diffusion from an infinitesimal planar source, taking the form of a Gaussian distribution at arbitrary time  $t$ . The concentration is presented in relative units, as the area under both curves is the same.

concentration distribution of a species observed at a given interface, a value of  $\sigma$  can be acquired, which has the following relation according to Equation 5.1

$$\sigma = \sqrt{2Dt}, \quad (5.26)$$

where  $D$  is the diffusivity of a species of interest and  $t$  is the time over which it diffused. Thus, from the concentration distribution observed for a species at the interface, parameters of diffusivity and time can be acquired.

However, diffusivity is temperature dependent according to the Arrhenius equation (Equation 1.5), which is uniquely defined for a single species diffusing through a specific medium over a temperature range. Thus, equation 5.26 is more accurately written as

$$\sigma = \sqrt{2D(T)t}, \quad (5.27)$$

and, from the  $\sigma$  derived from the concentration distribution of a species of interest, a convolved parameter of time and temperature can be determined if the Arrhenius relationship for the species of interest was known.

When considering that fallout is formed in a cooling fireball environment [92], the derived  $\sigma$  value is actually more accurately represented as

$$\sigma = \sqrt{2D_{avg}t}, \quad (5.28)$$

where  $D_{avg}$  is the average diffusivity over a specific temperature interval in the medium, where  $D_{avg}$  is defined as

$$D_{avg} = \frac{1}{b-a} \int_a^b D_0 e^{-\frac{E_a}{RT}} dT, \quad (5.29)$$

where the interval  $a$  to  $b$  represents the temperature range over which diffusion occurs.

In the context of a carrier in a cooling fireball environment, the parameter of  $T$  is the temperature of the molten soil through which the deposited material is diffusing. This temperature decreases according to the environment in which the droplet is entrained (*i.e.*, the fireball), which is a time dependent process. Thus, Equation 5.29 can be rewritten as

$$D_{avg} = \frac{1}{t} \int_0^t D_0 e^{-\frac{E_a}{RT(t)}} dt, \quad (5.30)$$

where  $T(t)$  is the cooling rate of the molten material as dictated by the cooling of the fireball, and  $t$  is the time interval over which diffusion is able to occur. By combining Equations 5.28 and 5.30, the following relationship is derived

$$\frac{\sigma^2}{2} = D_{avg} t = \int_0^t D_0 e^{-\frac{E_a}{RT(t)}} dt. \quad (5.31)$$

Therefore, by determining the  $\sigma$  value from fitting the concentration distribution of a species that diffused from the interface, the time of mass transport can be deconvolved from the temperature interval, if the parameters  $E_a$ ,  $D_0$ , and  $T(t)$  are defined. As illustrated in the subsequent sections, the parameters  $E_a$  and  $D_0$  can be acquired from studies conducted in similar materials (which are available in the literature), and the cooling rate  $T(t)$  can be modeled using empirical relationships from historical studies of fireballs from atmospheric testing.

## Effective binary diffusion of uranium

While the above treatment of diffusive mass transport is applicable for a 1-dimensional planar diffusion model, the rate of mass transport is not directly acknowledged. Diffusive mass transport is dictated by thermally induced random motion experienced by particles in a medium, which can be solid, liquid, or gas-phase (or some combination). As shown above, a concentration difference between two regions leads to mass transport of species between these regions, the rate of which is controlled by the state of the medium, the size of the diffusing species, and the chemical interactions between the diffusing species and the medium. This rate is directly related the diffusivity,  $D$ , of the species in a medium.

The simplest form of diffusion is binary diffusion, or diffusion in a system having two components. For example, in a layer having only a single species deposited onto the surface of a homogeneous molten medium, a model of binary diffusion could be applied to describe the rate of diffusion of the species into the medium. In that case, there is only one relationship (*i.e.*, one diffusivity) describing the mass transport of the species through the medium.

In this study, however, the deposited layer comprises multiple species, which are diffusing through a molten (liquid-phase or otherwise amorphous) glass constituent having multiple compositional components. To most accurately describe such a system, a series of flux relationships must be established describing the effect that the concentration gradient of each species has on the diffusion of each other species present in the system [89]. These relationships are defined as

$$J_1 = -D_{11}\nabla C_1 - D_{12}\nabla C_2 \dots - D_{1n}\nabla C_n, \quad (5.32)$$

$$J_2 = -D_{21}\nabla C_1 - D_{22}\nabla C_2 \dots - D_{2n}\nabla C_n, \quad (5.33)$$

and continuing for each of  $n$  species, until

$$J_n = -D_{n1}\nabla C_1 - D_{n2}\nabla C_2 \dots - D_{nn}\nabla C_n, \quad (5.34)$$

where each  $D$  is the diffusion coefficient that contributes to mass transport of a species as it is affected by another species in the system.

In multicomponent systems, the above system of equations is typically solved in matrix notation, where the diffusion coefficients make up an  $n \times n$  matrix known as the diffusivity matrix, which is uniquely defined for each multicomponent system [89]. For the silicate-based system observed in the glassy fallout in this study, however, there is no solution to the diffusivity matrix available in the literature. This is complicated further when considering diffusion of the species from a distinct deposition layer into the multicomponent soil composition.

In order to model diffusion in such complex systems, I use a simplified approach, known as effectively binary diffusion (EBD), to the multicomponent diffusion problem. In EBD, species of interest in a multicomponent systems can be treated as a series of approximately binary diffusion systems, where the diffusivity relates to the rate of mass transfer of a single species through the rest of the species combined. This method has been widely applied to mineral melts in the field of geochemistry, and has been used to understand multicomponent silicate systems similar to those found in the glassy fallout material in this study [89, 93].

For the EBD approach to be appropriate for a given multicomponent system, one of several distinct scenarios must be applicable [89]. In the first scenario, the concentration gradients in the multicomponent system are due to dilution caused by an increased concentration of a single minor component. In the second scenario, there is an interdependent compositional difference between two components in the system. In the third scenario EBD is used for diffusion couples of different composition for species having very large concentration changes between each end of the couple. In the last scenario, there are large gradients in multiple components in the same direction that have consistent relative magnitudes. In this case, an EBD approach is appropriate for the species with the largest gradient.

For this study, the fourth scenario is the most applicable – the observed layer being explained is enriched in multiple species (*e.g.*, Fe, Ca, and  $^{235}\text{U}$ ). The species in this layer

diffuse from the interface into both adjacent objects, which are typically very similar in major element composition (see Section 4.1). As observed in Table 4.7, the relative concentration increase is clearly the greatest in  $^{235}\text{U}$ . That is, the maximum concentration increased over 900% relative to the concentration in either adjacent glassy object. To derive the time and temperature of deposition the layer, as well as the time of mass transport from the layer, I found it most appropriate to apply a model of EBD of uranium in a molten system of rhyolitic composition.

The most pertinent study available regarding diffusion of uranium in a composition similar to fallout glass is by Mungall and Dingwell (1997) [93], where uranium diffusivity was determined in a haplogranitic melt (79%  $\text{SiO}_2$ , 12%  $\text{Al}_2\text{O}_3$ ). While the valence state of uranium in the fallout glass during deposition and diffusion is unknown, [93] suggests uranium is present in the hexavalent state in environments of high oxygen fugacity, which is assumed for this study at the temperature and pressure ranges of interest ( $< 2500$  K and  $\sim 1$  atm, respectively). Further, recent work using x-ray absorption near edge structures (XANES) on melt glass from a uranium-fueled test determined that the uranium predominantly existed in the hexavalent state (*i.e.*,  $\text{UO}_2^{2+}$ ) [94].

As expected, the equation dictating the temperature dependence of uranium diffusion in this system was found by Mungall to be Arrhenian,

$$D_u = 12.27e^{-\frac{363.8}{RT}}, \quad (5.35)$$

with the pre-exponential diffusivity given in  $\text{cm}^2\text{s}^{-1}$ , and the activation energy given in  $\text{KJ}\cdot\text{mol}^{-1}$ . These parameters were used with Equation 5.31 to determine the time and temperature parameters controlling the diffusion of uranium from the deposition layer in selected samples.

## Average temperature of tropospheric nuclear fireball

It is theorized that fallout debris is a mixture of liquid phase soil and vaporized or condensed device materials [15, 18, 23]. As the glass objects in this study are aerodynamic in shape, it is likely that these objects solidified before coming in contact with the ground. In order to acquire a layer of Fe, Ca, and U at the interface of two fused objects, at least their surfaces were in the liquid state when the layer was deposited and before the objects collided, subsequently solidifying before significant ground interaction. It follows that the cooling rate of the interfaces (where the still molten objects collided),  $T(t)$ , would be dictated by the cooling rate of the fireball. As the temperature history of the objects in the fireball is unknown, the average cooling rate of the fireball was used to determine the approximate cooling rate of the fallout objects.

As described in Section 1.3, historical fallout formation models make use of fireball temperatures as derived from empirical scaling equations, such as Hillendahl's equations from light output curves [92]:

$$T = 7000W^{-0.07}\left(\frac{1}{t_{fmax}}\right)^{-0.34}, \quad (5.36)$$

where  $T$  is temperature in K,  $W$  is the yield in kt, and  $t_{fmax}$  is the time (in seconds) of the second fireball light output maximum,

$$t_{fmax} = 0.037W^{0.49}. \quad (5.37)$$

These two equations were combined and differentiated to derive a yield-dependent fireball cooling rate after  $t_{fmax}$ :

$$-\frac{dT}{dt} = 776W^{0.10}t^{-1.34} \cong (3 \times 10^{-11})W^{-0.3}T^4. \quad (5.38)$$

Equation 5.38 is used as the ambient thermal environment input for modeling the cooling of fallout. As the event in question is anonymous, in Figure 5.4, the cooling curves for 0.1 kt, 1 kt, and 10 kt yields are given, as determined from Equation 5.38. The initial temperature was selected to be 2500 K, which is the boiling point of  $\text{SiO}_2$  [95], and for this study is considered the maximum temperature at which a deposition layer could have formed on the surface of molten soil carriers (deposition is unlikely to occur on a boiling surface). As seen in Figure 5.4, cooling becomes more gradual as yield increases: a 0.1 kt fireball cools to below 1500 K in approximately 1 second, while a 10 kt fireball takes almost 5-fold longer to cool to 1500 K. The cooling rates used for this diffusion study were modeled to be 0.1 kt, 1 kt and 10 kt, to show the effect of yield on the thermal environment dictating diffusion over a range of magnitudes.

Figure 5.4: The fireball cooling curves determined from Equation 5.38 for 0.1 kt, 1 kt, and 10 kt near-surface nuclear explosions for temperatures below 2500 K based empirical scaling equations derived from light output curves [92].

### Modeling cooling rate at selected interfaces

The temperature variation at the interface of agglomerated fallout objects was modeled using COMSOL Multiphysics Modeling Software, a finite element analysis solver based on coupled series of partial differential equations designed to simulate physical systems. Finite element analysis is a computational method for approximating the effect of a physical process on a geometric domain that cannot be directly solved otherwise. In finite element analysis, the geometry of a system is divided into a series of discrete polyhedra of predefined size (known as meshing) from which a series of interrelated partial differential equation boundary problems can be solved simultaneously.

