Belle (Ishikawa, 2006) earlier provided constraints on C_9 and C_{10} using 386M $B\bar{B}$ events, from a fit to the θ_ℓ distribution under the assumption that F_L follows the SM distribution.

17.9.7.5 Theoretical predictions for inclusive $B \to X_s \ell^+ \ell^-$

An inclusive measurement of $b \to s\ell^+\ell^-$ is expected to have reduced theoretical uncertainties in comparison with the exclusive decays $B \to K^{(*)}\ell^+\ell^-$. The situation is similar to $b \to s\gamma$, where understanding of exclusive decays is limited by knowledge of hadronic form factors. In the case of $b \to s\ell^+\ell^-$ these reduced theoretical uncertainties apply not only to the inclusive branching fraction, but also to the angular information, e.g. the zero crossing point in the di-lepton forward-backward asymmetry A_{FB}.

The angular decomposition of the inclusive decay $B \to X_s \ell^+ \ell^-$ provides three independent observables, H_T, H_A and H_L, from which one can extract the short-distance electroweak Wilson coefficients that test for new physics (Lee, Ligeti, Stewart, and Tackmann, 2007).

$$\frac{d^3\Gamma}{dq^2\,dz} = \frac{3}{8}\left[(1+z^2)H_T(q^2) + 2(1-z^2)H_L(q^2) + 2zH_A(q^2)\right].$$
(17.9.69)

Here, $z = \cos\theta_\ell$, H_A is equivalent to the forward-backward asymmetry in the exclusive decays, and the di-lepton mass spectrum is given by $H_T + H_L$. The observables depend on the Wilson coefficients C_7, C_9 and C_{10} in the SM. The present measurements of $B \to X_s \ell^+ \ell^-$ already favor the SM sign of the coefficient C_7, which is undetermined by the $B \to X_s\gamma$ mode (Gambino, Haisch, and Misiak, 2005).

The observables in inclusive $B \to X_s \ell^+ \ell^-$ are dominated by perturbative contributions in a low-q^2 region, $1 < q^2 < 6\,\text{GeV}^2/c^2$, and in the high-$q^2$ region above the $c\bar{c}$ resonances, $q^2 > 14.4\,\text{GeV}^2/c^2$. The present predictions are based on the perturbative calculations to NNLL

precision in QCD and to NLL precision in QED (Section 17.9.1). The branching fraction in the low-q^2 region is (Huber, Lunghi, Misiak, and Wyler, 2006):

$$\mathcal{B}(B \to X_s \ell^+ \ell^-)_{\text{low}} = \begin{cases} (1.59 \pm 0.11) \times 10^{-6} & (\ell = \mu) \\ (1.64 \pm 0.11) \times 10^{-6} & (\ell = e) \end{cases}$$
$$(17.9.70)$$

and in the high-q^2 region (Huber, Hurth, and Lunghi, 2008a):

$$\mathcal{B}(B \to X_s \ell^+ \ell^-)_{\text{high}} = \begin{cases} 2.40 \times 10^{-7} \times (1^{+0.29}_{-0.26}) & (\ell = \mu) \\ 2.09 \times 10^{-7} \times (1^{+0.32}_{-0.30}) & (\ell = e) \end{cases}$$
$$(17.9.71)$$

The value of q_0^2 for which the inclusive forward-backward asymmetry vanishes,

$$(q_0^2)[X_s \ell^+ \ell^-] = \begin{cases} (3.50 \pm 0.12)\,\text{GeV}^2/c^2 & (\ell = \mu) \\ (3.38 \pm 0.11)\,\text{GeV}^2/c^2 & (\ell = e), \end{cases}$$
$$(17.9.72)$$

is one of the most precise predictions in flavor physics. It determines the relative sign and magnitude of the coefficients C_7 and C_9 (Huber, Hurth, and Lunghi, 2008a). Unknown subleading non-perturbative corrections of order $\mathcal{O}(\alpha_s \Lambda_{\text{QCD}}/m_b)$ are estimated to give an additional uncertainty of order 5%, which has to be added to all $B \to X_s \ell^+ \ell^-$ observables. In all predictions it is assumed that there is no cut on the hadronic mass region.

After including the NLL QED matrix elements, the electron and muon channels receive different contributions. This is due to the fact, that the leptons can emit collinear photons, which generate large logarithms of the form $\ln(m_b^2/m_\ell^2)$. This generates a differences between these two channels. We note that in theoretical calculations all collinear photons are assumed to be included in the X_s system. The di-lepton invariant mass does not contain any additional photon, *i.e.* $q^2 = (p_{\ell^+} + p_{\ell^-})^2$. This differs from the experimental analyses which recover bremsstrahlung photons and add them to the di-lepton system, and therefore small modifications to the theoretical predictions are needed – see (Huber, Hurth, and Lunghi, 2008b).

17.9.7.6 Measurements of inclusive $B \to X_s \ell^+ \ell^-$

The fully inclusive approach has not been used for $b \to s \ell^+ \ell^-$ because the presence of large backgrounds from semileptonic B decays. In these background events the initial $B\overline{B}$ produces two oppositely charged leptons either directly from the two B mesons, or as a cascade from the $b \to c \to s$ decay chain. These backgrounds cannot be removed without further kinematic constraints. The reconstructed-B-tag approach (also not yet attempted) should remove the direct two-B-decay background component, leaving only the cascade decays, which can then be removed using missing energy variables. The difficulty here is the need for millions of B tags in order to measure an inclusive branching fraction of a few $\times 10^{-6}$. This

Table 17.9.14. Measurements of inclusive $B \to X_s \ell^+ \ell^-$ branching fractions (in 10^{-6}), with $m_{\ell^+ \ell^-} > 0.2\,\text{GeV}/c^2$, while the excluded regions around the J/ψ and ψ' are interpolated assuming the SM with no interference. Uncertainties are statistical and systematic, respectively.

