Received 2017 September 27; revised 2017 September 27; accepted 2017 September 28; published 2017 October 16

Abstract

We present UV, optical, and near-infrared (NIR) photometry of the first electromagnetic counterpart to a gravitational wave source from Advanced Laser Interferometer Gravitational-wave Observatory (LIGO)/Virgo, the binary neutron star merger GW170817. Our data set extends from the discovery of the optical counterpart at 0.47–18.5 days post-merger, and includes observations with the Dark Energy Camera (DECam), Gemini-South/FLAMINGOS-2 (GS/F2), and the *Hubble Space Telescope* (*HST*). The spectral energy distribution (SED) inferred from this photometry at 0.6 days is well described by a blackbody model with $T \approx 8300$ K, a radius of $R \approx 4.5 \times 10^{14}$ cm (corresponding to an expansion velocity of $v \approx 0.3c$), and a bolometric luminosity of $L_{\text{bol}} \approx 5 \times 10^{41}$ erg s⁻¹. At 1.5 days we find a multi-component SED across the optical and NIR, and subsequently we observe rapid fading in the UV and blue optical bands and significant reddening of the optical/NIR colors. Modeling the entire data set, we find that models with heating from radioactive decay of ⁵⁶Ni, or those with only a single component of opacity from *r*-process elements, fail to capture the rapid optical decline and red optical/NIR colors. Instead, models with two components consistent with lanthanide-poor and lanthanide-rich ejecta provide a good fit to the data; the resulting “blue” component has $M_{\text{ej}}^{\text{blue}} \approx 0.01 M_{\odot}$ and $v_{\text{ej}}^{\text{blue}} \approx 0.3 c$, and the “red” component has $M_{\text{ej}}^{\text{red}} \approx 0.04 M_{\odot}$ and $v_{\text{ej}}^{\text{red}} \approx 0.1 c$. These ejecta masses are broadly consistent with the estimated *r*-process production rate required to explain the Milky Way *r*-process abundances, providing the first evidence that binary neutron star (BNS) mergers can be a dominant site of *r*-process enrichment.

Key words: binaries: close – catalogs – gravitational waves – stars: neutron – surveys

1. Introduction

The era of gravitational wave (GW) astronomy began on 2015 September 14 when the Advanced Laser Interferometer Gravitational-wave Observatory (LIGO) made the first direct detection of gravitational waves, resulting from the merger of a stellar mass binary black hole (BBH; GW150914; Abbott et al. 2016a). LIGO has since announced the detection of three additional BBH events (Abbott et al. 2016b, 2017a; LIGO Scientific Collaboration et al. 2017). There are currently no robust theoretical predictions for electromagnetic (EM) emission associated with such mergers.

By contrast, mergers involving at least one neutron star can produce a wide range of EM signals, spanning from gamma-rays to radio (e.g., Metzger & Berger 2012). In the optical/near-infrared (NIR) bands, the most promising counterpart is the kilonova (KN), a roughly isotropic thermal transient powered by the radioactive decay of rapid neutron capture (*r*-process) elements synthesized in the merger ejecta (Li & Paczyński 1998; Metzger et al. 2010; Roberts et al. 2011; Metzger & Berger 2012; Barnes & Kasen 2013; Tanaka & Hotokezaka 2013). The properties of the KN emission (luminosity, timescale, spectral peak) depend sensitively on the ejecta composition. For ejecta containing Fe-group or light *r*-process nuclei with atomic

⁷⁶ Hubble, Carnegie-Dunlap Fellow.

mass number $A \lesssim 140$, the KN emission is expected to peak at optical wavelengths at a luminosity $L_p \sim 10^{41}\text{--}10^{42}$ erg s^{-1} on a short timescale of $t_p \sim 1$ day (a so-called “blue” KN; Metzger et al. 2010; Roberts et al. 2011; Metzger & Fernández 2014). By contrast, for ejecta containing heavier lanthanide elements ($A \gtrsim 140$) the emission is predicted to peak at NIR wavelengths with $L_p \sim 10^{40}\text{--}10^{41}$ erg s^{-1} over a longer timescale of $t_p \sim 1$ week (a so-called “red” KN; Barnes & Kasen 2013; Kasen et al. 2013; Tanaka & Hotokezaka 2013).