In order to model the temperature variation at the interface, a three-dimensional model was constructed in COMSOL as shown in Figure 5.5a. This model simulated two spherical objects that fused together, with the larger object having a diameter of 1.5 mm, and the smaller object having a diameter of 0.4 mm. As shown in the 3-dimensional model, the

Table 5.1: Literature values of some material properties of a rhyolite melt

Property	Value	Reference
thermal conductivity $k$	$0.5 \text{ W}/(\text{m} \cdot \text{K})$	Murase et al. (1973) [96]
density $\rho$	$2300 \text{ kg}/\text{m}^3$	Collier et al. (2006) [97]
ratio of specific heats $\gamma$	1.33	Collier et al. (2006) [97]
heat capacity at constant pressure $C_p$	$1200 \text{ J}/(\text{kg} \cdot \text{K})$	Romine et al. (2012) [98]
emissivity $\epsilon$	0.8	Harris, A. (2013) [99]

smaller object is partially embedded in the larger object. In this model, the 'interface' was defined as the outer edge of the larger sphere that lay within the smaller sphere. Meshing of this model used tetrahedra, which could be automatically generated by COMSOL to mesh the unusual geometry of the modeled agglomerated objects. The tetrahedra ranged in size from 1 micron to 25 microns, such that features of interest could be approximated most accurately while minimizing computational time. Figure 5.5b shows a 3-D wireframe image of the meshing tetrahedra that made up the volume of the modeled geometry.

The heat transfer model applied to this system included conductive, convective, and radiative heat transfer. Conduction was used to model heat transfer within the object itself, while convective and radiative heat transfer was used to model the external effect of the cooling fireball environment on change in temperature within the modeled fallout object. In order to most accurately model these modes of heat transfer, the model was imbued with key material properties of molten rhyolite. Specifically, these properties included the thermal conductivity  $k$ , density  $\rho$ , ratio of specific heats  $\gamma$ , the heat capacity at constant pressure  $C_p$ , and emissivity  $\epsilon$  (see Table 5.1) for a rhyolitic melt.

The differential equations that were used to simulate boundary conduction, convection, and radiative heat transfer between each discrete volume were

$$\rho C_p \frac{\delta T}{\delta t} + \rho C_p \vec{n} \cdot \nabla T = \nabla \cdot (k \nabla T) + Q, \quad (5.39)$$

$$-\vec{n} \cdot (-k \nabla T) = h \cdot (T_{ext} - T), \quad (5.40)$$

and

$$-\vec{n} \cdot (-k \nabla T) = \epsilon \sigma (T_{ext}^4 - T^4), \quad (5.41)$$

respectively, where  $\vec{n}$  is the unit vector,  $T_{ext}$  is the ambient temperature (as determined by Equation 6.38),  $T$  is the temperature of the discrete volume within the object,  $t$  is time,  $h$  is the heat transfer coefficient of air, and  $Q$  is the heat energy.

To simultaneously solve these equations over the entire system, COMSOL used an iterative minimization routine known as Generalized Minimal Residual algorithm (GMRES)

[100]. Using this minimization routine, COMSOL approximated the solution for each discrete volume in the defined geometry over a series of 50 iterations for each time step, which was 0.1 seconds over a period of 5 to 10 seconds for this simulation, depending on the modeled yield. Thus, for each time step, the temperature at each defined tetrahedra in the object could be determined and a temperature profile could be acquired.

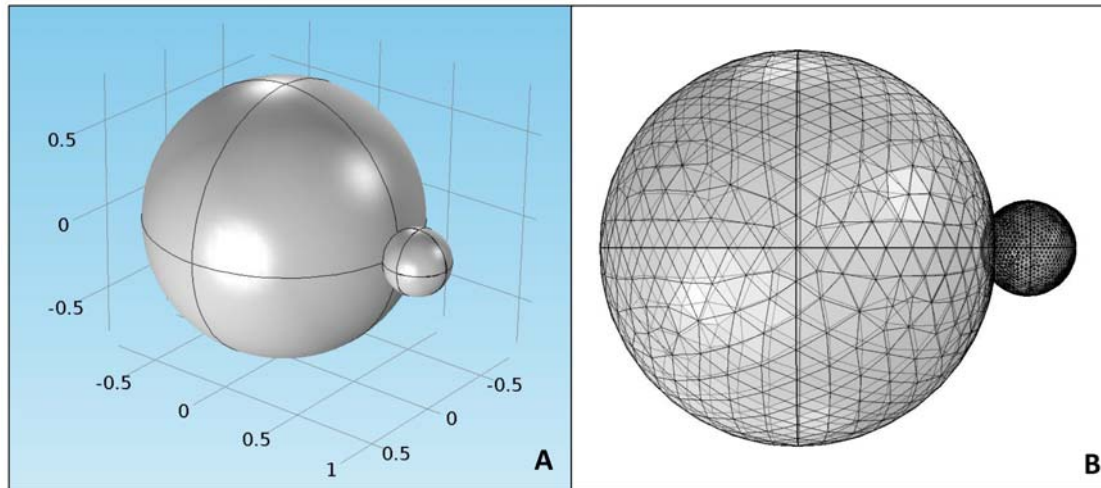

Figure 5.5: (A) COMSOL 3-D mockup of aerodynamic fallout glass where two objects have fused together, where the grid scale is in millimeters. The large object is 1.5 mm in diameter, and the smaller attached object is 0.4 mm in diameter. (B) Wire frame of the meshed geometry, using tetrahedra from 1 micron to 25 microns, to model the geometry.

In Figure 5.6, the temperature profile of the object is shown at 1.0 seconds for the modeled object, with an ambient cooling rate defined by the average temperature of a fireball from a 1 kt near-surface nuclear explosion as defined by Equation 5.38 (see Figure 5.4 for the cooling curve). For these models, an initial temperature of 2500 K was selected (the approximate boiling point of  $\text{SiO}_2$  [95]) for the fallout material. The models were run until the interface had cooled to approximately 1500 K (well below the solidification temperature posited by Freiling [16]). As seen in the temperature profile shown in Figure 5.6, there is a modeled temperature gradient of approximately 300 K across the object, with the interface (indicated by the black arrow) lying within the cooler temperature regime relative to the center of the larger object. Within the smaller attached object, there exists little thermal variation relative to the larger object. This difference is due to the large surface-to-volume ratio of the smaller object. As the modeled ambient temperature approaches 1500 K, cooling within the object is dominated by convective cooling, and the thermal gradient within the object effectively disappears.

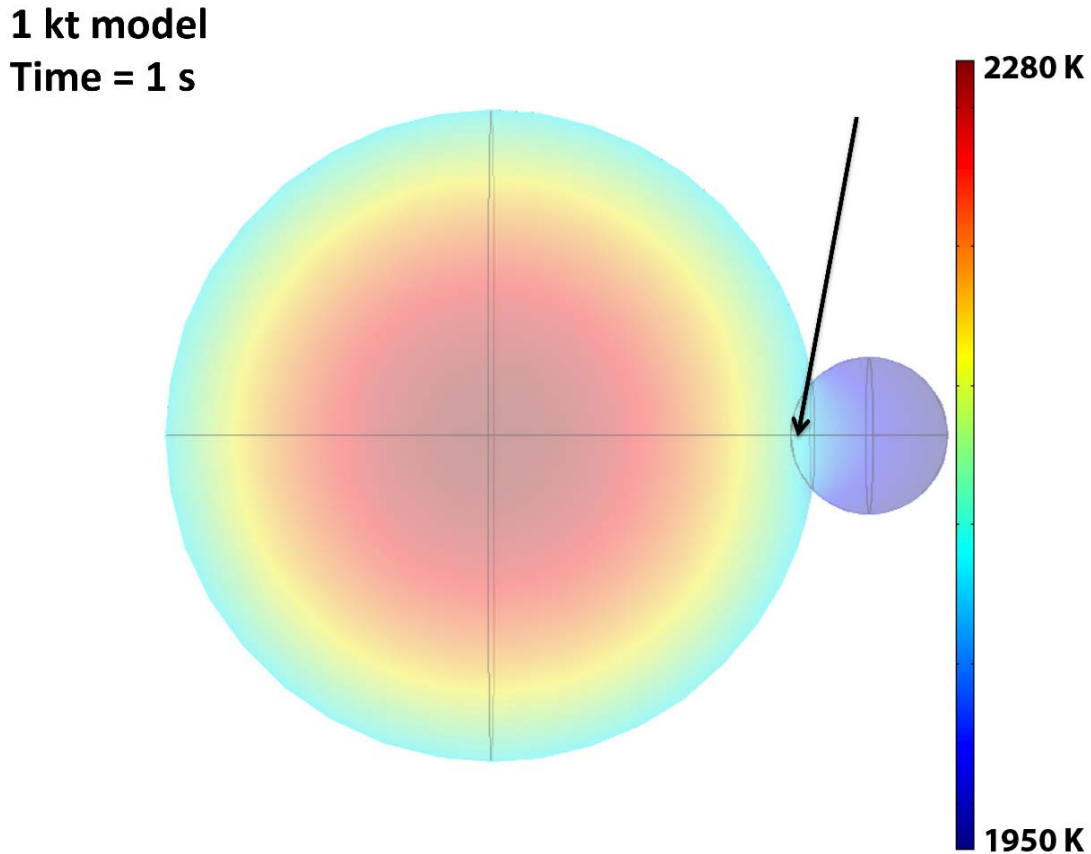

Figure 5.6: Temperature profile of the 3-D fallout mockup acquired by finite element analysis after 1.0 s of cooling in a 1 kt fireball from 2500 K. This model incorporates conductive and radiative thermal transport with the external environment and within the object. The black arrow indicates the interface point, where the cooling rate equation of the interface was determined for the yield series.

Most critical to this study, however, was the temperature change at the interface over time, which controls the rate of mass transport from the interface into either object. In order to understand the effect (if any) the thermal gradient had on mass transport as species diffused from the interface, the temperature difference at each time step was acquired across the interface (over  $\sim 5$  microns, consistent with the width of the interfaces, *e.g.*, Figure 5.2). In Figure 5.7, the thermal gradient is shown across the interface at  $t = 1.0$  seconds (as shown in Figure 5.6). As seen from this image, the temperature difference over 5 microns is less than 5 degrees K, which has a negligible effect on the rate of diffusion from the interface. At

any time step for an assumed yield from 0.1-10 kt, the temperature gradient did not exceed 10 degrees K. Thus, the cooling rate at the instantaneous interface point was used as the estimated cooling rate over the entire interface region.