Mode	BABAR	Belle	Average
$X_s e^+ e^-$	$6.0 \pm 1.7 \pm 1.3$	$4.0 \pm 1.3 \pm 0.9$	4.7 ± 1.3
$X_s \mu^+ \mu^-$	$5.0 \pm 2.8 \pm 1.2$	$4.1 \pm 1.1 \pm 0.8$	4.3 ± 1.3
$X_s \ell^+ \ell^-$	$5.6 \pm 1.5 \pm 1.3$	$4.1 \pm 0.8 \pm 0.8$	4.5 ± 1.0

is a challenging measurement even with the anticipated ultimate dataset of a super flavor factory.

The sum-of-exclusive method does provide sufficient constraints to discriminate against the semileptonic backgrounds using the m_{ES} and ΔE kinematic variables. In a similar fashion to the $B \to X_s \gamma$ analysis, the X_s state is reconstructed as one kaon and multiple pions (but including the zero pion case, which corresponds to $B \to K \ell^+ \ell^-$). Belle (Iwasaki, 2005) uses up to 4 pions of which one can be a π^0, and includes the X_s mass range below $2.0\,\text{GeV}/c^2$, while BABAR (Aubert, 2004h) uses up to 2 pions of which one can be a π^0, and includes the X_s mass below $1.8\,\text{GeV}/c^2$. After assuming that modes containing a K_L^0 have equal branching fractions to corresponding K_S^0 modes, both experiments account for $\sim 70\%$ of B decays in their measured X_s ranges. In order to reduce the semileptonic decay backgrounds, the analyses exploit the fact that energy is carried away by two or more neutrinos. Belle uses the total visible energy and missing mass, while BABAR uses the missing energy in the rest of the event (ROE) excluding the $X_s \ell^+ \ell^-$ candidate, as well as the m_{ES} of the ROE. If the two leptons originate from semileptonic background, they may have displaced vertices, which is used for further discrimination.

As with the exclusive $B \to K^{(*)} \ell^+ \ell^-$ analysis, it is necessary to remove the di-lepton mass ranges around the J/ψ and ψ'. In both analyses $e^+ e^-$ pairs with masses below $0.2\,\text{GeV}/c^2$ are removed. This makes the di-muon and di-electron samples consistent, and removes the theoretically less interesting region dominated by the virtual photon contribution.

Belle measures 31.8 ± 10.2 $X_s e^+ e^-$ and 36.3 ± 9.3 $X_s \mu^+ \mu^-$ signal events with a sample of 152M $B\overline{B}$, while BABAR measures 29.2 ± 8.4 $X_s e^+ e^-$ and 11.2 ± 6.3 $X_s \mu^+ \mu^-$ events with the smaller sample of 89M $B\overline{B}$. There are experimental systematic uncertainties associated with the background subtraction and the reconstruction efficiency, which total about 10%. However the dominant systematic uncertainties come from the modeling of the X_s system (as they did in $B \to X_s \gamma$). The fractions of exclusive $B \to K \ell^+ \ell^-$ and $B \to K^* \ell^+ \ell^-$ are varied, as well as the missing fractions of final states in the mass range above $1.1\,\text{GeV}/c^2$. Finally there is an extrapolation to the full X_s mass range, which uses a spectral shape of a Fermi-motion model (Ali, Hiller, Handoko, and Morozumi, 1997) with parameters determined from analyses of inclusive $B \to X_s \gamma$ and $B \to X_c \ell \overline{\nu}$. The q^2 distribution is mod-
Figure 17.9.15. From (Iwasaki, 2005). Belle's results on the differential branching fractions for $B \to X_s \ell^+ \ell^-$ as functions of (a) M_{X_s} and (b) q^2. All branching fractions have been interpolated through the vetoed J/ψ and $\psi(2S)$ regions. The M_{X_s} results correspond to all $q^2 > 0.04\,\mathrm{GeV}^2/c^2$, while the q^2 results follow an extrapolation to all values of M_{X_s}. Inner (outer) error bars are statistical (total) errors. Histograms represent the SM-based predictions described in the text.

eled based on (Ali, Hiller, Handoko, and Morozumi, 1997; Ali, Lunghi, Greub, and Hiller, 2002; Kruger and Sehgal, 1996) in which the J/ψ and $\psi(2S)$ regions are interpolated as if these contributions do not exist. The model-dependent effects give a total systematic error of 20%, still slightly smaller than the statistical error. The resulting inclusive branching fractions are given in Table 17.9.14. In Figure 17.9.15 Belle's results on the differential branching fractions for $B \to X_s \ell^+ \ell^-$ as functions of M_{X_s} and q^2 are shown. With more events the measurements could be broken into bins of di-lepton mass squared, and the forward-backward asymmetry A_{FB} could be studied.

The results for the inclusive $b \to s\ell^+\ell^-$ branching fraction are consistent with the SM prediction (*e.g.*, $\mathcal{B}(B \to X_s \mu^+ \mu^-) = (4.20 \pm 0.70) \times 10^{-6}$ assuming interpolation over the veto region (Ali, Lunghi, Greub, and Hiller, 2002)).[92] They can be interpreted as giving a preference to a negative sign for Wilson coefficient C_7, where the inclusive $b \to s\gamma$ branching fraction only determines the magnitude of C_7 and not the sign.

Belle has reported an unpublished preliminary result with 657M $B\bar{B}$, with several improvements in the analysis (Iijima, 2010). The largest improvement is that the X_s mass range is divided into the K, K^* and high mass range, and the high mass range alone has been measured with 3σ significance. In addition, several new background sources have been identified. They include a semileptonic B decay background that peaks in the m_{ES} distribution due to one additional misidentified lepton that compensates the missing neutrino, and contributions from higher $c\bar{c}$ resonances that were disregarded in the previous analyses. Although the preliminary results have been used in the HFAG averages and also in some literature, we do not include them in Table 17.9.14.

