3 16 **Abstract** This study investigates linkages between volume change, pore fluid drainage, shear  
4  
5  
6 17 wave velocity, and temperature of soft clays using a thermal triaxial cell equipped with bender  
7  
8 18 elements, a measurement approach that has not been explored widely in past thermo-  
9  
10 19 mechanical studies. Two kaolinite specimens were consolidated mechanically to a normally  
11  
12  
13 20 consolidated state and then subjected to drained and undrained heating-cooling cycles,  
14  
15 21 respectively. After cooling the specimens were subjected to further mechanical consolidation to  
16  
17  
18 22 evaluate changes in apparent preconsolidation stress. Both specimens showed net contractive  
19  
20 23 thermal strains after a heating-cooling cycle and overconsolidated behavior during mechanical  
21  
22  
23 24 compression immediately after cooling. The shear wave velocity increased during drained  
24  
25 25 heating but negligible changes were observed during drained cooling, indicating permanent  
26  
27  
28 26 hardening due to thermal consolidation during the heating-cooling cycle. The shear wave velocity  
29  
30 27 decreased during undrained heating due to a reduction in effective stress associated with  
31  
32  
33 28 thermal pressurization of the pore fluid, but subsequently increased when drainage was  
34  
35 29 permitted at elevated temperature. The shear wave velocity increased slightly during undrained  
36  
37  
38 30 cooling but decreased when drainage was permitted at room temperature. Net increases in  
39  
40 31 small-strain shear modulus of 17 and 11% after heating-cooling cycles under drained and  
41  
42  
43 32 undrained (with drainage after reaching stable temperatures) conditions, respectively, provide  
44  
45 33 further evidence to the potential of thermal soil improvement of normally consolidated clays.  
46  
47 34 Transient changes in shear modulus also highlight the importance of considering drainage  
48  
49  
50 35 conditions and corresponding changes in effective stress state during heating-cooling cycles.

## 1. Introduction

The impact of temperature on the behavior of clay is important to understand in many geotechnical engineering applications but is particularly critical in in-situ heating for soil improvement, also referred to as thermal soil improvement. Thermal soil improvement has been investigated to improve soft clay layers using thermal drains or energy piles (e.g., Abuel-Naga et al. 2006, Pothiraksanon et al. 2010; Samarakoon and McCartney 2020a, 2021; Ghaaowd and McCartney 2021; Ghaaowd et al. 2022). Thermal drains are vertical porous drains (sands or geosynthetic) that include a geothermal heat exchanger and improve soils by providing both a constant temperature and a free drainage boundary condition for thermal consolidation (Samarakoon and McCartney 2022). Energy piles are rigid elements that provide structural support and heat exchange capabilities, and the heat exchange process can be used to enhance the pullout capacity (Ghaaowd et al. 2022). Despite the development of these thermal soil improvement techniques, the mechanisms of thermal soil improvement are still not well understood, including coupled effects of pore fluid pressurization, effective stress changes, shear modulus changes, and volume changes. Accordingly, the objective of this study is to evaluate the impact of drainage conditions and thermo-mechanical loading paths on the thermal volume change and the corresponding changes in the shear modulus of the soil, as well as to evaluate the coupling between thermal pressurization of pore water during undrained heating or cooling, pore water dissipation during drained heating or cooling, and volume change in saturated normally consolidated clay specimens. Further, this study seeks to better understand the transient trends in the important variables during a thermo-mechanical loading path as many previous studies only focused on equilibrium conditions. Information on the transient linkages

1  
2  
3 60 between thermo-mechanical loading paths and soil shear modulus will be useful when  
4  
5  
6 61 determining design parameters in a thermal soil improvement application as well as in the design  
7  
8 62 of energy geostructures.  
9

10  
11 63 Several researchers have investigated the effect of temperature on soil behavior including  
12  
13 64 volume change, shear strength, stiffness, and hydraulic conductivity. Many of these studies were  
14  
15 65 focused on highly overconsolidated clays. General observations were that volumetric strains  
16  
17  
18 66 during drained heating are expansive and elastic for overconsolidated clays, and that the  
19  
20 67 magnitude of thermoelastic volumetric strains is dependent on the effective stress and the  
21  
22  
23 68 overconsolidation ratio (Baldi et al. 1988; Hueckel and Baldi 1990; Abuel-Naga et al. 2007a). On  
24  
25 69 the other hand, fewer studies have focused on normally consolidated clays. General observations  
26  
27  
28 70 are that drained heating results in plastic contractive volumetric strains whereas undrained  
29  
30 71 heating results in elastic expansion (Hueckel and Baldi 1990; Cekerevac and Laloui 2004; Abuel-  
31  
32 72 Naga et al. 2007a; Uchaipichat and Khalili 2009). The contractile thermal volumetric strains  
33  
34  
35 73 observed during drained heating of normally consolidated clays also leads to an increase in  
36  
37  
38 74 undrained shear strength (Houston et al. 1985; Kuntiwattanakul et al. 1995; Abuel-Naga et al.  
39  
40 75 2006; Samarakoon et al. 2018, 2022).  
41

42 76 The drained shear strength was also observed to increase with temperature as a result of the  
43  
44  
45 77 soil being subjected to a temperature history (Cekerevac and Laloui 2004; Abuel-Naga et al.  
46  
47 78 2007b). Alsherif and McCartney (2015) noted that temperature effects on the shear strength of  
48  
49  
50 79 soils also indirectly affects the secant Young's modulus in the axial strain range of 1-3%. The  
51  
52 80 small-strain shear modulus, typically corresponding to shear strains less than 0.001%, is an  
53  
54  
55 81 important parameter needed for characterizing the elastic soil behavior related to geotechnical  
56  
57  
58  
59  
60

