Abstract

Characterizing flow patterns and mixing of fossil fuel-derived CO₂ is important for effectively using atmospheric measurements to constrain emissions inventories. Here we used measurements and a model of atmospheric radiocarbon (¹⁴C) to investigate the distribution and fluxes of atmospheric fossil fuel CO₂ across the state of California. We sampled ¹⁴C in annual C₃ grasses at 128 sites and used these measurements to test a regional model that simulated anthropogenic and ecosystem CO₂ fluxes, transport in the atmosphere, and the resulting Δ¹⁴C of annual grasses (Δ_g). Average measured Δ_g in Los Angeles, San Francisco, the Central Valley, and the North Coast were 27.7 ± 20.0, 44.0 ± 10.9, 48.7 ± 1.9, and 59.9 ± 2.5‰, respectively, during the 2004-2005 growing season. Model predictions reproduced regional patterns reasonably well, with estimates of 27.6 ± 2.4, 39.4 ± 3.9, 46.8 ± 3.0, and 59.3 ± 0.2‰ for these same regions and corresponding to fossil fuel CO₂ mixing ratios (C_f) of 13.7, 6.1, 4.8, and 0.3 ppm. Δ_g spatial heterogeneity in Los Angeles and San Francisco was higher in the measurements than in the predictions, probably from insufficient spatial resolution in the fossil fuel inventories (e.g., freeways are not explicitly included) and transport (e.g., within valleys). We used the model to predict monthly and annual transport patterns of fossil fuel-derived CO₂ within and out of California. Fossil fuel CO₂ emitted in Los Angeles and San Francisco was predicted to move into the Central Valley, raising C_f above that expected from local emissions alone. Annually, about 21, 39, 35, and 5% of fossil fuel emissions leave the California airspace to the north, east, south, and west, respectively, with large seasonal variations in the proportions. Positive correlations between westward fluxes and Santa Ana wind conditions were observed. The southward fluxes over the Pacific Ocean were maintained in a relatively coherent flow within the marine boundary layer, while the eastward fluxes were more vertically dispersed. Our results indicate that state and continental scale atmospheric inversions need to consider areas where concentration measurements are sparse (e.g., over the ocean to the south and west of California), transport within and across the marine boundary layer, and terrestrial boundary layer dynamics. Measurements of Δ_g can be very useful in constraining these estimates.

Introduction

Fossil fuel combustion is the largest anthropogenic CO₂ source, accounting for approximately 7.0 Pg C yr⁻¹ in 2000, and increasing rapidly to over 7.9 Pg C yr⁻¹ in 2004 [Marland *et al.*, 2006; Raupach *et al.*, 2007]. This combustion is associated with a range of societal and economic benefits, including transportation, electricity generation, heating and air-conditioning, and others. There are, however, many costs associated with the climate consequences of this greenhouse gas that will occur across a wide range of time scales, including impacts to agricultural productivity, sea level, water resources, terrestrial and oceanic ecosystem health, disease propagation, and fire regimes [Parry *et al.*, 2007].

Accurate quantification of fossil fuel CO₂ emissions is needed to properly account for these costs [Stern, 2006], aid in policy development [Parry *et al.*, 2007], improve climate prediction and climate change attribution, and facilitate atmospheric inversion approaches used to quantify contemporary anthropogenic and ecosystem C fluxes [Fan *et al.*, 1998; Gurney *et al.*, 2002; Stephens *et al.*, 2007]. Further, other primary atmospheric pollutants of interest (e.g., carbon monoxide and black carbon) are often produced concurrently with CO₂ and surface emissions estimates for these gases and aerosols can be improved using accurate fossil fuel CO₂ emissions estimates (e.g., Turnbull [2006]). This paper describes an approach using the ¹⁴C content of annual grasses and an atmospheric transport model to characterize the impacts of spatially and temporally heterogeneous surface and atmospheric processes on fossil fuel CO₂ transport within and out of California.

The first attempts to quantify fossil fuel CO₂ emissions used inventories based on proxy measurements such as fuel sales and population density [Andres *et al.*, 1996; Franco, 2002; Olivier *et al.*, 1999]. The mix of fossil fuels used varies substantially around the world. In California, fossil fuel is used for transportation (~60%), electric power generation (~16%), industry (~13%), and residences (~10%) [Bemis, 2006; Franco, 2002]. Although important in characterizing regional fossil fuel CO₂ emissions, the accuracy of fuel use-based emissions inventories still requires improvement [Marr *et al.*, 2002], particularly at fine spatial scales. These inventories are also potentially vulnerable to political pressure, creating the need for independent verification approaches.

Another approach to estimating fossil fuel CO₂ emissions has been to use atmospheric measurements of radiocarbon (¹⁴C) in CO₂. Because ¹⁴C has a relatively short half live (~5730 y)

compared to the ancient plant material from which fossil fuels are derived, carbon in fossil fuels is effectively free of ^{14}C (i.e., $\Delta^{14}\text{C} = -1000\text{‰}$). With atmospheric nuclear weapon testing, the ^{14}C content of tropospheric CO_2 rapidly increased and by 1963 was over 900‰ in the northern hemisphere. Following the 1963 Test Ban treaty, atmospheric $\Delta^{14}\text{C}$ levels declined, primarily as a consequence of air-sea gas exchange, uptake by land plants, dilution from fossil fuel combustion, and radioactive decay. By 2000, atmospheric levels had dropped to about 60‰, with a rate of change of about 6‰ yr^{-1} [Levin *et al.*, 2003]. While there are important latitudinal and seasonal variations in the background atmospheric (i.e., remote marine boundary layer) $\Delta^{14}\text{C}$, almost all of the spatial variation over North America is due to fossil fuel CO_2 emissions [Hsueh *et al.*, 2007; Randerson *et al.*, 2002]. For current atmospheric CO_2 levels, about a 2.8‰ change in ^{14}C content is equivalent to 1 ppm fossil fuel CO_2

$\left(\frac{(60\text{‰})(380 \text{ ppm}) + (-1000\text{‰})(1 \text{ ppm})}{381 \text{ ppm}} \right)$. Since current ^{14}C accelerator mass spectrometry

measurement techniques have a precision of 2.5 to 3.0‰, measurements of the $\Delta^{14}\text{C}$ of atmospheric CO_2 can be used to infer fossil fuel CO_2 levels to a precision of about 1 ppm.

Turnbull *et al.* [2006] compared $^{14}\text{CO}_2$, CO, and SF_6 as tracers of fossil fuel CO_2 at two sites. They concluded that CO is limited as a tracer due to uncertainty in its CO_2 emission ratio, and that, as a tracer, SF_6 showed large biases as compared to $^{14}\text{CO}_2$, possibly because of differences in the spatial pattern of surface sources. Levin *et al.* [1995] studied two sites in Germany where atmospheric $^{14}\text{CO}_2$ and radon measurements had been made. They derived fossil fuel CO_2 emissions and concluded that emissions estimates derived from fuel sales substantially underestimated the seasonal amplitude, likely leading to errors in the inferred seasonal cycle of terrestrial biosphere exchange. Using a longer data record, Levin *et al.* [2003] applied a similar method at two sites to estimate fossil fuel CO_2 emissions. They concluded that their method compared well with bottom-up statistical emissions inventories and the seasonality of fossil fuel CO_2 emissions was substantially larger than previously assumed. Measurements of ^{14}C in plant biomass can be used as an integrator of spatial and temporal variability in fossil fuel CO_2 . Hsueh *et al.* [2007], for example, mapped patterns of ^{14}C content in an annual plant (*Zea mays*) across North America. They found that relative to the intermountain West, fossil fuel CO_2 mixing ratios were substantially higher in California and in the Ohio Valley.