In addition, *BABAR* has submitted for publication an updated measurement of $B \to X_s \ell^+ \ell^-$ based on 471M $B\bar{B}$ events (Lees, 2014). Along with the results in the

[92] The more recent theory publications used for Eqs 17.9.70 and 17.9.71 do not quote values for the full q^2 range.

usual q^2 bins, results are provided for the $1 < q^2 < 6\,\mathrm{GeV}^2/c^2$ range suitable for comparison to the most precise SM prediction.

17.9.7.7 $B \to \pi\ell^+\ell^-$

The $B \to \pi\ell^+\ell^-$ decay mode has been the first exclusive decay mode utilized in the search for the $b \to d\ell^+\ell^-$ transition. The analysis for $B \to \pi\ell^+\ell^-$ is almost identical to that for $B \to K\ell^+\ell^-$ (Section 17.9.7.1). Tight charged-pion identification, similar to that used for the measurement of $B \to \rho\gamma$ (Section 17.9.4.1), is applied to the pion in $B^+ \to \pi^+\ell^+\ell^-$. It is necessary to account for misidentified $B^+ \to K^+\ell^+\ell^-$ events, which give a peaking background in m_{ES}, but are shifted to lower ΔE. Both B Factories also include $B^0 \to \pi^0\ell^+\ell^-$ in their searches.

BABAR (Aubert, 2007ax) has analyzed 230M $B\bar{B}$ and finds one candidate in the $(m_{\mathrm{ES}}, \Delta E)$ signal region in each of $\pi^+e^+e^-$, $\pi^+\mu^+\mu^-$ and $\pi^0e^+e^-$. This is consistent with the expectations from background. Defining the isospin-constrained branching fraction

$$\mathcal{B}(B \to \pi\ell^+\ell^-) \equiv \mathcal{B}(B^+ \to \pi^+\ell^+\ell^-) \qquad (17.9.73)$$
$$= 2\frac{\tau_{B^+}}{\tau_{B^0}}\mathcal{B}(B^0 \to \pi^0\ell^+\ell^-)\,,$$

they set an upper limit of:

$$\mathcal{B}(B \to \pi\ell^+\ell^-) < 9.1 \times 10^{-8}\,. \qquad (17.9.74)$$

Belle (Wei, 2008a) has analyzed 657M $B\bar{B}$ and also finds a few candidate events. A fit gives a small excess with a significance of 1.2σ. They set an upper limit of:

$$\mathcal{B}(B \to \pi\ell^+\ell^-) < 6.2 \times 10^{-8}\,. \qquad (17.9.75)$$

The SM prediction of 2×10^{-8} is not far below these limits, and the backgrounds are quite manageable, and in fact the first observation for the charged mode $B^+ \to \pi^+\mu^+\mu^-$ has been recently reported by LHCb (Aaij et al., 2012e) with a branching fraction consistent with the SM.

17.9.8 Electroweak penguin decays $b \to s(d)\nu\bar{\nu}$

The $b \to s\nu\bar{\nu}$ decays are described by an electroweak penguin diagram including a Z^0 boson or a W^+W^- box diagram, with Wilson coefficients for the vector and axial-vector parts C_9 and C_{10}. Unlike $b \to s\ell^+\ell^-$, there is no contribution from a virtual photon penguin diagram (C_7). There is also no contribution from $c\bar{c}$ resonances. Measuring the branching fractions of these decays provides a powerful test of new physics complementary to other rare B decays (Altmannshofer, Buras, Straub, and Wick, 2009).

The experimental challenge is to identify a B decay to an X_s system and two missing neutrinos. This is similar to $B^- \to \tau^-\bar{\nu}$ decays, which have been first observed at the B Factories. All that has to be done is to replace the observable τ decay products (π, ρ, e, μ), with a K or K^* meson. However, the SM predictions for $B \to K\nu\bar{\nu}$ or
Figure 17.9.16. From (del Amo Sanchez, 2010p). Boosted Decision Tree output from the *BABAR* search for $B^+ \to K^+ \nu \bar{\nu}$, along with expected SM-signal and background contributions. Errors on the data are statistical, while those on the expected numbers include systematics.

The *BABAR* search for $K^* \nu \bar{\nu}$ uses a combination of hadronic and semileptonic tags (Aubert, 2008an). The efficiency is slightly lower with hadronic tags, but the background with the semileptonic tags is significantly higher. A fit to the distribution of extra energy in the events leads to comparable upper limits from the two types of tags, and yields combined upper limits at 90% C.L. of 12×10^{-5} for $K^{*0} \nu \bar{\nu}$ and 8×10^{-5} for $K^{*+} \nu \bar{\nu}$. These limits are lower than those reported by Belle (Chen, 2007b).

The experimental limits are already about 3 and 6 times the SM predictions for $K \nu \bar{\nu}$ and $K^* \nu \bar{\nu}$, respectively, but the backgrounds are severe. Initial studies of what could be done at a super flavor factory suggest that a data sample of about $50 \, \text{ab}^{-1}$ will be needed to observe either of these decays.

$B \to K^* \nu \bar{\nu}$ branching fractions are rather small, 4×10^{-6} and 13×10^{-6}, respectively. This makes suppression of the background from semileptonic B decays more difficult.

The recoil-B method is used, in which either fully-reconstructed hadronic B decays, or semileptonic $B \to D^{(*)} \ell \nu$ decays, are used as the tag (Section 7.4). The remaining charged tracks and neutral clusters then have to be consistent with the X_s system being searched for. The most powerful variables for suppressing background are associated with the missing energy carried by the neutrinos, and the lack of extra energy in the detector. Information on the momentum, charge and flavor of the recoil tag can be correlated with the X_s system to further reduce the backgrounds.

Belle (Chen, 2007b) uses hadronic B tags to search for $B \to h^{(*)} \nu \bar{\nu}$ where $h^{(*)}$ includes charged and neutral K, K^*, π, ρ and ϕ. They reconstruct 788k charged B and 491k neutral B decays from a sample of 535M $B\bar{B}$ events, with an overall tag efficiency of 2.5×10^{-3}. They observe between 1 and 30 candidate events in the different $h^{(*)}$ final states. These yields are consistent with the expectations from backgrounds, so they set upper limits at 90% C.L. between 4.4×10^{-4} for $\rho^0 \nu \bar{\nu}$ and 1.4×10^{-5} for $K^+ \nu \bar{\nu}$.