1  
2  
3 82 structures such as foundations, tunnels, pavements, deep excavations, and the soil response  
4  
5  
6 83 during earthquakes (Atkinson and Salfors 1991; Mair 1993; Ishihara 1996; Atkinson 2000). At  
7  
8 84 very small strains, the stress-strain behavior of soil is linear elastic with constant shear modulus  
9  
10  
11 85 whereas at higher strains, the soil behavior is observed to be non-linear with reductions in shear  
12  
13 86 modulus with increasing strain (Atkinson 2000). The small-strain shear modulus represents the  
14  
15  
16 87 mechanical response of a soil in its intact state and depends on factors such as void ratio,  
17  
18 88 confining stress, and apparent preconsolidation stress (Hardin and Black 1969; Khosravi and  
19  
20 89 McCartney 2012). In geotechnical engineering applications including the use of in-situ heating for  
21  
22  
23 90 soil improvement (Abuel-Naga et al. 2006, Pothiraksanon et al. 2010; Samarakoon and  
24  
25 91 McCartney 2020a, 2021) as well as energy geostructures such as energy foundations and soil  
26  
27  
28 92 borehole thermal energy storage systems (Brandl 2006, Laloui et al. 2006, Stewart et al. 2014,  
29  
30 93 Murphy et al. 2015), it is expected that the void ratio, effective stress, and apparent  
31  
32  
33 94 preconsolidation stress may change, which indicates that the small-strain shear modulus may be  
34  
35 95 a good indicator of the effects of these parameters which may be difficult to measure directly  
36  
37  
38 96 (i.e., the apparent preconsolidation stress). Most existing thermo-mechanical constitutive  
39  
40 97 models assume that the elastic moduli of soil are independent of temperature (Hueckel and  
41  
42 98 Borsetto 1990; Cui et al. 2000; Laloui and Cekerevac 2003). However, considering the effect of  
43  
44  
45 99 temperature on these parameters will allow for better predictions when designing geotechnical  
46  
47 100 structures subjected to temperature fluctuations. Furthermore, geotechnical structures such as  
48  
49  
50 101 pavements and other earthen structures are also subjected to fluctuations in temperature due  
51  
52 102 to climate effects (McCartney and Khosravi 2013; Vahedifard et al. 2020), so an understanding of  
53  
54  
55 103 the effects of temperature on the small-strain shear modulus may be useful in these applications.  
56  
57  
58  
59  
60

1  
2  
3 104 A limited number of studies have been conducted on the effect of temperature on the elastic  
4  
5  
6 105 moduli of soil (Young's modulus or shear modulus) defined at strains less than 0.001%. The effect  
7  
8 106 of temperature and thermal cycles on the small-strain shear modulus of saturated lateritic clay  
9  
10  
11 107 were investigated by Bentil and Zhou (2022) using a temperature-controlled oedometer setup  
12  
13 108 equipped with bender elements. It was observed that for a given vertical effective stress, the  
14  
15  
16 109 small-strain shear modulus at 40 °C was lower compared to its value at 5 °C. However, the small-  
17  
18 110 strain shear modulus was found to increase by about 16% for normally consolidated specimens  
19  
20 111 after being subjected to four thermal cycles ranging from 5 – 40 °C. Other have studied the effects  
21  
22  
23 112 of temperature on the secant Young's modulus of soils at higher strains, which can be related to  
24  
25 113 the secant shear modulus via the Poisson's ratio. Kuntiwattanakul et al. (1995) and Cekerevac  
26  
27  
28 114 and Laloui (2004) used triaxial tests to investigate the effects of temperature on the secant  
29  
30 115 Young's modulus of Kaolin clay at larger strains. The secant shear modulus was obtained at a  
31  
32  
33 116 strain of 0.1% in the study by Kuntiwattanakul et al. (1995) for a temperature range of 0 – 90 °C  
34  
35 117 whereas Cekerevac and Laloui (2004) determined the secant Young's modulus for an axial strain  
36  
37  
38 118 of 0.5% at temperatures ranging from 22 – 90 °C. In both studies, the secant Young's modulus  
39  
40 119 was found to increase with increasing temperature. Similar observations were made by Abuel-  
41  
42  
43 120 Naga et al. (2006) for Bangkok clay where the secant modulus was measured at different  
44  
45 121 deviatoric stress ratios corresponding to axial strains between 0.01% and 6%.

46  
47 122 The discrepancies observed in the limited data on soil stiffness parameters may arise due to  
48  
49 123 the differences in the stress or strain states, temperatures and drainage conditions used in the  
50  
51  
52 124 studies. For instance, at higher temperatures, the thermal volume change and its effects on soil  
53  
54  
55 125 stiffness can be more significant. On the other hand, heating and shearing under undrained

1  
2  
3 126 conditions will lead to generation of excess pore water pressure, reducing the effective stress of  
4  
5  
6 127 the clay which in turn will decrease the shear modulus. Furthermore, measuring the secant  
7  
8 128 modulus at higher strain levels may incorporate thermo-plasticity effects and soil fabric changes.  
9  
10 129 In addition, the elastic moduli of soil may also be dependent on the mechanical and thermal  
11  
12  
13 130 loading paths. For example, Bentil and Zhou (2022) saw a difference of about 8% in the small-  
14  
15 131 strain shear modulus of a saturated lateritic clay specimen subjected to a compression-cooling  
16  
17  
18 132 path vs. a cooling-compression path. Vahedifard et al. (2020) found a negligible change in small-  
19  
20 133 strain shear modulus of a saturated, compacted silt with an increase in temperature of 20 °C but  
21  
22  
23 134 found decreases in small-strain shear modulus during heating of unsaturated, compacted silt  
24  
25 135 with increasing suction. In view of the limited studies available in literature and the  
26  
27  
28 136 inconsistencies observed in reported data, further investigation is required to better understand  
29  
30 137 the effects of temperature on the small-strain elastic moduli of normally consolidated clay. To  
31  
32  
33 138 that end, this study focuses on the effect of a heating-cooling cycle on the volume change and  
34  
35 139 small strain shear modulus of normally consolidated clay using drained and undrained thermal  
36  
37  
38 140 triaxial tests in a cell that incorporates bender elements into the top and bottom platens.

39  
40 141 Bender elements are widely used in laboratory testing to measure shear wave velocity in soils  
41  
42 142 and have been integrated into many standard geotechnical laboratory testing devices including  
43  
44  
45 143 triaxial and oedometer cells (Shirley and Hampton 1978; Dyvik and Madshus 1985; Fam and  
46  
47 144 Santamarina 1995; Viggiani and Atkinson 1995; Pennington et al. 2001; Ghayoomi and McCartney  
48  
49  
50 145 2011). Bender elements are piezoelectric bending actuators which can convert electrical energy  
51  
52 146 to mechanical energy and vice versa. The transmitting element is excited with a small voltage  
53  
54  
55 147 where it generates a bending motion to induce a vertically propagating shear wave (or s-wave)