In addition to constraining surface emission estimates, accurately characterizing CO₂ transport out of a particular region is critical for testing larger-scale atmospheric inversions [Gurney *et al.*, 2002]. Such independent measures of fossil fuel CO₂ production and transport will become increasingly important as society develops regulations of regional and national GHG emissions (e.g., [Schwarzenegger, 2005]). Transport of CO₂ within and out of California is dominated by three transport mechanisms: the large-scale Pacific High, the Great Basin High (which, in combination with the Pacific High establishes wintertime offshore Santa Ana (SA) wind conditions [Conil and Hall, 2006; Raphael, 2003]), and the high elevation jet stream. The strong westerly jet stream flow has led some investigators to hypothesize that measuring CO₂ mixing ratios on the west and east coasts of the contiguous U.S. will facilitate continental CO₂ exchange estimates [Fan *et al.*, 1998]. One goal of the present work is to test this hypothesis by studying the impact of smaller scale, more variable mechanisms (e.g., Santa Ana winds) on CO₂ fluxes leaving the state.

As a first step towards characterizing transport of fossil fuel CO₂ within and out of California, we used ¹⁴C measurements in annual grasses to test a model that integrates fossil fuel CO₂ emissions, ecosystem CO₂ exchanges, and atmospheric transport. We then used the model over a full year to predict the pathways by which fossil fuel CO₂ leaves California and their relationships with atmospheric transport processes. Our results can be used to inform atmospheric inversion measurement strategies and inventory approaches to quantifying fossil fuel CO₂ emissions.

Methods

Δ¹⁴C Measurements of California C₃ Grasses

Samples of winter annual grasses were collected at 128 sites across California at the end of the 2004-2005 growing season. Packets were sent to colleagues with a specific sampling protocol and return envelope. To avoid point CO₂ sources, samples in relatively rural areas were collected more than 3.2 km away from highways, more than 45 m from paved roads, and more than 20 m from houses or buildings. In cities, where remote sample locations were difficult or impractical to find, samples were collected in residential streets, neighborhood parks, or abandoned parking lots. We collected samples throughout California, with relatively higher collection density in the San Francisco Bay Area, Los Angeles Basin, and Central Valley Region

to explore urban to rural gradients. At each site, three separate stalks of grass were collected. All of the samples consisted of annual plants that germinated in the fall of 2004 and senesced in the spring of 2005, primarily from the genera *Bromus* and *Avena*, which are highly invasive and currently widespread throughout California.

Upon arrival at UCI, samples were dried at 60-70°C for at least 48 hours. Plants were then ground to pass a size 40 sieve and stored in individual vials. Samples were then processed and analyzed at UC Irvine's W.M. Keck Carbon Cycle Accelerator Mass Spectrometer (KCCAMS) facility [Santos *et al.*, 2004]. To ensure that we quantified the overall accuracy and to minimize differences due to running samples in different batches (or sample wheels) on the AMS, we (1) included 6-7 primary and 6-7 secondary standards with each batch of plant samples (24-27 plant samples comprised a single batch); (2) repeatedly analyzed samples collected at five sites across different batches; and (3) used three secondary standards: barley (FIRI G; SD = 2.3‰ based on 20 replicates distributed across multiple batches), oxalic acid (SD = 3.2‰ with 5 replicates), and an Australian National University standard (SD = 2.6‰ with 5 replicates).

Coupled MM5, LSM1, and Atmospheric Tracer Model

MM5 [Grell *et al.*, 1995] is a nonhydrostatic, terrain-following sigma-coordinate mesoscale meteorological model used in weather forecasting and in studies of atmospheric dynamics, surface and atmosphere coupling, and pollutant dispersion. The model has been applied in many studies in a variety of terrains, including areas of complex topography and heterogeneous land-cover (for a partial list: <http://www.mmm.ucar.edu/mm5/Publications/mm5-papers.html>). The following physics packages were used for the simulations shown here: Grell convection scheme, simple ice microphysics, MRF planetary boundary layer (PBL) scheme, and the CCM2 radiation package. The MRF PBL scheme [Hong and Pan, 1996] is a high-resolution PBL transport model that includes both local and non-local vertical transport. The inert tracer model follows the current MM5 transport calculations for water vapor. We tested the numerical solution of the tracer transport predictions and successfully compared predicted and measured CO₂ mixing ratios at the Trinidad Head station (located on the northern California coast) [Riley *et al.*, 2005].

LSM1 [Bonan, 1996] is a "big-leaf" (e.g., Dickinson *et al.* [1986], Sellers *et al.* [1996]) land-surface model that simulates CO₂, H₂O, and energy fluxes between ecosystems and the

atmosphere. Modules are included that simulate aboveground fluxes of radiation, momentum, sensible heat, and latent heat; belowground energy and water fluxes, and coupled CO₂ and H₂O exchange between soil, plants, and the atmosphere. Twenty-eight land surface types, comprising varying fractional covers of thirteen plant types, are simulated in the model. Soil hydraulic characteristics are determined from soil texture. LSM1 has been tested in a range of ecosystems at the site level (e.g., *Bonan et al.* [1997], *Bonan et al.* [1995], and *Riley et al.* [2003]). *Cooley et al.* [2005] described the integration of LSM1 with MM5 and demonstrated that the model accurately predicted surface latent, sensible, and ground heat fluxes; near-surface air temperatures; and soil moisture and temperature by comparing model simulations with data collected during the FIFE campaign [*Betts and Ball*, 1998]. We imposed constant atmospheric CO₂ mixing ratio (380 ppm) and $\Delta^{14}\text{C}$ ($\Delta_b = 60\text{‰}$) boundary conditions at the edges of the domain. In reality, there are vertical, horizontal, and temporal variations in these boundary conditions. These variations should not, however, substantially impact predicted $\Delta^{14}\text{C}$ of grasses or impact our model predictions of fossil fuel CO₂ transport within and out of California.

Fossil Fuel CO₂ Emissions

We estimated spatially and temporally resolved fossil fuel CO₂ emissions by scaling fossil fuel NO_x emission estimates reported in the 2002 U.S. Environmental Protection Agency's National Emissions Inventory (NEI) in a manner similar to that used for CO by Gerbig et al. [2003]. This approach provides finer spatial and temporal resolution than is present in available inventories of fossil fuel consumption. For our work, the NEI emission estimates were distributed at 36 km resolution by the Lake Michigan Air Directors Consortium with hourly resolution on weekdays, Saturdays, and Sundays of each month in 2002 (<http://www.ladco.org/>). The overall scaling of CO₂ from NO_x emissions was estimated using the ratio of California's annual NO_x (1600 Mg NO_x y⁻¹) to CO₂ (370 ± 3 Tg CO₂ y⁻¹) emissions [*Blasing et al.*, 2004; *EIA*, 2003] for 2002. Fossil CO₂ emissions are concentrated in the urban centers of the Los Angeles Basin and the San Francisco Bay area, with significant emissions present in the Central Valley (Figure 1).