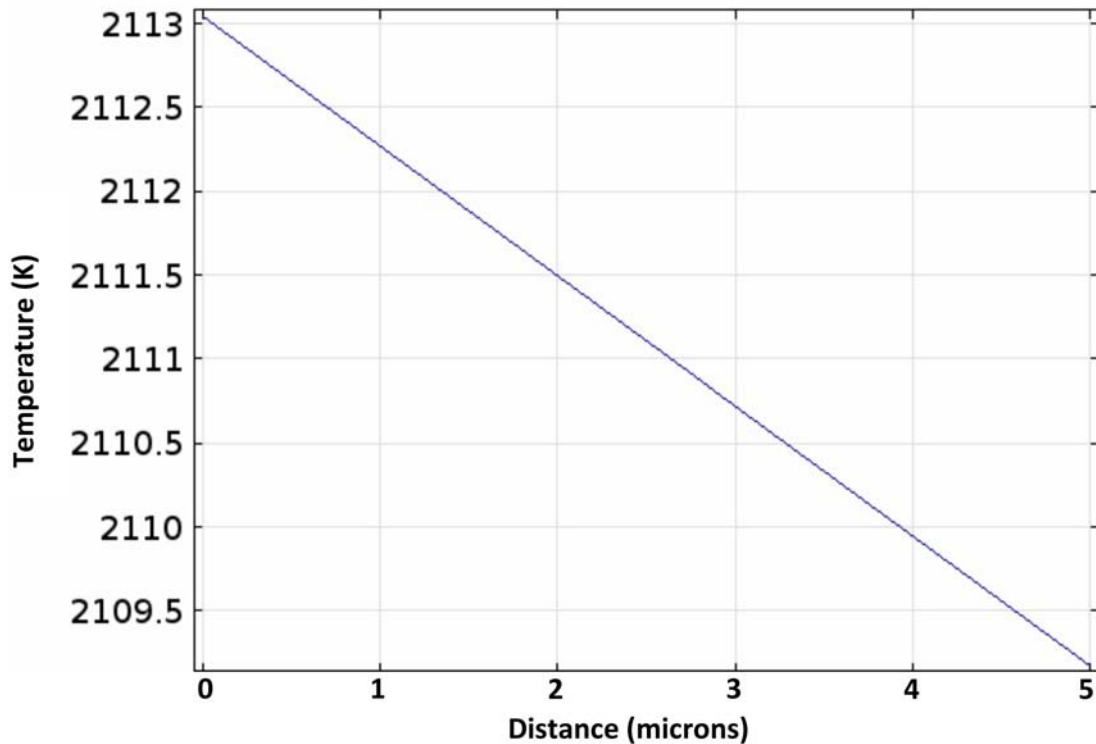

Figure 5.7: The temperature gradient across the modeled interface over 5 microns. The temperature gradient is negligible (<5 degrees K) across the interface after 1.0 seconds in a 1 kt fireball cooling from 2500 K.

The cooling curves at the interface point were acquired for the yield series 0.1 kt, 1 kt, and 10 kt from 2500 K to 1500 K, generated as described above. As described above, these curves were generated from a series of 0.1 s time steps and are reported over the time-scale necessary to reach 1500 K. Using non-linear least squares regression fitting of each point in the time series, the cooling rates for each yield were most accurately approximated as simple exponential functions. This is shown in Figure 5.8, where the temperature at the interface is shown over 2500 K to 1500 K for the 10 kt yield for each 0.1 s time step. The black line represents the exponential fit function (Equation 5.44).

For 0.1 kt, the interface cooling rate (in degrees K) was expressed as

$$T(t) = 1289 + 1242e^{-0.67t}, \quad (5.42)$$

for 1 kt, the interface cooling rate was expressed as

Figure 5.8: The temperature at the modeled interface from 2500 K to 1500 K for 10 kt fireball cooling rate environment (Equation 5.44) for each 0.1 s time-step. Mass transport would effectively stop (<1500 K) after approximately 8 seconds.

$$T(t) = 1306 + 1226e^{-0.46t}, \quad (5.43)$$

and for 10 kt, the interface cooling rate was expressed as

$$T(t) = 1300 + 1222e^{-0.28t}. \quad (5.44)$$

These cooling equations are presented in Figure 5.9, showing the cooling rate for each yield in the series. As expected, lower yield fireball environments corresponded to steeper temperature decreases, and higher yield fireball environments corresponded to a more gradual temperature decline at the interface.

The cooling rates represented by these curves and equations were incorporated into Equation 5.31 as  $T(t)$  for each yield in the series for the purposes of deriving time and temperature parameters of mass transport from measured diffusion profiles at agglomerate interfaces.

Figure 5.9: The cooling curves at the modeled interface from 2500 K to 1500 K for 0.1 kt, 1 kt, and 10 kt fireball cooling rates derived from Equation 5.38 from 2500 K. Equation 5.42 is shown by the blue line, Equation 5.43 is shown by the red line, and Equation 5.44 is shown by the black line.

Without knowing the time of deposition along a given cooling curve, the interval over which mass transport occurred, as defined in Equation 5.31, cannot be bounded. Instead, by combining 5.31, 5.35, and any of 5.42-5.44, an expression that defines mass transport over any given interval along the cooling curves of 5.42-5.44 can be constructed:

$$\frac{\sigma^2}{2} = D_{avg}t = \int_{t_1}^{t_2} D_{0U} e^{-\frac{E_{aU}}{RT(t)}} dt, \quad (5.45)$$

where  $D_{0U}$  is the pre-exponential diffusivity of uranium ( $10^{1.09 \pm 0.15} \text{cm}^2/\text{s}$ ), and  $E_{aU}$  is the activation energy of uranium ( $363.8 \pm 24.0 \text{kJ/mol}$ ) in molten rhyolite [93].

By setting a pre-defined maximum time ( $t_2$ ) as the time at which the interface reaches 1500 K (and mass transport effectively stops), we can solve for  $t_1$ , or the time of deposition along the cooling curve for a given yield in the series. This is illustrated in Figure 5.10 for

the 1 kt yield environment. As shown in the figure,  $t_2$  is defined for the given cooling curve to be the time at which the interface is at 1500 K, approximately 4 seconds. By knowing the rate of mass transport of a species, in this case uranium as defined by Equation 5.35, and the  $\sigma$  values for uranium from experimental measurements as defined by Equation 5.28, the time of deposition  $t_1$  can be approximated for along the cooling curve of a given yield for each applicable interface.

Figure 5.10: In order to bound the time of deposition ( $t_1$ ) along a cooling curve, we can solve Equation 5.45, if the time mass transport effectively stops, the diffusivity of a given species, and the extent of diffusion of a given species from the interface is known.

### 5.3 Results

#### Gaussian fits of the $^{235}\text{U}/^{30}\text{Si}$ ratio data at interfaces B1, C1, and D2

While enrichments of  $^{235}\text{U}/^{30}\text{Si}$  ratio were observed at nearly every interface, the pattern of variation was not always simply fit with Equation 5.25. Often, there was substantial skewing of the profile (Figure 4.19), sharp increases of  $^{235}\text{U}/^{30}\text{Si}$  ratio on either side of the interface

(Figures 4.17 and 4.20), or unclear patterns of variation (Figures 4.14 and 4.16). Thus, only samples illustrating distinct Gaussian peaks of  $^{235}\text{U}/^{30}\text{Si}$  ratio at the interface were ideal for applying this model.

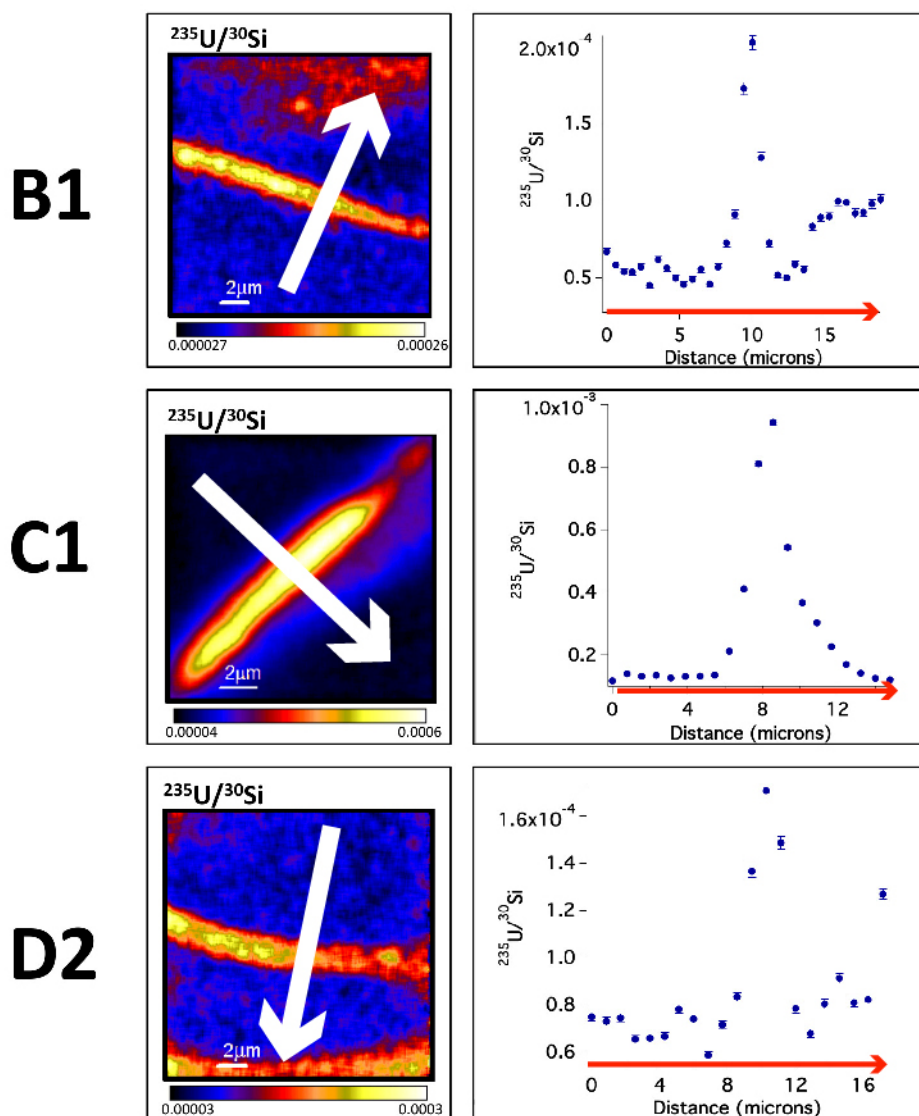

Figure 5.11: NanoSIMS ion images and isotope ratio variation profiles across the interface for  $^{235}\text{U}/^{30}\text{Si}$  for samples B1, C1, and D2 (see Figures 4.15, 4.18, 4.22). The isotope ratio profiles for these interfaces were the ones best fit with the modified Gaussian distribution of Equation 5.46 out of the sample set, with minimal variation on either side of the interface.

Interfaces of B1, C1, and D2 were selected to study mass transport given the minimal variation found on either side of these interfaces (Figure 5.11). At Interface B1, there is an

Table 5.2:  $D_{avg}t$  values from fits of B1, C1, and D2  $^{235}\text{U}/^{30}\text{Si}$  ratio using Equation 5.46.