The best limit on $K \nu \bar{\nu}$ comes from *BABAR* (del Amo Sanchez, 2010p), also using the hadronic B tag method. This analysis uses bagged decision trees with 26 (38) inputs to separate signal and background in the K^+ (K^0) modes as illustrated in Figure 17.9.16. The K^+ search is separated into high and low-q^2 regions, corresponding to low and high kaon momenta. The backgrounds are very large at high-q^2, so the sensitivity mainly comes from the low-q^2 region. This introduces some model-dependence into the extraction of the upper limit. The quoted upper limits at 90% C.L. are 5.6×10^{-5} for $K^0 \nu \bar{\nu}$ and 1.3×10^{-5} for $K^+ \nu \bar{\nu}$. *BABAR* also reports a search using semileptonic B tags (Aubert, 2009aq).

17.10 $B^+ \to \ell^+\nu(\gamma)$ and $B \to D^{(*)}\tau\nu$

Dana Lindemann

17.10.1 Overview

In this section, we review the measurements of purely leptonic decays, $B^+ \to \ell^+\nu$ ($\ell = e, \mu, \tau$), and the semileptonic B decays $B \to D^{(*)}\tau\nu$. As $b \to u$ and $b \to c$ quark transitions, these processes depend on the magnitudes of the CKM matrix elements V_{ub} and V_{cb}, respectively, however both have potential sensitivity to physics beyond the SM. In extensions of the SM which include an expanded Higgs sector, in particular the type-II two Higgs doublet model (2HDM) such as in the minimal supersymmetric extension of the Standard Model (MSSM), these processes are potentially sensitive to a charged Higgs boson ($H^\pm$). A number of benchmark new physics models, such as 2HDM and MSSM, are discussed in Section 25.2. The presence of the $H^\pm$ can impact the experimentally observed branching fractions for these decay modes and, in the case of $B \to D^{(*)}\tau\nu$, also the kinematic distributions of final state particles. Figure 17.10.1 shows Feynman diagrams for these tree level processes.
Figure 17.10.1. Feynman diagrams of $B^+ \to \ell^+\nu_\ell$ (top) and $B^+ \to \overline{D}^{(*)}\tau^+\nu_\tau$ (bottom).

Since $B^+ \to \ell^+\nu$ proceeds via a quark annihilation process with no hadrons in the final state, all hadronic effects are encapsulated in the B decay constant f_B,

$$\langle 0|\overline{b}(0)\gamma_\mu\gamma_5 q(0)|B(p)\rangle = ip_\mu f_B \ , \qquad (17.10.1)$$

which can be interpreted as the wave function of the light quark at the location of the b quark. In contrast, in semileptonic $B \to D^{(*)}\tau\nu$ decays the hadronic transition is described by form factors, which are functions of the momentum transfer squared, q^2, resulting in larger theoretical uncertainties in the decay kinematics and branching fractions.

The effective Hamiltonian describing $B \to D^{(*)}\tau\nu$ and $B \to \tau\nu$ transitions mediated by $W^\pm$ or $H^\pm$ can be written as,

$$\mathcal{H}_{eff} = \frac{G_F}{\sqrt{2}}V_{\mathrm{qb}}\{[\overline{q}\gamma^\mu(1-\gamma_5)b][\overline{\tau}\gamma_\mu(1-\gamma_5)\nu_\tau]$$
$$- \frac{M_b M_\tau}{M_B^2}\overline{q}[g_S + g_P\gamma_5]b[\overline{\tau}(1-\gamma_5)\nu_\tau]\}$$
$$+ \text{h.c.}, \qquad (17.10.2)$$

where G_F is the Fermi coupling constant, V_{qb} is the CKM matrix element and M_B is the B meson mass. The first term corresponds to the SM $W^\pm$ couplings. The second term, which can occur in beyond-SM models, represents scalar couplings to $H^\pm$. Since these couplings are proportional to the fermion masses, which are relatively large for B mesons and tau leptons, it is natural to look for new physics in leptonic or semileptonic B decays involving tau leptons.

In the MSSM, the couplings $g_{S,P}$ in Eq. (17.10.2) are written as

$$g_S = g_P = \frac{M_B^2\tan^2\beta}{M_H^2}\frac{1}{(1+\epsilon_0\tan\beta)(1-\epsilon_\tau\tan\beta)}, \qquad (17.10.3)$$

where $\tan\beta$ is the ratio of the two Higgs vacuum expectation values and M_H is the charged Higgs boson mass. The parameters $\epsilon_{0,\tau}$ arise from sparticle loop contributions and their values depend on other MSSM parameters. These are typically expected to be of $\mathcal{O}(10^{-2})$. Since these contributions to $g_{S,P}$ are relatively small for moderate values of $\tan\beta$, and in the absence of other experimental evidence for SUSY, studies of $B \to \tau\nu$ and $B \to D^{(*)}\tau\nu$ are usually interpreted in the context of the simpler extension of the SM with only the addition of a second Higgs doublet (that is, with only the Type-II 2HDM and no other heavy new physics contributions). In this case, $\epsilon_0 = \epsilon_\tau = 0$, and measurements of $B \to (D^{(*)})\tau\nu$ provide information on $\tan\beta/M_H$.

Experimentally, it is challenging to study these processes due to the presence of neutrinos in the final state. The decays $B^+ \to \tau^+\nu$ and $B \to D^{(*)}\tau\nu$ involve two or more neutrinos and hence cannot be fully constrained kinematically. Although the $B^+ \to e^+\nu$ and $B^+ \to \mu^+\nu$ modes have only a single neutrino in the final state, they have very small branching fractions compared with $B^+ \to \tau^+\nu$, due to helicity suppression. However, the $B^+ \to \tau^+\nu$ branching fraction is roughly two orders of magnitude smaller than the semileptonic $B \to D^{(*)}\tau\nu$ modes due to the relative sizes of $|V_{ub}|$ and $|V_{cb}|$, and the contribution of f_B.