1  
2  
3 148 in a soil layer. The vibration propagating through the soil is detected by the receiver element that  
4  
5  
6 149 outputs a voltage signal. The transmitted and the received waveforms can be used to obtain the  
7  
8 150 shear wave velocity. The shear wave velocity ( $V_s$ ) is calculated using the time required for the  
9  
10 151 wave to travel from the transmitter to the receiver and the tip-to-tip distance between benders:

$$12 \quad 13 \quad 14 \quad 15 \quad 16 \quad 17 \quad 18 \quad 19 \quad 20 \quad 21 \quad 22 \quad 23 \quad 24 \quad 25 \quad 26 \quad 27 \quad 28 \quad 29 \quad 30 \quad 31 \quad 32 \quad 33 \quad 34 \quad 35 \quad 36 \quad 37 \quad 38 \quad 39 \quad 40 \quad 41 \quad 42 \quad 43 \quad 44 \quad 45 \quad 46 \quad 47 \quad 48 \quad 49 \quad 50 \quad 51 \quad 52 \quad 53 \quad 54 \quad 55 \quad 56 \quad 57 \quad 58 \quad 59 \quad 60$$

$$152 \quad V_s = \frac{\text{tip-to-tip distance}}{\text{travel time}} \quad (1)$$

16 153 The small strain shear modulus ( $G_0$ ) can be obtained using the following relationship where  $\rho$   
17  
18 154 is the total density of the soil (Hardin and Blandford 1989):

$$20 \quad 21 \quad 22 \quad 23 \quad 24 \quad 25 \quad 26 \quad 27 \quad 28 \quad 29 \quad 30 \quad 31 \quad 32 \quad 33 \quad 34 \quad 35 \quad 36 \quad 37 \quad 38 \quad 39 \quad 40 \quad 41 \quad 42 \quad 43 \quad 44 \quad 45 \quad 46 \quad 47 \quad 48 \quad 49 \quad 50 \quad 51 \quad 52 \quad 53 \quad 54 \quad 55 \quad 56 \quad 57 \quad 58 \quad 59 \quad 60$$

$$21 \quad 155 \quad G_0 = \rho V_s^2 \quad (2)$$

23 156 The total density of the soil can be estimated using the following relationship:

$$25 \quad 26 \quad 27 \quad 28 \quad 29 \quad 30 \quad 31 \quad 32 \quad 33 \quad 34 \quad 35 \quad 36 \quad 37 \quad 38 \quad 39 \quad 40 \quad 41 \quad 42 \quad 43 \quad 44 \quad 45 \quad 46 \quad 47 \quad 48 \quad 49 \quad 50 \quad 51 \quad 52 \quad 53 \quad 54 \quad 55 \quad 56 \quad 57 \quad 58 \quad 59 \quad 60$$

$$26 \quad 157 \quad \rho = \frac{(G_s + Se)\rho_w}{1 + e} \quad (3)$$

29 158 where  $G_s$  is the specific gravity of the soil,  $S$  is the degree of saturation (equal to 1 for the  
30  
31 159 saturated clay in this study),  $e$  is the void ratio, and  $\rho_w$  is the density of water. The form of  
32  
33  
34 160 Equation (2) indicates that changes in total density of the soil due to thermal volume changes  
35  
36 161 (i.e., changes in void ratio) may affect the value of  $G_0$  calculated from the value of  $V_s$  in addition  
37  
38 162 to the changes in tip-to-tip distance associated with the calculation of the value of  $V_s$ .  
39  
40  
41 163 Accordingly, thermal volume change and  $G_0$  should be closely linked. The density of water in  
42  
43  
44 164 Equation (3) varies with temperature as follows (Hillel 1981):

$$45 \quad 46 \quad 47 \quad 48 \quad 49 \quad 50 \quad 51 \quad 52 \quad 53 \quad 54 \quad 55 \quad 56 \quad 57 \quad 58 \quad 59 \quad 60$$

$$46 \quad 165 \quad \rho_w = 1 - 7.37 \times (10^{-6}) \times (T - 4)^2 + 3.79 \times (10^{-8}) \times (T - 4)^3 \quad (4)$$

48 166 where  $\rho_w$  has units of  $\text{g/m}^3$  and  $T$  is in  $^\circ\text{C}$ . While the effects of temperature on  $\rho_w$  cancel out in  
49  
50  
51 167  $\rho_w G_s$  in the first term of the numerator in Equation (3), they are still present in the second term  
52  
53  
54 168 of the numerator in Equation (3) and should be included in the calculation of total density. It  
55  
56 169 should be noted that the effects of temperature on the water density are more important in

1  
2  
3 170 drained conditions as the water entering or exiting the specimen may have a different density  
4  
5  
6 171 after temperature changes, while in undrained conditions the mass is constant and only the  
7  
8 172 volume of the specimen changes.  
9

10  
11 173 Relationships for  $G_0$  such as those developed by Hardin and Black (1969) and Khosravi and  
12  
13 174 McCartney (2012) indicate that  $G_0$  is not only sensitive to the void ratio but also to the effective  
14  
15 175 stress state and preconsolidation stress. For example, these values follow the power law  
16  
17 176 relationship of Hardin and Black (1966) expressed as follows, neglecting the effects of void ratio  
18  
19 177 and overconsolidation ratio:  
20  
21

$$G_0 = AP_{atm} \left( \frac{\sigma'_{mean}}{P_{atm}} \right)^n \quad (5)$$

22  
23  
24  
25  
26 178 where  $\sigma'_{mean}$  is the mean effective normal stress,  $P_{atm}$  is the atmospheric pressure (101.3 kPa),  
27  
28 179 and  $A$  and  $n$  are dimensionless fitting parameters. The presence of effective stress in Equation (5)  
29  
30 180 indicates further possible linkages between  $G_0$  and thermal processes as it is well known that  
31  
32 181 heating of saturated normally consolidated clays will lead to thermal pressurization which may  
33  
34 182 change the effective stress state (Uchaipchat and Khalili 2009; Ghaaowd et al. 2017) and the  
35  
36 183 apparent preconsolidation stress (Uchaipchat and Khalili 2009; Samarakoon and McCartney  
37  
38 184 2020b). As noted, heating and cooling of clays will also result in changes in void ratio (Campanella  
39  
40 185 and Mitchell 1968; Hueckel and Baldi 1990).  
41  
42  
43  
44  
45

46 186 Compression wave velocities can be determined using uniaxial piezoelectric actuators in a  
47  
48 187 similar manner to the shear wave velocities from bender elements, by imparting a vertically  
49  
50 188 propagating compressive pulse on a soil layer. However, the compression wave velocity in  
51  
52 189 saturated soils is typically not measured for saturated soils because the pore water has a higher  
53  
54 190 compressive wave velocity than the soil skeleton (Valle-Molina and Stokoe 2012). Consequently,  
55  
56  
57  
58  
59  
60

1  
2  
3 191 the changes in compression wave velocity are not examined in this study. Materials tested,  
4  
5  
6 192 experimental procedures and the results of this study are discussed in the following sections.