Sample ID	$D_{avg}t(\mu\text{m}^2)$
B1	$0.33 \pm 0.03$
C1	$0.40 \pm 0.06$
D2	$0.44 \pm 0.10$

approximately symmetric peak, with a slight increase in the  $^{235}\text{U}/^{30}\text{Si}$  ratio towards the top of the image. At Interface C1, there is a slight skewing across the interface, but was found to be approximately Gaussian. At Interface D2, there is a symmetrical peak at the interface, with a sharp increase in the  $^{235}\text{U}/^{30}\text{Si}$  ratio towards the bottom of the image. The aberrant points in both B1 and D2, however, were sufficiently far from the interface so that they did not interfere with the Gaussian fit.

The  $^{235}\text{U}/^{30}\text{Si}$  ratio data acquired from NanoSIMS ion imaging (see Section 4.2) was fit in IGOR Pro software using non-linear least squares regression analysis with a modified version of Equation 5.25:

$$G = A + Bx + Cx^2 + \frac{D}{\sigma\sqrt{2\pi}}e^{-\frac{(x-\mu)^2}{2\sigma^2}}, \quad (5.46)$$

where the quadratic expression is added to allow for minor variation on either side of the interface and still acquire a Gaussian fit of the peak. The interface data for B1, C1, and D2 are shown with fit Equation 5.46 in Figures 5.12 - 5.14. The  $D_{ave}t$  values are given in Table 5.2, as derived from Equation 5.28 and the acquired  $\sigma$  values of the fits.

As seen in Figures 5.12 - 5.14, the peak widths are all approximately the same for the three studied interfaces ( $\sim 7$  microns). The addition of the quadratic expression to Equation 5.25 visually appears to properly fit the variation on either side of the peak in B1, C1, and D2, without interfering with the peak width.

Figure 5.12:  $^{235}\text{U}/^{30}\text{Si}$  Isotope ratio profile for sample B1 fit with Equation 5.46,  $D_{avg}t = 0.33 \pm 0.03 \mu\text{m}^2$ ). The fit intersects with every data point in the fit, and is within  $1 \sigma$  of all but 2 of the data points.

Figure 5.13:  $^{235}\text{U}/^{30}\text{Si}$  Isotope ratio profile for sample C1 fit with Equation 5.46,  $D_{avg}t = 0.40 \pm 0.06 \mu\text{m}^2$ ). Despite the slight skewing of the data, 7 of the 10 peak data points are within  $1 \sigma$  of the fit.

Figure 5.14:  $^{235}\text{U}/^{30}\text{Si}$  Isotope ratio profile for sample D2 fit with Equation 5.46,  $D_{avg}t = 0.44 \pm 0.10 \mu\text{m}^2$ ). Despite the variation on either side of the peak, the fit intersects with 60% of the peak data points and provides a good approximation of the peak shape.

## Probability distributions for the time of deposition

The  $D_{avg}t$  parameters given in Table 5.2, in combination with Equation 5.45 and the cooling equations  $T(t)$  for the interfaces at each yield, allow for the determination of the time of deposition  $t_1$  along each given interface cooling curve for B1, C1, and D2. As Equation 5.45 cannot be solved analytically for  $t_1$ , and there are uncertainties on the values of  $D_{0U}$ ,  $E_{aU}$ , and  $D_{avg}t$ , probability distributions of the time of deposition  $t_1$  were solved numerically in MATLAB software.

A maximum value of  $t_2$  of 3 seconds, 4 seconds, and 8 seconds were used for the 0.1, 1, and 10 kt interface cooling curves, respectively. These values were used to ensure that the temperature would have dropped to below 1500 K (as shown in Figure 5.9), ending diffusive mass transport. All of the parameters for Equation 5.45 that went into the MATLAB numerical determination of  $t_1$  probability distributions are defined in Table 5.3. Thus, a total of 9 probability distributions for the value of  $t_1$  were calculated (3 interfaces, 3 different yields).

Probability distributions were calculated by generating 1000 values at each of 100 predefined  $t_1$  values for each cooling curve. Each of these 100  $t_1$  values are equal time steps between  $t_1 = 0$  (where the interface temperature is 2500 K), and  $t_1 = t_2$ , thus effectively solving for  $t_1$  within the range of possible values. At each time-step, the 1000 values represent the difference between the integral in Equation 5.45 and the  $D_{avg}t$  value for a randomly selected value from normal distributions of  $D_{0U}$ ,  $E_{aU}$ , and  $D_{avg}t$  based on their given value and uncertainties. The probability at each time-step was determined based on the number of values out of the 1000 randomly generated values for each time-step produced a negative value for the following relationship:

Table 5.3: Parameters used in  $D_{avg}t = \int_{t_1}^{t_2} D_{0U} e^{-\frac{E_{aU}}{RT(t)}} dt$  to solve for  $t_1$  for each interface, at the corresponding cooling curve for each yield.

Sample ID	$D_{avg}t(\mu m^2)$	$t_2$ (seconds)
B1 - 0.1 kt	$0.33 \pm 0.03$	3
B1 - 1 kt	$0.33 \pm 0.03$	4
B1 - 10 kt	$0.33 \pm 0.03$	8
C1 - 0.1 kt	$0.40 \pm 0.06$	3
C1 - 1 kt	$0.40 \pm 0.06$	4
C1 - 10 kt	$0.40 \pm 0.06$	8
D2 - 0.1 kt	$0.44 \pm 0.10$	3
D2 - 1 kt	$0.44 \pm 0.10$	4
D2 - 10 kt	$0.44 \pm 0.10$	8

\* $D_{0U} = 10^{1.09 \pm 0.15} cm^2/s$

\*\* $E_{aU} = 363.8 \pm 24.0$  kJ/mol

$$\int_{t_1}^{t_2} D_{0U} e^{-\frac{E_a U}{RT(t)}} dt - D_{avg} t = Z, \quad (5.47)$$

where, if  $Z$  was negative, the time of deposition  $t_1$  did not correspond to a cooling interval sufficiently long enough to allow for mass transport of uranium from the interface that would produce the observed  $D_{avg} t$  value. By calculating the probability for each time-step in this fashion, a probability distribution representing a complimentary error function was calculated for each interface-yield combination. This is illustrated in Figure 5.10, which shows the number of negative values of  $Z$  for each time-step for the B1 interface with the 1 kt cooling curve. The blue line is the complimentary error function fit of the generated dataset based on

$$a + b \cdot \text{Erfc}\left(\frac{\mu_{t_1} - x}{|2 \cdot c|}\right), \quad (5.48)$$

where  $a$  is the background value (approximately zero in this case),  $b$  is the magnitude of the function (approximately 500 in this case),  $\mu_{t_1}$  is the average value of  $t_1$ , and  $c$  is the width of the error function.

Given that

$$\text{erf}(x) = \frac{1}{\sqrt{\pi}} \int_{-x}^x e^{-t^2} dt, \quad (5.49)$$

we can derive a Gaussian probability distribution from Equations 5.25 and 5.48, where

$$c = \frac{\sigma_{t_1} \sqrt{2}}{2}, \quad (5.50)$$

when  $\sigma_{t_1}$  is the standard deviation of the probability distribution of  $t_1$ .

Figure 5.15: Illustrated here is the cumulative probability distribution function of deposition times for interface B1 in a 1 kt cooling environment. Number of  $Z = \textit{negative}$  values based on Equation 5.47 for each time-step (shown as red points) for the B1, 1kt model (Table 5.3). The blue line represents the error function fit of the dataset, which was used to derive uncertainties on the time of deposition (Table 5.4)

### Time and temperature of deposition

Using Equation 5.48,  $\mu_{t_1}$  and  $\sigma_{t_1}$  were determined for each of the interface-yield combinations (Table 5.4). Using these values, the temperature of deposition  $T_{dep}$  was determined for each interface-yield combination using Equations 5.42-5.44, the respective cooling curves for each yield. Note that only the values for  $t_1$  have normally distributed uncertainties ( $\sigma =$  standard deviation). As the cooling curves are exponential functions, the uncertainties on  $T_{dep}$  simply represent the temperature interval that corresponds to  $1\sigma$  uncertainty on  $t_1$ . As seen in Table 5.4, there is little variation between the time and temperature of deposition between the interfaces at each corresponding yield. There is substantial relative time variation between each yield in the series, however, ranging from about 0.5 seconds at 0.1 kt to about 1.65 seconds at 10 kt. From 0.1 kt to 10 kt, there is approximately 100 K difference in the temperature of deposition for each studied interface.

Table 5.4: Time and temperatures of deposition as modeled for B1, C1, and D2 at 0.1, 1, and 10 kt yield scenarios.

Sample ID	time of deposition $t_1$ (seconds)	$T_{dep}$ (degrees K)
B1 - 0.1 kt	$0.56 \pm 0.27^*$	$2144 \pm_{140}^{169}$
B1 - 1 kt	$0.97 \pm 0.43$	$2093 \pm_{141}^{171}$
B1 - 10 kt	$1.75 \pm 0.74$	$2049 \pm_{140}^{173}$
C1 - 0.1 kt	$0.50 \pm 0.30$	$2179 \pm_{161}^{197}$
C1 - 1 kt	$0.87 \pm 0.45$	$2130 \pm_{154}^{188}$
C1 - 10 kt	$1.63 \pm 0.75$	$2075 \pm_{147}^{181}$
D2 - 0.1 kt	$0.49 \pm 0.31$	$2185 \pm_{167}^{206}$
D2 - 1 kt	$0.83 \pm 0.47$	$2145 \pm_{162}^{201}$
D2 - 10 kt	$1.59 \pm 0.76$	$2084 \pm_{150}^{185}$

## 5.4 Implications of diffusive mass transport from agglomerated interfaces

### $^{235}\text{U}/^{30}\text{Si}$ profiles at interfaces indicate different formation environments

Agglomerated aerodynamic fallout glasses preserve a record of the thermal histories experienced prior to quenching in the fireball. The patterns of  $^{235}\text{U}/^{30}\text{Si}$  variation seen at the studied interfaces are indicative of a range of formation environments experienced by the objects. The most symmetrical profiles, as shown in Figure 5.11 indicate that, upon collision of the small droplet and large droplet in the fireball, the temperature difference between these two objects was negligible at their surfaces. In an environment where both objects were approximately the same temperature, species would not preferentially diffuse into either object from the interface, forming a more symmetrical profile. This suggests that in the sample with the most symmetrical profiles, the fallout droplets were in a similar temperature regime of the fireball prior to collision.

Interfaces B1, C1, and D2 (Figure 5.11) all have similar  $D_{avg}t$  values (Table 5.2). As this parameter is directly related to the extent of diffusion from the interface, and they are similarly sized objects, it is likely that these objects also experienced similar formation environments (*i.e.*, fireball temperature regimes). However, as previously stated, Interface E1 (Figure 4.23) shows a much broader peak width ( $\sim 12$  microns, versus  $\sim 7$  microns for B1, C1, and D2). This width corresponds to either a longer duration in the same temperature regime as the other samples, or the droplets that formed Interface E1 experienced a higher temperature, creating a broader diffusion profile.