One of the largest errors in our CO₂ emissions estimates was likely a result of spatial variations in the CO₂:NO_x emission ratio. However, the model's relatively large spatial resolution (36 km) and the expected variety of sources within this resolution (particularly in

urban areas where the preponderance of CO₂ emissions occur) will reduce uncertainty resulting from spatial variability in emission ratios associated with different point sources. Further, although seasonal cycles of the NEI emissions inventory are specific to a given state or region, the diurnal and day-to-day temporal variations in fossil CO₂ emissions are characterized by national averages. We expect these small time-scale errors to have a relatively small impact when integrated over monthly or seasonal variability in photosynthetic uptake.

Simulation Approach

We used the standard initialization procedure for MM5v3.5, which applies first-guess and boundary condition fields interpolated from the NOAA National Center for Environmental Prediction (NCEP) reanalysis data [Kalnay *et al.*, 1996; Kistler *et al.*, 2001] to the outer computational grid. The model was run with a single domain with horizontal resolution of 36 km and 18 vertical sigma layers between the surface and 5000 Pa; the time step used was 108 s, and output was generated every two hours. The two-hourly model output was used in all the analyses that follow by integrating or averaging over hourly, seasonal, or annual periods.

We simulated a twelve-month period (July, 2004 through June, 2005) that encompasses the typical growing season for C₃ plants (November through May). The model was then run again over the same period, but with ecosystem respiration scaled by a constant factor so that the annual net CO₂ flux was zero at each grid cell [Denning *et al.*, 1996]. The most abundant vegetation cover type inferred from the USGS 1 km surface cover map was used to identify the dominant vegetation in each 36×36 km grid cell. Since many grid cells are not dominated by C₃ grasses, we estimated C₃ gross primary production (GPP, G_p , $\mu\text{mol m}^{-2} \text{s}^{-1}$) at each grid cell over the simulation period to ensure that the life history, and therefore the time history of CO₂ assimilation, was properly accounted for. C₃ grass GPP was estimated using the MM5 meteorological forcing, the offline version of LSM1.0, and MODIS LAI profiles (<http://LPDAAC.usgs.gov>) for this time period spatially averaged over California. To ensure that the LAI profiles were representative of C₃ grasses, we set LAI to zero during June through October, the typical period between plant senescence and germination. Predicted grass $\Delta^{14}\text{C}$ (Δ_g , ‰) did not change significantly when we used GPP calculated from the LAI time series of default vegetation in the coupled model (versus using the GPP derived from MODIS LAI time series).

$\Delta^{14}\text{C}$ of Near-Surface CO_2

The $\Delta^{14}\text{C}$ of near-surface CO_2 at a particular grid cell and time depends on CO_2 and $^{14}\text{CO}_2$ fluxes from advection from adjacent cells, respiration, and fossil fuel combustion. Assuming that the $\Delta^{14}\text{C}$ of respiration does not vary, a steady-state mass balance gives a relationship for the $\Delta^{14}\text{C}$ of near-surface atmospheric CO_2 (Δ_a , ‰):

$$\Delta_a = \frac{\Delta_b C_b + \Delta_r C_r + \Delta_f C_f}{C_b + C_r + C_f}. \quad (1)$$

Here, the subscripts b , r , and f refer to background, heterotrophic respiration, and fossil fuel, respectively; Δ refers to the $\Delta^{14}\text{C}$ (‰); C refers to the atmospheric CO_2 mixing ratio (ppm); and $\Delta_f = -1000$ ‰. Note that because $\Delta^{14}\text{C}$ notation normalizes for variations in fractionation using concurrent ^{13}C observations [Stuiver and Polach, 1977], fractionation by photosynthesis does not impact Δ_a . Temporal variations in background CO_2 mixing ratio (C_b) and $\Delta^{14}\text{C}$ (Δ_b) occur over the year and probably introduce some error into our estimates of C_f derived from the observations via equation (1). For the model analysis, this error source is likely to be small compared to uncertainties arising from the fossil fuel emissions inventory and biases in model transport. Further, these variations will not impact our analysis of flow patterns of fossil fuel CO_2 emitted within California.

We estimated Δ_r by combining heterotrophic respiration impulse functions derived from the CASA model [Thompson and Randerson, 1999] and a $\Delta^{14}\text{C}$ record of the atmosphere since 1890 [Levin and Hesshaimer, 2000; Levin and Kromer, 2004]. The impulse functions were generated for an area-weighted combination of eleven biome types present in California. The area-weighted $\Delta^{14}\text{C}$ of heterotrophic respiration was calculated to be 112‰, with a range between 101‰ for grasslands and 118‰ for evergreen needle leaf trees. Assuming that ecosystem respiration was 50% heterotrophic and 50% autotrophic [Litton *et al.*, 2007; Waring *et al.*, 1998], and that autotrophic respiration had a $\Delta^{14}\text{C}$ of Δ_a , we estimated that $\Delta_r = \frac{(60 + 112)}{2} = 89$ ‰.

We note that *Turnbull et al.* [2006] (their equation 1) and *Levin et al.* [2003] (their equation 3) used different relationships than equation (1) for estimating fossil fuel CO_2 mixing ratios based on atmospheric $\Delta^{14}\text{C}$ measurements. The derivation of equation (1) assumes that the $\Delta^{14}\text{C}$ of photosynthesis and autotrophic respiration are Δ_a , while that of *Turnbull et al.* [2006],

for example, assumed a $\Delta^{14}\text{C}$ of photosynthesis equivalent to background air (Δ_b). The impact of this difference is often small, but can be as high as 0.5 ppm in the inferred value of C_f .

Estimating the $\Delta^{14}\text{C}$ of C_3 Grasses

To estimate $\Delta^{14}\text{C}$ of C_3 grasses (Δ_g), we computed the GPP-weighted sum of Δ_a at each grid cell:

$$\Delta_g = \frac{\int \Delta_a G_p dt}{\int G_p dt}, \quad (2)$$

where the integrals are evaluated over the entire year of the simulation. Thus, the predicted biomass ^{14}C composition reflects both the atmospheric $\Delta^{14}\text{C}$ and the temporal variation in plant C assimilation. We evaluated Δ_g with both default (i.e., using the default vegetation type and LAI time series used in LSM1.0) and satellite-derived C_3 grass LAI time series.

Near-Surface Fossil Fuel CO_2 Versus Local Emissions

To characterize impacts of local (i.e., from the same model grid cell) fossil fuel CO_2 emissions on Δ_a , we developed a non-dimensional index (I). I is calculated, for each grid cell, as the ratio of local surface fossil fuel CO_2 mixing ratio to local fossil fuel CO_2 emissions (E_f , $\text{kg m}^{-2} \text{s}^{-1}$) normalized by the statewide average of these quantities:

$$I = \frac{\overline{C}_f / \int_{\text{Calif}} \overline{C}_f dA}{\overline{E}_f / \int_{\text{Calif}} \overline{E}_f dA}, \quad (3)$$

where the overbars indicate time averaging over the year and A represents the area of California. While this index does not give a direct measure of the impact of local versus distant sources, it allows a relative comparison between regions within the state.

