## RESEARCH ARTICLE

10.1002/2017JD027315

## Key Points:

- A PBM-MCM model was developed to simulate gas-phase RONO<sub>2</sub> measured at an urban and a mountainous site in Hong Kong
- RONO<sub>2</sub> formation depended upon not only the abundances of precursors but also the photochemical reactivity
- RONO<sub>2</sub> degradation influencing O<sub>3</sub> production included NO<sub>2</sub> stimulating, NO<sub>2</sub> suppressing, and RO stimulating processes

**Abstract** As intermediate products of photochemical reactions, alkyl nitrates (RONO<sub>2</sub>) regulate ozone (O<sub>3</sub>) formation. In this study, a photochemical box model incorporating master chemical mechanism well reproduced the observed RONO<sub>2</sub> at an urban and a mountainous site, with index of agreement in the range of 0.66–0.73. The value 0.0003 was identified to be the most appropriate branching ratio for C<sub>1</sub> RONO<sub>2</sub>, with the error less than 50%. Although levels of the parent hydrocarbons and nitric oxide (NO) were significantly higher at the urban site than the mountainous site, the production of C<sub>2</sub>–C<sub>3</sub> RONO<sub>2</sub> was comparable to or even lower than at the mountainous site, due to the lower concentrations of oxidative radicals in the urban environment. Based on the profiles of air pollutants at the mountainous site, the formation of C<sub>2</sub>–C<sub>4</sub> RONO<sub>2</sub> was limited by NO<sub>x</sub> (volatile organic compounds (VOCs)) when total volatile organic compounds (TVOCs)/NO<sub>x</sub> was higher (lower) than 10.0 ± 0.4 parts per billion by volume (ppbv)/ppbv. This dividing ratio decreased ( $p < 0.05$ ) to 8.7 ± 0.4 ppbv/ppbv at the urban site, mainly due to the different air pollutant profiles at the two sites. For the formation of C<sub>1</sub> RONO<sub>2</sub>, the NO<sub>x</sub>-limited regime extended the ratio of TVOCs/NO<sub>x</sub> to as low as 2.4 ± 0.2 and 3.1 ± 0.1 ppbv/ppbv at the mountainous and urban site, respectively. RONO<sub>2</sub> formation led to a decrease of simulated O<sub>3</sub>, with reduction efficiencies (O<sub>3</sub> reduction/RONO<sub>2</sub> production) of 4–5 parts per trillion by volume (pptv)/pptv at the mountainous site and 3–4 pptv/pptv at the urban site. On the other hand, the variations of simulated O<sub>3</sub> induced by RONO<sub>2</sub> degradation depended upon the regimes controlling O<sub>3</sub> formation and the relative abundances of TVOCs and NO<sub>x</sub>.

### 1. Introduction

Alkyl nitrates (RONO<sub>2</sub>) are a group of organic nitrates in which the nitrogen is stabilized in the molecular structure of R-O-NO<sub>2</sub>. As an important constituent of reactive odd nitrogen (NO<sub>y</sub>), particularly in areas far from urban sources (Buhr et al., 1990; Roberts & Fajer, 1989), RONO<sub>2</sub> participate in nitrogen cycling in their role as a temporary nitrogen reservoir (Clemmitshaw et al., 1997). Generally, oceanic emission (Atlas et al., 1993), photochemical formation (Arey et al., 2001; Bertman et al., 1995), and to a lesser extent biomass burning (Simpson et al., 2002) are the main sources of RONO<sub>2</sub>. The photochemically formed RONO<sub>2</sub> are actually by-products in the process of O<sub>3</sub> formation and are formed through the reactions between volatile organic compounds (VOCs) and nitrogen oxides (NO<sub>x</sub>). These combined formation pathways, as a result, generally lead to the tight association between RONO<sub>2</sub> and O<sub>3</sub> (Muthuramu et al., 1994; Rosen et al., 2004).

Many formation mechanisms have been proposed to explain observed RONO<sub>2</sub> levels in urban settings, including RO<sub>2</sub> reacting with NO (Carter & Atkinson, 1989; Darnall et al., 1976) and RO reacting with NO<sub>2</sub> (Atkinson et al., 1982), which are well documented and play dominant roles in RONO<sub>2</sub> formation, particularly in daytime hours. For the reactions of RO<sub>2</sub> + NO, two branches exist, leading to the formation of RONO<sub>2</sub> (R1) and O<sub>3</sub> (R2), respectively (Atkinson, 1990). The branching ratio ( $\alpha$ ) is a quantitative measure of RONO<sub>2</sub> yield from RO<sub>2</sub> reacting with NO. It is defined as the ratio of  $k_1/(k_1 + k_2)$  (Atkinson, 1990), where  $k$  is the reaction rate constant. Generally, the branching ratio increases with increasing pressure and decreasing temperature (Atkinson et al., 1987). In addition, more complicated molecular structures of RO<sub>2</sub> tend to have higher

branching ratios. For example, the branching ratios for *n*-alkanes increase from  $\leq 1\%$  for ethane to  $\sim 33\%$  for *n*-octane, with an upper limit of  $\sim 35\%$  for larger *n*-alkanes (Atkinson et al., 1982). This theory was repeatedly confirmed by kinetic calculations and model simulations (Bertman et al., 1995; Simpson et al., 2006). In combination with laboratory studies, Carter and Atkinson (1985, 1989) proposed formulas (1)–(3) for calculating branching ratios under the atmospheric conditions in the troposphere. According to the calculations, the branching ratio of the methyl peroxy radical ( $\text{CH}_3\text{O}_2$ ) was approximately 0.001 in the lower stratosphere and 0.003 in the lower troposphere. This suggests that the branching ratio of  $\text{CH}_3\text{O}_2$  at the surface could also be acquired by applying a correction factor of  $\sim 3$  to the branching ratio in lower stratosphere. In contrast to theoretical calculations, the smaller-chain  $\text{RONO}_2$ , particularly methyl ( $\text{CH}_3\text{ONO}_2$ ) and ethyl nitrate ( $\text{C}_2\text{H}_5\text{ONO}_2$ ), often have mixing ratios higher than what can be explained by the reaction of  $\text{RO}_2$  with  $\text{NO}$  in urban environments (Flocke, Volz-Thomas et al., 1998). Depending on the location, direct marine emissions could be one reason (Atlas et al., 1993). In addition, the exact branching ratios for these  $\text{RONO}_2$  remain uncertain. For example, Lightfoot et al. (1992) proposed an upper limit of 0.005 for  $\text{CH}_3\text{ONO}_2$  in the lower troposphere. However, through  $\text{RONO}_2$  observations in the lower stratosphere, Flocke, Atlas et al. (1998) found a much lower  $\text{CH}_3\text{ONO}_2$  branching ratio of  $5\text{--}10 \times 10^{-5}$ , meaning it could only reach a maximum of 0.0003 even under surface conditions, when applying the adjusted factor of 3 to the branching ratio in lower stratosphere. Simpson et al. (2006) accepted the upper limit of 0.0003 and indicated that  $\text{RO}$  reacting with  $\text{NO}_2$  was the main pathway of  $\text{CH}_3\text{ONO}_2$  in highly polluted environments. Fewer studies on the branching ratios of  $\text{C}_2\text{--C}_4$   $\text{RONO}_2$  have been conducted. Based on laboratory experiments at  $299 \pm 2^\circ\text{K}$  and 735 torr, 1982 found that the branching ratios for  $\text{RO}_2$  forming  $\text{RONO}_2$  following the oxidation of ethane, propane and *n*-butane were  $\leq 0.014$ ,  $0.036 \pm 0.005$ , and  $0.077 \pm 0.009$ , respectively. For primary  $\text{RO}_2$  radicals, the branching ratios might be lower by a factor of 2 (Ranschaert et al., 2000). However, the branching ratios for  $\text{RONO}_2$  formation remain to be further examined.

$$\alpha = \left[ \frac{Y_0^{300} [M] \left(\frac{T}{300}\right)^{-m_0}}{1 + \frac{Y_0^{300} [M] \left(\frac{T}{300}\right)^{-m_0}}{Y_\infty^{300} \left(\frac{T}{300}\right)^{-m_\infty}}} \right] F^z \quad (1)$$

$$z = \left\{ 1 + \left[ \log \frac{Y_0^{300} [M] \left(\frac{T}{300}\right)^{-m_0}}{Y_\infty^{300} \left(\frac{T}{300}\right)^{-m_\infty}} \right] \cdot 2 \right\}^{-1} \quad (2)$$

$$Y_0^{300} = \beta e^{\gamma n} \quad (3)$$

where  $T$  is the temperature (K),  $M$  represents the number of molecules ( $\text{molecules}/\text{cm}^3$ ), and  $n$  is the carbon number in  $\text{RO}_2$ . The values of the constants  $\beta$  ( $1.95 \times 10^{-22} \text{ cm}^3/\text{molecule}$ ),  $\gamma$  (0.947),  $Y_\infty^{300}$  (0.435),  $m_0$  (2.99),  $m_\infty$  (4.69), and  $F$  (0.556) are all from Carter and Atkinson (1985). On the basis of the calculated results, the branching ratios for the primary and tertiary  $\text{RO}_2$  radicals are calibrated by a factor of 0.4 and 0.25, respectively.

It is well known that  $\text{O}_3$  formation is closely related to the relative abundances of VOCs and  $\text{NO}_x$ , mainly due to the dual role of  $\text{NO}_x$  in  $\text{O}_3$  production (i.e., fueling and suppressing  $\text{O}_3$  formation in low and high  $\text{NO}_x$  regimes, respectively) (Shao et al., 2009; Sillman & He, 2002). As by-products of  $\text{O}_3$  formation, the production of  $\text{RONO}_2$  is also expected to be influenced by the abundances of VOCs and  $\text{NO}_x$ . In brief,  $\text{NO}$  reacts with the hydroperoxyl radical ( $\text{HO}_2$ ) and  $\text{RO}_2$ , and  $\text{NO}_2$  combines with hydroxyl radical ( $\text{OH}$ ), regulating the equilibrium budgets of oxidative radicals including  $\text{RO}_2$  and  $\text{RO}$  (Thornton et al., 2002). As such, the  $\text{RONO}_2$  production will also be influenced by  $\text{NO}_x$  similar to  $\text{O}_3$ . It was found that  $\text{RONO}_2$  levels increased with increasing  $\text{NO}_x$  in London

(Aruffo et al., 2014). However, in Houston  $\text{RONO}_2$  and other nitrogen-containing species except for  $\text{NO}_x$  were found to increase during the decrease of  $\text{NO}_y$  (Rosen et al., 2004), indicating the anticorrelation between  $\text{RONO}_2$  and  $\text{NO}_x$ . This might imply the  $\text{NO}_x$ -limited (e.g., London) and VOC-limited regime (e.g., Houston) in  $\text{RONO}_2$  formation. Therefore, the relationship between  $\text{RONO}_2$  production and  $\text{NO}_x$  needs further study.