Substantial skewing of the profile in one direction is indicative of either a distinct com-

positional difference or a temperature difference. As the composition of these fallout objects are approximately the same, skewing in this case suggests a temperature difference between molten objects prior to collision. The most obvious example of this observed in the sample set is illustrated in Figure 4.19, which shows the  $^{235}\text{U}/^{30}\text{Si}$  variation at the interface of Object C2. At this interface, the  $^{235}\text{U}/^{30}\text{Si}$  profile is sharply skewed towards Sample C, indicating that diffusion occurred essentially unidirectionally from the interface. As discussed in Section 4.3, the sphericity and the relative compositional homogeneity of Object C2 itself is indicative of a relatively lower temperature when compared to the larger host object of Sample C. The evidence of preferential diffusive transport into Sample C bolsters this observation. Thus, it is clear that Object C2 had an opportunity to cool to a greater extent than the larger host. While the bulk temperature would be expected to be different in a cooling environment between the objects given the larger surface-to-volume ratio of the smaller object, the immediate surface temperatures of both objects would be expected to be similar prior to collision. Thus, the skewed  $^{235}\text{U}/^{30}\text{Si}$  profile suggests that the smaller object may have originated from a cooler temperature regime in the fireball itself.

Historical fallout formation theories, such as Miller's [15], model condensation and incorporation of radionuclides, as well as the subsequent fractionation of radionuclides, using fireball scaling equations. These models are reliant on average fireball temperatures, which can be determined from empirical light output observations, but do not address potential temperature gradients that exist within the fireball itself [1]. However, it is clear from this limited sample set that similarly sized fallout objects may experience a different time-temperature history based on composition profiles found at agglomerated interfaces. Thus, localized fireball temperature heterogeneity is likely to have an effect on the rate of incorporation of radionuclides and other vaporized species into carriers, particularly via the condensation-diffusion process.

## Constraining the timescale of mass transport and temperature of deposition

The modeled time of deposition shown in Table 5.4 for the interface-yield combinations, compared to the modeled times that the interfaces reach 1500 K based on the yield-dependent fireball cooling rate (Figure 5.9), indicate a maximum time of mass transport of  $\sim 2$  seconds,  $\sim 3$  seconds, and  $\sim 4.5$  seconds for the 0.1 kt, 1 kt, and 10 kt yield models, respectively. These values are comparable to the time of surface closure of fallout as determined by Cassata et al. (2014) ( $< 2.9$  s, [54]). While neither the yield of the test for this study, nor the yield of the test in the Cassata et al. study are known to the author, the overlapping timeframes of mass transport strongly suggest that incorporation of fission products, unfissioned device materials, and other vaporized constituents into aerodynamic glassy fallout objects occurred over the course of a few seconds. As discussed in Chapter 4, the Cassata et al. study posits two possible scenarios explaining this rapid closure time: that either the location in the fireball where the fallout formed cooled to 1500 K within that timeframe, or that the

fallout glasses were ejected from the fireball and rapidly quenched within the given timeframe (<2.9 seconds) [54]. The cooling rate modeling for the yield series shown in Figure 5.9 is entirely consistent with average fireball temperatures reaching quenching temperatures within seconds of reaching the vaporization temperature of SiO<sub>2</sub> (2500 K).

As also shown in Table 5.4, the temperature of deposition derived from fireball modeling by yield for each interface of interest increases as the yield increases. This observation is not unexpected - the smaller yield fireball cools more quickly, thus in order to acquire the same diffusion profile as observed at larger modeled yields, the temperature would have to be higher. In this study, 0.1, 1, and 10 kt yields were modeled to not only observe the effect of varying fireball environments, but to constrain a maximum temperature of deposition. The lowest modeled yield, 0.1 kt, is on the lower end of US nuclear weapons test yields, as published by the US Department of Energy [101]. Thus, while the yield of the test from which these samples were acquired is unknown, it is unlikely that the temperature of deposition would greatly exceed the values reported for the 0.1 kt model for the studied interfaces from this test.

Even using 0.1 kt as a yield limit, the temperature of deposition did not substantially vary when the modeled yield was increased by two orders of magnitude. Specifically, for each of the modeled interfaces, the temperature of deposition only changed by ~100 K between the 0.1 kt and 10 kt models, which is well within the uncertainty determined from the  $1\sigma$  on the time of deposition (Table 5.4). For the three roughly symmetrical interfaces B1, C1, and D2, that were used as model inputs, the most likely maximum temperature of deposition is 2185 K. The temperatures of deposition for each interface at each yield are shown in Figure 5.16 and fit by linear least squares regression. According to the model (as illustrated in Figure 5.16) the temperature of deposition changes by ~200 K over 5 orders of magnitude of modeled yield.

There are large uncertainties on the derived  $T_{dep}$  for each studied interface at each yield in the series. As shown in Figure 5.16, the  $1\sigma$  uncertainties on each value exceed 140 K. While this model provides a ballpark estimate of the temperature at which condensation processes may be occurring for these species, constraining these uncertainties is critical to understanding the speciation of vaporized constituents, which can change depending on the temperature (further detailed in Chapter 6).

Figure 5.16: Temperature of deposition for each interface vs the log of the modeled yield, with  $1\sigma$  uncertainties. The red line is a linear fit, from which the approximate temperature of deposition can be extrapolated for varying yields. While the fit line is applied to the data points only, the uncertainties in  $T_{dep}$  at each yield are systematic (*i.e.*, each is dependent on the uncertainties of the diffusivity parameters of uranium), thus the slope of the fit line would remain the same taking into account the uncertainties. As shown here, the estimated maximum deposition temperature is 2200 K, with uncertainties of roughly 200 K.

## Temperature of deposition and the speciation of vaporized constituents

When considering deposition of species onto molten fallout objects from the perspective of condensation sequence of vapor phase constituents, the temperature regime under consideration based on the model output is roughly 2000 K to 2200 K over a broad range in yields (Figure 5.16). Fallout formation models dictate that refractory species will condense first and incorporate into molten carriers while volatile species will deposit onto the surface of already quenched carriers [15]. As shown in Chapter 4, the interfaces of agglomerated fallout objects reveal enrichments of some refractory species (*i.e.*, calcium, iron, and uranium) and depletion in others (*i.e.*, aluminum and titanium). Based on boiling point data, both FeO

and CaO, which were likely derived in large part from the soil (see Section 4.1), though may have had additional anthropogenic contributions (see Section 4.3) vaporize around 3000K, and are considered refractory [82, 83, 84, 85]. Uranium metal and  $\text{UO}_2$  (from the device) are generally even more refractory, with boiling points of 4000 K and 3800 K, respectively [102]. As seen in Figure 5.17, the maximum calculated  $T_{dep}$  has a lower temperature than the boiling point of any of the species present at the interface, as well as certain species present in the soil that were found to be depleted at the interface (*i.e.*,  $\text{Al}_2\text{O}_3$  and  $\text{TiO}_2$ ). Thus, all of the rock forming species would be expected to condense out of the vapor phase based on boiling point data alone.

Figure 5.17: Boiling points of selected species of interest at the interface (section 4.1). Boiling point can serve as one potential metric of the relative volatility of these species relative to each other.

As already stated in Section 4.3, the boiling point may be a poor metric for the relative volatility of species in fireball environments with multiple vapor-phase constituents. The condensation behavior of each species, which is dictated by temperature-dependent vapor pressures, depends on the relative concentration of vaporized constituents as dictated by Raoult's law (Equation 1.1). The vapor pressure of the Al-species in atmospheric conditions is approximately two orders of magnitude lower than for the Ca-species at  $\sim 2200$  K, and they are approximately the same in reducing conditions at that temperature ([87]). Given this

observation, and the fact that  $\text{Al}_2\text{O}_3$  has a much higher concentration in soil compared to  $\text{CaO}$  (see Section 4.2), a higher concentration of  $\text{Al}_2\text{O}_3$  in the vapor would be expected, and thus, a higher vapor pressure based on Raoult's law, if both of these species were derived from the soil. Therefore a source of Ca in addition to that found in the soil may have been present, such as a cement structure (Section 4.3), that dramatically increased the concentration of  $\text{CaO}$  in the vapor, and subsequently increase vapor pressure of  $\text{CaO}$ , relative to  $\text{Al}_2\text{O}_3$ , at  $\sim 2200$  K.

The co-location of  $\text{Na}_2\text{O}$  and  $\text{CaO}$  at most interfaces is also at odds with current understanding of relative volatilities of species. Assuming equilibrium conditions, at  $\sim 2200$  K, the vapor pressure of  $\text{CaO}$  is over 7 orders of magnitude lower than Na (the constituent with the highest vapor pressure of the Na-oxide species) in an oxygen-rich environment [103, 87]. In a reducing environment, the vapor pressure of Ca (the constituent with the highest vapor pressure in reducing environments) is 11 orders of magnitude lower than Na at  $\sim 2200$  K. Thus, in either environment, Ca-species and Na-species would be expected to experience considerable chemical fractionation, particularly given that  $\text{Na}_2\text{O}$  is more than 2 fold more abundant in the soil than  $\text{CaO}$ . However, in an oxygen-rich environment, the vapor pressure of Na approaches atmospheric pressure at around 2200 K [103]; this does not happen until temperatures cool to 1400 K in reducing conditions. Thus, co-location of Na- and Ca-species would be possible in an oxygen-rich environment (which the fireball is theorized to be during fallout formation [6, 15]), where there was substantial contribution of Ca to the vapor from an additional source undergoing continuous fractionation (as described in Section 4.3).

The assertion that sodium deposition is the result of an oxygenated fireball is in apparent contrast to what was shown by Cassata et al. (2014), where measurements of volumetric xenon isotope concentrations indicate that the fireball was in a reducing state [54]. However, as shown in the recent XANES study of melt glass from near-surface nuclear tests [94], the cooling rate of the fireball (and the carriers entrained in the fireball) can affect the final redox state of the glasses. Thus, the incorporation of xenon isotope precursors (the decay products of fission products) into the volume of molten fallout glasses may have occurred in an earlier, anoxic state, while the deposition layers observed in the agglomerated fallout objects in this study are likely the result of late stage addition in a more oxygenated fireball. This is the first definitive evidence of a transition from anoxic to oxidized conditions in a fireball.

Further, while Raoult's law, and studies such as those by Lamoreaux et al. (1984, 1987), can be used to estimate the vapor pressure and condensation behavior of individual species in a multi-component vapor, they are only accurate for ideal solutions. This interpretation is further complicated when taking into account the effect of oxidation on a multicomponent vapor, resultant condensates, and the multicomponent carrier materials in a high temperature environment. These effects are evident by the fact that uranium fractionation studies have observed both refractory and volatile behavior of uranium in post-detonation environments [20]. As illustrated above, the boiling point of both U and  $\text{UO}_2$  are around 4000 K; as such both species are considered highly refractory. There are several potential species of gaseous uranium oxide that may exist, each having different thermochemical properties, including

but not limited to  $\text{UO}$ ,  $\text{UO}_2$ , and  $\text{UO}_3$  [104]. Further, the interaction of uranium with other constituents in a multicomponent vapor could form numerous other complex species, each with a distinct condensation behavior that could effect fractionation, and explain a temperature of deposition much lower than what is anticipated by the boiling points of uranium metal or  $\text{UO}_2$ . This complex behavior is not limited to uranium. In vaporization experiments comprising multiple oxides, such as those found in the soil (*e.g.*,  $\text{CaO}$ ,  $\text{MgO}$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{TiO}_2$ , and  $\text{SiO}_2$ ), complex gaseous oxides such as  $\text{CaAlO}$ ,  $\text{CaSiO}_3$ ,  $\text{MgAlO}$ ,  $\text{AlSiO}$ , and  $\text{CaTiO}_3$  have been observed [105].