Santa Ana Winds

Santa Ana winds are an important component of southern California meteorology, partly because they substantially increase wildfire risk [Westerling *et al.*, 2004], but also because they cause transport that opposes the prevailing jet stream. Santa Ana events are characterized by dry

and often hot offshore winds. *Raphael* [2003] described a 33-year record of SA occurrences and the conditions necessary for their development: a high pressure region in the Great Basin and a surface low pressure system off the Southern California coast. SA conditions occur typically between September and April, with peak occurrences in December. *Conil and Hall* [2006] describe three October-March southern California wind regimes (alongshore, onshore, and offshore Santa Ana flows). They concluded that none of the large-scale teleconnection patterns (e.g., the Pacific-North American mode) are more likely than any of the others to coincide with the three southern California wind regimes.

As we discuss below, Santa Ana winds substantially impact fossil fuel CO₂ transport toward the south and west from September to May. Further, there is large inter-annual variability in the number of Santa Ana days [*Raphael*, 2003]. To place our results for a single year into a broader context with respect to this transport mechanism, we developed a simple method to predict the number of SA wind days (N_S) using the six-hour NCEP surface pressure and wind direction predictions. We identified Santa Ana days as those with both (1) a 3 AM (Pacific Standard Time) pressure difference between grid cells over the Great Basin and Interior West (lower left corner: 118°W 36°N; upper right corner: 103°W 43°N) and over the Pacific Ocean (lower left corner: 126°W 29°N; upper right corner: 114°W 35°N) that was larger than 1400 Pa and (2) winds in Los Angeles from between northerly and easterly. The predicted N_S compared well with the monthly and inter-annual variability estimated by *Raphael* [2003] (Figure 2).

Results and Discussion

Measured $\Delta^{14}C$ of C_3 Grasses

Measured Δ_g for the sites across California are shown in Figure 3. Additional information on site coordinates, elevation, and species type is provided in Table 1. Annual grasses growing on the coast in the northern part of the state had the highest radiocarbon levels (and thus were exposed to the least amount of locally-added fossil fuel CO₂). The mean of northern coastal samples from sites near Crescent City, McKinleyville, Rohnerville, and Mendocino was $59.5 \pm 2.1\%$. Coastal sites in the central part of the state were also relatively clean, with a mean of $58.2 \pm 2.7\%$ for samples collected near Carmel, Fort Hunter-Liggett, Gorda, Los Osos, and Santa Cruz Island.

Within urban areas, Δ_g was substantially lower and more variable. For example, in the Los Angeles Basin, Δ_g ranged from -14.3 to 60.5% , with a mean of $27.7 \pm 20.0\%$ (Table 2). Samples collected near the center of the Los Angeles metropolis, including those near the cities of Vernon, South Gate, Bellflower, Buena Park, and Westminster, had a mean of $19.1 \pm 2.1\%$. Relative to the mean Δ_g from the north coast (and assuming C_a equal to 380 ppm), these cities near the center of the Los Angeles metropolis had 15.1 ± 5.5 ppm of locally added CO_2 (weighted by diurnally and seasonally varying photosynthetic C uptake). In contrast, urban and suburban samples collected near the coast to the west and south of Los Angeles had markedly less exposure to fossil fuel CO_2 . The mean Δ_g of samples from Newport Beach, Dana Point, and Laguna Woods was $48.3 \pm 3.1\%$. The relative depletion of Δ_g for these coastal samples as compared with those from Central and Northern California may reflect 1) local fossil fuel sources that offset the cleansing impact of on-shore winds and 2) entrainment of fossil fuel CO_2 from Los Angeles into the land-sea circulation and subsequent along-shore transport and onshore flow (e.g., Riley et al. [2005]).

In the San Francisco Bay region, measured Δ_g ranged from 25.5 to 57.4%, with a mean of $44.0 \pm 10.1\%$. Two samples collected along the peninsula (Redwood City and Woodside) had values below 28% and one sample collected along the transportation corridor near the Sacramento Delta had a $\Delta^{14}\text{C}$ of 37.0%. Samples from grassland parks south of San Jose were also relatively depleted with a mean of $44.7 \pm 2.1\%$, probably as a result of the trapping of fossil fuel CO_2 from San Jose between the two roughly parallel southwest to northeast coastal mountain ranges.

Within the Central Valley, measured Δ_g was lowest directly to the east of the San Francisco Bay area and increased both to the north and south. These gradients are consistent with transport and mixing of San Francisco Bay area and Sacramento fossil fuel CO_2 sources within the valley. The mean of samples collected to the east of the Bay Area (and including those collected near Lodi, Byron, Mariposa, Merced, and Fresno) was $47.7 \pm 1.9\%$. Samples collected from the northern part of the Central Valley (including samples near Redding, Rosewood, Mendocino, Orland, Red Bluff, and Mill Creek) were considerably more enriched in ^{14}C , with a mean of $58.6 \pm 3.7\%$.

There were strong gradients in Δ_g for transects starting in the Central Valley and terminating in the Sierra. The first such transect started near Corcoran (elev. 55 m) in the middle of the Central Valley and ended near Kaiser Pass (elev. 2136 m). Δ_g increased monotonically from 50.3 to 60.7‰ for 6 samples collected across this elevation gradient. A second transect further south ran from Arvin to Welden, and spanned about a 20‰ gradient. The increase in Δ_g with elevation along the western slope of the Sierra was likely caused by dilution of Central Valley air (with high fossil fuel CO₂ mixing ratios) with air from the free troposphere. Diurnal upslope and downslope flows along the western slope of the Sierra also probably influenced Δ_g [Dillon *et al.*, 2002]. Several studies have reported analogous elevation patterns for air pollutants transported from the Los Angeles Basin, including large nitrogen deposition [Fenn and Bytnerowicz, 1997; Fenn *et al.*, 2000] and ozone concentration [Lee *et al.*, 2003; Miller *et al.*, 1986] gradients across the San Bernardino Mountains. This pollution gradient has caused significant and well-documented changes in the physiology and ecology of montane forests in this region [Arbaugh *et al.*, 1998; Fenn *et al.*, 1996; Grulke *et al.*, 1998; Grulke and Balduman, 1999; Grulke *et al.*, 2001; Miller *et al.*, 1998].

Predicted $\Delta^{14}C$ of C₃ Grasses

Model estimates of Δ_g (Figure 4) captured much of the observed spatial variability (Figure 3). Care should be taken in comparing these two contour plots because of difficult-to-quantify uncertainties introduced from our interpolation approach. Predicted mean values of Δ_g for Los Angeles, San Francisco, the Central Valley, and the North Coast were similar to observed values (Table 2).

Within the Los Angeles basin, the eastward propagation of the fossil fuel CO₂ plume from Los Angeles was relatively well represented. Within the San Francisco Bay region, mean predicted and measured Δ_g differed by 5‰. The model over predicted the fossil fuel CO₂ mixing ratios (and depletion of Δ_g) to the east and north of the San Francisco Bay region within the Central Valley. It was not possible from our simulations to determine if the over prediction occurred because errors in sampling, transport from the San Francisco Bay region, mixing of local sources within the Valley, or CO₂ emissions estimates.