Due to the associated formation pathways of  $\text{RONO}_2$  and  $\text{O}_3$ , good correlations are often found between single or total  $\text{RONO}_2$  ( $\Sigma\text{ANs}$ ) and  $\text{O}_3$  or  $\text{O}_x$  ( $\text{O}_x = \text{O}_3 + \text{NO}_2$ ) (Perring et al., 2010; Rosen et al., 2004). A roughly quantitative relationship can be established between  $\text{O}_x$  and  $\Sigma\text{ANs}$ , that is,  $\text{O}_x/\Sigma\text{ANs} = 2(1-\alpha)/\alpha$  (Day et al., 2003), where  $\alpha$  represents the overall branching ratio for the total  $\text{RONO}_2$ . More importantly,  $\text{RONO}_2$  photochemistry, including their formation and degradation (photolysis- and OH-initiated oxidation) also influences  $\text{O}_3$  formation. Based on correlations between  $\text{O}_x$  and  $\Sigma\text{ANs}$ , Aruffo et al. (2014) stated that  $\text{RONO}_2$  played important roles in  $\text{O}_3$  formation in both urban and suburban London. Perring et al. (2010) indicated that the peak  $\text{O}_3$  production in the near field of Mexico City (source region of  $\text{RONO}_2$ ) was reduced by as much as 40% due to the formation of total  $\text{RONO}_2$ . Farmer et al. (2011) even claimed that VOC reductions might cause an  $\text{O}_3$  increment because the branching ratios of  $\text{RONO}_2$  formation decreased when fuels containing low boiling point VOCs products were used. This view was also held by Perring et al. (2013), who estimated a theoretical 8%  $\text{O}_3$  increment even under VOCs reduction of 20%, due to the unexpected decrease of the average branching ratio for total  $\text{RONO}_2$  from 8% to 4%. Overall, in urban areas  $\text{RONO}_2$  serve as a reservoir for nitrogen and reactive radicals, releasing them in remote areas and fueling  $\text{O}_3$  formation. Therefore,  $\text{RONO}_2$  photochemistry regulates  $\text{O}_3$  formation in both source and receptor regions.

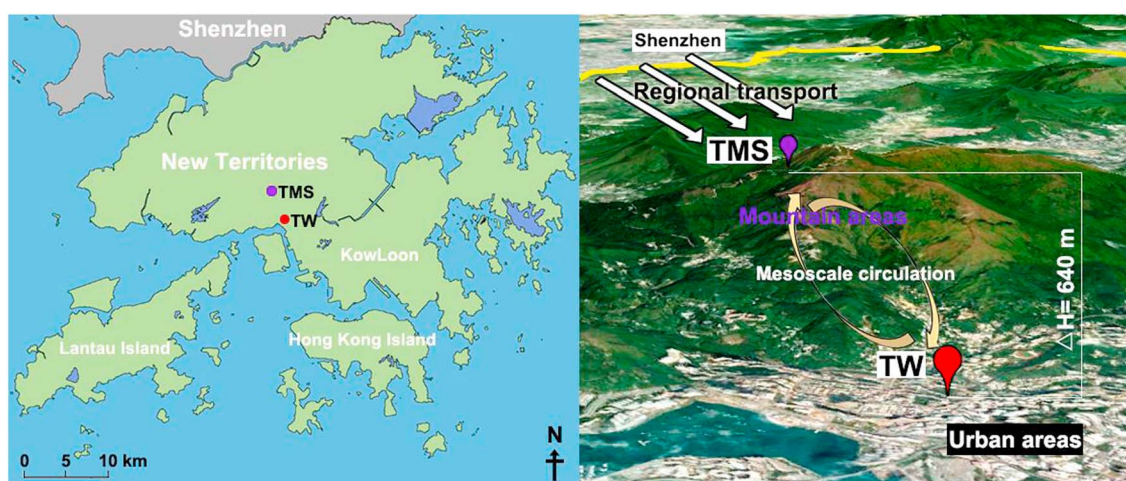

Despite numerous studies,  $\text{RONO}_2$  modeling is still rather difficult (Khan et al., 2015; Williams et al., 2014), resulting in an insufficient understanding of  $\text{RONO}_2$  formation mechanisms and impacts on  $\text{O}_3$  production. Furthermore, previous studies (Rosen et al., 2004; Sobanski et al., 2016) focused on measuring the combined sum of all alkyl nitrates, rather than matching multiple  $\text{RONO}_2$  species as attempted by this study. To fill in these research gaps, an observation-based model was constructed to near-explicitly simulate  $\text{C}_1\text{--}\text{C}_4$   $\text{RONO}_2$  in Hong Kong and address the following terms: (1) the most appropriate branching ratios for the formation of  $\text{C}_1\text{--}\text{C}_4$   $\text{RONO}_2$  in Hong Kong, (2) the pathway contributions of  $\text{RO}_2 + \text{NO}$  and  $\text{RO} + \text{NO}_2$  to  $\text{RONO}_2$ , (3) the relationship between  $\text{RONO}_2$  production and their precursors (i.e. VOCs and  $\text{NO}_x$ ), and (4) the impacts of  $\text{RONO}_2$  formation and degradation on  $\text{O}_3$  production.

## 2. Methodology

### 2.1. Site Description and Sampling

From 6 September to 29 November 2010, an intensive sampling campaign was carried out concurrently at a mountainous site and an urban site in Hong Kong (Figure 1). The mountainous site (22.41°N, 114.12°E, 640 m above ground level (agl)) was located on the mountainside of Hong Kong's highest mountain (Mount Tai Mo Shan), referred to as TMS hereafter. The dominant winds at TMS were from the north that transported air pollutants from the inland Pearl River Delta (PRD) of southern China. In addition, mesoscale circulation (e.g., mountain-valley breezes) caused interaction of mountainous air with urban plumes at the foot of the mountain. The urban site (22.37°N, 114.11°E, 10 m agl) is located in a newly developed town (Tsuen Wan, referred to as TW hereafter) and is an air quality monitoring station of Hong Kong Environmental Protection Department (HKEPD, accessible at <http://www.aqhi.gov.hk/en/monitoring-network/air-quality-monitoring-stations228e.html?%20stationid=77>). The prevailing winds at TW were from the southeast. Detailed information about the two sites is given in Guo et al. (2013) and Ling et al. (2014, 2016).

Real time measurements of trace gases including  $\text{SO}_2$ ,  $\text{CO}$ ,  $\text{NO}$ ,  $\text{NO}_2$ , and  $\text{O}_3$  at TMS were achieved with the instruments listed in Table S1 in the supporting information, which also shows the analytical techniques, detection limits, and precision. Trace gas data at TW were downloaded from the HKEPD website (<http://epic.epd.gov.hk/EPICDI/air/station/>). VOC samples at these two sites were collected using 2 L electropolished stainless steel canisters. Prior to sampling, the canisters were treated with 10 torr of degassed, distilled water to quench the active surface sites of the inner walls and then were cleaned and evacuated. A valve was connected to the inlet of the canisters to maintain a sampling time of about 1 h. A total of 384 samples was simultaneously collected in daytimes of 10  $\text{O}_3$  episode days (23–24 and 29–31 October and 1–3, 9, and 19 November 2010) and 10 non- $\text{O}_3$  episode days (28 September, 2, 8, 14, 18–19, and 27–28 October,

**Figure 1.** Geographic (left) locations and (right) topographies of the sampling sites (TMS and TW). Regional transport and mesoscale circulation at TMS are presented according to Guo et al. (2013). The boundary between mainland China and Hong Kong is highlighted in yellow.

and 20–21 November 2010) at TMS and TW, except those samples not collected at TW on October 23. Samples were collected at 21:00, 0:00, and 3:00 and at each hour from 7:00 to 19:00 during  $O_3$  episodes, while they were collected every 2 h from 07:00 to 19:00 on non- $O_3$  episode days. In this study, days with at least 1-hourly  $O_3$  mixing ratio exceeding 100 ppbv were defined as  $O_3$  episode days (China's Grade II standards, accessible at <http://210.72.1.216:8080/gzaqi/Document/gjzlbz.pdf>). The  $O_3$  values at TMS were used to define the  $O_3$  episodes and nonepisodes, because freshly emitted NO from vehicular exhaust strongly titrated  $O_3$  at TW (Guo et al., 2013).

## 2.2. Chemical Analysis of $RONO_2$

The collected VOC samples were delivered to the Rowland/Blake group at the University of California, Irvine (UCI), for chemical analyses. Detailed descriptions about the analytical system, analysis techniques, precision, accuracy, and quality control protocols can be found in Colman et al. (2001) and Simpson et al. (2006).

Specifically, for the quantification of  $C_1$ – $C_4$   $RONO_2$ , that is, methyl nitrate ( $CH_3ONO_2$  or  $C_1$   $RONO_2$ ), ethyl nitrate ( $C_2H_5ONO_2$  or  $C_2$   $RONO_2$ ), *i*-propyl nitrate ( $2-C_3H_7ONO_2$  or  $2-C_3$   $RONO_2$ ), *n*-propyl nitrate ( $1-C_3H_7ONO_2$  or  $1-C_3$   $RONO_2$ ), and *sec*-butyl nitrate ( $2-C_4H_9ONO_2$  or  $2-C_4$   $RONO_2$ ), a gas chromatography-electron capture detector system was used. Two whole air working standards were analyzed every four samples to calibrate the  $RONO_2$  measurements. The precision was 2% for mixing ratios above 5 parts per trillion by volume (pptv) and 10% for mixing ratios below 5 pptv. The accuracy was 10–20%, and the detection limit for  $C_1$ – $C_4$   $RONO_2$  was 0.01 pptv. It is worth noting that the  $RONO_2$  calibration scale changed in 2008 (Simpson et al., 2011) and all measurements are reported on the new calibration scale.

## 2.3. Construction of PBM-MCM Model

A photochemical box model-master chemical mechanism (PBM-MCM) model was developed to simulate  $RONO_2$ . Master chemical mechanism (MCM) is an explicit chemical mechanism, which has been successfully used in photochemical simulation in Hong Kong and many other regions of the world (Lam et al., 2013; Ling et al., 2014; Saunders et al., 2003). The latest version of MCM (MCM v3.3) includes 17,242 reactions and 5,836 species (Jenkin et al., 2015). Reactions of biogenic VOCs including limonene and myrcene, and  $RONO_2$  were added into MCM by our team. In particular, the model describes reactions of more than 100  $RONO_2$  species. The main formation pathways of  $RONO_2$  that are considered are  $RO_2 + NO$  and  $RO + NO_2$ , while  $RONO_2$  degradation is presented as photolysis (reaction (5)) and OH initiated oxidation (reaction (6)). More details about model setup,  $RONO_2$  reactions, and photochemistry of limonene and myrcene are given in Text S1 in the supporting information.