## 8 193 **2. Material and Test Methods**

### 10 194 **2.1. Material**

13 195 This study was conducted on Kaolinite clay obtained from M&M Clays Inc. of McIntyre, GA.  
14  
15 196 The properties of the clay are summarized in Table 1, including the compression indices obtained  
16  
17  
18 197 from an isotropic compression test at room temperature. The clay specimens evaluated in this  
19  
20 198 study were prepared by mixing clay powder with deionized water in a commercial planetary  
21  
22  
23 199 mixer to form a slurry with a gravimetric water content of 115%. The slurry was then poured into  
24  
25 200 a steel hollow cylinder of diameter 88.9 mm with porous stones and filter paper placed at the  
26  
27  
28 201 top and bottom. The slurry was first consolidated using a compression frame at a constant rate  
29  
30 202 of 0.04mm/min for 48 hours. Then it was subjected to constant vertical stresses of 26, 52, 103  
31  
32 203 and 181 kPa in 24 hour-long increments. The sedimented clay layer was extracted and trimmed  
33  
34  
35 204 to a smaller cylindrical specimen with a diameter of 72.4 mm and a height of 73 mm.

### 37 205 **2.2. Experimental Set-up**

40 206 A triaxial cell with a cell pressure capacity of 4 MPa and internal instrumentation obtained  
41  
42 207 from GDS Instruments of Hook, UK was modified to perform temperature-controlled tests. The  
43  
44  
45 208 internal instrumentation includes a linearly variable differential transformer (LVDT) to measure  
46  
47 209 the axial displacement of the specimen (suitable for pressures up to 3500 kPa and a temperature  
48  
49  
50 210 range of -20 to 110 °C), as well as piezoelectric bender elements embedded in the top and bottom  
51  
52 211 caps to measure the compressional and shear wave velocities of the specimen. While the thermal  
53  
54  
55 212 triaxial system has an additional LVDT for measuring the radial displacement of the specimen,

1  
2  
3 213 this system could not be effectively mounted to the soft clay specimen, so only the axial  
4  
5 214 deformation was measured, even though Samarakoon et al. (2022) noted that anisotropic  
6  
7 215 thermal volume changes may occur in the clay. A pore water pressure transducer was used to  
8  
9 216 monitor the changes in pore water pressure at the bottom of the specimen. Temperature control  
10  
11 217 was achieved by circulating the cell fluid through a closed-loop copper heat exchanger that was  
12  
13 218 embedded within a Julabo heat pump (model DYNEO DD-600F). The cell fluid was circulated using  
14  
15 219 a high pressure, high temperature, circulating pump used in solar thermal panel applications  
16  
17 220 (model S5 from US Solar Pumps). The closed-loop heat exchanger was connected to the top and  
18  
19 221 bottom of the cell to mix the cell fluid and ensure uniform temperatures within the cell. The  
20  
21 222 triaxial cell and the heat exchanger sections exposed to the environment were covered with  
22  
23 223 insulation. The cell fluid temperature was measured using a thermocouple inserted at the top of  
24  
25 224 the cell. It was assumed that the measured cell fluid temperature is representative of the  
26  
27 225 specimen temperature. The cell and back pressures were controlled using a pressure panel. A  
28  
29 226 picture and schematic of the thermal triaxial system are shown in Figure 1.

30  
31 227 It is important to characterize the thermal deflections of the triaxial system during an  
32  
33 228 application of temperatures as the mounts for the LVDT may expand and contract. Machine  
34  
35 229 deflections due to temperature were obtained by using a dummy Aluminum specimen (linear  
36  
37 230 thermal expansion coefficient,  $\alpha$  of  $2.3 \times 10^{-5}$  m/m°C) of height of 71.2 mm and diameter of  
38  
39 231 71.11 mm. The aluminum dummy specimen had recesses around the bender elements for  
40  
41 232 protection during the machine deflection tests. The machine deflections for the thermal triaxial  
42  
43 233 system obtained from a test where a heating-cooling cycle was applied to the cell containing the  
44  
45 234 aluminum dummy specimen with incremental temperature changes from 23 to 63 °C are shown  
46  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 235 in Figure 2. The maximum temperature applied in the machine deflection test was the same as  
4  
5  
6 236 that used in the tests on soils. The machine deflections were calculated by subtracting the known  
7  
8 237 elastic thermal deflections of the aluminum dummy specimen from the measured LVDT readings  
9  
10 238 (raw displacement in Fig. 2). The machine deflections can then be used to correct the LVDT  
11  
12  
13 239 readings obtained in tests on soils.

### 14 15 240 **2.3. Procedure**

16  
17  
18 241 The trimmed clay specimen was placed atop the bottom pedestal of the thermal triaxial cell,  
19  
20 242 carefully pushing the bender element in the base pedestal into the soft clay specimen to ensure  
21  
22  
23 243 intimate contact. The specimen was then encased within a Neoflex membrane from Karol  
24  
25 244 Warner. The Neoflex membrane is made from pure latex coated with a layer of neoprene that  
26  
27  
28 245 can be used to temperatures up to 120 °C. The top cap was then carefully pushed into the top of  
29  
30 246 the specimen, taking care that the bender element was aligned with the bottom bender element.  
31  
32  
33 247 After assembly of the internal LVDT and filling of the cell and heat exchange system with water,  
34  
35 248 the specimen was back-pressure saturated by applying cell pressure and back-pressure in stages  
36  
37  
38 249 until the Skempton's pore water pressure parameter B value was at least 0.95. The specimen was  
39  
40 250 then isotropically consolidated in stages to a mean effective stress of 250 kPa, which corresponds  
41  
42  
43 251 to normally-consolidated conditions. After mechanical consolidation, the specimen was  
44  
45 252 subjected to a heating-cooling cycle, then compressed further to high stresses to measure any  
46  
47  
48 253 changes in mean apparent preconsolidation stress.