Model estimates of annual mean $\Delta^{14}C$ of near-surface atmospheric CO₂ (Δ_a ; not shown) were almost the same as those of predicted Δ_g . In Los Angeles, where Δ_a and Δ_g were largely

impacted by local emissions, the covariance of nighttime fossil fuel CO₂ emissions and small PBL depths led to lower annual mean Δ_a than Δ_g . Similar mechanisms impacted Central Valley Δ_a and Δ_g . Also, some of the fossil fuel CO₂ emitted during the daytime in Central Valley urban areas moves laterally into rural parts of the Central Valley during the evening and night, further enhancing the differences between Δ_a and Δ_g in this region. To illustrate these interactions, the annual average difference between midnight and noon surface fossil fuel CO₂ mixing ratios were 0.02, 0.1, 2.8, and 1.4 ppm in the Coastal North, San Francisco Bay, Los Angeles, and Central Valley regions, respectively. The relatively higher nighttime fossil fuel CO₂ mixing ratios in Los Angeles and the Central Valley are consistent with the lower predicted value for annual mean Δ_a as compared with Δ_g in these regions.

The impacts of boundary layer dynamics on the relationship between fossil fuel CO₂ emissions, Δ_a , and Δ_g are substantial. For example, during the summer in Los Angeles, when fossil fuel CO₂ emissions are relatively high, the Pacific High often causes low daytime boundary layer depths. This lowering of the effective atmospheric mixing volume enhances the impact of fossil fuel emissions on Δ_a and Δ_g . Concurrent changes in mixing rates between the PBL and overlying free troposphere may also be important. Figure 5 illustrates the relationship between monthly mean noon fossil fuel CO₂ emissions, PBL depth, C_f , and Δ_a for a single point (34 °N, 118 °W) in the Los Angeles Basin. For this point, there is a strong correlation between C_f , PBL depth, and Δ_a . To illustrate the impact of PBL depth, we compared April and August conditions using monthly means. Between these months, fossil fuel CO₂ emissions increased about 0.8%, PBL depth decreased about 60%, C_f increased by ~8 ppm (170%), and Δ_a decreased by 19‰ (from 47‰ to 28‰). This simple comparison indicates that, in Los Angeles, a substantial portion of the changes in C_f and Δ_a between these months resulted from changes in PBL properties. Therefore, the impact of intra-annual variations in PBL dynamics must be accounted for when using Δ_g to infer fossil fuel CO₂ emissions.

Measured Δ_g were more spatially heterogeneous than predicted Δ_g in urban areas (Table 2), likely because of spatial resolution limits associated with the meteorological model and the fossil fuel emissions inventory, both of which had a 36 km horizontal resolution. This relatively coarse spatial resolution would not resolve many topographical features, such as small valleys, which might concentrate fossil fuel CO₂. Also, fine scale CO₂ emissions (e.g., associated with

freeways and industrial point sources) were not resolved in our emissions estimates. However, the mean predictions accurately reproduced the patterns in measured Δ_g , with the means differing by 0.6, 4.6, 0.1, and 1.9‰ in the North Coast, San Francisco Bay, Los Angeles, and Central Valley regions, respectively (Table 2). The mean predicted GPP-weighted fossil fuel CO₂ mixing ratios are 0.3 (0.08), 6.1 (1.1), 13.7 (0.4), and 4.8 (0.9) ppm for the same regions.

Near-Surface Fossil-Fuel CO₂ Mixing Ratios Versus Local Emissions

The index I (equation (3)) qualitatively describes the extent to which factors (e.g., transport, local mixing conditions) other than local emissions impact local near-surface fossil fuel CO₂ mixing ratios. Since fossil fuel CO₂ is a good tracer (on moderate spatial and temporal scales) of primary combustion-generated pollutants, this index can also be helpful in attributing other air pollution issues (e.g., particulate matter, tropospheric O₃) to local versus distant sources.

Predicted values of I were relatively larger in portions of the western Central Valley, Sierra Mountains, Owens Valley, and Northern California (Figure 6). Large values of I in the Sierra Mountains and Owens Valley occurred because very little fossil fuel CO₂ is emitted in these areas, yet near-surface fossil fuel CO₂ mixing ratios can become elevated from CO₂ transport from the urban air basins and the Central Valley. Fossil fuel CO₂ was also predicted to move from Los Angeles down the Coachella and Imperial Valleys, where fossil fuel emissions are lower. A second Southern California region just east of San Diego also had relatively larger values of I , again resulting from transport from San Diego and relatively low local emissions. These results indicate that a number of areas in California are exposed to higher primary air pollution concentrations than would result from local emissions alone.

Exit Pathways for California's Fossil Fuel CO₂

A three-dimensional representation of fossil fuel CO₂ leaving the California airspace is shown in Figure 7. On an annual basis, a large fraction of fossil fuel CO₂ exited California to the south and within the marine boundary layer (Figure 8a). A broad and more diffuse plume exited to the east, with relative maxima at latitudes corresponding approximately to Los Angeles, the middle of the Central Valley, and the San Francisco Bay area (Figure 8b). Accumulated over the year, about 21, 39, 35, and 5% of fossil fuel CO₂ left the California airspace to the north, east, south, and west, respectively. We note that, because of the limited boundary of our simulation

domain, our analysis framework is unable to characterize whether CO₂ exiting in any particular direction could be re-circulated back into the California airspace. Given the large-scale atmospheric circulation associated with the Pacific High that results in transport of CO₂ from North America to Hawaii [Lintner *et al.*, 2006], we believe this recirculation to be small for air exiting to the west and south.

The predicted large fraction of fossil fuel CO₂ leaving California to the south has important implications for continental scale inversions used to infer fossil fuel and ecosystem CO₂ fluxes. Future measurements of CO₂ and its isotopes on the islands offshore from southern California could help better characterize this transport pathway. East-west aircraft transects in the marine boundary layer near the U.S. – Mexico border (and extending several hundred kilometers offshore) would also be helpful in this regard. A second, and smaller, predicted southward flux of fossil fuel CO₂ occurred further east (approximately between 114°W and 115°W), also primarily below the boundary layer (Figure 8a). This portion of the flux resulted from eastward transport of fossil fuel CO₂ out of Los Angeles and San Diego, and then southward transport down the Coachella and Imperial Valleys. Unfortunately, we lacked measurements in these valleys to corroborate model predictions.

Some of the flux moving eastward out of the Los Angeles Basin escaped directly toward Arizona, resulting in coherent fossil fuel CO₂ plumes centered just north of the Mexican border (Figure 8b). Much of the remaining eastward flux manifested as a broad and more diffuse plume over the Sierra Nevada. Peaks in this broad plume associated with Los Angeles (between about 33° and 36° N) and the Central Valley (between about 35° and 36° N) were discernible. In contrast to the southward fossil fuel CO₂ plume, the eastward plume extended further upward into the atmosphere. Of the 21% of fossil fuel CO₂ that left the California airspace via the north, most was centered on 122°W (approximately due north of the San Francisco Bay region). Very little fossil fuel CO₂ (5%) exited the airspace to the west.

There were distinct seasonal patterns of fossil fuel CO₂ fluxes in the four compass directions (Figure 9). The fraction of the monthly flux leaving towards the south had a maximum in November, with a secondary peak in March. Northward fluxes peaked in December and January while the westward flux peaked one month later in February. The eastward fluxes peaked in the summer and were relatively smaller during winter. Between November and March,

the northward fluxes were roughly out of phase with the southward fluxes, implying a trade-off in transport patterns during these months.