In summary, by constraining the temperature of deposition ( $\sim 2000$ - $2200$  K), there is evidence that the Ca, Fe, and  $^{235}\text{U}$  species in these interface layers originated, at least in part, from anthropogenic sources. Further, the presence of  $\text{Na}_2\text{O}$  co-located with these species at some interfaces indicates that the fireball was likely oxygenated at the time and temperature of deposition. The co-location of  $\text{Na}_2\text{O}$  with Ca, Fe, and  $^{235}\text{U}$ , along with the volumetric incorporation of at least  $^{235}\text{U}$  as shown in previous studies [55, 56], show that these species underwent a continuous chemical fractionation process as these species condensed, and are suggestive of an oxygenated fireball during deposition. However, in order to more completely understand these processes and their effect on fallout formation, the speciation of the vaporized constituents under fireball conditions needs to be studied in-depth.

## Chapter 6

# Uranium diffusivity in rhyolitic melts

### 6.1 Background

#### Diffusion literature

While there is extensive literature on diffusion in molten silicate material of varying composition for numerous species [106], there is comparatively little on diffusive mass transport of uranium. The literature on mass transport of uranium in molten silicates has traditionally focused on geochemical study as well as fabrication and stability of nuclear waste vitrification glasses [107, 108, 109, 93]. Each of these studies addresses a specific scenario under which uranium diffuses, including a range of temperatures, concentrations, and melt compositions. For example, in one study addressing nuclear waste glass, the composition was a borosilicate material of approximately 60% SiO<sub>2</sub> and 17% B<sub>2</sub>O<sub>3</sub> [109], while another study addressed diffusion in a haplobasaltic SiO<sub>2</sub>-Al<sub>2</sub>O<sub>3</sub>-MgO-CaO composition (48%, 16%, 17%, and 19%, respectively) [108]. These studies show that the activation energy of uranium diffusion changes dramatically based on compositional changes: diffusion in the borosilicate composition had an activation energy of ~300 kJ/mol, versus ~214 kJ/mol in the haplobasaltic composition (representing a 40% increase in activation energy).

The most pertinent diffusion study to the model defined in Chapter 5 is by Mungall et al. (1997) [93]. In that study, the composition of the melt is very similar to that of the fallout glass in this study. Specifically, a U-doped and undoped haplogranitic melt glass was prepared as a mixture of 79.1% SiO<sub>2</sub>, 12.1% Al<sub>2</sub>O<sub>3</sub>, 4.6% Na<sub>2</sub>O, and 4.2% K<sub>2</sub>O. The doped haplogranitic material had 0.1% U by weight. These materials were homogenized by heating at 1600 °C and stirring for several days. Diffusion couples were assembled by polishing cored sections of the resultant doped and undoped glass, and heating adjacent cored sections in both high pressure and atmospheric conditions. The high pressure experiments were conducted in a piston cylinder at pressures between 1.0 and 3.5 GPa, while the 1 atm experiments were conducted in a open platinum cylinder within a box furnace.

The pressure regime of interest to the modeling described in Chapter 5 is ~1 atm - the approximate pressure of the fireball when the temperature is below 2500 K [1]. Thus, from

the Mungall et al. (1997) study, the 1 atm experimental data is of particular interest. The values of  $E_a$  and  $D_0$  derived from these experiments were incorporated into the diffusion model (see Table 5.3). As shown in Section 5.4, however, the uncertainties on these values are large, with the uncertainties on  $E_a$  exceeding 6%, and the uncertainties on  $D_0 > 40\%$  [93]. In Figure 6.1, with these uncertainties incorporated into Equation 5.35, the  $1\sigma$  uncertainty in the diffusivity at any given temperature spans roughly two orders of magnitude

Figure 6.1: The  $1\sigma$  uncertainty band of the temperature-dependent diffusivity (Equation 5.35) from the study of Mungall et al. (1997) spans two orders of magnitude at any given temperature.

In [93], the diffusivity was determined by diffusion couple experiments conducted at a series (1200 - 1600°C) of temperatures. In such experiments, the expected concentration distribution takes the functional form of an error function over time at constant temperature

$$C(x, t) = C_0 - \frac{\Delta C}{2} \operatorname{Erf}\left(\frac{x}{\sqrt{4Dt}}\right), \quad (6.1)$$

where  $C_0$  is the initial concentration,  $\Delta C$  is the difference in concentration between the halves of the diffusion couple,  $D$  is the diffusivity at a constant temperature, and  $t$  is the time of diffusion. To derive the diffusivity from the resultant concentration profile, two approaches can be taken. The first approach uses non-linear least squares regression fitting using an equation of the form of Equation 6.1. The second method, elected by Mungall et al. (1997), is to transform the dataset into values of  $\operatorname{Erf}^{-1}(C)$  versus  $x/\sqrt{2t}$ , effectively linearizing Equation 6.1, allowing one to derive  $D$  from linear regression analysis [93]. In this manner, the diffusivity was acquired from the diffusion couple experiments at each temperature, and was used to derive  $E_a$  and  $D_0$  from the Arrhenius equation, which can be rewritten as

$$\ln(D) = \frac{-E_a}{R} \cdot \frac{1}{T} + \ln(D_0) \quad (6.2)$$

from linear regression analysis, with  $-E_a/R$  and  $\ln(D_0)$  as fitting parameters.

### Motivation to improve uranium diffusivity parameters

The data from Mungall et al. (1997) was sufficient to produce an approximation for the maximum temperature of deposition [93]; however, the uncertainties on the acquired  $T_{dep}$  were very large ( $>140$  K) due to the aforementioned uncertainties on the 1 atm diffusion parameters. The uncertainties on these data are hypothesized to be controlled by two major contributing factors. The first factor, and likely the one most influencing the uncertainties, is the limited number of diffusion couple runs acquired at 1 atm. The second factor is the uncertainties on the acquired  $D$  values for each individual experiment. Regarding the first factor, there were only 4 runs reported under atmospheric conditions: one at 1200 °C, one at 1400 °C, and two at 1600 °C. Thus, only three temperatures over a 400 degree range were used to construct the Arrhenius plot from which  $E_a$  and  $D_0$  were derived [93]. Regarding the second factor, the study reports uncertainties on each acquired diffusivity as 50% and 80% confidence intervals. Notably, even at the 50% confidence interval, there is up to 20% variability in the acquired value of the diffusivity at a given temperature (*ibid.*). This could be attributed to either the inverse error function data transformation cited above that was used by the authors in the study, or to the uncertainty based on the data acquisition method (*i.e.*, uncertainty derived from the analytical conditions of electron probe microanalysis).

By halving the literature uncertainty values, the precision on the temperature of deposition could be improved by  $\sim 50\%$ , as illustrated in Figure 6.2. This improvement has the potential to improve the understanding of speciation of vapor phase constituents in the fireball based on the temperature of deposition, as exemplified in Figure 6.3. Figure 6.3 shows the vapor pressure of gaseous aluminum species as a function of temperature, described in Section 4.3 [87]. As illustrated in the figure, the evaporation of  $\text{Al}_2\text{O}_3$  favors Al in one temperature regime ( $<2200$  K) and  $\text{Al}_2\text{O}$  in the higher temperature regime ( $>2200$  K). Thus, if the temperature of deposition on the surface of agglomerated fallout objects is  $\sim 2200$  K with uncertainties in excess of 140 K, it is unclear which species would be favored in a condensation re-evaporation process based on this vapor pressure data. However, if the uncertainties were cut in half, the process would clearly favor  $\text{Al}_2\text{O}$  evaporation.

Figure 6.2: Probability distribution of the time of deposition for sample B1 in a 1 kt cooling environment based on the Mungall et al. (1997) values (Table 5.3) compared to a hypothesized distribution if these uncertainties were halved.

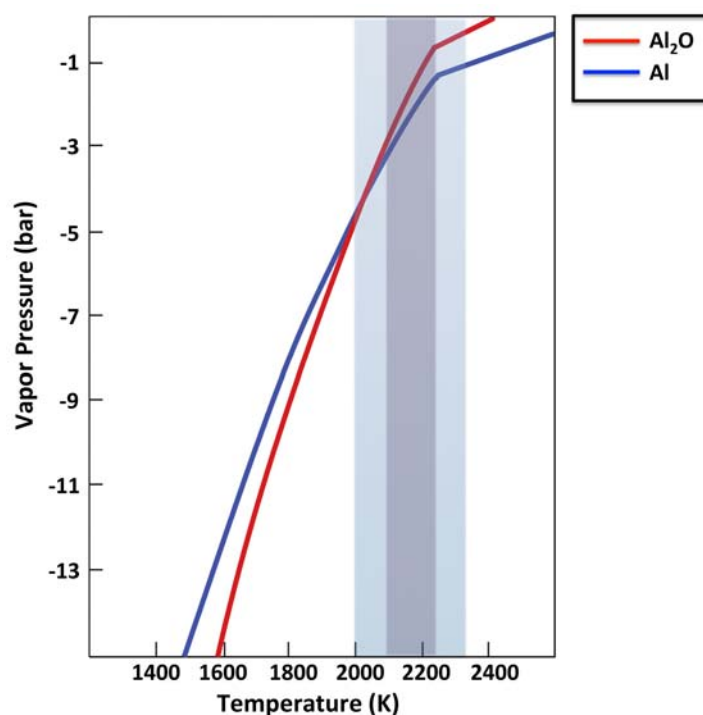

Figure 6.3: Vapor pressure of gaseous aluminum species  $\text{Al}$  vs.  $\text{Al}_2\text{O}$  over  $\text{Al}_2\text{O}_3$  in vacuum, derived from Lamoreaux et al. (1987) [87]. The light shaded region is the maximum modeled  $T_{dep}$  uncertainty, while the dark region is  $T_{dep}$  with uncertainties, if halved.

By increasing the number of incremental temperature measurements in a series of diffusion couple experiments, a higher precision can be acquired for the diffusivity parameters for use in the model described in Chapter 5. Further, by using modern data acquisition techniques with non-linear least squares regression analysis, subsequent diffusion couple concentration profiles can yield diffusivities having lower uncertainties. Thus, in this chapter, a series of diffusion couple experiments are described, designed to improve the uncertainties on  $E_a$  and  $D_0$  in order to further constrain the temperature of deposition acquired from the modeling described in Chapter 5. Additionally, preliminary results of high-pressure experiments (2 GPa) are presented, along with the derived  $E_a$  and  $D_0$  from these experiments.