The first direct detection of gravitational waves from the inspiral and merger of a binary neutron star (BNS) was made on 2017 August 17 (GW170817; LIGO Scientific Collaboration & Virgo Collaboration 2017a, 2017b, 2017c). This source was coincident with a short burst of gamma-rays detected by both *Fermi*/Gamma-ray Burst Monitor (GBM) and *INTEGRAL* (GRB 170817A; Blackburn et al. 2017; Goldstein et al. 2017a, 2017b; Savchenko et al. 2017a, 2017b; von Kienlin et al. 2017). Rapid optical follow-up by our Dark Energy Camera (DECam) program (Flaugher et al. 2015), starting just 11.4 hr after the GW trigger, led to the discovery of an associated optical counterpart in the nearby ($d \approx 39.5$ Mpc; Freedman et al. 2001) galaxy NGC 4993 (Allam et al. 2017; Soares-Santos et al. 2017). This optical source was independently discovered by several groups (Abbott et al. 2017b), and first announced as SSS17a by Coulter et al. (2017a, 2017b). The source has also been independently named DLT17ck (Valenti et al. 2017; Yang et al. 2017) and AT2017gfo.

Here we present rapid-cadence UV, optical, and NIR observations spanning from the time of discovery to 18.5 days post-merger. We construct well-sampled light curves and spectral energy distributions (SEDs) using data from DECam, along with Gemini-South/FLAMINGOS-2 (GS/F2) and *Hubble Space Telescope* (*HST*). We show that the data cannot be fit by a model with heating from ^{56}Ni radioactive decay and Fe-peak opacities (as in normal supernovae), but instead requires heating from r -process nuclei and at least two components consistent with lanthanide-poor and lanthanide-rich opacities. We further use the data to determine the ejecta masses and velocities for each component.

All magnitudes presented in this work are given in the AB system and corrected for Galactic reddening⁷⁷ with $E(B - V) = 0.105$, applying the calibration of Schlafly & Finkbeiner (2011). We assume a negligible reddening contribution from the host (Blanchard et al. 2017).

2. Observations and Data Analysis

A summary of the observations and photometry described in this section is available in the [Appendix](#).

2.1. DECam

We processed all of the DECam images using the photpipe pipeline (e.g., Rest et al. 2005, 2014) in order to perform single-epoch image processing and image subtraction using the hotpants software package (Becker 2015). Point-spread function (PSF) photometry was performed on the subtracted images using an implementation of DoPhot optimized for difference images (Schechter et al. 1993). We performed astrometric and photometric calibration relative to

the Pan-STARRS1/ 3π catalog (PS1/ 3π ; Chambers et al. 2016), with appropriate corrections between magnitude systems (Scolnic et al. 2015). The typical calibration error is on the order of $\approx 3\%$. Image subtraction was performed using stacked images from the PS1/ 3π survey as reference images for gr -band. DECam images from 2017 August 25 and 2017 August 31 were used as reference images for u -band and iZ -band, respectively, after the transient had faded away.

2.2. HST

We obtained *HST* Target-of-Opportunity observations of GW170817 on 2017 August 27.28 (9.8 days post-trigger) UT using ACS/WFC with the F475W, F625W, F775W, and F850LP filters, WFC3/UVIS with the F336W filter, and WFC3/IR with the F160W and F110W filters (PID: 15329; PI: Berger). We retrieved the calibrated data from the Mikulski Archive for Space Telescopes and used the DrizzlePac⁷⁸ software package to create final drizzled images from the individual dithered observations in each filter. We used the astrodrizzle task to correct for optical distortion and improve the resolution from that sampled by the instrumental PSF. We measure the flux of the optical counterpart by fitting a model PSF, constructed from multiple stars in each image, using a custom Python wrapper for DAOPHOT (Stetson 1987). We removed contaminating flux from the host galaxy at the transient location using local background subtraction. After subtraction, the typical contribution from the host flux is $\lesssim 5\%$. We calibrated the photometry for each image using the zeropoints provided by the *HST* analysis team.⁷⁹