The fraction of each month's fossil fuel CO₂ flux leaving toward the east and west and the monthly number of Santa Ana wind days (N_S) predicted from the NCEP reanalysis data were correlated; correlation coefficients (p value) were: -0.56 (0.06) and 0.70 (0.01) for the east and west directions, respectively. Almost none of the annual cumulative flux exited toward the west outside of the Santa Ana winds season. Our one-year simulation (during 2004-2005) does not allow us to directly infer inter-annual variability in the directional partitioning of fossil fuel CO₂ fluxes out of the state. However, since intra-annual variability in partitioning was correlated to Santa Ana wind conditions, we conclude from our simple inter-annual N_S estimates (Figure 2) that the relative proportion of fossil fuel CO₂ leaving California in each of the four directions can vary substantially between years. More work needs to be performed to characterize the impact of these short duration and intermittent events on atmospheric transport of fossil fuel derived CO₂.

These results are also relevant to tropospheric air quality issues and for characterizing the net climate impact of fossil fuel combustion. Tropospheric air quality can be deleteriously impacted by fossil fuel combustion, with consequent impacts to human health [*Peel et al.*, 2005; *Schwartz et al.*, 1996], vegetation [*Davison and Barnes*, 1998], precipitation [*Rosenfeld and Givati*, 2006], the Earth's radiation budget [*Ramanathan et al.*, 2001], and snow albedo and the timing of snow melt [*Flanner et al.*, 2007]. Although atmospheric pollutant generation and transport has been the focus of many California air quality studies (e.g., [*Blumenthal et al.*, 1978; *Carreras-Sospedra et al.*, 2006; *Croes and Fujita*, 2003; *Dillon et al.*, 2002; *Edinger*, 1973; *Lu and Turco*, 1995; *McElroy and Smith*, 1986; *Rinehart et al.*, 2006]), much less is known about transport of pollutants out of the state. Characterizing whether pollutants generated in California move toward Arizona, Nevada, the Pacific Ocean, or Mexico is important for characterizing the broader implications of California's fossil fuel combustion, including consequences for aerosol radiative forcing and the albedo of snow in the Sierra-Nevada and Rocky Mountain systems. For example, California emissions of black carbon aerosols, which can have a relatively short atmospheric residence time, will have a different impact on climate if they are lofted above the bright Arizona desert as compared with transport over the much darker Pacific Ocean.

Conclusions

Our prediction that 21, 39, 35, and 5% of California's fossil fuel CO₂ exits to the north, east, south, and west, respectively, has several important implications. Proposals have been made to use CO₂ measurements on the coastal boundaries of the continental U.S. to infer CO₂ emissions and exchanges [Wofsy and Harris, 2002]. Our estimate that a substantial portion of California's fossil fuel CO₂ emissions exit California towards the south implies that flask networks need to sample this plume. Since there are relatively few islands in the southward transport path, regular measurements on ships or buoys may be required. Further, many current global and regional models do not accurately simulate boundary layer development and exchanges with the free troposphere [Stephens *et al.*, 2007], processes critical to interpreting these proposed measurements.

Our results are relevant to other atmospheric components of interest. Pollutants generated concurrently with CO₂ or from atmospheric photochemical reactions will be impacted by the transport patterns described here. Issues relevant to tropospheric air quality include characterizing southward transport into Mexico of ozone, NO_x, particulate matter, and acid compounds, and how these fluxes impact local ecosystems, visibility, and human health.

Model predictions indicated that some areas within California had higher near-surface fossil fuel CO₂ mixing ratios than would be expected from local emissions alone. The additional fossil fuel CO₂ loading resulted from transport of fossil fuel CO₂ generated in the San Francisco Bay, Sacramento, and Los Angeles air basins. Similar behavior of other contaminants co-emitted with fossil fuel CO₂, or secondary pollutants associated with combustion byproducts, would analogously be expected to contribute to air pollution in these areas.

It is likely that ecosystem respiratory and photosynthetic CO₂ fluxes also have substantial southward flux components. Finally, given the significant correlation between southern California wildfires and Santa Ana winds, it is likely that a large fraction of wildfire CO₂ exits the California airspace to the south. Overall, our results indicate that the paradigm that California's air pollutants travel predominantly from west to east across the continental U.S. needs to be re-examined.

Acknowledgements

We would like to thank the following people for collecting plant samples for us: B. Adamus, P. Adamus, D. Baldocchi, M.S. Carbone, A.M. Delaney, L. Feinstein, D.T. Fischer, M.L. Fischer, J.G. Hatch, F.M. Kai, P.G. Kennedy, L.E. Koteen, E.A. Lyons, M. and R. Lyons, R. Redmond, A.V. Rocha, D.L. Serio, J.K. Shake, M.V. Talluto, S.E. Trumbore, S. Weiss. J.G. Hatch was supported by a Summer Undergraduate Research Education internship at LBNL through the DOE Global Change Education Program. We also wish to thank M.V. Talluto, P.A. Bowler, and M.A. Elvin for identifying grass samples; and Y. Fung for characterizing the $\Delta^{14}\text{C}$ of respiration. ¹We used barley (FIRI G) as a secondary standard, and its standard deviation was 2.3‰ based on 20 replicates scattered across multiple batches. The two other secondary standards we used were an oxalic acid (OX-II) and an Australian National University (ANU) standard. These had standard deviations of 3.2‰ (with 5 replicates) and 2.6‰ (with 5 replicates), respectively. Based on the accuracy of these three standards (FIRI G, OX-II, and ANU), we assumed that the accuracy of an individual measured was $\pm 2.7\%$.

Table 2. Predicted and measured mean (SD) Δ_g and GPP-weighted C_f inferred from measured Δ_g for four regions: North Coast, San Francisco Bay Area, Los Angeles Basin, and Central Valley. Measured means in Los Angeles do not include February samples measured near freeways, as described in text.

	<u>North</u>	<u>San</u>	<u>Central</u>	<u>Los Angeles</u>
	<u>Coast</u>	<u>Francisco</u>	<u>Valley</u>	
Measured mean (SD) $\Delta^{14}\text{C}$ (‰)	59.9 (2.5)	44.0 (10.9)	48.7 (1.9)	27.7 (20.0)
Predicted mean (SD) $\Delta^{14}\text{C}$ (‰)	59.3 (0.2)	39.4 (3.9)	46.8 (3.0)	27.6 (2.4)
Predicted mean (SD) GPP-weighted C_f (ppm)	0.3 (0.08)	6.1 (1.1)	4.8 (0.9)	13.7 (0.4)