## 6.2 Experimental setup

In this study, Lake County obsidian (LCO), which is a rhyolitic volcanic glass, was used for diffusion couple experiments. This material closely matches the fallout glass composition for this study (see Table 6.1), and was used to create diffusion couples (see Figure 5.1) comprised of both uranium-doped and pure LCO. To produce uranium-doped LCO, the obsidian was ground in an agate mortar and pestle under ethanol, fused in air at 1450 °C, then reground for 60 minutes. Depleted uranium (<0.72%  $^{235}\text{U}$ ) was then added as a nitrate solution, reground in ethanol, and fused at 1450 °C. The resultant material was a homogeneous rhyolitic powder, and, in the case of the doped material, contained  $\sim 1000$  ppm of depleted uranium (sufficiently high concentration to be detectable by EPMA).

The diffusion couples were assembled in graphite cylinders, where equal masses of doped and undoped LCO were added sequentially, then compressed in the cylinder, forming the setup depicted in Figure 6.4. Before heating, the concentration profile across assemblies is a step-function (as shown to the right of the top illustration). After heating at constant pressure and temperature, the resultant diffusion profile in the diffusion couple is expected to follow an error function (Equation 6.1), as illustrated in Figure 6.4 (bottom illustration).

Table 6.1: Oxide composition (wt.%) of Lake County obsidian [66] versus fallout glass composition from this test [55].

Oxide	LCO	Fallout Glass
SiO <sub>2</sub>	76.1	72.0-75.0
Al <sub>2</sub> O <sub>3</sub>	13.0	10.0-12.0
FeO	0.7	3.0
CaO	0.5	1.0-2.0
MgO	0.1	0.5
Na <sub>2</sub> O	3.7	3.0-3.5
K <sub>2</sub> O	4.8	4.0-5.0

Figure 6.4: Diagram of diffusion couple experiments using U doped and undoped LCO, with the theorized form of the concentration profile before and after heating.

The graphite furnaces containing the LCO powder were contained within a larger assembly, as shown in Figure 6.5. The assembly was constructed of a combination of highly refractory ceramic parts, including MgO spacers to position the graphite chamber in the middle of the assembly to limit the effects of potential thermal gradients through the assembly during heating. The top MgO spacers have  $\sim 1$  mm diameter slots to accommodate the thermocouple wires (type S) used to monitor the temperature of the assembly. As this diffusion assembly is heated resistively, a graphite sleeve and base plug surrounds the assembly, contained within a plexiglass sleeve. The entire diffusion assembly was inserted into salt cells, which deform under high pressure such that the applied experimental pressure approaches equilibrium conditions. The cylindrical assembly was designed to be 0.5" ( $\sim 1.25$  cm) in diameter.

A McNutt hydraulic piston press was used for the high pressure experiments. The piston press setup for the high pressure experiments is shown in Figure 6.6. The piston press assembly comprises a stack of steel spacing members supporting a large steel pressure vessel between the top of the chamber and the piston. A 0.5" steel piston adapter was used in conjunction with a hollow steel support bridge to compress the diffusion assembly to 2 GPa. A slotted steel plate was situated above the pressure vessel to accommodate the thermocouple wires for temperature modulation and monitoring. The diffusion assembly was resistively heated by applying a current through the assembly via terminals on the slotted steel plate and the bridge. Temperature ramping was set at  $100$  °C/min, at an input power of 18 W.

After compression and heating, assemblies were quenched via cold water circulation through the piston press setup ( $< 60$  s). The graphite furnace was extracted from the as-

Figure 6.5: Schematic of the graphite furnace assembly containing the doped and undoped LCO.

sembly, and was bisected to expose the fused glass diffusion couple. The exposed glass was polished to 1 micron surface roughness and coated with a 5 nm layer of carbon for conductivity. Each couple was measured across its entire length for uranium concentration using electron probe microanalysis, as described in Chapter 2. The electron probe analyses were conducted with an accelerating voltage of 15 kV at a current of  $10 \times 10^{-8}$  A. The traverse across the length of the diffusion couple consisted of a series of 10 micron spots, spaced  $\sim 10$  microns apart. Uranium  $M_\alpha$  x-rays were acquired on a PETH crystal for 60 seconds, acquiring a maximum count rate of  $>200$  cps.

Table 6.2: Preliminary diffusion couple experiments conducted at 2 GPa

Run	Temperature (degrees K)	Time (s)
1	2023	14400
2	1923	28800
3	1823	86400
4	1723	100800

Four preliminary diffusion couple experiments were carried out at 2 GPa to assess the reproducibility of the experiments of Mungall et al. (1997) (see Table 6.2). These preliminary assemblies were approximately 2.5 mm in length, such that >100 EPMA spots would be acquired for each resultant glass diffusion couple (see Appendix D for full data set). The resultant glassy diffusion couples had obvious cracks and fractures within them (*e.g.*, Figure 6.7), as rapid quenching results in high internal sample stress. Electron probe analyses acquired on or near such fractures were ignored, and subtracted from the total length of the sample such that the diffusion length would not be obscured by count rate fluctuations caused by surface topography.

Figure 6.6: Schematic of the piston cylinder apparatus used for the diffusion couple experiments.

### 6.3 Initial results and discussion

Preliminary results were acquired as standardless analyses, and concentration is presented as raw counts of uranium x-rays. The concentration profiles across the measured diffusion couples were fit with non-linear least squares regression, using Equation 6.1 to derive a parameter  $\sqrt{Dt}$ , as shown in Figure 6.8. The measured variation in uranium concentration at either end of the diffusion couples was 4-8% for each of the measured diffusion couples in the preliminary dataset. However, the  $1\sigma$  uncertainty on the diffusivity values acquired from the preliminary results illustrated in Figure 6.8 were generally around 10% (see Table 6.3).

When compared to the previously acquired literature values, the  $1\sigma$  uncertainty on the diffusivity values acquired here were substantially lower ( $<10\%$ ) than the 50% confidence interval established in previous experiments under similar conditions ( $\sim 30\%$  at 1.9 GPa; see Table 1 of [93]). While the Mungall et al. (1997) reference does not provide the dataset from which the diffusivity values were acquired, the improvement in the diffusivity value is either due to the fitting methodology and/or due to smaller analytical uncertainties.

The diffusivity values presented in Table 6.3 were used to construct an Arrhenius plot using Equation 6.2, where the  $\ln$  of the diffusivity values were plotted against the given inverse temperatures (in degrees K). The Arrhenius plot for the preliminary 2 GPa dataset is shown in Figure 6.9. The blue fit line is a linear least squares regression fit of the data from the 4 preliminary runs, weighted by the uncertainty on each diffusivity, which had an  $r^2$  of 0.99. The linear regression fit parameters were  $E_a/R$  and  $\ln(D_0)$ ;  $E_a$  was calculated to be  $308 \pm 10$  kJ/mol, and  $\ln(D_0)$  was  $0.85 \pm 0.66$ , respectively.

The uncertainty on the activation energy in this dataset was improved  $>2$ -fold over those in the study by Mungall et al. (1997). Specifically, the % uncertainty on  $E_a$  was 3%, versus 7% determined by Mungall et al. from their 1 atm experiments. While the same number of runs were used to calculate  $E_a$  in this study, they were spread over 4 different temperatures, rather than 3 in the Mungall et al. (1997) study. The value for  $\ln(D_0)$  acquired by this preliminary dataset had much larger uncertainties than those reported in the literature: the uncertainty acquired by Mungall et al. was approximately 14%, compared to 78% as determined here. As the value with the most influence over the uncertainty on temperature-

Table 6.3: Diffusivity and  $1\sigma$  uncertainty derived from preliminary diffusion couple experiments conducted at 2 GPa.

Run	Temperature (degrees K)	Diffusivity ( $\text{cm}^2/\text{s}$ )
1	2023	$(2.20 \pm 0.20) \times 10^{-8}$
2	1923	$(1.15 \pm 0.10) \times 10^{-8}$
3	1823	$(3.95 \pm 0.19) \times 10^{-9}$
4	1723	$(9.49 \pm 0.71) \times 10^{-10}$

dependent diffusivity is the activation energy, it is encouraging that the value determined by this preliminary dataset was substantially improved in comparison to that by Mungall et al. (1997). To determine if the uncertainties can be further improved upon, more runs at smaller temperature intervals are required.

Figure 6.7: Optical image of a polished diffusion couple within the graphite furnace. The location of sequential EPMA spot analyses is indicated by the red arrow.

Figure 6.8: Uranium variation data from diffusion couples at 2 GPa for various times and temperatures: (a) 2023 K, 14400 s; (b) 1923 K, 28800 s; (c) 1823 K, 86400 s; (d) 1723 K, 100800 s. Each dataset was fit with Equation 7.1 to determine the  $\sqrt{Dt}$  from which the diffusivity  $D$  was determined (Table 6.3).

Figure 6.9: Arrhenius plot of the 2 GPa diffusivity data set. The activation energy and pre-exponential diffusivity was derived from the linear fit. Uncertainties are  $1\sigma$ .

## 6.4 Planned diffusion experiments

While the preliminary results of 2 GPa diffusion couples illustrated the value of expanding upon the diffusion experiments designed by Mungall et al. (1997), further experimentation is needed to further limit the uncertainties on the temperature-dependent diffusivity, particularly in the  $\sim 1$  atm pressure regime, which is more in line with the theorized pressure in the fireball at the temperatures of interest ( $\sim 2000$ - $2200$  K), as described above.

New diffusion couple experiments are proposed to improve the  $E_a$  uncertainty and  $\ln(D_0)$  determined at 2 GPa. The proposed diffusion couple experiments would include reproducing runs already taken at 1723, 1823, 1923, and 2023 K, and adding diffusion couple experiments in 50 K increments between them. I further propose to expand the temperature range down to 1523 K, as well as increase the range up to 2123 K if the required input power does not exceed the safety tolerance of the power supply ( $< 24$  W). By acquiring multiple diffusivity measurements at each temperature, for an increased and more continuous temperature range, it is anticipated that a much more precise value of the  $E_a$  can be determined.

To acquire the diffusivity parameters in the 1 atm pressure regime, two approaches may be considered for further diffusion couple experimentation. The first approach follows the method set forth by Mungall et al. (1997), where diffusion couples are assembled in open cylinders made of a material having high thermal conductivity and melting temperature (*e.g.*, platinum), and heated in a box furnace. While this approach was sufficient in the study of Mungall et al. (1997) to acquire diffusivity parameters, there are intrinsic uncertainties associated with this method. These uncertainties are associated primarily with the ramping time for the diffusion couples to reach the temperature of interest, and the cooling times associated with open-air cooling. As these values are not presented in the Mungall et al. (1997) study, a simple preliminary experiment will be performed to understand the ramping/cooling times, and to determine if they affect the subsequent diffusion length. The second approach is to acquire a full dataset over a range of pressures to establish a pressure-dependence for  $E_a$  and  $D_0$ . This approach has two primary disadvantages: 1) it will require a much more extensive dataset (*i.e.*, many more diffusion couple runs) to cover a range of pressures from which it would be possible to extrapolate the 1 atm diffusivity parameters; and 2) the diffusivity may have unexpected, non-Arrhenian behavior over differing pressure regimes, such that a pressure-dependence could not be established. However, studies have shown that under these melt conditions, Arrhenian behavior would be expected [93, 110]. Ideally, both approaches to understanding the 1 atm temperature-dependent diffusivity parameters and limiting their uncertainties will be taken for comparison. Thus, the ideal outcome of the proposed experiments is improved uncertainties on the temperature-dependent diffusivity parameters at 1 atm, as well as a pressure-dependent relationship determined from experiments over a range of pressures. The diffusion couple runs for these proposed experiments are outlined in Table 6.4.