2.3. GS/F2

We obtained several epochs of HK_s band photometry using FLAMINGOS-2 on the Gemini-South 8 m telescope (Eikenberry et al. 2012) starting on 2017 August 19.00 (1.47 days post-merger). We processed the images using standard procedures in the gemini IRAF⁸⁰ package. We created an average sky exposure from the individual dithered frames and then scaled and subtracted from each science image prior to the registration and combination of the images. We performed PSF photometry using field stars and host galaxy subtraction as described in Section 2.2, and calibrated the photometry relative to the 2MASS point source catalog.⁸¹

2.4. Swift/UVOT

The UVOT instrument on board *Swift* (Gehrels et al. 2004; Roming et al. 2005) began observing the field of the optical counterpart on 2017 August 18.167 UT with the U , $W1$, $W2$, and $M2$ filters (Cenko et al. 2017; Evans et al. 2017a, 2017b). We used the latest HEASOFT release (v6.22) with the corresponding calibration files and updated zeropoints in order to independently analyze the data. We performed photometry in a $3''$ photometric aperture to in order minimize the contamination from host galaxy light, following the prescriptions by Brown et al. (2009). We estimated and subtracted the contribution from host galaxy light using deep UVOT

⁷⁷ This is computed from <http://irsa.ipac.caltech.edu/applications/DUST/> using the coordinate transients in Soares-Santos et al. (2017).

Figure 1. UV, optical, and NIR light curves of the counterpart of GW170817. The two-component model for r -process heating and opacities (Section 4) is shown as solid lines. The right panels focus on the g (top), i (middle), and H -band photometry (bottom) over the first 10 nights. Triangles represent 3σ upper limits. Error bars are given at the 1σ level in all panels, but may be smaller than the points.

observations acquired at later times, when the UV emission from the transient was no longer present in the images (*Swift* ID 07012979003). The systematic effect from the host light contamination is $\approx 3\%$ (see e.g., Brown et al. 2009).

3. Light Curves and Spectral Energy Distributions

3.1. Light Curves

Our UV/optical/NIR light curves are shown in Figure 1. The data span from 0.47 to 18.5 days post-merger, with bluer bands fading below the detection limits at earlier times. The light curve coverage was truncated by the proximity of the source to the Sun. We first note that the light curves are not well described by a power law, indicating minimal contribution from a GRB optical afterglow over the timescale of our observations. This is consistent with modeling of the afterglow based on X-ray and radio observations (Margutti et al. 2017; Alexander et al. 2017).

The light curves exhibit a rapid decline in the bluest bands (ug), an intermediate decline rate in the red optical bands ($rizY$), and a shallow decline in the NIR (HK_s). However, while the u - and g -band light curves decline by ≈ 2 mag day $^{-1}$ starting with the earliest observations, the redder optical bands exhibit a more complex behavior: they exhibit a comparatively slow decline (≈ 0.3 mag day $^{-1}$) over the first 1.5 days, develop a shoulder at about 4 days, and subsequently begin to decline at about 8 days.

We find a similar rapid evolution in the colors of the transient (Figure 2). In particular, the $u - g$ and $g - r$ colors become redder by about 1 mag between about 1.5 and 3.5 days. The colors in the redder optical bands exhibit slower evolution, with $r - i \approx 0.5 - 1$ mag, $i - z \approx 0 - 0.5$ mag, and $z - Y \approx 0.3$ mag. These colors are significantly redder than those of known supernovae near explosion (e.g., Folatelli et al. 2010; Bianco et al. 2014; Galbany et al. 2016).