At B Factories, one can fully reconstruct one of the B mesons produced in an $\Upsilon(4S) \to B\overline{B}$ event, referred to as the "tag B" (B_{tag}), and examine the properties of the remaining particles in the event, which are collectively

referred to as the "signal B" (B_{sig}), to look for evidence of a signal decay (see Chapter 7). This method strongly suppresses the combinatorial background and provides a unique identification of the decay daughters of the signal B decay. The disadvantage of this method is the low efficiency of the B_{tag} reconstruction, which is at the level of $\mathcal{O}(0.1)\%$. In spite of this, the high luminosity B Factories have provided a sufficiently large number of events to enable measurements of these decays for the first time.

In this section we describe the theoretical and experimental status of $B^+ \to \ell^+\nu$ and $B \to D^{(*)}\tau\nu$ studies. A theoretical introduction to leptonic decays is presented in Section 17.10.2.1. The experimental status of $B^+ \to \tau^+\nu$ and $B^+ \to \ell^+\nu$ (with $\ell = e, \mu$) is described in Sections 17.10.2.2 and 17.10.2.3, respectively. Searches for radiative leptonic decays are discussed in Section 17.10.2.4. $B \to D^{(*)}\tau\nu$ are likewise presented in the remaining sections, with a brief theory introduction in Section 17.10.3 followed by a description of experimental measurements in Section 17.10.3.1 and interpretation of these results in Section 17.10.3.2. Some comments on the current status and future prospects for studies of these decays conclude this section, while additional interpretation is provided in the context of global fits to the Unitarity Triangle in Chapter 25.

17.10.2 $B^+ \to \ell^+\nu(\gamma)$

17.10.2.1 Theory of leptonic decays

In the SM, the purely leptonic decay $B^+ \to \ell^+\nu$ proceeds via the annihilation of $\bar{b}$ and u quarks to a W^+ boson (see Figure 17.10.1). The branching fraction is given by

$$
\begin{aligned}
\mathcal{B}(B^+ \to \ell^+\nu)_{\text{SM}} = {} & \frac{G_F^2 M_B M_\ell^2}{8\pi}\left(1 - \frac{M_\ell^2}{M_B^2}\right)^2 \\
& \times f_B^2 |V_{ub}|^2 \tau_B ,
\end{aligned}
\tag{17.10.4}
$$

where the M_ℓ is is the mass of the lepton, and τ_B is the B meson lifetime. The B meson decay constant $f_B = 0.191 \pm 0.009$ GeV is obtained from the most recent lattice QCD calculations (Na et al., 2012). The helicity suppression of the leptonic decays can be seen in the lepton mass dependence in Eq. (17.10.4). The expected branching fraction for the τ mode is

$$
\mathcal{B}_{\text{SM}}(B^+ \to \tau^+\nu) = (1.01 \pm 0.29) \times 10^{-4} , \tag{17.10.5}
$$

using $|V_{ub}| = (3.95 \pm 0.38_{\text{exp}} \pm 0.39_{\text{th}}) \times 10^{-3}$, which is an average of $|V_{ub}|$ values determined using charmless semileptonic B decay data, see Eq. (17.1.70). Due to the relatively small mass of the e and μ compared with the τ, these modes are suppressed by factors of 1.05×10^{-7} and 4.49×10^{-3}, respectively, relative to the τ mode.

Within the Type-II 2HDM, the addition of the charged Higgs boson in Eq. (17.10.2) and Eq. (17.10.3) modifies the $B^+ \to \ell^+\nu$ branching fraction (Hou, 1993),

$$
\mathcal{B}(B^+ \to \ell^+\nu)_{\text{2HDM}} = \mathcal{B}(B^+ \to \ell^+\nu)_{\text{SM}} \times r_H , \tag{17.10.6}
$$

where the ratio r_H is given by

$$
r_H = (1 - M_B^2 \tan^2\beta / M_H^2)^2 . \tag{17.10.7}
$$

The interference between the SM $W^\pm$ and $H^\pm$ contributions is destructive. Consequently, the charged Higgs contribution suppresses the branching fraction relative to the SM expectation, resulting in $r_H < 1$, unless the $H^\pm$ is sufficiently large that it dominates the SM $W^\pm$ contribution. The case where $M_B^2 \tan^2\beta / M_H^2 = 2$ is indistinguishable from the SM. It is notable that Eq. (17.10.7) applies equally to the other leptonic decay modes, $B^+ \to \mu^+\nu$ and $B^+ \to e^+\nu$. As the $H^\pm$ is expected to decrease the observed branching fraction, much of the present constraint on charged Higgs bosons results from the *lower* bound on the experimental value of the $B^+ \to \tau^+\nu$ branching fractions rather than the *upper* bound on the branching fraction. A much weaker bound is currently obtained from $B^+ \to \mu^+\nu$ decays because only upper limits on its branching fraction have been reported.

The radiative decays $B^+ \to \ell^+\nu_\ell\gamma$ are also of interest since the presence of the radiated photon can remove the helicity suppression of the purely leptonic modes, possibly by coupling the spin-0 B meson to the spin-1 $W^\pm$ boson through an intermediate off-shell state (Burdman, Goldman, and Wyler, 1995). Consequently, the predicted branching fractions of $B^+ \to e^+\nu_\ell\gamma$ and $B^+ \to \mu^+\nu_\ell\gamma$ are considerably larger than the corresponding non-radiative modes, in spite of an additional suppression by the factor α_{EM}. The branching fractions for $B^+ \to \ell^+\nu_\ell\gamma$ (with $\ell = e, \mu, \tau$) are predicted to be of order 10^{-6} independent of the lepton type, making these modes potentially accessible at the B Factories. They potentially provide an additional method to access $|V_{ub}|$, and they are also a potential background to the non-radiative mode searches.