49  
50 254 Two kaolinite specimens were tested in this study: one subjected to a drained heating-cooling  
51  
52 255 cycle and the other subjected to an undrained heating-cooling cycle that included drainage stages  
53  
54  
55 256 after reaching a stable temperature after heating and after cooling, respectively. The purpose of

1  
2  
3 257 performing these tests is to evaluate the impact of drainage conditions on the thermal volume  
4  
5  
6 258 change of the soil, and to evaluate the coupling between thermal pressurization of pore water,  
7  
8 259 pore water dissipation, and volume change in the specimens. Schematics of the thermo-  
9  
10 260 mechanical paths for the drained and undrained tests are shown in Figures 3(a) and 3(b),  
11  
12  
13 261 respectively. Both specimens were first consolidated to normally-consolidated conditions (paths  
14  
15 262 A-B and A'-B', respectively). For the specimen with drained heating (path B-C in Fig. 3(a)), the  
16  
17  
18 263 temperature was increased from 23 °C to 63 °C at a rate of 0.3 °C/hr that was sufficient to  
19  
20 264 minimize the generation of thermally-induced excess pore water pressure within the specimen  
21  
22  
23 265 such that no change in mean effective stress occurs. After the temperature and axial displacement  
24  
25 266 of the specimen were confirmed to be stable, the specimen was cooled back to room  
26  
27  
28 267 temperature (path C-D) at the same rate. Following this heating-cooling cycle, the specimen was  
29  
30 268 isotropically compressed to a mean effective stress of 393 kPa (path D-E in Fig. 3(a)).

31  
32 269 In the undrained heating-cooling test, drainage valves were closed during heating and cooling  
33  
34  
35 270 and the pore water pressure was measured at the base of the specimen. After stabilization of the  
36  
37  
38 271 pore water pressures during each stage of undrained heating and cooling, drainage was  
39  
40 272 permitted only from the top of the specimen to track dissipation of thermally induced excess  
41  
42  
43 273 pore water pressure at the base. For the specimen with undrained heating (path B'-C' in Fig. 3(b)),  
44  
45 274 the temperature was increased rapidly at a rate of 22 °C/hr to 63 °C from room temperature  
46  
47  
48 275 which was maintained until the thermally induced excess pore water pressure was observed to  
49  
50 276 stabilize (approximately 80 hrs). The top drain valve was then opened to permit the specimen to  
51  
52 277 drain after heating (path C'-D' in Fig. 3(b)). The specimen was then subjected to undrained cooling  
53  
54  
55 278 (path D'-E' in Fig. 3(b)) at the same rate as heating. The top drain valve was then opened again

1  
2  
3 279 to permit the specimen to drain after cooling (path E'-F'). Isotropic compression up to a mean  
4  
5  
6 280 effective stress of 393 kPa after a heating-cooling cycle is shown as path F'-G' in Figure 3(b).  
7

8 281 The shear wave velocity was determined using bender elements following ASTM D8295-19 as  
9  
10 282 closely as possible, and the shear modulus was calculated from the shear wave velocity and  
11  
12  
13 283 current value of total density using Equation (2). A deviation from the standard is that the  
14  
15 284 specimen height/diameter ratio was 1:1 to facilitate reasonable times for the thermo-hydraulic  
16  
17  
18 285 processes, but different from typical applications of bender elements in triaxial cells, no shear  
19  
20 286 stress was applied in the isotropic tests reported in this study. Shear wave velocity measurements  
21  
22  
23 287 were performed during each stage of testing and were analyzed using the GDS Bender Element  
24  
25 288 Software. A sinusoidal wave with an amplitude of 14 V and excitation frequency 200 kHz was  
26  
27  
28 289 transmitted through the specimen. The arrival time was determined using the position of the first  
29  
30 290 major peak of the received signal. The tip-to-tip distance at a given time was determined based  
31  
32  
33 291 on the initial height of the specimen and the axial displacement measured from the LVDT. Typical  
34  
35 292 transmitted and received shear wave signals from the pair of bender elements in the triaxial cell  
36  
37  
38 293 are shown in Figure 4. Despite the short travel distance in the specimens, clean signals like those  
39  
40 294 shown in Figure 4 were consistently obtained during the tests and no effect of temperature on  
41  
42 295 the bender elements themselves was detected.  
43  
44

### 45 296 **3. Experimental Results**

#### 46 47 297 **3.1. Typical Time Series Results**

48  
49 298 Time series of axial strain and temperature during the heating-cooling cycles for the two  
50  
51  
52 299 specimens are shown in Figure 5, where compressive strains are defined as positive. The key  
53  
54  
55 300 transition points in these time series are labelled using the same notation as in Figure 3. The  
56  
57  
58  
59  
60

1  
2  
3 301 mean effective stress in both specimens at the onset of the heating-cooling phase was  
4  
5  
6 302  $p'=250$  kPa. The results for the specimen experiencing a drained heating-cooling cycle are shown  
7  
8 303 in Figure 5(a). The axial strain increases to 0.32% as the temperature increases followed by a  
9  
10 304 slight decrease to 0.28% after drained cooling. The fact that thermal axial strains only occur  
11  
12 305 during the applied changes in temperature confirms that the rate of heating used in this test was  
13  
14 306 sufficient for the soil to be fully drained during heating and cooling. The axial strain of 0.28% at  
15  
16 307 the end of the drained heating-cooling cycle confirms permanent contraction of the soil. The  
17  
18 308 results for the specimen experiencing an undrained heating-cooling cycle are shown in  
19  
20 309 Figure 5(b). The axial strain is observed to decrease to -0.32% as the temperature increases,  
21  
22 310 corresponding to undrained expansion. Once the specimen is allowed to drain at the elevated  
23  
24 311 temperature the specimen contracts to an axial strain of 0.23%. This is slightly smaller than the  
25  
26 312 axial strain observed in the test with drained heating. During undrained cooling, the specimen  
27  
28 313 contracts further to an axial strain of 0.47%. Once the specimen is allowed to drain at room  
29  
30 314 temperature, the specimen expands slightly to an axial strain of 0.39%. The thermal axial strain  
31  
32 315 after an undrained heating-cooling cycle with drainage permitted after the heating and cooling  
33  
34 316 stages is 0.39%, which is greater than that observed in the drained heating-cooling cycle. This  
35  
36 317 difference is attributed to the effective stress in the specimen at the onset of drainage.  
37  
38  
39  
40  
41  
42  
43  
44

45 318 Time series of excess pore water pressure during the two tests are shown in Figure 6. The  
46  
47 319 excess pore water pressure generated during the test on the specimen with a drained heating-  
48  
49 320 cooling cycle is negligible with fluctuations between 1-2 kPa in Figure 6(a). During undrained  
50  
51 321 heating a much larger thermally induced excess pore water pressure of 218 kPa is generated as  
52  
53 322 observed in Figure 6(b), corresponding to a decrease in mean effective stress. After the specimen  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 323 is allowed to drain under elevated temperatures, these pore water pressures dissipate back to  
4  
5  
6 324 zero, corresponding to an increase in effective stress back to the original value. During undrained  
7  
8 325 cooling the excess pore water pressures decrease to -102 kPa, corresponding to an increase in  
9  
10 326 mean effective stress. After the specimen is allowed to drain at room temperature the excess  
11  
12  
13 327 pore water pressures dissipate again back to zero. The temperatures presented were measured  
14  
15 328 using a thermocouple inserted at the top of the cell, and it is assumed that the cell fluid  
16  
17  
18 329 temperature is representative of the specimen temperature (i.e., it is assumed that the  
19  
20 330 temperature is homogeneous throughout the specimen). However, the use of multiple  
21  
22  
23 331 thermocouples in future tests may provide a better estimate of the temperature distribution  
24  
25 332 within the specimen and whether a temperature gradient exists within the specimen due to the  
26  
27  
28 333 high thermal conductivity of the metallic base pedestal.