3.2. Spectral Energy Distribution

We construct SEDs from photometry at several epochs from about 0.6 to 10 days post-merger (Figure 2). The SEDs exhibit rapid evolution from an initial peak at ~ 3500 Å to a final peak at $\gtrsim 15000$ Å by 10 days. Moreover, the SED at 1.5 days appears to consist of two components, as indicated by the changing slope in the NIR emission. The same rapid evolution and structure are apparent in the optical and NIR spectra at comparable epochs (Chornock et al. 2017; Nicholl et al. 2017).

The SED at 0.6 days is well described by a blackbody with $T \sim 8300$ K and $R \sim 4.5 \times 10^{14}$ cm, corresponding to an expansion velocity of $v \sim 0.3c$. This is somewhat larger than the velocities observed in broad-lined SNe Ic (for which $v \approx 0.1c$; Modjaz et al. 2016), but is consistent with expectations for ejecta resulting from a BNS merger (Metzger 2017). The SEDs at later times are not well described by a blackbody curve, instead exhibiting strong flux suppression at

Figure 2. Top: optical colors from DECam observations as a function of time. We observed rapid and early reddening in $g - r$ compared to the relatively flat but red $i - z$ colors. Also shown are template Ia SN colors relative to the explosion for comparison (Nugent et al. 2002). Middle: SEDs at four representative epochs (assuming isotropic emission). The transition from a blue dominated spectrum at early times to a spectrum dominated by a red component at late times is clearly visible. Bottom: Bolometric light curve spanning $ugrizYH$. Expected values for r -process heating from Metzger et al. (2010) are shown for comparison, indicating that the observed emission requires few $\times 10^{-2} M_{\odot}$ of r -process ejecta. Error bars are given at the 1σ level in all panels, but may be smaller than the points.

blue wavelengths that leads to a spectrum with a sharper peak than a blackbody. This behavior is also present in our optical spectra (Nicholl et al. 2017).

3.3. Bolometric Light Curve

We construct a bolometric light curve from the $ugrizYH$ data spanning 11 days. We fit the time evolution in each band independently with a linear model and interpolate the magnitudes to a common grid of times. The bolometric luminosity is determined using the integrated total flux at each time step; see Figure 2. The peak bolometric luminosity of $\sim 5 \times 10^{41} \text{ erg s}^{-1}$ at 0.6 days is broadly consistent with the luminosity predicted for r -process heating by a few $\times 10^{-2} M_{\odot}$

ejecta, similar to the original predictions of Metzger et al. (2010) for blue KN emission from Fe-opacity ejecta. The total radiated energy during the first ~ 10 days is $\approx 10^{47}$ erg.

3.4. Qualitative Comparisons to Kilonova Emission

Before exploring detailed models, there are several lines of preliminary evidence that suggest the optical counterpart is an r -process-powered KN. The presence of an initially blue SED, which then transitions to a multi-component SED and finally to a red SED, is strongly suggestive of both blue and red KN emission; this is consistent with lanthanide-poor and rich ejecta components, respectively (Metzger et al. 2010; Barnes & Kasen 2013; Tanaka & Hotokezaka 2013; Metzger & Fernández 2014; Kasen et al. 2015; Wollaeger et al. 2017). Furthermore, the deviations from a pure blackbody spectrum at late times are indicative of the strong UV line blanketing expected for lanthanide-rich material, lending further evidence to the existence of a red KN component. This behavior is also seen in optical/NIR spectra of the transient (Chornock et al. 2017; Nicholl et al. 2017).

The fact that this red component does not initially obscure the emission from a blue component suggests that we require two separate emitting regions with distinct sources of ejecta. If the KN outflow is quasi-spherical, then the blue component must reside *outside* of the material with red emission. Alternatively, if the outflow is not spherically symmetric, the blue and red ejecta should occupy distinct portions of the outflowing solid angle. This feature is suggested in several models that consider lanthanide-rich material ejected in the equatorial plane while the lanthanide-poor material is ejected from the polar regions (Kasen et al. 2015; Metzger 2017).