The branching ratios were acquired from previous studies (Flocke, Atlas et al., 1998; Lightfoot et al., 1992) or calculated according to the formulas recommended by Carter and Atkinson (1985). For  $C_1$  RONO<sub>2</sub>, branching ratios of 0.00015, 0.0003, 0.001, 0.003, 0.0041, and 0.005 were examined and considered. The one that resulted in the highest IOA between the simulated and observed  $C_1$  RONO<sub>2</sub> was adopted (see section 3.2 for details). However, since branching ratio data for  $C_2$ – $C_4$  RONO<sub>2</sub> were rather limited, the values calculated using formulas (1)–(3) were used as the branching ratios, which were 0.0094, 0.048, 0.019, and 0.085 for  $C_2$ , 2- $C_3$ , 1- $C_3$ , and 2- $C_4$  RONO<sub>2</sub>, respectively.

In addition to the chemical reactions, many modules were compiled in the PBM-MCM model. For example, the photolysis rate module enables us to calibrate the photolysis rates of many air pollutants. The tropospheric ultraviolet and visible radiation model, which considers actual location and modeling time periods, is used to calibrate the photolysis rates (Madronich & Flocke, 1997). Moreover, the concentrations of air pollutants can be specified to initiate the model in the initial concentration module. This is important, because the background RONO<sub>2</sub> existed prior to photochemical reactions is generally nonnegligible due to their long lifetimes. The dry deposition module considers the dry deposition of air pollutants, which are parameterized as an average deposition rate within the height of the mixed layer (HMIX).

Since this study mainly focused on the in situ photochemistry of RONO<sub>2</sub>, the on-site observations of 41 hydrocarbons, 10 halocarbons, 6 OVOCs, 5 inorganic trace gases, and 2 meteorological parameters (temperature and relative humidity) from 08:00 to 19:00 at each site were used as the model input to constrain the modeling (the hourly observed RONO<sub>2</sub> at 08:00–19:00 were not input to constrain the simulated RONO<sub>2</sub>). Moreover, to initiate the modeling, observed concentrations of the aforementioned species including RONO<sub>2</sub> at 07:00 were set as initial conditions. These initial conditions were expected to be significantly influenced by regional transport and mesoscale circulation at this mountainous site (because of low on-site emissions). Note that these species were not constrained at their initial values but were allowed to vary over time. Since the daily values of these pollutants varied, different initial concentrations for each pollutant were used for the simulation of each day. The integration of simulated RONO<sub>2</sub> within each hour automatically given by the model was compared with the observed RONO<sub>2</sub> to validate the model performance. The simulations were carried out only during the daytime hours (07:00–19:00). In terms of dry deposition, Zhang et al. (2002) indicated that the dry deposition velocity for organic nitrates ranged from 0.03 to 0.56/HMIX cm/s (HMIX denotes height of mixed layer). Within this range, deposition rates of 0.03, 0.13, 0.23, 0.33, 0.43, and 0.53/HMIX cm/s were examined for  $C_1$ – $C_4$  RONO<sub>2</sub> in this study (step = 0.1/HMIX cm/s). Dry deposition rates were also available for other species such as O<sub>3</sub> and its precursors, in-line with the settings in previous studies (Lam et al., 2013; Saunders et al., 2003).

Overall, based on the observed mixing ratios of air pollutants, including RONO<sub>2</sub> precursors, the PBM-MCM model simulated RONO<sub>2</sub> in different scenarios with changes of branching ratios and dry deposition rates, and consideration of initial conditions. The model uncertainty was discussed and roughly estimated with the root-mean-square error method (Willmott, 1982) in Text S2 in the supporting information.

### 3. Results and Discussion

#### 3.1. Overview of RONO<sub>2</sub> Sources

As mentioned earlier, the air quality at TMS was significantly influenced by regional transport and mesoscale circulation. Figure S1 shows the distributions of wind fields, that is, wind direction (WD) and wind speed (WS), and their correlations with RONO<sub>2</sub> precursors at TMS during the sampling campaign. North winds ( $0^\circ < WD < 90^\circ$  and  $270^\circ < WD < 360^\circ$ ) were much more frequent than south winds ( $90^\circ < WS < 180^\circ$ ) at TMS (82.8% and 17.2%, respectively). While the mixing ratios of NO and NO<sub>2</sub> were comparable ( $p > 0.05$ ) for north and south winds,  $C_1$ – $C_4$  *n*-alkanes were more abundant ( $p < 0.05$ ) under north versus south winds, suggesting the transport of RONO<sub>2</sub> precursors from the inland PRD to TMS. During this study the average wind direction at TMS switched from northeast at night to north during the day (Guo et al., 2013), implying that regional transport was constant throughout the day or night. Besides regional transport, our previous paper (Guo et al., 2013) clearly confirmed the mesoscale circulations between TMS and TW through the good intersite correlations of SO<sub>2</sub> and CO, good reproduction of O<sub>3</sub> at TMS with precursors at TW to initialize the model, and the simulation of mountain-valley breezes by Weather Research Forecast model. Mesoscale circulations were identified on the sampling days of 24 and 29–31 October and 1–3, 9, and 19 November,

**Table 1**

Contributions of Regional Transport, Mesoscale Circulation and In Situ Formation to Individual RONO<sub>2</sub> Levels at TMS (Unit: pptv) (From Ling et al., 2016)

Sources	CH <sub>3</sub> ONO <sub>2</sub>	C <sub>2</sub> H <sub>5</sub> ONO <sub>2</sub>	2-C <sub>3</sub> H <sub>7</sub> ONO <sub>2</sub>	1-C <sub>3</sub> H <sub>7</sub> ONO <sub>2</sub>	2-C <sub>4</sub> H <sub>9</sub> ONO <sub>2</sub>
Regional transport	7.67 ± 0.50	8.44 ± 0.62	16.86 ± 1.17	2.11 ± 0.22	15.15 ± 1.49
Mesoscale circulation	9.97 ± 0.85	7.38 ± 0.44	18.7 ± 0.77	3.08 ± 0.16	34.7 ± 3.14
In situ formation	3.61 ± 0.48	2.18 ± 0.29	3.68 ± 0.45	1.03 ± 0.13	10.9 ± 1.31

when the valley breeze brought the urban plume at the foot of the mountain to the mountain site in the daytime, while the mountain breeze drove the mountain air to the urban site at night. In addition, the air pollution at TMS was also partially dominated by in situ photochemistry. With the same set of data, Ling et al. (2016) apportioned the observed RONO<sub>2</sub> at TMS to the sources of regional transport, mesoscale circulation, and in situ formation, as shown in Table 1. Although regional transport and mesoscale circulation made considerable contributions to RONO<sub>2</sub> at TMS, in situ formation cannot be neglected, which was the main focus of this study.

It is well known that photochemical formation, biomass burning, and oceanic emission are the main sources of RONO<sub>2</sub> (Atlas et al., 1993; Bertman et al., 1995; Simpson et al., 2002). Using positive matrix factorization model, Ling et al. (2016) resolved the sources of RONO<sub>2</sub> at TW (Table 2). Secondary formation (46.6 ± 2.4%) and biomass burning (46.7 ± 2.1%) made comparable contributions to total RONO<sub>2</sub>, with the rest from oceanic emission (6.8 ± 1.2%). It should be noted that the secondary formation identified by Ling et al. (2016) was not exactly the same as the in situ formation, because the secondarily formed RONO<sub>2</sub> in background and regional air masses were also included in the secondary formation source. Further analysis was conducted on the relationship between primarily emitted RONO<sub>2</sub> and source origin of air masses. In-line with our previous paper (Guo et al., 2013), the air masses under north winds with WS higher than 2 m/s were treated as regional air. Otherwise, the air masses were local or originated from the South China Sea (SCS). Figure S2 shows the total RONO<sub>2</sub> emitted from biomass burning and oceanic emission versus wind fields. RONO<sub>2</sub> levels in local air or SCS outflow from both biomass burning (40.0 ± 1.9 pptv) and oceanic emissions (5.4 ± 0.7 pptv) were significantly higher ( $p < 0.05$ ) than in regional air (biomass burning: 35.9 ± 2.2 pptv and oceanic emission: 3.2 ± 1.4 pptv). The higher RONO<sub>2</sub> emissions from biomass burning in local air was expected to be caused by biofuel usage in small villages and barbecues nearby (Ling et al., 2016, and references therein). The greater oceanic emissions of RONO<sub>2</sub> in local air or SCS outflow indicated the higher oceanic contributions to RONO<sub>2</sub> in Hong Kong under south or calm winds ( $WS < 2$  m/s), though we note that the RONO<sub>2</sub> levels in the oceanic air are still fairly low (far away from equator).

### 3.2. Modeling of C<sub>1</sub>–C<sub>4</sub> RONO<sub>2</sub>

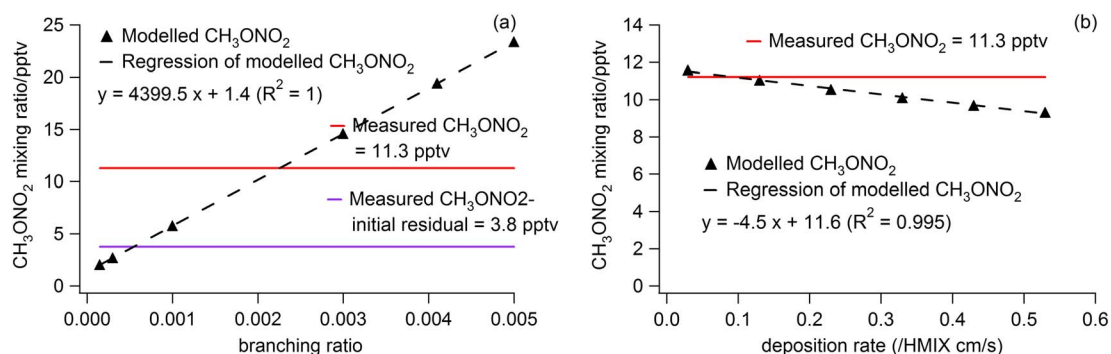

#### 3.2.1. Branching Ratio and Deposition Velocity

This study mainly focused on the in situ formation of RONO<sub>2</sub> at TMS and TW. However, the regional transport and mesoscale circulation were also partially considered based on the following settings: (i) RONO<sub>2</sub> and other air pollutants measured at 07:00 on each day were used to initiate the model; the initial RONO<sub>2</sub> at 07:00, which accounted for ~85% of the total simulated RONO<sub>2</sub> (see Figure 3), consisted of the regionally transported and locally circulated RONO<sub>2</sub>; and (ii) the regionally transported and locally circulated fractions of RONO<sub>2</sub> precursors were included in the hourly measured data, which were used to construct the model. Despite the above settings, the impacts of regional transport and mesoscale circulations were not fully simulated in the model, demonstrated by the fact that the simulated RONO<sub>2</sub> mixing ratios were generally lower than the observed levels during O<sub>3</sub> episodes when these impacts were significant (see Figures S4 and S5),

**Table 2**

Source Contributions to Individual RONO<sub>2</sub> at TW in Different Scenarios (Unit: pptv) (From Ling et al., 2016)

Sources	CH <sub>3</sub> ONO <sub>2</sub>	C <sub>2</sub> H <sub>5</sub> ONO <sub>2</sub>	2-C <sub>3</sub> H <sub>7</sub> ONO <sub>2</sub>	1-C <sub>3</sub> H <sub>7</sub> ONO <sub>2</sub>	2-C <sub>4</sub> H <sub>9</sub> ONO <sub>2</sub>
Secondary formation	4.0 ± 0.3	6.2 ± 0.5	12.1 ± 0.9	2.1 ± 0.2	18.3 ± 1.3
Biomass burning	5.7 ± 0.3	5.7 ± 0.3	12.4 ± 0.6	1.6 ± 0.1	14.2 ± 0.6
Oceanic emission	2.5 ± 0.3	1.1 ± 0.1	1.1 ± 0.1	0.10 ± 0.01	0.4 ± 0.1

**Figure 2.** Modeled average CH<sub>3</sub>ONO<sub>2</sub> as a function of (a) branching ratio (no initial or dry deposition) and (b) deposition rate (branching ratio = 0.0003, and the initial CH<sub>3</sub>ONO<sub>2</sub> was set as the values measured at 07:00 (LT) at TMS for each day.

most likely due to the insufficient consideration of regional transport and local circulation. However, the simulations of in situ formation of RONO<sub>2</sub> should not be significantly influenced.