The decay rate for $B^+ \to \ell^+\nu_\ell\gamma$ is given by

$$
\frac{d\mathcal{B}}{dE_\gamma} = \frac{\alpha_{\text{EM}} G_F^2 |V_{ub}|^2}{48\pi^2} M_B^5 \tau_B \left[f_A^2(E_\gamma) + f_V^2(E_\gamma)\right](1-y)y^3
\tag{17.10.8}
$$

where $y = 2E_\gamma / M_B$. The axial-vector and vector $B \to \gamma X$ form factors, f_A and f_V, respectively, are assumed to be equal in most models. The branching fraction can be approximated as (Korchemsky, Pirjol, and Yan, 2000)

$$
\mathcal{B}(B^+ \to \ell^+\nu_\ell\gamma) \approx \frac{\alpha_{\text{EM}} G_F^2 |V_{ub}|^2}{288\pi^2} f_B^2 M_B^5 \tau_B \left(\frac{Q_u}{\lambda_B} - \frac{Q_b}{M_b}\right)^2 ,
\tag{17.10.9}
$$

where Q_i is the quark charge, and λ_B is the first inverse moment of the B-meson wave function. This last parameter plays an important role in QCD factorization (Descotes-Genon and Sachrajda, 2003; Lunghi, Pirjol, and Wyler, 2003). It also enters into calculations of the $B \to \pi X$ form factor at zero momentum transfer and the branching fractions of two-body hadronic B-meson decays such as $B \to \pi\pi$, a benchmark channel for measuring the CKM angle ϕ_2 (Le Yaouanc, Oliver, and Raynal, 2008). However, λ_B has a large theoretical uncertainty, so $B^+ \to \ell^+\nu_\ell\gamma$ is a useful decay for obtaining a clean measurement of λ_B.

17.10.2.2 $B^+ \to \tau^+ \nu$ measurements

Methodology common to Belle and BABAR

Among the leptonic B decays, $B^+ \to \tau^+ \nu$ has the largest branching fraction and, in spite of the difficulties associated with multiple neutrinos in the final state, was the first of these modes to be successfully measured at the B Factories. Both Belle and *BABAR* use a similar analysis method in which they fully reconstruct the accompanying B meson (B_{tag}) using either hadronic or semileptonic decays, and examine the rest of the event to search for a $B^+ \to \tau^+ \nu$ decay. In both experiments, analyses employing hadronic- and semileptonic-tag methods were performed and published as separate measurements. Since there is essentially no overlap between the tag samples, the analyses are statistically independent $B^+ \to \tau^+ \nu$ and the two results from each collaboration can be combined into a single branching fraction measurement.

Details of B_{tag} reconstruction are described in Section 7. Analyses using semileptonic tags have higher efficiency than the hadronic tag searches, but suffer from a lower signal-to-background ratio. This is a consequence of the less stringent kinematic constraints associated with the presence of the undetectable tag-B neutrino. As a result, searches using the hadronic and semileptonic tag methods employ somewhat different optimizations.

Once a B_{tag} has been reconstructed, using either the hadronic or semileptonic tag method, the selection of $B^+ \to \tau^+ \nu$ candidates exploits the low multiplicity and missing energy signatures of the signal mode. Since the τ^+ decays into final states in which one or two neutrinos accompany either hadrons or a charged lepton, it is not possible to reconstruct the two-body kinematics of $B^+ \to \tau^+ \nu$ from the final state particles. Tau decays to leptons, $\tau^+ \to \ell^+ \nu \bar{\nu}$ ($\ell = e, \mu$) comprise approximately 35% of the branching fraction, while decays to $\pi^+ \bar{\nu}$, $\pi^+ \pi^0 \bar{\nu}$, $\pi^+ \pi^0 \pi^0 \bar{\nu}$ and $\pi^+ \pi^- \pi^+ \bar{\nu}$ contribute approximately 11%, 25%, 9% and 10%, respectively. The $\pi^+ \pi^0 \bar{\nu}$ and $3\pi \bar{\nu}$ modes proceed primarily through the $\rho(770)$ and $a_1(1260)$ resonances, hence mass constraints can be imposed on the pions to provide background rejection. However, these states are broad and so the suppression is modest. Since modes decaying to kaons (charged or neutral) make up only $\sim 1\%$ of τ decays, a kaon veto is usually applied to suppress large $B\bar{B}$ backgrounds involving charm mesons. The leptonic modes have a clean signature, but because the lepton has relatively low momentum, efficient and high-purity particle identification is needed. In tau decay modes with charged hadrons the pions are usually efficiently identified but large backgrounds must be overcome. Modes with one or more neutral pions have both low reconstruction efficiency and high backgrounds. The entire $B^+ \to \tau^+ \nu$ signal selection is optimized on a mode-by-mode basis so as to maximize the overall sensitivity. Due to differences in detectors and data samples, *BABAR* and Belle do not utilize exactly the same set of tau decay modes in their respective searches.