4. Kilonova Modeling

We test the conjecture that the UV/optical/NIR transient is an r -process KN by fitting several isotropic, one-zone, gray opacity models to the light curves. For each model, we assume a blackbody SED which evolves assuming a constant ejecta velocity until it has reached a minimum temperature, at which point the photosphere has receded into the ejecta and the temperature no longer evolves. A similar temperature “floor” is predicted in Barnes & Kasen (2013), and we include this minimum temperature as a fitted parameter. We additionally fit for a “scatter” term, added in quadrature to all photometric errors, which roughly accounts for additional systematic uncertainties that are not included in our model.

We use `MOSFIT`⁸² (Guillochon et al. 2017; Nicholl et al. 2017), an open-source light curve fitting tool that utilizes a Markov Chain Monte Carlo (MCMC) to sample the model posterior. For each model, we ensure convergence by enforcing a Gelman-Rubin statistic < 1.1 (Gelman & Rubin 1992). We compare models using the Watanabe–Akaike Information Criteria (WAIC; Watanabe 2010; Gelman et al. 2014), which accounts for both the likelihood score and the number of fitted parameters. The best-fit parameters, uncertainties, and WAIC scores for each model are provided in Table 1.

We first attempt a simple supernova model, namely heating by the radioactive decay of ^{56}Ni and Fe-peak opacity of

⁸² <https://github.com/guillochon/MOSFIT>

Figure 3. Top left: fitting the data with a Type I b/c SN model powered by the radioactive decay of ^{56}Ni . This model clearly fails to capture the late-time NIR behavior and requires an unphysically large fraction of the ejecta to be synthesized into nickel ($\sim 75\%$). Top right: fitting the data with a single-component “blue” KN model. Like the SN model, this fit is unable to capture the late-time NIR behavior and overall spectra shape. Bottom left: fitting the data with a single-component “red” KN model. This model clearly fails to capture any of the observed behavior. Bottom right: fitting the data with a single-component KN model with the opacity as a free parameter. Again, this model fails to capture the late-time NIR behavior. This is suggestive of the fact that we need to model multiple ejecta components simultaneously. Error bars are given at the 1σ level in all panels, but may be smaller than the points.

$\kappa = 0.1 \text{ cm}^2 \text{ g}^{-1}$ (see Villar et al. 2017). The model parameters are the ejecta mass and velocity, and the ^{56}Ni mass fraction in the ejecta (as well as the temperature floor and scatter). The best-fit model has $M_{\text{ej}} \approx 0.01 M_{\odot}$, $v_{\text{ej}} \approx 0.26 \text{ c}$, and $f^{\text{Ni}} \approx 0.75$. The parameters are comparable to those we inferred from blackbody fits to the flux and SEDs in the previous section, but the overall fit is poor. In particular, this model severely underestimates the NIR light curves, while the high ^{56}Ni fraction is inconsistent with the optical spectra (Nicholl et al. 2017). We therefore conclude that the transient is not powered by the radioactive decay of ^{56}Ni .

We next turn to r -process heating, using the model outlined in Metzger (2017) and implemented in Villar et al. (2017). This model includes the ejecta mass, ejecta velocity, and opacity as fitted parameters (as well as the temperature floor and scatter). Within this context we first assume an Fe-peak