Figures

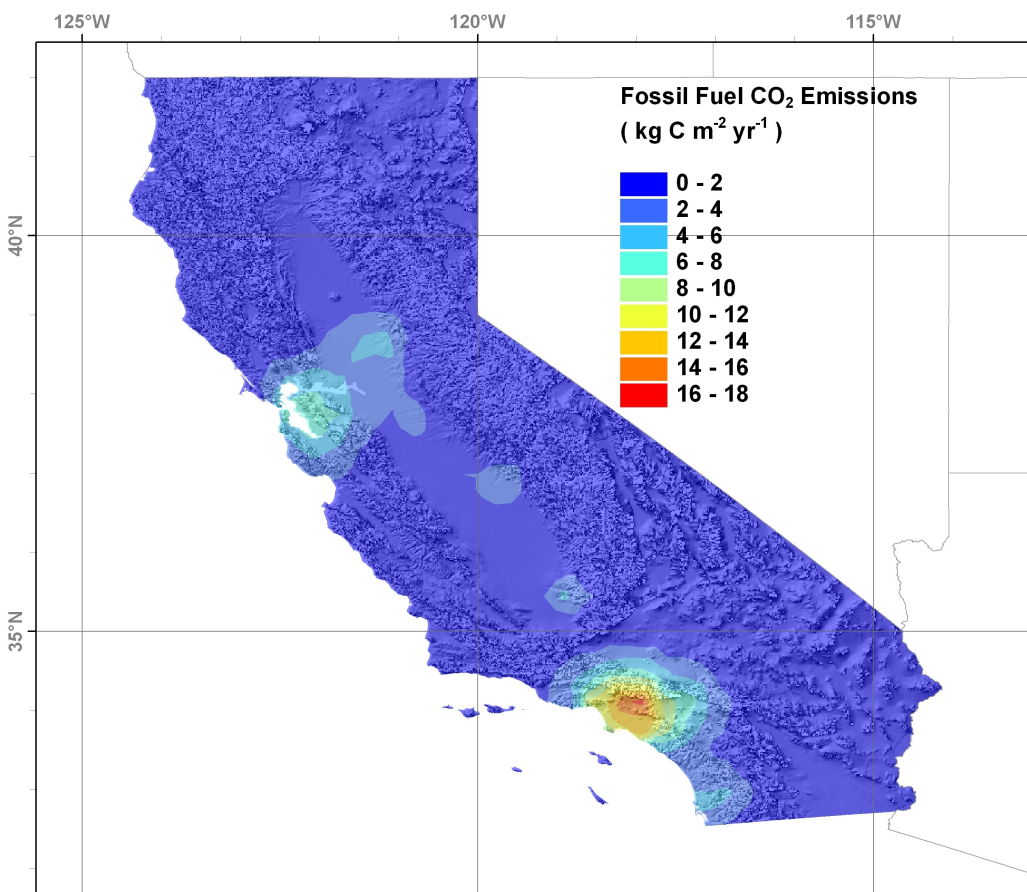

Figure 1. Cumulative annual fossil fuel CO₂ emissions (kg m⁻² yr⁻¹) with the spatial pattern derived from a high resolution NO_x inventory and scaled to match state-wide CO₂ emissions inventory. Background color interpolation was generated using the Inverse Distance Weighted (IDW) method based on 15 nearest neighbors within the Geostatistics Analyst tools in ESRI's ArcMap software. (contour.ff_CO2_emissions.annual.lay)

(see Figure_2.eps)

Figure 2. Predicted Santa Ana days per year using the NCEP reanalysis and the 28 year estimates from *Raphael* [2003]: (a) yearly total N_S ; (b) monthly average N_S between 1968 and 1995. The simple method to predict N_S using the NCEP reanalysis sea level pressure and wind direction data captures much of the monthly and inter-annual variability.

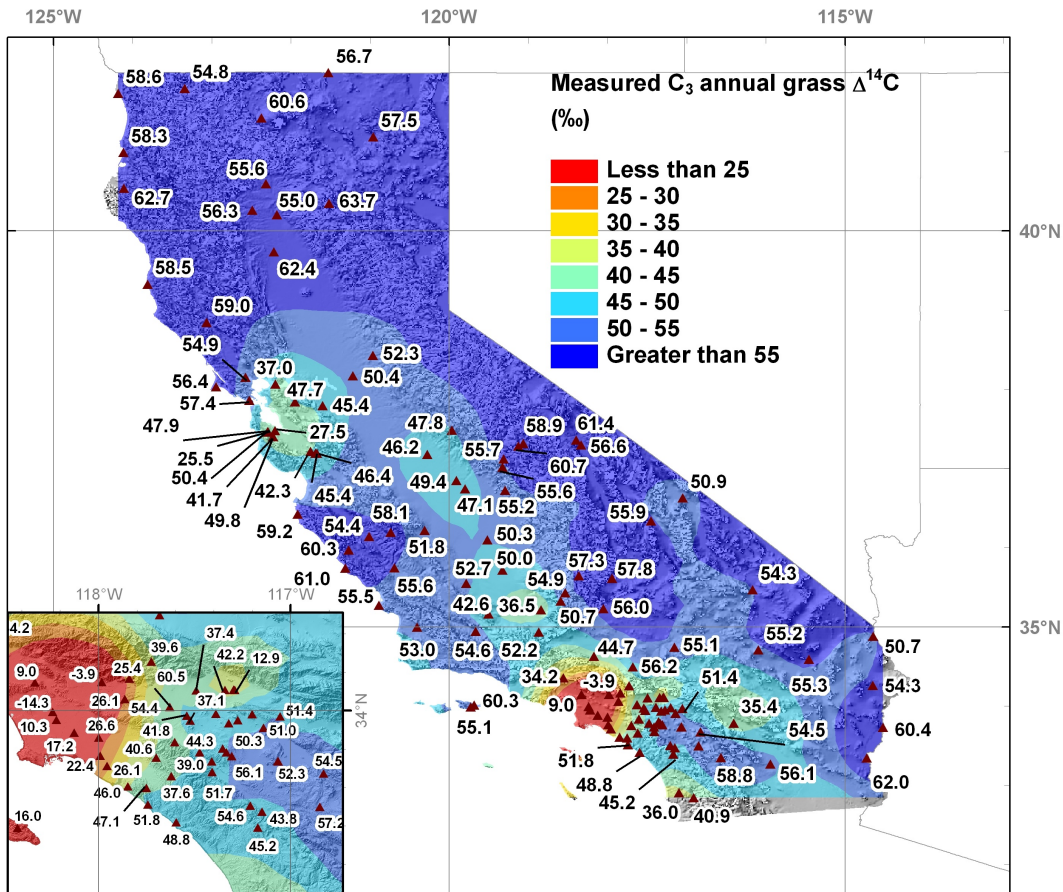

Figure 3. Measured $\Delta^{14}\text{C}$ of California C_3 grasses (‰); (inset) expanded view of the Los Angeles Basin. Background interpolation color was built based on thirteen nearest neighbors using a cokriging method (including elevation) using Geostatistics Analyst tools in ESRI's ArcMap software.