Charged particles from tau decays are selected as tracks that are not identified as the daughters of the reconstructed B_{tag}. It is required that exactly three such tracks are present in the case of the $\pi^+ \pi^- \pi^+ \bar{\nu}$ final state and exactly one track otherwise. The summed charge of these tracks is required to be consistent with that expected based on the reconstructed B_{tag}. Particle identification criteria are applied to the track(s) to distinguish leptons and pions, and to veto kaons. In the case of a single identified charged pion, π^0 candidates are reconstructed from $\gamma\gamma$ combinations which do not overlap with B_{tag} daughters. These are combined with the π^+ and constraints are applied to identify $\rho(770)$ or $a_1(1260)$ candidates. Events containing identified leptons are vetoed if a π^0 is also reconstructed in the event. Once each event has been uniquely classified as one of the candidate tau decay modes and π^0 candidates have been associated to the tau mode when applicable, there should be no additional energy deposition in the electromagnetic calorimeter in signal events. In practice, a small amount of energy is usually present due to accelerator beam backgrounds and reconstruction effects. In particular, hadronic shower fragments ("split-offs") from pions or kaons interacting in the calorimeter are sometimes reconstructed as separate calorimeter clusters rather than being associated with the originating particle. The most powerful variable for separating signal and background is the sum of the energies of neutral clusters that are not associated with decays of the B_{tag} or the tau. This quantity is denoted as E_{ECL} in Belle and E_{extra} in *BABAR* (and hereafter referred to as E_{extra}). The specific definition of E_{extra} depends of the low energy threshold applied to calorimeter clusters and differs between analyses. In *BABAR* analyses, cluster thresholds range from $30 - 100$ MeV, while in Belle they are chosen to be 50 MeV for the barrel and 100 (150) MeV for the forward (backward) end-cap ECL. Signal events are expected to peak at or near $E_{\text{extra}} = 0$. In contrast, many background events contain one or more additional neutral clusters from unreconstructed π^0 mesons or other particles. Consequently, for backgrounds E_{extra} extends to higher values. The E_{extra} distributions are estimated based on MC simulations. In order to reproduce the effects of beam backgrounds, data recorded with random triggers are overlaid on simulated events in both *BABAR* and Belle analyses. Furthermore, to take into account the possible difference between MC and data description of split-off showers, the signal E_{extra} distribution is calibrated, both for hadronic and semileptonic B_{tag} analyses, using "double tagged" event samples. In these events, a B_{tag} is reconstructed as described above, but a second hadronic or semileptonic B decay is also exclusively reconstructed in the same event using tracks and calorimeter clusters not already assigned to the B_{tag}.

Background from $e^+ e^- \to \tau^+ \tau^-$ and other continuum processes are suppressed using signal-mode-specific criteria relating to event shapes, in particular the ratio of the second and zeroth Fox-Wolfram moments (R_2, see Chapter 9), and the angle between the thrust axis computed using the daughters of the B_{tag} and the thrust axis computed using all other track and clusters in the event. $B\bar{B}$ backgrounds in which the B_{tag} has been correctly reconstructed are suppressed by using kinematic variables of

the signal track (and π^0 in the case of $\tau^+ \to \rho^+\overline{\nu}$) and any additional calorimeter clusters. These include the CM frame momentum of the signal track (p^*_{trk}) and the angle ($\cos\theta_{miss}$) of the missing momentum vector of the event with respect to the beam axis, computed using the B_{tag} four-vector, the signal track, and any additional calorimeter clusters.

A blind analysis (Chapter 14) procedure was adopted and the signal selection was optimized to obtain the smallest uncertainty on the measured branching fraction. The signal yield is extracted using an extended unbinned maximum likelihood fit to the E_{extra} distribution for the various tau decay signal modes. In the fit, the background yields are allowed to vary independently, while the signal yields in all of the tau modes are constrained to a common $B^+ \to \tau^+\nu$ branching fraction.

Belle results

The Belle collaboration reported the first evidence of the $B^+ \to \tau^+\nu$ decay by applying the hadronic tagging method on a sample of 449×10^6 $B\overline{B}$ pairs. The extracted signal yield is $N_S = 24.1^{+7.6}_{-6.6}(\text{stat})^{+5.5}_{-6.3}(\text{syst})$ events, corresponding to 3.5 σ significance. The branching fraction is measured to be $\mathcal{B}(B^+ \to \tau^+\nu) = (1.79^{+0.56}_{-0.49}(\text{stat})^{+0.46}_{-0.51}(\text{syst})) \times 10^{-4}$ (Ikado, 2006).

More recently, Belle has reported an updated result using a similar method on the full $\Upsilon(4S)$ data sample containing 772×10^6 $B\overline{B}$ pairs (Adachi, 2012b). This analysis has a number of significant improvements compared to the previous one, improved hadronic tagging efficiency (a factor of 2.2 times larger), and improved signal efficiency due to less restrictive selection criteria (a factor of 1.8 times larger). The τ lepton is identified in the $\tau^+ \to e^+\nu_e\overline{\nu}_\tau$, $\mu^+\nu_\mu\overline{\nu}_\tau$, $\pi^+\overline{\nu}_\tau$, and $\pi^+\pi^0\overline{\nu}_\tau$ decay channels. Multiple neutrinos in the final state are distinguished using the missing mass squared $M^2_{\text{miss}} = (E_{\text{CM}} - E_{B_{\text{tag}}} - E_{B_{\text{sig}}})^2/c^4 - |\boldsymbol{p}_{B_{\text{tag}}} + \boldsymbol{p}_{B_{\text{sig}}}|^2/c^2$, where $E_{B_{\text{sig}}}$ and $\boldsymbol{p}_{B_{\text{sig}}}$ are the energy and the momentum, respectively of the B_{sig} candidate in the CM frame. For the B_{sig} selection, the event is required to have no extra π^0 or K^0_L candidates ("K^0_L veto"). The signal yield is extracted from a two-dimensional extended maximum likelihood fit to E_{extra} and M^2_{miss}. By combining the four τ decay modes, the extracted signal yield is $62^{+23}_{-22}(\text{stat}) \pm 6(\text{syst})$ events, corresponding to a significance of 3.0 σ. The branching fraction is measured to be $\mathcal{B}(B^+ \to \tau^+\nu) = (0.72^{+0.27}_{-0.25}(\text{stat}) \pm 0.11(\text{syst})) \times 10^{-4}$. Figure 17.10.2 (a) shows the E_{extra} distribution overlaid with the fit results for the sum of the individual τ decay modes.