opacity of $\kappa = 0.1 \text{ cm}^2 \text{ g}^{-1}$ (our “blue” model; e.g., as assumed historically in Li & Paczyński 1998) and fit for the ejecta mass and velocity. This model, with $M_{\text{ej}} \approx 0.03 M_{\odot}$ and $v_{\text{ej}} \approx 0.18 \text{ c}$, adequately describes the early light curves ($\lesssim 3$ days), but again is a poor fit to the NIR light curves. More recent calculations indicate that lanthanide-rich ejecta are expected to have a much higher opacity of $\kappa = 10 \text{ cm}^2 \text{ g}^{-1}$, leading to a “red” KN (e.g., Barnes & Kasen 2013). However, such a model (our “red” model), with best-fit values $M_{\text{ej}} \approx 0.03 M_{\odot}$ and $v_{\text{ej}} \approx 0.27 \text{ c}$, produces a poor fit to the data as well. In particular, the model light curves exhibit an initial rise for ≈ 4 days, in contrast to the observed rapid decline at early times, especially in the UV and blue optical bands. Finally, we allow the opacity to vary as a free parameter, finding a best-fit value of $\kappa \approx 0.82 \text{ cm}^2 \text{ g}^{-1}$, and an associated $M_{\text{ej}} \approx 0.04 M_{\odot}$ and $v_{\text{ej}} \approx 0.27 \text{ c}$. However, this model again

Table 1
Kilonova Model Fits

Model	$M_{\text{ej}}^{\text{blue}}$ (M_{\odot})	$v_{\text{ej}}^{\text{blue}}$ (c)	κ^{blue} ($\text{cm}^2 \text{g}^{-1}$)	$M_{\text{ej}}^{\text{purple}}$ (M_{\odot})	$v_{\text{ej}}^{\text{purple}}$ (c)	κ^{purple} ($\text{cm}^2 \text{g}^{-1}$)	$M_{\text{ej}}^{\text{red}}$ (M_{\odot})	$v_{\text{ej}}^{\text{red}}$ (c)	κ^{red} ($\text{cm}^2 \text{g}^{-1}$)	f^{Ni}	WAIC
2-Comp	$0.014_{-0.001}^{+0.002}$	$0.266_{-0.002}^{+0.007}$	(0.5)	$0.036_{-0.002}^{+0.001}$	$0.123_{-0.014}^{+0.012}$	$3.349_{-0.337}^{+0.364}$...	-102
3-Comp	$0.014_{-0.001}^{+0.002}$	$0.267_{-0.011}^{+0.006}$	(0.5)	$0.034_{-0.002}^{+0.002}$	$0.110_{-0.010}^{+0.011}$	(3.0)	$0.010_{-0.001}^{+0.002}$	$0.160_{-0.025}^{+0.030}$	(10.0)	...	-106

Blue	$0.032_{-0.004}^{+0.002}$	$0.180_{-0.002}^{+0.002}$	(0.1)	17
Red	$0.026_{-0.008}^{+0.010}$	$0.271_{-0.002}^{+0.008}$	(10)	...	153
1-Comp	$0.040_{-0.007}^{+0.002}$	$0.274_{-0.093}^{+0.007}$	$0.817_{-0.135}^{+0.146}$	11

Note. Model parameters and WAIC scores. Numbers in parentheses indicate fixed parameters of the model. The errors represent the 1σ confidence interval. Both the 2-component (“2-Comp”) and 3-component (“3-Comp”) models have significantly smaller WAIC scores (indicating better fits) compared to the four single-component models.

fails to reproduce the initial rapid decline in the UV, as well as the NIR light curves. We therefore conclude that r -process heating with a single value for the opacity cannot explain the observed light-curve evolution and colors. The final light curves for these models can be seen in Figure 3.

Inspired by the multi-component observed SED (Figure 2) and by the failure of single-component models to capture both the early rapid decline and the late-time red colors, we explore two multi-component models: (i) a two-component “blue” ($\kappa = 0.5 \text{ cm}^2 \text{ g}^{-1}$) plus “red” (κ as a free parameter) model; and (ii) a three-component “blue” ($\kappa = 0.5 \text{ cm}^2 \text{ g}^{-1}$) plus “purple” ($\kappa = 3 \text{ cm}^2 \text{ g}^{-1}$) plus “red” ($\kappa = 10 \text{ cm}^2 \text{ g}^{-1}$) model. These values were recently shown by Tanaka et al. (2017) to roughly capture the detailed opacity from radiative transfer simulations. For each component, we leave M_{ej} and v_{ej} as free parameters.