Figure 2a shows the average in situ production of CH<sub>3</sub>ONO<sub>2</sub> at TMS as a function of the branching ratio (section 2.3), without consideration of initial concentrations and dry deposition. Noticeably, the CH<sub>3</sub>ONO<sub>2</sub> production linearly increases with increasing branching ratio (CH<sub>3</sub>ONO<sub>2</sub> mixing ratio in parts per trillion by volume =  $(4400 \times \text{branching ratio}) + 1.4$ ). A branching ratio of approximately 0.0023 was determined to match the observed CH<sub>3</sub>ONO<sub>2</sub> (11.3 pptv). This branching ratio was within the range of 0.00015 to 0.005 as reported earlier (Carter & Atkinson, 1985; Flocke, Atlas et al., 1998; Lightfoot et al., 1992). However, the initial mixing ratio (8.8 pptv) was not considered in Figure 2a, which should also be a part of the observed CH<sub>3</sub>ONO<sub>2</sub> even though it was subject to degradation and dry deposition. Even taking into account the degradation (OH initiated oxidation and photolysis) and dry deposition (rate = 0.13/HMIX cm/s), the average residual of the initial CH<sub>3</sub>ONO<sub>2</sub> was still 7.5 pptv. Based on this value, photochemically formed CH<sub>3</sub>ONO<sub>2</sub> was about 3.8 pptv, which corresponded to a branching ratio of 0.00055, also within the range of 0.00015–0.005. However, this value was calculated based on model simulation rather than laboratory experiment and has never been reported in previous studies. More importantly, factors other than photochemical reactions (such as regional transport and mesoscale circulation) might influence the determination of this value. Therefore, 0.00055 was only treated as a rough estimate of the branching ratio, and we preliminarily accepted a branching ratio of 0.0003, reported by Flocke, Atlas et al. (1998) and adopted by Simpson et al. (2006), which was the closest to 0.00055 among the examined values.

To validate the suitability of the branching ratio, we conducted a set of comparative simulations with the branching ratios tested above. The initial concentrations were taken from the observed CH<sub>3</sub>ONO<sub>2</sub> at 07:00 on each day, and the mean of 0.03/HMIX–0.53/HMIX was set as the dry deposition rate. Table S2 shows the IOAs between the observed and simulated CH<sub>3</sub>ONO<sub>2</sub> with different branching ratios. Noticeably, the best agreement was acquired when the branching ratio of 0.0003 was applied. Furthermore, the observed and simulated CH<sub>3</sub>ONO<sub>2</sub> with branching ratio of 0.0003 were compared on several selected days with the wind speeds less than 2 m/s and typical patterns of photochemically formed RONO<sub>2</sub> (peak observed in earlier afternoon), as presented in Figure S3. It was found that the variations of CH<sub>3</sub>ONO<sub>2</sub> were well simulated, with IOA reaching 0.75 at TMS and 0.86 at TW. The average positive and negative biases of the simulations were 18.3% and –12.1% at TMS, and 14.3% and –13.5% at TW, respectively. Under the assumption that the daytime variation of CH<sub>3</sub>ONO<sub>2</sub> was exclusively caused by in situ formation on the selected days, the biases of simulations could be treated as the errors in branching ratio, because CH<sub>3</sub>ONO<sub>2</sub> production linearly correlated with the branching ratio (Figure 2). By setting the initial concentration and deposition velocity as zero, the average contribution of photochemical formation to the total simulated CH<sub>3</sub>ONO<sub>2</sub> on the selected days was determined to be ~44% and ~34% at TMS and TW, respectively. Therefore, to count the maximum biases of the simulated CH<sub>3</sub>ONO<sub>2</sub> (18.3% at TMS and

**Figure 3.** Comparisons between the measured and modeled CH<sub>3</sub>ONO<sub>2</sub> in different scenarios at TMS. The O<sub>3</sub> episode days are highlighted in red.

**Table 3***Model Settings for the Simulations of C<sub>1</sub>–C<sub>4</sub> RONO<sub>2</sub> As Well As IOAs Between the Simulated and Measured RONO<sub>2</sub> at TMS and TW*

	CH <sub>3</sub> ONO <sub>2</sub>	C <sub>2</sub> H <sub>5</sub> ONO <sub>2</sub>	1-C <sub>3</sub> H <sub>7</sub> ONO <sub>2</sub>	2-C <sub>3</sub> H <sub>7</sub> ONO <sub>2</sub>	2-C <sub>4</sub> H <sub>9</sub> ONO <sub>2</sub>
Branching ratio	0.0003	0.0094	0.019	0.048	0.085
Dry deposition	0.07/HMIX	0.07/HMIX	0.07/HMIX	0.07/HMIX	0.07/HMIX
IOA at TMS	0.67	0.72	0.72	0.72	0.72
IOA at TW	0.66	0.70	0.69	0.67	0.73

Note. HMIX is the time-dependent mixed layer height, as shown in Figure S6.

14.3% at TW), the uncertainty of the branching ratio was ~42% at both sites. Further consideration of the model uncertainty (~13%) with the root-mean-square error method (see Text S2) resulted in the uncertainty of the branching ratio less than 50%. Therefore, 0.0003 was identified as the most appropriate branching ratio for CH<sub>3</sub>O<sub>2</sub> + NO → CH<sub>3</sub>ONO<sub>2</sub>, with the error less than 20%. It is noticeable that 0.00055 was beyond the range of 0.00015–0.00045 (0.0003 with uncertainty of 50%). This discrepancy might be caused by the fact that the determination of 0.00055 was more influenced by the factors other than photochemical reactions, while 0.0003 was determined based on the simulations on the selected days when in situ photochemical formation of CH<sub>3</sub>ONO<sub>2</sub> was more significant.

Although 0.0003 was proposed and adopted in some previous studies (Flocke, Atlas et al., 1998; Simpson et al., 2006), other branching ratios over a wide range (0.00015–0.01) have also been used as the branching ratio of CH<sub>3</sub>O<sub>2</sub> reacting with NO (e.g., Carter & Atkinson, 1989; Scholtens et al., 1999). Here the determination of the branching ratio of 0.0003 and the associated uncertainty may reconstrain the impacts of CH<sub>3</sub>ONO<sub>2</sub> on global oxidative capacity of the atmosphere.

Furthermore, by considering dry deposition, Figure 2b presents the modeled CH<sub>3</sub>ONO<sub>2</sub> with the branching ratio of 0.0003 and dry deposition velocities of 0.03/HMIX, 0.13/HMIX, 0.23/HMIX, 0.33/HMIX, 0.43/HMIX, and 0.53/HMIX cm/s. The modeled CH<sub>3</sub>ONO<sub>2</sub> decreased linearly with increasing dry deposition velocity (CH<sub>3</sub>ONO<sub>2</sub> mixing ratio in pptv = −4.5 × deposition rate + 11.6). A dry deposition velocity of 0.07/HMIX was determined to best reproduce the observed CH<sub>3</sub>ONO<sub>2</sub>. As such, the branching ratio of 0.0003 and dry deposition velocity of 0.07/HMIX cm/s were treated as the most appropriate settings for CH<sub>3</sub>ONO<sub>2</sub> simulation.

With these settings, the factors influencing the simulated CH<sub>3</sub>ONO<sub>2</sub> were sequentially considered. Figure 3 shows the CH<sub>3</sub>ONO<sub>2</sub> simulated in different scenarios at TMS, that is, (i) “reaction,” (ii) “reaction + initial,” and (iii) “reaction + initial + dry deposition.” Scenario (i) only considered the formation and degradation reactions of CH<sub>3</sub>ONO<sub>2</sub>, while the initial concentrations and dry deposition were progressively considered in scenarios (ii) and (iii). The modeled CH<sub>3</sub>ONO<sub>2</sub> in scenario (i) was typically bell shaped on a diurnal basis, coincident with the characteristics of photochemical reactions. However, the mean modeled CH<sub>3</sub>ONO<sub>2</sub> (2.6 ± 0.3 pptv) was much lower than the observed average (11.3 ± 0.3 pptv). By introducing the initial conditions, the modeled CH<sub>3</sub>ONO<sub>2</sub> in scenario (ii) increased to a comparable level (11.7 ± 0.3 pptv) to the measurements, in-line with the finding that background initial concentrations are an important constituent of the observed RONO<sub>2</sub> (Ling et al., 2016). Further consideration of dry deposition in scenario (iii) resulted in a slight decrease of the modeled CH<sub>3</sub>ONO<sub>2</sub> to 11.0 ± 0.3 pptv, which best agreed with the observed CH<sub>3</sub>ONO<sub>2</sub>. By subtracting the modeled CH<sub>3</sub>ONO<sub>2</sub> in scenario (i) from scenario (ii) and that in scenario (ii) from scenario (iii), the respective contributions of the processes, including reaction, initial conditions, and dry deposition to the total modeled CH<sub>3</sub>ONO<sub>2</sub>, were determined to be 21.5 ± 1.8%, 85.1 ± 2.0%, and −6.6 ± 0.3% (negative contribution means removal of CH<sub>3</sub>ONO<sub>2</sub>). It is noteworthy that the initial concentrations included both primarily emitted RONO<sub>2</sub> and residues of secondarily formed RONO<sub>2</sub> in background and regionally transported air masses. C<sub>2</sub>–C<sub>4</sub> RONO<sub>2</sub> were simulated with the branching ratios calculated according to Carter and Atkinson (1985, 1989) and the dry deposition velocities identical to that for CH<sub>3</sub>ONO<sub>2</sub>.