29  
30 334 The axial strains from Figure 5(b) and the excess pore water pressures from Figure 6(b) from  
31  
32 335 the undrained heating-cooling test are shown in Figure 7 to demonstrate the linkage between  
33  
34  
35 336 these variables. This figure is included to confirm that when the temperature is increased or  
36  
37  
38 337 decreased rapidly in undrained conditions, both the axial strains and excess pore water pressures  
39  
40 338 will take some time to stabilize. Uchaipichat and Khalili (2009) observed that during undrained  
41  
42 339 heating, the thermal expansion and decrease in effective stress correspond to movement along  
43  
44  
45 340 a recompression line, but the results in this figure indicate that movement along this  
46  
47  
48 341 recompression line will be a time dependent process.

### 342 **3.2. Shear Wave Velocity Measurements**

343  
344 The measured shear wave velocities and the corresponding thermal axial strains for the  
drained and undrained tests are shown in Figures 8(a) and 8(b), respectively. The key transition

1  
2  
3 345 points from Figure 3 are labelled in these figures next to the shear wave velocity values for  
4  
5  
6 346 simplicity. For the specimen subjected to a drained heating-cooling cycle, the shear wave velocity  
7  
8 347 increases with temperature by 17 m/s and remained almost constant during cooling. This  
9  
10 348 increase can be attributed to the plastic thermal strains observed in the clay specimen. The  
11  
12  
13 349 results for shear wave velocity and the thermal axial strain for the specimen subjected to an  
14  
15 350 undrained heating-cooling cycle is shown in Figure 8(b). During undrained heating the shear wave  
16  
17  
18 351 velocity is observed to decrease with temperature by 96 m/s. However, during drainage at  
19  
20 352 elevated temperature, the shear wave velocity increases again by 34 m/s. A slight increase in  
21  
22  
23 353 velocity is observed during undrained cooling which again is reduced during drainage after  
24  
25 354 cooling. A net increase of about 12 m/s is observed after the heating-cooling cycle including the  
26  
27  
28 355 drainage stages after each heating and cooling stages. The differences in the initial shear wave  
29  
30 356 velocity of the two specimens are attributed to the differences in the initial conditions of the  
31  
32  
33 357 sedimented specimens, which had slightly different initial void ratios. Despite this difference, the  
34  
35 358 results from the long-duration tests on both specimens follow expectations from our current  
36  
37  
38 359 understanding of thermal volume change and thermal pressurization and provides useful insight  
39  
40 360 into the differences in behavior expected for drained and undrained heating-cooling cycles which  
41  
42  
43 361 is an important aspect to be considered in the design of energy geostructures.

#### 362 **4. Analysis**

##### 363 **4.1. Thermal Strains**

364 The change in thermal axial strain with temperature is shown in Figure 9(a) for the drained  
365 test and in Figure 9(b) for the undrained test. The key transition points from Figure 3 are labelled  
366 in these figures. Compressive strains observed during drained heating and the slight elastic

1  
2  
3 367 expansion during cooling agree with the observations made in literature for normally  
4  
5  
6 368 consolidated clays (Hueckel and Baldi 1990; Cekerevac and Laloui 2004; Abuel-Naga et al. 2007a).  
7  
8 369 The net change in axial strain after a drained heating-cooling cycle was 0.28% and was observed  
9  
10 370 to be contractive. The specimen subjected to an undrained heating-cooling cycle also observed  
11  
12  
13 371 a net contraction of 0.39%, which was slightly greater than that obtained from a drained heating-  
14  
15 372 cooling cycle. The dissipation of thermally induced excess pore water pressure during undrained  
16  
17  
18 373 heating and cooling may have contributed to the increase in the axial displacement observed.

19  
20 374 The overall time series of axial strain and temperature for the specimen subjected to a  
21  
22  
23 375 drained heating-cooling cycle including the initial and final compression stages are shown in  
24  
25 376 Figure 10(a) and the corresponding compression curve is shown in Figure 10(b). The key  
26  
27  
28 377 transition points from Figure 3(a) are labelled in these figures. The axial strain of the specimen  
29  
30 378 after consolidation under an isotropic load of 250 kPa is 3.3% as shown in Figure 10(a). As a result  
31  
32 379 of being subjected to drained heating, the axial strain of the specimen increases to 3.6% then  
33  
34  
35 380 reduces slightly to 3.5% after drained cooling. After further mechanical compression up to a  
36  
37  
38 381 mean effective stress of 393 kPa, the specimen experienced an axial strain of 4.4%.  
39  
40 382 Overconsolidated behavior can be observed in the compression curve in Figure 10(b) as the  
41  
42  
43 383 specimen is subjected to mechanical compression after a heating-cooling cycle, although the  
44  
45 384 specimen was at a normally consolidated state prior to heating. The specimen regains a normally  
46  
47  
48 385 consolidated state at a higher stress state upon further loading. This stress state can be  
49  
50 386 approximated as 300 kPa although additional data points will provide a more accurate estimate.  
51  
52 387 Nevertheless, this observation conforms the thermal hardening behavior observed in literature  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 388 (Hueckel and Borsetto 1990; Abuel-Naga et al. 2007a) where the yield surface expands after a  
4  
5  
6 389 heating-cooling cycle.