First, we explore the two-component model (with eight free parameters); we vary the ejecta masses, ejecta velocities, and temperature floors, the red component opacity, and a single scatter term. We find that the “blue” component has $M_{\text{ej}}^{\text{blue}} \approx 0.01 M_{\odot}$ and $v_{\text{ej}}^{\text{blue}} \approx 0.27c$ (with errors of roughly 10%), in good agreement with our inference from the SED at early times (Section 3.2). The “red” component has a much larger mass of $M_{\text{ej}}^{\text{red}} \approx 0.04 M_{\odot}$ but a slower velocity of $v_{\text{ej}}^{\text{red}} \approx 0.12 c$. The best-fit opacity of this component is $\kappa \approx 3.3 \text{ cm}^2 \text{ g}^{-1}$, lower than expected for lanthanide-rich ejecta. We find that most of the parameters are uncorrelated, with the exception of the red component’s opacity and ejecta velocity, which have a Pearson correlation coefficient of ~ 0.67 . The resulting parameters and uncertainties from the MCMC fitting are summarized in Table 1.

For the three-component model (with 10 free parameters) we find similar values for the “blue” component ($M_{\text{ej}}^{\text{blue}} \approx 0.01 M_{\odot}$ and $v_{\text{ej}}^{\text{blue}} \approx 0.27 c$) and the “purple” component ($M_{\text{ej}}^{\text{purple}} \approx 0.03 M_{\odot}$ and $v_{\text{ej}}^{\text{purple}} \approx 0.11 c$). The “red” component is subdominant with $M_{\text{ej}}^{\text{red}} \approx 0.01 M_{\odot}$ and $v_{\text{ej}}^{\text{red}} \approx 0.16 c$; see Table 1. These ejecta parameters are consistent with those determined from independent modeling of the optical and NIR spectra (Chornock et al. 2017; Nicholl et al. 2017).

Both sets of models are shown in Figure 1 and are essentially indistinguishable. Both provide a much better fit to the data than the single-component models described above, capturing both the initial blue colors and rapid decline, as well

as the later redder colors and NIR light curves. Their similar WAIC scores suggest that neither model is statistically preferred. The two models differ most drastically at $\lesssim 5$ days in the K_s -band, where the two-component model is double-peaked, while the three-component model is single peaked. While neither model fully captures every feature of the light curves, it is remarkable that these simplified semi-analytic models produce such high-quality fits over a wide range of wavelength and time.

5. Implications

In the multi-component models, we can interpret each component as arising from distinct physical regions within the merger ejecta. In both models, the high velocity of the blue KN ejecta suggests that it originates from the shock-heated polar region created when the neutron stars collide (e.g., Oechslin et al. 2007; Bauswein et al. 2013; Sekiguchi et al. 2016). This dominant blue component is also seen in early-time optical spectra (Nicholl et al. 2017). By contrast, the low velocity red KN component in our three-component model could originate from the dynamically ejected tidal tails in the equatorial plane of the binary (e.g., Rosswog et al. 1999; Hotokezaka et al. 2013), in which case the relatively high ejecta mass $\approx 0.01 M_{\odot}$ suggests an asymmetric mass ratio of the merging binary ($q \lesssim 0.8$; Hotokezaka et al. 2013).

In both multi-component models we find that the $\kappa \approx 3 \text{ cm}^2 \text{ g}^{-1}$ ejecta dominates by mass. The lower velocity of this component suggests an origin in the post-merger accretion disk outflow. Our inferred ejecta mass is consistent with that expected for a massive $\sim 0.1 M_{\odot}$ torus (e.g., Just et al. 2015; Siegel & Metzger 2017). Similarly, the disk outflow composition is predicted to be dominated by $Y_e \sim 0.3$ matter that produces the $\kappa \approx 3 \text{ cm}^2 \text{ g}^{-1}$ component of the KN emission (Tanaka et al. 2017) as we observe. The fitted opacity indicates that the hyper-massive neutron star remnant is relatively short-lived (~ 30 ms; Fernández & Metzger 2013; Just et al. 2015; Kasen et al. 2015). We additionally find that in both models the total kinetic energy is roughly $(1-2) \times 10^{51}$ erg.