### 3.2.2. Model Validation

Table 3 lists the model settings that best reproduced the magnitudes and patterns of the observed RONO<sub>2</sub> at TMS and TW (shown in Figures S4 and S5 in the supporting information). Overall, the simulated RONO<sub>2</sub> agreed well with the measurements (index of agreement is discussed below). However, the morning peaks of RONO<sub>2</sub> (e.g., 28 September, 8 and 23 October, and 1 and 2 November) were not well reproduced by the model. Since in situ photochemical formation could not be the main source of RONO<sub>2</sub> in the morning

when solar radiation was weak, the discrepancies between modeling and observation were most likely to be caused by direct emissions and/or regional transport, which were not considered in the model. In addition, the modeled RONO<sub>2</sub> levels were generally ~50% lower than the observations on O<sub>3</sub> episode days (23–24 and 29–31 October and 1–3, 9, and 19 November). Methyl chloride (CH<sub>3</sub>Cl) levels at both TMS (episode: 1100 ± 33 pptv and nonepisode: 926 ± 27 pptv) and TW (episode: 1116 ± 32 pptv and nonepisode: 1031 ± 45 pptv) increased noticeably ( $p < 0.05$ ) during O<sub>3</sub> episodes, so did levoglucosan in fine particles (84.8 ± 27.8 and 31.6 ± 18.5 ng/m<sup>3</sup> during episode and nonepisode at TMS, respectively). These suggested emissions of RONO<sub>2</sub> from biomass burning. Furthermore, the frequency of northerly winds was higher during O<sub>3</sub> episodes (78% at TMS and 29% at TW) than during non-O<sub>3</sub> episodes (51% at TMS and 21% at TW). In view of severe photochemical pollution in the adjacent inland PRD cities and increased transport of secondary pollutants from the inland PRD to Hong Kong during O<sub>3</sub> episodes (Guo et al., 2009; Lam et al., 2005), regional transport might also contribute to the higher observed RONO<sub>2</sub> on episode days. Additionally, Ling et al. (2016) indicated that mesoscale circulation made higher contribution to RONO<sub>2</sub> at TMS during O<sub>3</sub> episodes. An exception was CH<sub>3</sub>ONO<sub>2</sub> at TW on 19 November when the modeled CH<sub>3</sub>ONO<sub>2</sub> remarkably exceeded the measured values (Figure S5). This overestimation was believed to be caused by the abnormally high aromatic levels on that day (30.2 ± 23.4 ppbv, compared to the average of 4.9 ± 0.6 ppbv over the whole sampling period excluding that day). Briefly, the photochemical degradation of aromatics generated CH<sub>3</sub>O<sub>2</sub> and CH<sub>3</sub>O in the model. Without consideration of diffusion, these precursors of CH<sub>3</sub>ONO<sub>2</sub> were more significantly overestimated than those in normal periods, leading to overestimation of CH<sub>3</sub>ONO<sub>2</sub>.

To quantitatively evaluate the simulations, IOA between the simulated and observed RONO<sub>2</sub> was calculated (Table 3). IOA is a statistical parameter commonly used to evaluate model performance, as calculated using formula (4) (Hurley et al., 2001; Wang et al., 2015). Ranging from 0 to 1, higher IOAs represent better agreement between the simulated and observed values.

$$\text{IOA} = 1 - \frac{\sum_{i=1}^n (O_i - S_i)^2}{\sum_{i=1}^n (|O_i - \bar{O}| + |S_i - \bar{O}|)^2}, \quad (4)$$

where  $O_i$  and  $S_i$  are the observed and simulated values and  $\bar{O}$  is the average observed value of  $n$  samples.

The IOA ranged from 0.67 to 0.72 and 0.66 to 0.73 for RONO<sub>2</sub> simulations at TMS and TW, respectively. Given that other sources (e.g., biomass burning and oceanic emission) and regional transport impact were not considered in the model, the IOAs indicated that the simulations were acceptable.

### 3.3. Secondary RONO<sub>2</sub> Formation

#### 3.3.1. RONO<sub>2</sub> Formation at TMS and TW

Based on the above settings, the in situ production of RONO<sub>2</sub> (referred to as secondary RONO<sub>2</sub> hereafter) was simulated without consideration of initial conditions and dry deposition, as summarized in Table 4. Also shown are the concentrations of parent hydrocarbons, corresponding RO<sub>2</sub> radicals, NO, and NO<sub>2</sub>.

The measured mixing ratios of parent hydrocarbons and NO<sub>x</sub> (both NO and NO<sub>2</sub>) were significantly higher at TW than at TMS ( $p < 0.05$ ). Likewise, simulated C<sub>1</sub> and 2-C<sub>4</sub> RONO<sub>2</sub> levels at TW were significantly higher than at TMS ( $p < 0.05$ ), while the simulated C<sub>2</sub> and C<sub>3</sub> RONO<sub>2</sub> levels at TW were comparable to or even lower than those at TMS. To explore the reasons for these differences, the relative contributions of RO<sub>2</sub> + NO and RO + NO<sub>2</sub> were quantified (Table 5), using the method described by Lyu et al. (2015). Briefly, the two pathways were switched off in turn. The simulated RONO<sub>2</sub> was subtracted from that simulated in base scenario with both pathways switched on. In this way, RONO<sub>2</sub> produced by the each pathway was obtained. The pathway of RO<sub>2</sub> + NO dominated the formation of C<sub>2</sub>–C<sub>4</sub> RONO<sub>2</sub> at both sites. In contrast, the reaction of RO + NO<sub>2</sub> made considerable contributions to CH<sub>3</sub>ONO<sub>2</sub> (mean ± 95% confidence interval (CI): 2.7 ± 0.3 pptv or 41.9 ± 5.9% at TMS and 4.8 ± 1.0 pptv or 76.2 ± 15.7% at TW). In addition to higher CH<sub>4</sub> levels, the more abundant secondary CH<sub>3</sub>ONO<sub>2</sub> at TW was likely because that NO<sub>2</sub> at TW (31.6 ± 3.1 ppbv) was significantly higher than that at TMS (8.7 ± 0.8 ppbv) ( $p < 0.05$ ). Indeed, following suggestions that RO + NO<sub>2</sub> could be an important pathway for CH<sub>3</sub>ONO<sub>2</sub> formation in polluted environments (Flocke, Volz-Thomas et al., 1998; Simpson et al., 2006), Archibald et al. (2007) confirmed that this pathway becomes important at about 10 ppb of NO<sub>2</sub>, and dominant at about 35 ppb, based on MCM simulations for European conditions. It is noteworthy

Secondary 2-C <sub>4</sub> H <sub>9</sub> ONO <sub>2</sub> (pptv)	13.5 ± 1.4	17.6 ± 2.4*

Note. Error bars represent 95% CIs. \*Significant difference between the two sites ( $p < 0.05$ ). Bolded are species with observed values, and the rest are simulated values. Note. Error bars represent 95% CIs.

that the in situ contributions of CH<sub>3</sub>O + NO<sub>2</sub> to CH<sub>3</sub>ONO<sub>2</sub> at both sites in the present study were much higher than those simulated in our previous studies (Ling et al., 2016; Lyu et al., 2015), which considered the dispersion and transport of air masses. This was mainly due to the fact that air masses containing NO<sub>2</sub> during the dispersion and transport were diluted based on the model setup in previous studies. Therefore, the simulated contribution of CH<sub>3</sub>O+NO<sub>2</sub> pathway was lower in the previous studies when NO<sub>2</sub> concentration was reduced.

For C<sub>2</sub>–C<sub>3</sub> RONO<sub>2</sub>, although the measured parent hydrocarbons were less abundant at TMS than at TW, the simulated concentrations of RO<sub>2</sub> radicals were all remarkably higher under low NO<sub>x</sub> conditions but still in VOC-limited regime (as discussed below), leading to comparable (for C<sub>2</sub>H<sub>5</sub>ONO<sub>2</sub> and 2-C<sub>3</sub>H<sub>7</sub>ONO<sub>2</sub>) or even higher (for 1-C<sub>3</sub>H<sub>7</sub>ONO<sub>2</sub>) mixing ratios of RONO<sub>2</sub> at TMS. The difference in NO<sub>x</sub> levels was considered to be the main cause of the anticorrelation between the parent hydrocarbons and related RO<sub>2</sub> radicals. As O<sub>3</sub> formation is generally limited by VOCs at both sites (Guo et al., 2013; Ling et al., 2014), the reaction chains of O<sub>3</sub> formation were terminated by NO<sub>x</sub> reacting with reactive radicals. Figure S7 shows that the simulated OH and HO<sub>2</sub> levels were much lower at TW than at TMS. This is because the higher NO<sub>x</sub> at TW consumed more oxidative substances (e.g., O<sub>3</sub>) and radicals (OH and HO<sub>2</sub>). Consequently, reactions including the oxidation of parent hydrocarbons at TW were more suppressed, leading to lower production of RO<sub>2</sub> radicals.

However, 2-C<sub>4</sub>H<sub>9</sub>ONO<sub>2</sub> was higher at TW. In addition to the role of NO as the reactant, this was also attributable to the fact that the concentration of 2-C<sub>4</sub>H<sub>9</sub>O<sub>2</sub> at TW was lower than at TMS only by a factor of 4.2, compared to 6.7, 6.6, and 13.3 for C<sub>2</sub>H<sub>5</sub>O<sub>2</sub>, 2-C<sub>3</sub>H<sub>7</sub>O<sub>2</sub>, and 1-C<sub>3</sub>H<sub>7</sub>O<sub>2</sub>, respectively.