7  
8 390 The overall time series of axial strain and temperature for the specimen subjected to a  
9  
10 391 undrained heating-cooling cycle including the initial and final compression stages are shown in  
11  
12 392 Figure 11(a) and the corresponding compression curve is shown in Figure 11(b). The key  
13  
14 393 transition points from Figure 3(b) are included in these figures. The time series results of axial  
15  
16 394 strain indicates that the specimen has an axial strain of 3.7% after isotropic consolidation under  
17  
18 395 a mechanical load of 250 kPa. During undrained heating, the axial strain decreases to 3.4% then  
19  
20 396 increases to 3.9% following drainage at elevated temperature. Undrained cooling leads to an  
21  
22 397 increase in axial strain up to 4.2% but then is reduced to 4.1% after drainage at room  
23  
24 398 temperature. The specimen had a final axial strain of 4.4% after being subjected to further  
25  
26 399 mechanical compression up to 393 kPa. The corresponding compression curve is shown in Figure  
27  
28 400 11(b). Consistent with the observations of Uchaipichat and Khalili (2009), elastic expansion along  
29  
30 401 the recompression line is observed during undrained heating. Similar observations were made  
31  
32 402 by Ghaaowd et al. (2017) during undrained heating of the same kaolinite clay. Upon further  
33  
34 403 mechanical compression after cooling the observed results were similar to those of the specimen  
35  
36 404 subjected to drained heating and cooling, where overconsolidated behavior is observed after  
37  
38 405 cooling. Interestingly, the contraction during undrained cooling is observed to fall onto the same  
39  
40 406 path of the compression curve where the specimen displayed overconsolidated behavior during  
41  
42 407 mechanical compression after cooling. The effective stress is higher during this stage due to the  
43  
44 408 negative excess pore water pressures generated during undrained cooling. However, once the  
45  
46  
47  
48  
49  
50

55  
56  
57  
58  
59  
60

1  
2  
3 409 specimen was allowed to drain, the excess pore water pressures dissipated and the specimen  
4  
5  
6 410 regains its previous stress state.

7  
8 411 The compression curves in terms of volumetric strain for the drained and undrained  
9  
10 412 specimens are shown in Figures 12(a) and 12(b), respectively where the volumetric strain was  
11  
12  
13 413 calculated using the axial strain results. The key transition points from Figure 3 are labelled in  
14  
15 414 these figures. Although radial strains are expected to be higher than axial strains because of the  
16  
17  
18 415 specimen preparation process (Samarakoon et al. 2022), a simplified approach assuming  
19  
20 416 isotropic conditions was used to estimate the volumetric strain where the volumetric strain was  
21  
22  
23 417 assumed to be equal to 3 times the measured axial strain.

#### 24 25 418 **4.2. Small Strain Shear Modulus Estimates**

26  
27  
28 419 Calculation of the variations in small-strain shear modulus from the measured shear wave  
29  
30 420 velocity must include the impacts of thermal volume change on the total density. Accordingly,  
31  
32 421 the variations in total density were calculated using Equation (3) by converting the volumetric  
33  
34  
35 422 strains in Figure 12 into void ratio and accounting for the impact of temperature on the water  
36  
37  
38 423 density using Equation (4). In drained conditions, the changes in volume of the specimen will be  
39  
40 424 equal to the volume of water flowing in or out of the specimen as it is water saturated, but the  
41  
42 425 water density will change with temperature. In undrained conditions, the mass of the specimen  
43  
44  
45 426 is constant while the volume of the specimen is measured directly. The calculated total densities  
46  
47 427 for the drained and undrained specimens during the different stages of the test are shown in  
48  
49  
50 428 Figures 13(a) and 13(b), respectively. The key transition points from Figure 3 are included in these  
51  
52 429 figures. The trends in total densities are similar to the trends in the axial strains shown in Figure 8,  
53  
54  
55 430 which implies that including the effect of temperature on the water density in the calculation of  
56  
57  
58  
59  
60

1  
2  
3 431 the total density is negligible compared to the effect of thermal volume changes but can be  
4  
5  
6 432 considered for completeness.

7  
8 433 The values of  $G_0$  were then calculated for the two specimens using the measured shear  
9  
10 434 modulus and the estimated total density using Equation (2). The calculated changes in  $G_0$  and  
11  
12 435 thermal volumetric strain with temperature for the drained heating-cooling test are shown in  
13  
14 436 Figure 14(a), along with the key transition points from Figure 3(a) shown next to the transitions  
15  
16 437 in  $G_0$ . Like the shear wave velocity, the shear strain modulus increases during drained heating but  
17  
18 438 shows no significant change during drained cooling. The thermal volumetric strain after a drained  
19  
20 439 heating-cooling cycle is 0.84% whereas the corresponding increase in small strain shear modulus  
21  
22 440 is 14%. This increase can be attributed to the plastic thermal strains observed and the  
23  
24 441 corresponding increase in density (0.4% increase after a heating-cooling cycle) in the clay  
25  
26 442 specimen (Eq. (2)). Samarakoon et al. (2022) also observed an increase in undrained shear  
27  
28 443 strength in specimens subjected to drained heating. The trends in Figure 14(a) are also similar to  
29  
30 444 trends in  $G_0$  measured for an unsaturated silt during drying and wetting by Khosravi and  
31  
32 445 McCartney (2012) indicating that the permanent change in  $G_0$  could be associated with both the  
33  
34 446 thermal volume change and the change in apparent preconsolidation stress. The calculated  
35  
36 447 values of  $G_0$  and the corresponding thermal volumetric strains for the specimen subjected to an  
37  
38 448 undrained heating-cooling cycle are shown in Figure 14(b), along with the key transition points  
39  
40 449 from Figure 3(b) shown next to the transitions in  $G_0$ . Trends like to those observed for shear wave  
41  
42 450 velocity are observed where the small strain shear modulus decreases with temperature during  
43  
44 451 undrained heating then increases during drainage at elevated temperature. An increase in  $G_0$  is  
45  
46 452 observed during undrained cooling then decreases during drainage at room temperature. The  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 453 thermal volumetric strain after being subjected to an undrained heating-cooling cycle is 1.2% and  
4  
5  
6 454  $G_0$  is observed to increase by 9%. Key results from the two tests are summarized in Table 2.  
7