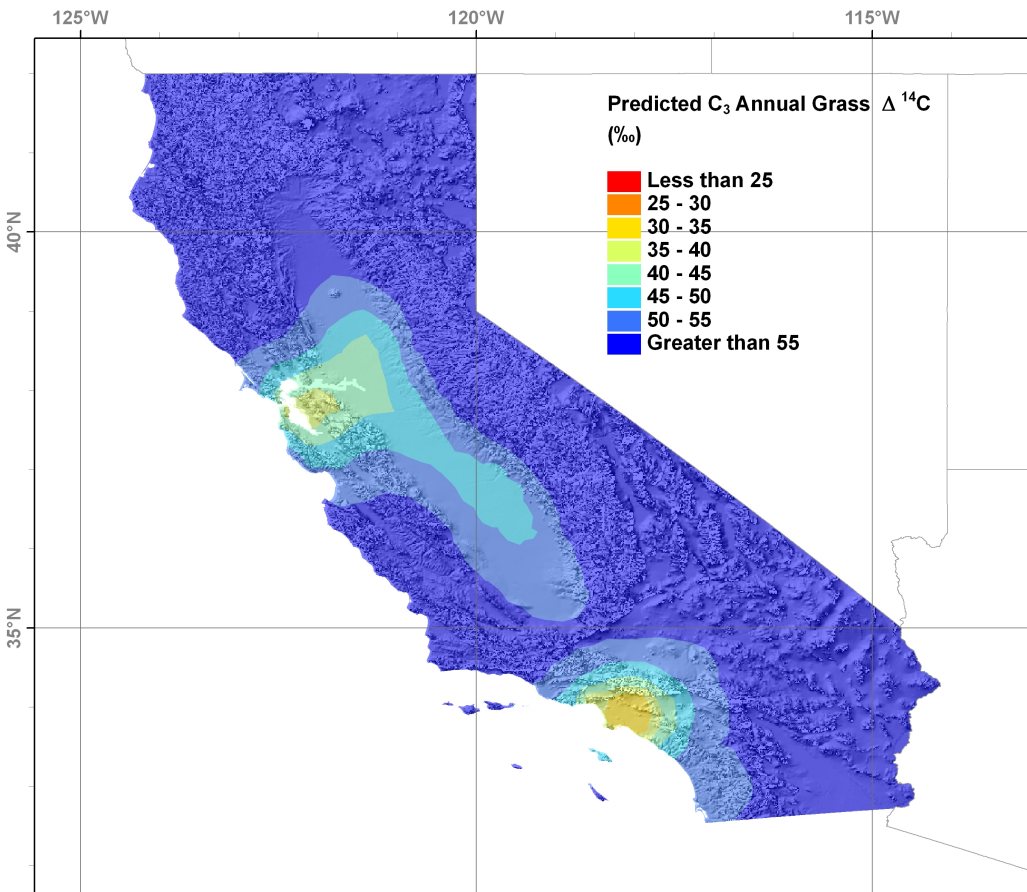

Figure 4. Predicted C₃ $\Delta^{14}\text{C}$ (‰) averaged over the growing season, calculated as the gross primary production-weighted $\Delta^{14}\text{C}$ of surface-layer atmospheric CO₂. Background color interpolation was generated using the same method as Figure 3. (contour.atmos_14co2.lay, contour.C₃_gpp_weighted_14co2.lay)

(See Figure_5.eps)

Figure 5. Comparison for a single model point in Los Angeles (34°N, 118°W) of mid-day fossil fuel CO₂ emissions (left axis), fossil fuel CO₂ mixing ratio (left axis), PBL depth (first right axis), and $\Delta^{14}\text{C}$ of near-surface air (second right axis, Δ_a). Δ_a is largely in phase with PBL depth and out of phase with fossil fuel CO₂ emissions. (pbl_ffco2_d14c.lay)

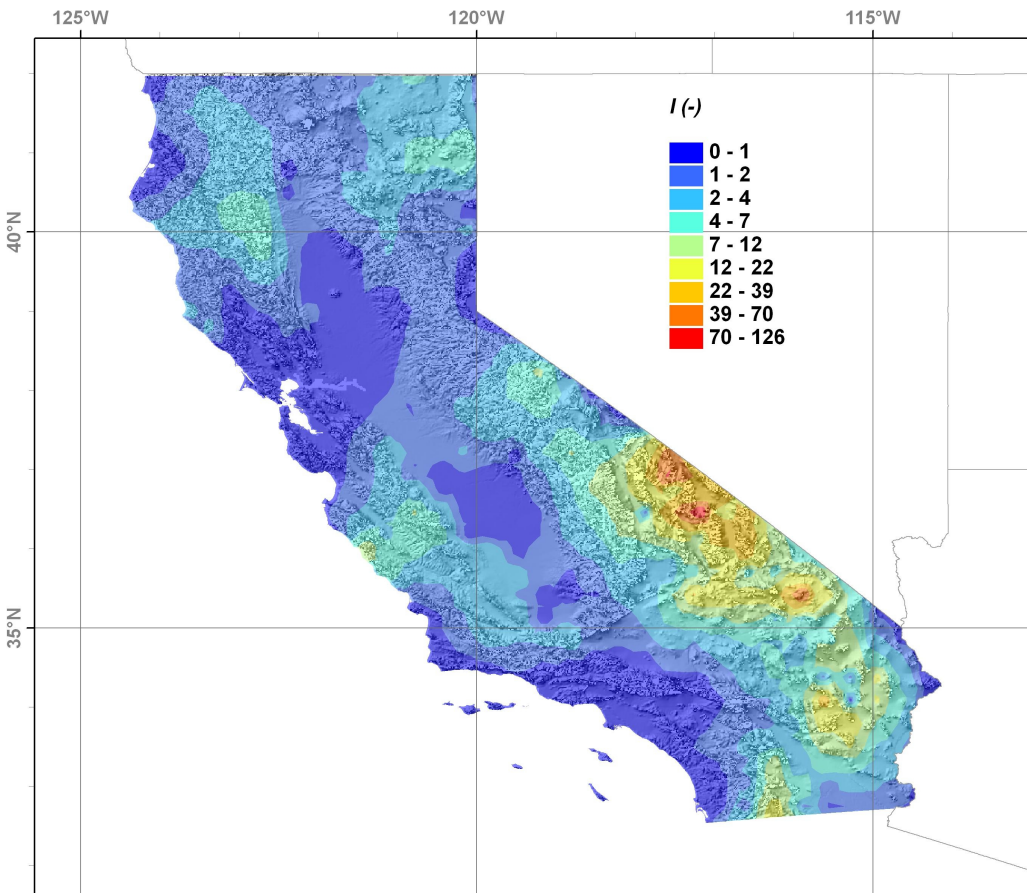

Figure 6. The index, I , indicating the ratio of local fossil fuel CO₂ (normalized by the state-wide average mixing ratio) to local fossil fuel CO₂ emissions (normalized by the state-wide total inventory). Areas with I larger than one have fossil fuel CO₂ contributions from other regions in the state (that exceed what would be expected from local emissions). Background color interpolation was generated using the same method as Figure 3. (index.lay)

(see Figure_7.eps)

Figure 7. Cumulative annual fossil fuel CO₂ transport out of California. The figure shows contour plots on each vertical face of the cube surrounding California. (contour.ff_co2_flux.3d.lay)

(see figure_8.eps)

Figure 8. Cumulative annual fossil fuel CO₂ transport out of California for the (a) south and (b) east vertical faces of the cube surrounding California. Note the different altitude scales and contour intervals. (2d.faces.ffco2.contour.eps; 2d.faces.ffco2.contour.lay)

(See Figure_9.eps)

Figure 9. Percent of monthly fossil fuel CO₂ leaving the California airspace in each of the four directions (left axis) and the number of Santa Ana days each month (N_S) predicted from the NCEP reanalysis data (right axis). Westward CO₂ flux and N_S were positively correlated ($r = 0.70$; $p = 0.01$) and eastward CO₂ flux and N_S were negatively correlated ($r = -0.56$; $p = 0.06$). (ncep.sad.ffco2_fluxes.lay)