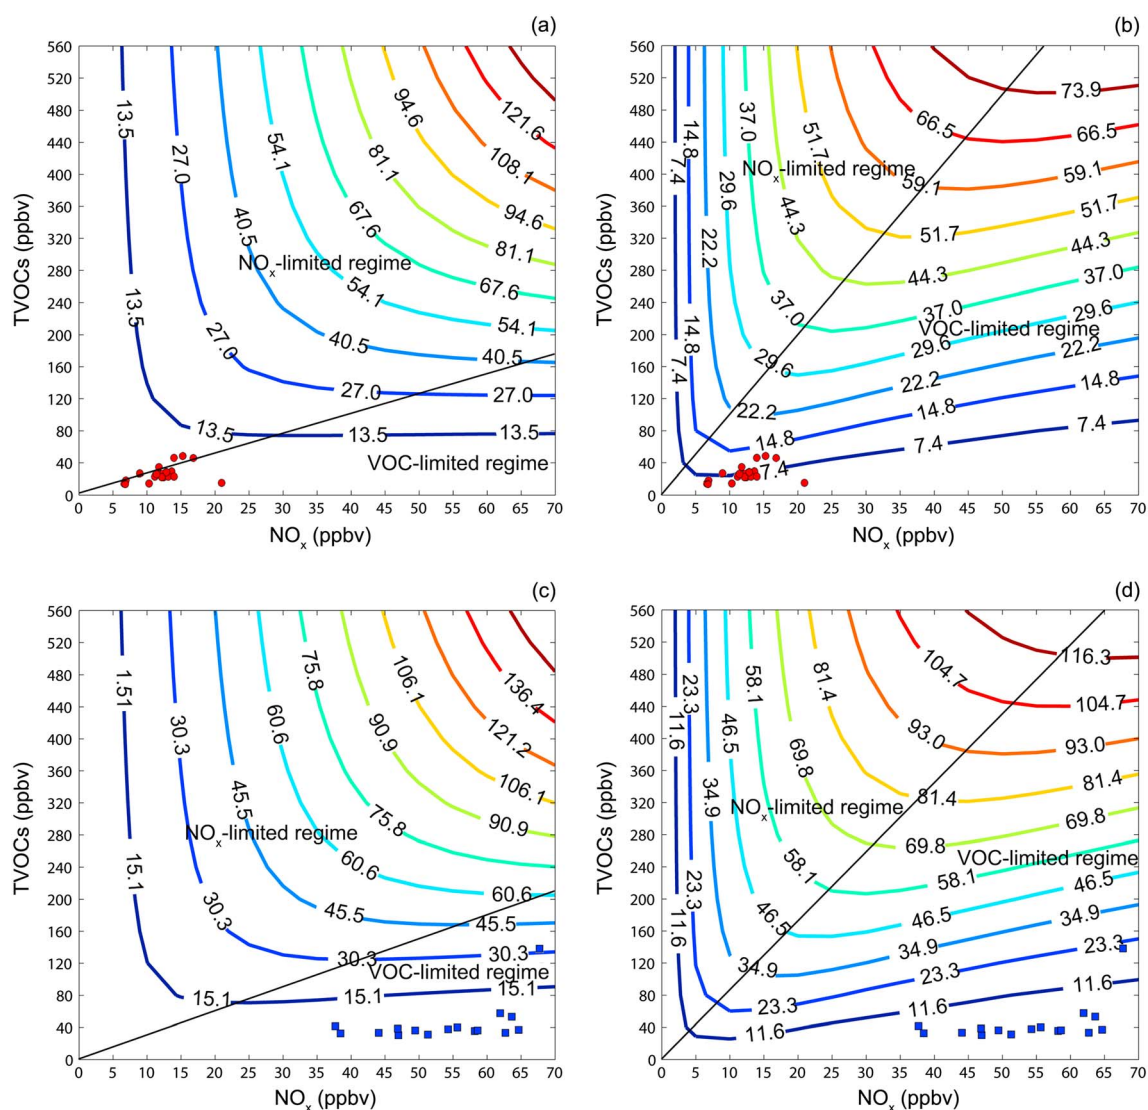

### 3.3.2. RONO<sub>2</sub> Formation in Various Environments

To further investigate RONO<sub>2</sub> formation in different environments, a total of 196 scenarios was designed for model simulations. The simulations were conducted in daytime hours (07:00–19:00), in which the concentrations of total volatile organic compounds (TVOCs) and NO<sub>x</sub> were allowed to evolve over time. The simulated hourly RONO<sub>2</sub> during 07:00–19:00 in each scenario of the simulations were averaged to create the corresponding isopleths. RONO<sub>2</sub> production was simulated with a matrix of total VOCs (TVOCs) and NO<sub>x</sub> ranging from 40 to 560 ppbv and 5 to 70 ppbv, with a consistent scale of 40 ppbv and 5 ppbv, respectively. The ranges of TVOCs and NO<sub>x</sub> were chosen to include not only the observed TVOCs and NO<sub>x</sub> in the middle of the sequence but also the best representative NO<sub>x</sub>-limited and VOC-limited regimes as discussed below. Apart from their mixing ratios, the

**Table 5**  
Relative Contributions (%) of the RO<sub>2</sub> + NO and RO + NO<sub>2</sub> Pathways to RONO<sub>2</sub> at TMS and TW

RONO <sub>2</sub>	TMS		TW

**Figure 4.** Isopleths of photochemical production (pptv) of (a)  $\text{CH}_3\text{ONO}_2$  and (b)  $\text{C}_2\text{H}_5\text{ONO}_2$  (as an example of  $\text{C}_2\text{--C}_4$   $\text{RONO}_2$ ) based on the air pollutant profiles at TMS; (c)  $\text{CH}_3\text{ONO}_2$  and (d)  $\text{C}_2\text{H}_5\text{ONO}_2$  (as an example of  $\text{C}_2\text{--C}_4$   $\text{RONO}_2$ ) based on the air pollutant profiles at TW. The black line separates  $\text{NO}_x$ -limited regime from VOCs-limited regime. The red and blue symbols in the figure show the daily average observed TVOCs and  $\text{NO}_x$  at TMS (red) and TW (blue), respectively.

composition of TVOCs and  $\text{NO}_x$  might also influence the production of  $\text{RONO}_2$ . Therefore, the ratios between VOC species and NO and  $\text{NO}_2$  (referred to as air pollutant profiles hereafter) at TMS and TW were used to distribute VOCs species in TVOCs, and NO and  $\text{NO}_2$  in  $\text{NO}_x$ . The mixing ratios of TVOCs and  $\text{NO}_x$  were  $24.0 \pm 2.2$  and  $12.2 \pm 0.6$  ppbv at TMS and  $48.4 \pm 7.2$  and  $50.5 \pm 2.3$  ppbv at TW, respectively. The ratio of  $\text{NO}_2/\text{NO}$  at TMS ( $2.5 \pm 0.3$ ) was about twice that at TW ( $1.2 \pm 0.2$ ). Further inspection into the OH reactivity indicated that TVOCs and  $\text{NO}_x$  accounted for  $\sim 55\%$  ( $3.7 \text{ s}^{-1}$ ) and  $\sim 45\%$  ( $3.0 \text{ s}^{-1}$ ) of total OH reactivity at TMS. In contrast, the OH reactivity of  $\text{NO}_x$  at TW ( $14.3 \text{ s}^{-1}$ ,  $\sim 65\%$ ) dominated over that of TVOCs ( $7.7 \text{ s}^{-1}$ ,  $35\%$ ).

Figure 4 shows the isopleths of  $\text{CH}_3\text{ONO}_2$  and  $\text{C}_2\text{H}_5\text{ONO}_2$  production with the changes of TVOCs and  $\text{NO}_x$  based on the air pollutant profiles at TMS (a and b) and TW (c and d). The isopleth of  $\text{C}_2\text{H}_5\text{ONO}_2$  production was selected as an example of  $\text{C}_2\text{--C}_4$   $\text{RONO}_2$ , which had the same pattern variations in response to the changes of TVOCs and  $\text{NO}_x$  (see Figure S8). It is noteworthy that both formation pathways of  $\text{RO}_2 + \text{NO}$  and  $\text{RO} + \text{NO}_2$  were considered for  $\text{C}_1\text{--C}_4$   $\text{RONO}_2$ . Based on Figure 4, the  $\text{NO}_x$ -limited and VOC-limited regimes in  $\text{RONO}_2$  formation were identified. Briefly, the points with the lowest TVOCs on each isopleth line were linked in a straight line (dividing line), and  $\text{RONO}_2$  formation in the area below and above the line was limited by VOCs and  $\text{NO}_x$ , respectively (Ou et al., 2016). Linear regressions were carried out for these dividing

lines and a TVOC/NO<sub>x</sub> ratio of approximately  $10.0 \pm 0.4$  ppbv/ppbv ( $R^2 = 0.97$ ) was obtained for the simulated production of C<sub>2</sub>–C<sub>4</sub> RONO<sub>2</sub> based on the air pollutant profiles at TMS. In other words, when the ratio of TVOCs/NO<sub>x</sub> was higher (lower) than  $10.0 \pm 0.4$  ppbv/ppbv, the C<sub>2</sub>–C<sub>4</sub> RONO<sub>2</sub> formation was limited by NO<sub>x</sub> (VOCs). However, this ratio was significantly ( $p < 0.05$ ) lower based on the air pollutants profiles at TW (TVOCs/NO<sub>x</sub> =  $8.7 \pm 0.4$  ppbv/ppbv,  $R^2 = 0.96$ ). The differences were likely attributable to the higher fraction of NO<sub>2</sub> in NO<sub>x</sub> at TMS ( $70.6 \pm 2.4\%$ ) than at TW ( $54.0 \pm 4.1\%$ ). NO<sub>2</sub> reacts with OH more quickly than NO, which serves as an important sink of OH in the VOC-limited regime. A higher fraction of NO<sub>2</sub> in NO<sub>x</sub> meant that the system was more NO<sub>x</sub> suppressed (VOC limited), and a higher ratio of TVOCs/NO<sub>x</sub> was needed to change the RONO<sub>2</sub> formation from a VOC-limited regime to a NO<sub>x</sub>-limited regime. When using OH reactivity to present the dividing ratios, the ratios of  $\frac{\text{OH reactivity of TVOCs}}{\text{OH reactivity of NO}_x}$  between TMS ( $6.4 \pm 0.3 \text{ s}^{-1}/\text{s}^{-1}$ ) and TW ( $5.6 \pm 0.3 \text{ s}^{-1}/\text{s}^{-1}$ ) were still not comparable ( $p < 0.05$ ). This might be due to the fact that O<sub>3</sub> formation was not only determined by the reactions between OH and VOCs (NO<sub>x</sub>). For example, the reaction of NO and OH cannot be treated as a destruction to O<sub>3</sub> in daytime, because OH can be regenerated through the photolysis of HONO. In addition, the same reactivity of TVOCs might correspond to different potentials of O<sub>3</sub> formation, due to the different potentials of RO<sub>2</sub> in oxidizing NO and regenerating HO<sub>2</sub>. Analysis of the relationship between RONO<sub>2</sub> production and the TVOC/NO<sub>x</sub> ratio found that in the NO<sub>x</sub>-limited regime, increasing NO<sub>x</sub> stimulated the production of RONO<sub>2</sub> (RO<sub>2</sub> + NO → RONO<sub>2</sub>). However, increasing NO<sub>x</sub> led to a direct or indirect reduction of OH (OH + NO<sub>2</sub> → HNO<sub>3</sub> and NO + O<sub>3</sub> → NO<sub>2</sub> + O<sub>2</sub>) and subsequent reductions of HO<sub>2</sub>, RO<sub>2</sub>, and RO in the VOC-limited regime. Conversely, an increase of TVOCs elevated the production of these radicals. Therefore, in the VOC-limited regime, an increase of TVOCs (NO<sub>x</sub>) resulted in an increase (decrease) of RO<sub>2</sub>, subsequently stimulating (suppressing) RONO<sub>2</sub> formation.