8 455 As described previously, the small strain shear modulus is dependent on factors including  
9  
10 456 void ratio, effective confining stress and the apparent preconsolidation stress. When subjected  
11  
12  
13 457 to a heating-cooling cycle, thermally induced changes occur in the clay specimen. In addition,  
14  
15 458 these thermal changes will also depend on the drainage conditions used. In a saturated normally  
16  
17  
18 459 consolidated clay, as investigated in this study, plastic contractive volume changes attributed to  
19  
20 460 the effects of a drained heating cooling cycle. This reduction in void ratio and the densification of  
21  
22  
23 461 the soil will lead to an increase in the small-strain shear modulus. On the other hand, during  
24  
25 462 undrained heating, expansion is observed and the small-strain shear modulus decreases.  
26  
27  
28 463 However, this expansion is thermo-elastic and is recovered during drainage and subsequent  
29  
30 464 cooling where the shear modulus is observed to increase correspondingly. Furthermore, the  
31  
32  
33 465 generation of excess pore water pressure during undrained heating will decrease the effective  
34  
35 466 stress within the clay specimen. This decrease in effective stress will also contribute to the  
36  
37  
38 467 reduction in the small strain shear modulus according to Equation (5). This indicates the  
39  
40 468 importance of the changes in effective stress due to thermal pressurization on the value of  $G_0$ , as  
41  
42  
43 469 the impacts of permanent thermal volume change and changes in apparent preconsolidation  
44  
45 470 stress are not expected to occur until drainage is permitted. On the other hand, during undrained  
46  
47  
48 471 cooling, the negative pore water pressures generated increases the effective stress of the  
49  
50 472 specimen. Accordingly, an increase can be observed in the small strain shear modulus. When  
51  
52  
53 473 drainage is permitted, the pore pressures dissipated and the shear modulus is seen to reduce.  
54  
55 474 Under both drainage conditions, after being subjected to a heating-cooling cycle, an increase in  
56  
57  
58  
59  
60

1  
2  
3 475 the apparent preconsolidation stress of the clay was observed in Figures 10 through 12. Due to  
4  
5  
6 476 thermal hardening of the clay, the elastic domain is expanded where the initially normally-  
7  
8 477 consolidated specimen behaves as an overconsolidated specimen immediately after a heating-  
9  
10  
11 478 cooling cycle. This increase in the apparent preconsolidation stress is another contributing factor  
12  
13 479 to the changes in the small-strain shear modulus observed.

14  
15 480 As mentioned, the tests presented in this study are time consuming and complex. Although  
16  
17  
18 481 only two tests are considered in this paper, the data presented has value in understanding the  
19  
20 482 impacts of drainage conditions on soil thermo-mechanical behavior. Further testing is needed to  
21  
22  
23 483 better understand the effect of different specimen conditions and to understand uncertainty.  
24  
25 484 Based on the results of this study, some useful insights can be drawn with respect to the thermal  
26  
27  
28 485 volume change and pressurization behavior of clay and their linkages with stiffness  
29  
30 486 characteristics. This information is beneficial in geotechnical applications involving thermal  
31  
32  
33 487 loading such as the use of in-situ heating for soil improvement. The experimental approach  
34  
35 488 described herein has not been used to study the different mechanisms of soil behavior during  
36  
37  
38 489 heating-cooling cycles with different drainage conditions, and only a limited number of studies  
39  
40 490 have been performed on the thermal effects on small-strain shear modulus. Further  
41  
42  
43 491 investigations considering different conditions (i.e., stress states, initial void ratios, temperature  
44  
45 492 ranges, rate of heating, soil types, etc.) will help enhance the understanding of the thermal  
46  
47 493 effects on small-strain shear modulus.

## 494 **5. Conclusion**

51  
52 495 This study presents the results of an experimental investigation where the transient linkages  
53  
54  
55 496 between thermal volume change and small-strain shear modulus were evaluated for two  
56  
57  
58  
59  
60

1  
2  
3 497 normally consolidated kaolinite specimens subjected to drained and undrained heating-cooling  
4  
5  
6 498 cycles, respectively. In the specimen undergoing a drained heating-cooling cycle, the rates of  
7  
8 499 heating and cooling were sufficiently slow to minimize the generation of thermally induced  
9  
10 500 excess pore water pressures. In the specimen undergoing undrained heating and cooling,  
11  
12  
13 501 drainage was permitted after reaching thermo-hydraulic equilibrium at the end of cooling. In  
14  
15 502 both specimens, net contractive thermal strains were observed at the end of the heating-cooling  
16  
17  
18 503 cycle with slightly higher strains obtained for the specimen subjected to the undrained heating-  
19  
20 504 cooling cycle. Upon further mechanical compression after cooling, both specimens exhibited  
21  
22  
23 505 overconsolidated behavior, even though the specimens were at a normally consolidated state  
24  
25 506 prior to heating. The shear wave velocity was observed to increase with temperature during  
26  
27  
28 507 drained heating and remained constant during drained cooling, leading to a net increase in shear  
29  
30 508 wave velocity after the heating-cooling cycle. On the other hand, shear wave velocity was  
31  
32  
33 509 observed to decrease dramatically during undrained heating due to the increase in thermally  
34  
35 510 induced pore water pressure followed by an increase during drainage at elevated temperature.  
36  
37 511 During undrained cooling, a slight increase in velocity was observed with a subsequent reduction  
38  
39  
40 512 during drainage after cooling, but still resulting in a net increase in shear wave velocity after the  
41  
42 513 heating-cooling cycle. The changes in small strain shear modulus calculated using the change in  
43  
44  
45 514 volume of the specimens were also observed to follow a similar trend to that of shear wave  
46  
47 515 velocity for the kaolinite specimens. A net increase in small-strain shear modulus was observed  
48  
49  
50 516 in specimens after a heating-cooling cycle which can be attributed to the contractive thermal  
51  
52 517 volume changes and the thermal hardening associated with the increase in preconsolidation  
53  
54  
55 518 stress observed in normally consolidated clay. Overall, the methodology and experimental  
56  
57  
58  
59  
60

1  
2  
3 519 approach presented in this study can be used to better understand the effects of thermal  
4  
5  
6 520 improvement of soft clays.

637 **Table 1** Properties of Georgia kaolinite clay

Parameter	Value
Liquid Limit	47
Plasticity Index	19
Specific Gravity	2.6
Slope of VCL ( $\lambda$ )	0.09
Slope of RCL ( $\kappa$ )	0.02
USCS Classification	CL

638

639 **Table 2** Summary of results

Parameter	Drained heating-cooling cycle	Undrained heating-cooling cycle
Initial void ratio	1.03	1.1
Initial total density (kg/m <sup>3</sup> )	1788	1755
Thermal axial strain after a heating-cooling cycle (%)	0.28	0.39
$V_s$ before heating (m/s)	255.9	312.7
$V_s$ after a heating-cooling cycle (m/s)	272.8	325.9
$G_0$ before heating (MPa)	122.7	180.8
$G_0$ after a heating-cooling cycle (MPa)	140.1	197.6
Final void ratio	0.84	0.82