Table 6.4: Proposed diffusion couple runs over a range of temperatures and pressures to further constrain the uncertainty in uranium diffusivity parameters.

Experiment	Temperature (degrees K)	Pressure (Pa)	Time (s)	# of runs
1	2023	0.1 MPa; 1, 2, 3 GPa	14400	2 at 2 GPa, 3 at each other pressure
2	1973	0.1 MPa; 1, 2, 3 GPa	14400	3 at each pressure
3	1923	0.1 MPa; 1, 2, 3 GPa	28800	2 at 2 GPa, 3 at each other pressure
4	1873	0.1 MPa; 1, 2, 3 GPa	28800	3 at each pressure
5	1823	0.1 MPa; 1, 2, 3 GPa	86400	2 at 2 GPa, 3 at each other pressure
6	1773	0.1 MPa; 1, 2, 3 GPa	86400	3 at each pressure
7	1723	0.1 MPa; 1, 2, 3 GPa	100800	2 at 2 GPa, 3 at each other pressure
8	1673	0.1 MPa; 1, 2, 3 GPa	100800	3 at each pressure
9	1623	0.1 MPa; 1, 2, 3 GPa	172800	3 at each pressure
10	1573	0.1 MPa; 1, 2, 3 GPa	172800	3 at each pressure
11	1523	0.1 MPa; 1, 2, 3 GPa	345600	3 at each pressure

# Chapter 7

## Conclusion

### 7.1 Summary and Conclusions

Understanding fallout formation is critical to fallout dispersion modeling and post-detonation sample analysis; however, the processes that control formation are not adequately understood. This dissertation explored the interdependent processes of vaporization, condensation, and diffusion in fallout through the study of a distinct compositional layer, identified in agglomerated fallout glass from a near-surface nuclear test. Specifically, the layer was identified at the interface of where smaller, spheroidal glassy objects fused to the surface of a larger piece of aerodynamic fallout glass, using modern analytical techniques. This interface layer was found to be continuous around the surface of the smaller attached objects, and was used to probe the composition of a suspected deposition layer of condensed material, originating as vaporized constituents within the fireball.

The composition of the interface layer revealed enrichments and depletions of major elements relative to the interior composition of the glassy objects. Relative enrichments of Fe and Ca were distinctly observed at every interface that was analyzed, while enrichments of Na were apparent but not ubiquitous. Depletions of Al and Ti were also noted at every interface that was measured, relative to the interior composition. The enrichments and depletions of each of these measured major elements were found to be approximately collocated (within 1.5 microns). Trace element analysis by NanoSIMS also revealed relative chemical enrichment of uranium (as  $^{235}\text{U}/^{30}\text{Si}$  ratio) in 7 of the 9 measured interfaces. This pattern of enrichment and depletion was unexpected from the perspective of fractionation as dictated by historical fallout models, which anticipate refractory species to condense first and incorporate into molten carriers, while more volatile species condense later onto the surfaces of already frozen carriers. As  $\text{Al}_2\text{O}_3$  and  $\text{CaO}$  have very similar volatilization behaviors in silicates, and are generally much more refractory than  $\text{Na}_2\text{O}$  according to vapor pressure studies, these observations are at odds with what was expected.

To further understand this unusual behavior, an estimate of time and temperature of mass transport was derived from the concentration profiles of uranium at the interface, which was

consistent with diffusion from a planar source. By modeling uranium diffusion using the cooling rates of fireballs of varying yields, a maximum temperature at which this layer was deposited was found to be roughly 2200 K. According to vapor pressure studies of pure  $\text{Na}_2\text{O}$ , Na-species in oxidizing conditions may begin condensing around this temperature, while reducing conditions would require much lower temperatures ( $\sim 1400$  K). Thus, the presence of Na-species on the surfaces of agglomerated fallout objects at this temperature is suggestive of an oxygen-rich fireball.

This temperature is substantially lower than the boiling points of the refractory species of interest (Al, Ca, Fe, and U, which were all assumed to be in oxide form). As the vapor pressure of Al-species and Ca-species are both negligible at 2200 K, condensation would be expected to occur at a much higher temperature. Further, the vapor pressures of Al-species are generally higher than Ca-species (both negligible at 2200 K), and fractionation between Al- and Ca-species would not be expected at this temperature. Two possibilities are proposed to explain this discrepancy. The first possibility is that unknown anthropogenic sources contributed additional Ca to the vapor-phase. As Ca is co-located with Fe and U, which likely originated as vaporized device material, it is possible that a source adjacent to the device, such as a concrete support structure, may have contributed excess Ca to the vapor-phase. This material, would not only increase the vapor pressure of Ca-species, but potentially dilute any remaining Al-species in the vapor phase, and subsequently extending the duration over which Ca-species could condense as the fireball cooled. Given the refractory nature of CaO, it is likely that this was a continuous process over the cooling period. The second possibility is that the condensation and re-evaporation process of vaporized material and carrier material is dictated by the speciation of these constituents, and the behavior of these species in the vapor phase. As speciation of these constituents under these conditions is largely unknown, it is likely that unexpected oxides or complexes form in the vapor phase which subsequently control their corresponding condensation behavior. There is some evidence suggesting that this is possible, given that uranium (which is typically understood to be refractory) has been observed to behave as a volatile species (as discussed in Section 5.4). Given the above observations, it is likely that both of these processes occurred together to form these fallout objects.

In summary, the co-location of Na- and Ca-species would be possible in an oxygen-rich environment (which the fireball is theorized to be during fallout formation [6, 15]), where there was substantial contribution of Ca to the vapor from an additional source undergoing continuous fractionation (as described in Section 4.3). The assertion that sodium deposition is the result of an oxygenated fireball is in apparent contrast to what was shown by Cassata et al. (2014), where measurements of volumetric xenon isotope concentrations indicate that the fireball was in a reducing state [54]. However, as shown in the recent XANES study of melt glass from near-surface nuclear tests [94], the cooling rate of the fireball (and the carriers entrained in the fireball) can affect the final redox state of the glasses. Thus, the incorporation of xenon isotope precursors (the decay products of fission products) into the volume of molten fallout glasses may have occurred in an earlier, anoxic state, while the deposition layers observed in the agglomerated fallout objects in this study are likely the

result of late stage addition in a more oxygenated fireball. This is the first definitive evidence of a transition from anoxic to oxidized conditions in a fireball. This is supported by the evidence that this layer must have deposited in the fireball while the carrier was still molten, and likely constitutes a late-stage deposition, as it is preserved where two glassy objects are fused together. Further still, the substantial increase in concentration of uranium at the interfaces of agglomerated fallout glasses indicates that this deposition was, in fact, highly favored immediately prior to quenching of carrier materials.

While the above observations and constraints improve our understanding of these processes and provide insight into the fallout formation environment, they raise more questions than they answer. For example, the extent of temperature and compositional heterogeneities in the fireball are largely unknown, though both of these factors can affect fallout formation, as shown in this dissertation. Further, it is still unclear how vapor phase soil constituents interact with fission products and device materials in the fireball, and how the resultant speciation affects the incorporation of radionuclides into molten carriers. It is clear from this study that much more work is required to produce a comprehensive fallout formation model.

## 7.2 Future Work

### Constraining uranium diffusion to improve model accuracy

Current vapor pressure data could provide insight into how speciation affects the deposition of at least the major elements observed at the interface. However, the uncertainties acquired on the maximum temperature of deposition are too high to properly compare the vapor pressure data between individual constituents (with  $1\sigma$  uncertainties  $>140$  K, see Section 6.1). The modeled uncertainties could be narrowed by improving the uncertainties on literature values of uranium diffusivity parameters. Preliminary diffusivity experiments have provided promising results that these parameters can be determined with greater precision. By conducting further experiments to narrow the diffusivity parameters, I hope to constrain the maximum temperature of deposition such that existing vapor pressure data could provide insight into the question of speciation.

While the experiments set forth in Table 6.4 are likely to improve the uncertainties on uranium diffusion parameters in rhyolitic material, they could be further expanded by measuring uranium diffusion in a range of melt compositions. By studying diffusion in melt compositions having a range of  $\text{SiO}_2$  concentrations, for example, the effect of polymerization on diffusivity could be better understood. Such data would also allow for uranium diffusion modeling between compositionally distinct zones within individual fallout objects, as well as expand the uranium diffusion model to fallout from different testing environments (*i.e.*, different geologies). This could be extended even further by varying the composition of other minor and major elements in diffusion couples, to better understand their effects on the diffusivity of uranium through a multicomponent system such as fallout.

## Determining the relative volatilities of species in a multicomponent system

In order to truly understand the effect of vapor composition on fallout formation, experiments should be conducted to determine which vapor-phase constituents would be present in the fireball. More specifically, scaled heating experiments (*e.g.*, by laser heating or box-furnace) on soil material of varying composition would reveal the relative volatilities of major and minor soil components, and how the initial composition of the melt would affect vaporization behaviors. Experiments could be conducted over a range of temperatures (*e.g.*, 1500 K to 3000 K), such that the relative volatility of these species was understood as a function of temperature. Species could either be measured in real-time (*e.g.*, by using Knudsen effusion mass spectrometry to measure vapor pressures), or by measuring the remaining material post-heating using bulk dissolution mass spectrometric techniques (*e.g.*, inductively coupled plasma mass spectrometry).

These experiments could also be used to understand the speciation of vapor-phase constituents during volatilization. Experiments have been conducted to determine the speciation and concentration of vapor-phase constituents from multicomponent systems, including silicates [111, 112], though these compositions diverge substantially, and are thus not relevant, to fallout glasses from this study. However, a similar technique (*i.e.*, Knudsen effusion mass spectrometry) could be applied, along with high-temperature vaporization experiments, to a multicomponent system reflecting fallout glass composition.

Further confounding vaporization and condensation behavior is the conflicting understanding of the fireball oxygen content – this study, and historical fallout studies [6, 15] present evidence that the fireball was in an oxidized state, while another study presents evidence of a reducing fireball environment [54]. Thus, the effect of oxygen fugacity on relative volatility could be established by conducting these experiments in both atmospheric and anoxic conditions. By understanding each of these effects, the relative volatilities and condensation rates of vaporized materials could be used to inform a more comprehensive fallout formation model.

# Appendix B

## EPMA dataset

Figure B.1: BSE images of samples and objects, with the locations of sequential EPMA spot analyses indicated by red, dashed arrows.

Table B.1: Electron probe microanalysis spots across interfaces for 9 agglomerated aerodynamic fallout glass samples, presented as major element oxides

Sample	Spot	A <sub>2</sub> O <sub>3</sub>	MnO	Na <sub>2</sub> O	K <sub>2</sub> O	SiO <sub>2</sub>	FeO	MgO	CaO	TiO <sub>2</sub>