Note that the threshold ratios of TVOC/NO<sub>x</sub> turning to VOC limited were lower for CH<sub>3</sub>ONO<sub>2</sub> formation than for C<sub>2</sub>–C<sub>4</sub> RONO<sub>2</sub> at both TMS and TW, which were around  $2.4 \pm 0.2$  ppbv/ppbv ( $R^2 = 0.96$ ) and  $3.1 \pm 0.1$  ppbv/ppbv ( $R^2 = 0.99$ ) based on the air pollutant profiles at TMS and TW, respectively. In contrast to C<sub>2</sub>–C<sub>4</sub> RONO<sub>2</sub>, which were mainly generated from RO<sub>2</sub> reacting with NO, CH<sub>3</sub>ONO<sub>2</sub> had two pivotal formation pathways, that is, RO<sub>2</sub> + NO and RO + NO<sub>2</sub> (Table 5). Figures 5a and 5b show the respective isopleths of CH<sub>3</sub>ONO<sub>2</sub> produced by the pathways of CH<sub>3</sub>O<sub>2</sub> + NO and CH<sub>3</sub>O + NO<sub>2</sub> based on the air pollutant profiles at TMS (the isopleths at TW are presented in Figures 5c and 5d). The CH<sub>3</sub>ONO<sub>2</sub> generated by CH<sub>3</sub>O<sub>2</sub> + NO (Figures 5a and 5c) followed the same patterns as C<sub>2</sub>–C<sub>4</sub> RONO<sub>2</sub> (TVOCs/NO<sub>x</sub> ratio of  $10.0 \pm 0.4$  and  $8.7 \pm 0.4$  ppbv/ppbv as the threshold between the VOC- and NO<sub>x</sub>-limited regimes at TMS and TW, respectively). However, based on the air pollutants profiles at TMS, the formation of CH<sub>3</sub>ONO<sub>2</sub> from the CH<sub>3</sub>O+NO<sub>2</sub> always increased with increasing NO<sub>x</sub>, implying a continuous NO<sub>x</sub>-limited regime. In contrast, NO<sub>x</sub> facilitated the pathway of CH<sub>3</sub>O + NO<sub>2</sub> → CH<sub>3</sub>ONO<sub>2</sub> when TVOC/NO<sub>x</sub> was higher than  $2.9 \pm 0.1$  ppbv/ppbv, based on the air pollutants profiles at TW. The VOC-limited regime under condition of TVOCs/NO<sub>x</sub> <  $2.9 \pm 0.1$  ppbv/ppbv was due to the inhabitation of CH<sub>3</sub>O formation by NO<sub>x</sub>. The production of CH<sub>3</sub>ONO<sub>2</sub> through this pathway depended upon the product of CH<sub>3</sub>O and NO<sub>2</sub>. Since TW had lower fraction of NO<sub>2</sub> in NO<sub>x</sub>, the decrease of CH<sub>3</sub>O with NO<sub>x</sub> increasing cannot be compensated by NO<sub>2</sub> increasing, causing a VOC-limited regime for the pathway of CH<sub>3</sub>O + NO<sub>2</sub>. Moreover, for the scenarios with TVOCs ≥ 240 ppbv, CH<sub>3</sub>ONO<sub>2</sub> generated from CH<sub>3</sub>O + NO<sub>2</sub> continuously increased with increasing NO<sub>x</sub> (continuous NO<sub>x</sub>-limited regime). The continuous stimulation effect of NO<sub>x</sub> on CH<sub>3</sub>ONO<sub>2</sub> formation at low ratios of TVOC/NO<sub>x</sub> (high NO<sub>x</sub>) was also identified by Archibald et al. (2007), which might be caused by the competitiveness of NO<sub>2</sub> associating with CH<sub>3</sub>O relative to the oxidation of CH<sub>3</sub>O (CH<sub>3</sub>O + O<sub>2</sub> → HCHO + HO<sub>2</sub>) increasing under high NO<sub>x</sub>. Since RO reacting with NO<sub>2</sub> was an important pathway for C<sub>1</sub> RONO<sub>2</sub>, a higher fraction of NO<sub>2</sub> in NO<sub>x</sub> at TMS meant a higher production of C<sub>1</sub> RONO<sub>2</sub> through this route. Therefore, the NO<sub>x</sub>-limited regime appeared under conditions of lower ratios of TVOCs/NO<sub>x</sub> at TMS.

It should be noted that the aforementioned dividing ratios were obtained based on the average air pollutants profile at each site. In fact, the dividing ratios should vary in a range, due to the change of air pollutant profiles. To further confirm the influence of air pollutant profiles on the dividing ratios, RONO<sub>2</sub> formation isopleths were simulated based on the air pollutant profiles at TMS and TW on 9 November 2010, when the air pollutants profiles at TMS and TW were obviously different. Details are given in Text S3 and Table S3 in the supporting information. Noticeably, the distinctive air pollutant profiles on 9 November led to completely different dividing ratios of TVOCs/NO<sub>x</sub> from the average ratios. Table 6 lists the ranges of TVOC/NO<sub>x</sub> ratios

**Figure 5.** Isopleths of  $\text{CH}_3\text{ONO}_2$  production (pptv) from the pathway of (a)  $\text{CH}_3\text{O}_2+\text{NO}$  and (b)  $\text{CH}_3\text{O}+\text{NO}_2$  based on the air pollutant profiles at TMS; (c)  $\text{CH}_3\text{O}_2+\text{NO}$  and (d)  $\text{CH}_3\text{O}+\text{NO}_2$  based on the air pollutant profiles at TW. The red and blue symbols in the figure show the daily average observed TVOCs and  $\text{NO}_x$  at TMS (red) and TW (blue), respectively.

corresponding to the  $\text{NO}_x$ -limited and VOCs-limited regimes in  $\text{RONO}_2$  formation, which were simulated on the basis of the air pollutant profiles at TMS and TW. Please note that these values were the slopes derived from linear regressions. The uncertainty of model simulation was roughly estimated by root-mean-square of the accuracies of input parameters, which was  $\sim 13\%$ .

The ratios of  $\text{TVOCs}/\text{NO}_x$  that divide  $\text{NO}_x$ - and VOC-limited regimes were verified by the observed secondary  $\text{RONO}_2$ , which were resolved by positive matrix factorization model. Details about the source apportionment of  $\text{RONO}_2$  have been provided in Ling et al. (2016). Figure S9 shows the relationships between the secondary  $\text{RONO}_2$  and the ratio of  $\text{TVOCs}/\text{NO}_x$ . The samples were grouped using the dividing ratios of  $\text{TVOCs}/\text{NO}_x$  listed in Table 6 to categorize them into the theoretically VOC-limited and  $\text{NO}_x$ -limited regimes (Figure S9).  $\text{C}_2$   $\text{RONO}_2$  was selected as an example of  $\text{C}_2$ - $\text{C}_4$   $\text{RONO}_2$ , as they all had similar patterns with changing  $\text{TVOCs}/\text{NO}_x$ . Both  $\text{C}_1$  and  $\text{C}_2$   $\text{RONO}_2$  increased with increasing  $\text{TVOCs}/\text{NO}_x$  in the VOC-limited regime and decreased with increasing  $\text{TVOCs}/\text{NO}_x$  in the  $\text{NO}_x$ -limited regime (not applicable to  $\text{C}_2$ - $\text{C}_4$   $\text{RONO}_2$  since only one sample was in  $\text{NO}_x$ -limited regime). In other words, the relationships between secondary  $\text{RONO}_2$  resolved from the observational data and their precursors followed the patterns predicted by  $\text{RONO}_2$  formation isopleths.

**Table 6**  
Ranges of TVOC/NO<sub>x</sub> Ratios Corresponding to Regimes Controlling RONO<sub>2</sub> Formation Based On the Air Pollutant Profiles at TMS and TW

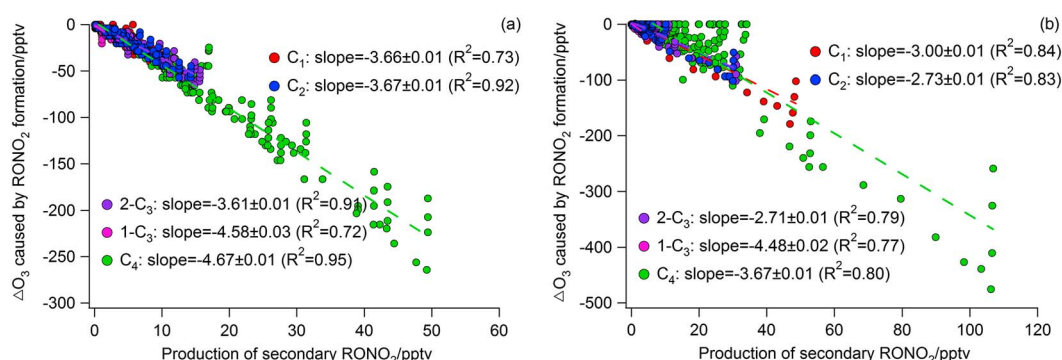

TVOCs/NO <sub>x</sub> (ppbv/ppbv)	Profiles of air pollutants at TMS		Profiles of air pollutants at TW

### 3.4. Impacts on O<sub>3</sub> Production

#### 3.4.1. O<sub>3</sub> Variation Induced by RONO<sub>2</sub> Formation at TMS and TW

To investigate the impacts of RONO<sub>2</sub> formation on O<sub>3</sub> production, two categories of scenarios, that is, a base case and five constrained cases, were tested for each sampling day in this study. Briefly, in the base case all reaction pathways were switched on in the model, while the formation pathways (RO<sub>2</sub> + NO and RO + NO<sub>2</sub>) of each individual RONO<sub>2</sub> were switched off in each corresponding constrained case. The five constrained cases corresponded to five RONO<sub>2</sub>. All other settings were identical between the base and constrained cases. The initial concentrations of C<sub>1</sub>-C<sub>4</sub> RONO<sub>2</sub> were set as zero for both the base and constrained cases, because we focused on the impacts of in situ RONO<sub>2</sub> formation on O<sub>3</sub> production. The base case simulated the secondary production of RONO<sub>2</sub>. The O<sub>3</sub> variations (ΔO<sub>3</sub>) induced by RONO<sub>2</sub> formation were obtained by subtracting O<sub>3</sub> in the constrained cases from that in the base case, as were the variations of NO, NO<sub>2</sub>, OH, and HO<sub>2</sub>. Figure 6 shows the relationship between hourly ΔO<sub>3</sub> and secondary RONO<sub>2</sub> production at TMS and TW using all measured data points for the whole sampling period. Each point denotes hourly simulated O<sub>3</sub> reduction induced by RONO<sub>2</sub> formation in that hour. Overall, as secondary RONO<sub>2</sub> production increased, O<sub>3</sub> levels decreased. The formation of CH<sub>3</sub>ONO<sub>2</sub>, C<sub>2</sub>H<sub>5</sub>ONO<sub>2</sub>, 2-C<sub>3</sub>H<sub>7</sub>ONO<sub>2</sub>, 1-C<sub>3</sub>H<sub>7</sub>ONO<sub>2</sub>, and 2-C<sub>4</sub>H<sub>9</sub>ONO<sub>2</sub> caused an average O<sub>3</sub> reduction (mean ± 95% CI) of 9.7 ± 1.1, 14.7 ± 1.6, 18.4 ± 1.9, 6.9 ± 0.6, and 60.2 ± 6.8 pptv at TMS, and 10.5 ± 3.2, 7.1 ± 2.0, 8.3 ± 2.1, 2.0 ± 0.5, and 40.0 ± 9.8 pptv at TW, respectively. Note that these values were different from those reported at the same sites in Ling et al. (2016), which considered both RONO<sub>2</sub> formation on site and during mesoscale circulation. O<sub>3</sub> reduction was linearly correlated with the production of secondary RONO<sub>2</sub> (0.72 < R<sup>2</sup> < 0.95 at TMS, 0.77 < R<sup>2</sup> < 0.84 at TW) for CH<sub>3</sub>ONO<sub>2</sub>, C<sub>2</sub>H<sub>5</sub>ONO<sub>2</sub>, 2-C<sub>3</sub>H<sub>7</sub>ONO<sub>2</sub>, 1-C<sub>3</sub>H<sub>7</sub>ONO<sub>2</sub>, and 2-C<sub>4</sub>H<sub>9</sub>ONO<sub>2</sub>, respectively. Furthermore, the daily average O<sub>3</sub> reduction correlated well with the reduction of OH (R<sup>2</sup> = 0.83 and 0.71 at TMS and TW, respectively) and of HO<sub>2</sub> (R<sup>2</sup> = 0.84 and 0.98 at TMS and TW, respectively), while poor correlations were found between O<sub>3</sub> reduction and the variation of NO or NO<sub>2</sub> (Figures S10 and S11). This was consistent with our previous finding that O<sub>3</sub> reduction in RONO<sub>2</sub> formation was related to the reductions of oxidative radicals in VOC-limited regime (Lyu et al., 2015). More

**Figure 6.** Relationship between O<sub>3</sub> reductions and the simulated secondary RONO<sub>2</sub> productions at (a) TMS and (b) TW.