The fact that our multi-component models fit the data well provides strong evidence for the production of both light and heavy r -process nuclei, addressing one of the long-standing mysteries in astrophysics (Burbidge et al. 1957; Cameron

1957). We quantify this statement by comparing our blue and red ejecta masses to those necessary to reproduce the Milky Way (MW) r -process production rate. For heavy r -process elements (red KN), the MW inferred production rate is $\dot{M}_{\text{rp}, A \gtrsim 140} \approx 10^{-7} M_{\odot} \text{ yr}^{-1}$ (Bauswein et al. 2014). For light r -process elements (blue KN), the production rate is $\dot{M}_{\text{rp}, A \gtrsim 100} \approx 7 \times 10^{-7} M_{\odot} \text{ yr}^{-1}$ (Qian 2000). Using a conservative estimate on the local BNS merger rate estimated by Abbott et al. (2016), $R_0 \approx 1000 \text{ Gpc}^{-3} \text{ yr}^{-1}$, and a volume density of MW-like galaxies of $\approx 0.01 \text{ Mpc}^{-3}$, we estimate the MW rate of KN as $R_{\text{MW}} \approx 100 \text{ Myr}^{-1}$. Using this MW rate, we find that the average ejecta mass for a red KN is $\dot{M}_{\text{rp}, A \gtrsim 140} / R_{\text{MW}} \approx 0.001 M_{\odot}$ and for a blue KN it is $\dot{M}_{\text{rp}, A \gtrsim 100} / R_{\text{MW}} \approx 0.007 M_{\odot}$. These order-of-magnitude estimates are smaller than our inferred ejecta masses for this event, although the discrepancy can potentially be mitigated when properly taking into account the fraction of r -process materials that remains in a gas phase in the ISM and galactic halo. Nevertheless, this exercise suggests that BNS mergers can reproduce the r -process yields found in the MW and may be a dominant source of cosmic r -process nucleosynthesis.

6. Discussions and Conclusions

We have presented a comprehensive UV, optical, and NIR data set for the first electromagnetic counterpart to be associated with a gravitational wave event. Analysis of these data reveals that the emission is due to an r -process-powered KN consisting of both “blue” and “purple/red” ejecta components. Models with ^{56}Ni heating, Fe-peak opacities, or a single component of r -process opacity fail to match the observations.

Our models indicate that the total ejecta mass is $\approx 0.05 M_{\odot}$, with a high velocity ($v \approx 0.3c$) blue component and a slower ($v \approx 0.1\text{--}0.2c$) purple/red component. The presence of both components and the relatively large ejecta mass suggests that binary neutron star mergers (like GW170817) dominate the cosmic r -process nucleosynthesis.

The data presented in this paper (and others in this series) represent by far the best observations of an r -process powered KN, and it is remarkable how well the observations match theoretical models. This event also marks the true beginning of joint GW–EM multi-messenger astronomy. We expect that this event will serve as a benchmark for future efforts to model and understand the behavior of these transients, and for the first time allow the development of data-driven KN models. The next Advanced LIGO/Virgo observing run (starting in Fall 2018) is expected to detect many more BNS events (Abbott et al. 2016c). The follow-up of these events will provide further understanding of the ubiquity of the features seen in this event, the relationship between event and host properties, and place even stronger constraints on r -process enrichment from BNS mergers.

Note. Summary of photometry from Section 2. Dates are give in days relative to the time of the GW trigger (MJD = 57982.529). Photometry *is not* corrected for extinction. Limits are given at the 3σ level. Error bars are given at the 1σ level.