**Figure 7.** Simulated variations of (a)  $O_3$ , (b) NO, (c)  $NO_2$ , (d) OH, and (e)  $HO_2$  at TMS and TW induced by  $C_1$ – $C_4$   $RONO_2$  degradation.

importantly, the  $O_3$  reduction efficiencies ( $\Delta O_3$ /secondary  $RONO_2$ ) were significantly lower at TW than at TMS ( $p < 0.05$ ), as reflected from the slopes in Figure 6. In view of the higher OH and  $HO_2$  at TMS than at TW (Figure S7), the higher  $O_3$  reduction efficiency at TMS suggested that  $RONO_2$  formation led to  $O_3$  reduction more significantly in the atmosphere with higher oxidative capacity. This is reasonable because the promotion of OH and  $HO_2$  to the propagation of chain reactions forming  $O_3$  is faster in the more oxidative atmosphere. This finding should be applicable to the regions where  $O_3$  formation is limited by VOCs.

### 3.4.2. $O_3$ Variation Induced by $RONO_2$ Degradation at TMS and TW

The impacts of  $RONO_2$  degradation on  $O_3$  production at TMS and TW were studied with two simulation scenarios, that is, a base scenario with all the reaction pathways switched on and a constrained scenario in which OH oxidation and photolysis for all five  $C_1$ – $C_4$   $RONO_2$  were switched off. The differences of model output between the two scenarios (base scenario–constrained scenario) reflected the impact of  $RONO_2$  degradation, referred to as “variation” hereafter. For example, positive variations of  $O_3$  meant that  $O_3$  increased due to  $RONO_2$  degradation. Note that this impact was studied in the form of total  $C_1$ – $C_4$   $RONO_2$  rather than individual species, because the  $O_3$  variation induced by individual  $RONO_2$  was generally minor. During  $RONO_2$  degradation  $NO_2$  is released, which decomposes and generates NO and O, allowing  $O_3$  to be formed through the association between  $O_2$  and O. On the other hand, the released  $NO_2$  also consumes OH, reducing  $O_3$

production subsequently. RO released from RONO<sub>2</sub> degradation fuels O<sub>3</sub> formation. Therefore, O<sub>3</sub> variation in RONO<sub>2</sub> degradation is the combination of these effects.

Figure 7 shows the simulated daily average variations of O<sub>3</sub>, NO, NO<sub>2</sub>, OH, and HO<sub>2</sub> induced by degradation of the C<sub>1</sub>–C<sub>4</sub> RONO<sub>2</sub>. The daily average O<sub>3</sub> variations ranged from –7.4 pptv to 2.3 pptv at TMS but increased at TW throughout the sampling campaign (average increase of 2.9 ± 0.8 pptv). At TMS, the O<sub>3</sub> variation correlated well with the OH and HO<sub>2</sub> variations ( $R^2$  of 0.86 and 0.85, respectively) but negatively with the variations of NO and NO<sub>2</sub> ( $R^2$  of 0.89 and 0.76, respectively). This implied that O<sub>3</sub> formation at TMS was generally VOC limited (NO<sub>x</sub> suppressed). When NO and NO<sub>2</sub> levels increased at TMS, O<sub>3</sub>, OH, and HO<sub>2</sub> decreased. This might be due to the consumption of OH by NO<sub>2</sub> and/or NO titration with O<sub>3</sub>. Since NO increases resulted from the decomposition of NO<sub>2</sub>, we defined this impact of RONO<sub>2</sub> degradation on O<sub>3</sub> production as NO<sub>2</sub> suppressing. In contrast, O<sub>3</sub> formation was enhanced by RONO<sub>2</sub> degradation on several days (29–31 October and 2 and 21 November), when NO and NO<sub>2</sub> decreased (due to increases of O<sub>3</sub> and OH) while OH and HO<sub>2</sub> increased. That is, NO<sub>x</sub> led to an O<sub>3</sub> reduction. Conversely, RO released from RONO<sub>2</sub> promoted O<sub>3</sub> formation. The overall O<sub>3</sub> enhancements indicated that the RO stimulating effect overrode the NO<sub>2</sub> suppressing effect in these cases, causing an O<sub>3</sub> increase. Thus, the impact of RONO<sub>2</sub> degradation on O<sub>3</sub> production manifested as RO stimulating. Consistently, O<sub>3</sub>, OH and HO<sub>2</sub> all increased while NO decreased at TW, induced by RONO<sub>2</sub> degradation. O<sub>3</sub> enhancement exhibited moderate to good correlations with the simulated increase of OH ( $R^2 = 0.50$ ) and HO<sub>2</sub> ( $R^2 = 0.81$ ), which were generated from the evolution of RO in the photochemical reaction chain. As such, the impact of RONO<sub>2</sub> degradation on O<sub>3</sub> production at TW was dominated by the effect of RO stimulating. We found that the ratio of TVOC/NO<sub>x</sub> in the cases of O<sub>3</sub> increase (average: 1.6 ppbv/ppbv) was lower than in the cases of O<sub>3</sub> decrease (average ratio: 2.1 ppbv/ppbv) at TMS. The lower ratio of TVOC/NO<sub>x</sub> means that O<sub>3</sub> formation was more limited by VOCs, which enabled the added RO to more efficiently stimulate O<sub>3</sub> formation and resulted in the increase of O<sub>3</sub>. Coincidentally, the low ratio of TVOC/NO<sub>x</sub> (0.9 ppbv/ppbv) at TW also caused O<sub>3</sub> increase during RONO<sub>2</sub> degradation.

Further, Text S4 and Figures S12–S14 in the supporting information present the impacts of RONO<sub>2</sub> degradation on O<sub>3</sub> production in different environments, through 196 scenarios of simulation. NO<sub>2</sub> released from RONO<sub>2</sub> degradation was found to promote O<sub>3</sub> production in NO<sub>x</sub>-limited regime, which was defined as NO<sub>2</sub> stimulating effect. Due to the long lifetimes of C<sub>1</sub>–C<sub>4</sub> RONO<sub>2</sub> and their abundances in specific environments, for example, up to 50 pptv for CH<sub>3</sub>ONO<sub>2</sub> within the marine boundary layer near equator (Blake et al., 1999), the degradation of C<sub>1</sub>–C<sub>4</sub> RONO<sub>2</sub> might cause greater O<sub>3</sub> variations, particularly in pristine environments with sparse emission of O<sub>3</sub> precursors.

#### 4. Conclusions

A PBM-MCM model was developed to simulate gas-phase RONO<sub>2</sub> measured at an urban and a mountainous site in Hong Kong. The magnitudes and variations of the observed C<sub>1</sub>–C<sub>4</sub> RONO<sub>2</sub> at both sites were well reproduced by the model. A branching ratio of 0.0003 with the uncertainty of less than 50% was determined for the reaction of CH<sub>3</sub>O<sub>2</sub> + NO leading to CH<sub>3</sub>ONO<sub>2</sub> formation, which would be an important reference for modeling the global oxidative capacity of the atmosphere. The modeling results indicated that RONO<sub>2</sub> formation depended upon not only the abundances of precursors but also the concentrations of oxidative radicals, which was closely related to the levels of VOCs and NO<sub>x</sub>. Although the precursors of RONO<sub>2</sub> at the mountainous site were less abundant than at the urban site, the higher concentrations of oxidative radicals led to higher production of RO<sub>2</sub> radicals, resulting in comparable or even higher RONO<sub>2</sub>. The regimes in which the formation of C<sub>2</sub>–C<sub>4</sub> RONO<sub>2</sub> was NO<sub>x</sub> limited and VOC limited were identified when the ratio of TVOCs/NO<sub>x</sub> was higher and lower than 10.0 ± 0.4 ppbv/ppbv, respectively, based on the air pollutants profiles at the mountainous site. The simulated dividing ratio of TVOCs/NO<sub>x</sub> based on the air pollutants profiles at the urban site was slightly lower (8.7 ± 0.4 ppbv/ppbv), due to the differences in air pollutant profiles at these two sites. However, the dividing ratios decreased to 2.4 ± 0.2 and 3.1 ± 0.1 ppbv/ppbv for the formation of CH<sub>3</sub>ONO<sub>2</sub> at the mountainous and urban site, respectively. This was mainly because CH<sub>3</sub>ONO<sub>2</sub> produced from CH<sub>3</sub>O + NO<sub>2</sub> continued to increase with increasing NO<sub>x</sub> when the ratios of TVOCs/NO<sub>x</sub> were relatively low (high NO<sub>x</sub>). RONO<sub>2</sub> formation generally resulted in O<sub>3</sub> reductions, and the O<sub>3</sub> reduction efficiency was higher at the mountainous site due to the higher oxidative capacity of the atmosphere. On the other

hand, the mechanisms of RONO<sub>2</sub> degradation influencing O<sub>3</sub> production included NO<sub>2</sub> stimulating, NO<sub>2</sub> suppressing, and RO stimulating processes. At the mountainous site, the impact of RONO<sub>2</sub> degradation on O<sub>3</sub> production was dominated by NO<sub>2</sub> suppression under the condition of relatively high ratios of TVOCs/NO<sub>x</sub>, leading to the decrease of O<sub>3</sub>, while RO stimulation occurred at relatively low ratios of TVOCs/NO<sub>x</sub>, resulting in the increase of O<sub>3</sub>. However, the O<sub>3</sub> production always increased due to RO stimulation at the urban site.