Belle has also reported a result using the semileptonic tagging method, based on a sample of 657×10^6 $B\overline{B}$ events (Hara, 2010). In this analysis, B_{tag} candidates were reconstructed via $B^- \to D^{*0}\ell^-\overline{\nu}$ and $B^- \to D^0\ell^-\overline{\nu}$ decays, where ℓ is an electron or muon. D^0 mesons were reconstructed in the $K^-\pi^+$, $K^-\pi^+\pi^0$, and $K^-\pi^+\pi^-\pi^+$ modes. For the B_{sig}, Belle considered τ^+ decays to one charged particle and neutrinos, *i.e.* $\tau^+ \to \ell^+\nu_\ell\overline{\nu}_\tau$ and

$\tau^+ \to \pi^+\overline{\nu}_\tau$. Figure 17.10.2 (b) shows the E_{extra} distribution overlaid with the fit results for the sum of the τ decay modes. Belle reported a clear excess of signal events in the region near zero and obtained a signal yield of 143^{+36}_{-35} events, corresponding to a significance of 3.6σ. The branching fraction was determined to be $\mathcal{B}(B^+ \to \tau^+\nu) = (1.54^{+0.38}_{-0.37}(\text{stat})^{+0.29}_{-0.31}(\text{syst})) \times 10^{-4}$.
Figure 17.10.2. (a) Distribution of residual energy E_{ECL} (referred to as E_{extra} in the text) reported by Belle using hadronic tags (Adachi, 2012b). The solid circles with error bars are data. The solid histograms show the projection of the fit. The dashed and dotted histograms show the signal and background components, respectively. (b) The same distribution obtained using semileptonic tagged events (Hara, 2010). The points with error bars are data. The hatched histogram and solid open histogram are the background and the total signal plus background contributions, respectively.

BABAR results

BABAR has published searches for $B^+ \to \tau^+\nu$ using both the hadronic and semileptonic tag reconstruction methods. The most recent hadronic tag search is based on the full *BABAR* dataset of 467.8×10^6 $B\bar{B}$ events (Lees, 2013a). This search utilized the four tau decay channels $\tau^+ \to e^+\nu\bar{\nu}$, $\tau^+ \to \mu^+\nu\bar{\nu}$, $\tau^+ \to \pi^+\bar{\nu}$, and $\tau^+ \to \rho^+(\to \pi^+\pi^0)\bar{\nu}$, totaling approximately 70% of the total branching fraction. This search utilizes an expanded set of hadronic tag reconstruction modes (see Chapter 7) that includes $B^- \to J/\psi X^-$ along with lower purity modes to increase the overall tag reconstruction efficiency by almost a factor of two compared to previous searches by *BABAR*.

Exactly one charged track is required in addition to the reconstructed tag B daughter particles. Events are classified into τ decay modes according to electron, muon and pion particle identification criteria applied to the track. If the signal track is identified as a π^+, the event is considered to be a $\tau^+ \to \rho^+\bar{\nu}$ candidate if a π^0 candidate satisfies the condition $115 < M_{\gamma\gamma} < 155$ MeV/c^2. Otherwise it is considered to be a $\tau^+ \to \pi^+\bar{\nu}$ candidate. Multivariate likelihood ratios are constructed, for each signal mode, for signal and background hypotheses. For the $\tau^+ \to e^+\nu\bar{\nu}$, $\tau^+ \to \mu^+\nu\bar{\nu}$ and $\tau^+ \to \pi^+\bar{\nu}$ modes, the likelihoods are constructed from the products of *p.d.f.*s for p^*_{trk} and $\cos\theta_{\text{miss}}$. For the $\tau^+ \to \rho^+\bar{\nu}$ mode, the reconstructed invariant mass of the $\gamma\gamma$ combination and of the $\pi^+\pi^0$ combination are also used as inputs. The signal yield is extracted using an unbinned maximum likelihood fit to the E_{extra} distribution for the four signal modes. The combinatorial background *p.d.f.* is obtained from data in the m_{ES} sideband region and combined with a B^+B^- "peaking" component from MC to define an overall background *p.d.f.* to use in the fit. The fit yields a positive signal with a significance of approximately 3.8σ and a branching fraction of $\mathcal{B}(B^+ \to \tau^+\nu) = (1.83^{+0.53}_{-0.49}(\text{stat}) \pm 0.24(\text{syst})) \times 10^{-4}$. Figure 17.10.3 (a) shows the E_{extra} distribution obtained from this analysis. An earlier version of this search based on 383×10^6 $B\bar{B}$ events (Aubert, 2008c) and utilizing the same four tau decay modes reported a similar branching fraction central value $\mathcal{B}(B^+ \to \tau^+\nu) = 1.8^{+0.9}_{-0.8}(\text{stat}) \pm 0.4 \pm 0.2(\text{syst})$. However, the statistical significance (2.2σ) was not sufficient to provide compelling evidence for the signal decay.

BABAR has also performed searches for $B^+ \to \tau^+\nu$ using semileptonic tag reconstruction (Aubert, 2006a, 2007a, 2010a). The most recent *BABAR* study (Aubert, 2010a) was based on 458.9×10^6 $B\bar{B}$ events and analyzed the four tau decay modes $\tau^+ \to e^+\nu\bar{\nu}$, $\tau^+ \to \mu^+\nu\bar{\nu}$, $\tau^+ \to \pi^+\bar{\nu}$, and $\tau^+ \to \rho^+(\to \pi^+\pi^0)\bar{\nu}$. Two likelihood ratios are constructed from kinematic and event shape variables designed, respectively, for suppression of continuum backgrounds and non-signal $B\bar{B}$ backgrounds. Signal and background *p.d.f.*s are obtained from MC for each of the four signal channels and likelihood ratios are constructed from the product of the *p.d.f.*s. The selection is optimized to maximize the expected signal significance for each of the signal modes. Three variables are optimized: the outputs

of the continuum and $B\bar{B}$ likelihood ratio selectors and E_{extra}. In the optimized selection the cut on E_{extra} ranges from 200 MeV to 350 MeV and predicted background yields range from approximately 60 to 230 events, depending on the signal mode. The overall selection efficiency, including both B_{tag} reconstruction and signal selection, is at the level of $\sim 10^{-3}$. Figure 17.10.3 (b) shows the E_{extra} distribution obtained. A slight excess of events in data compared with the predicted background is found in each of the four signal modes resulting in a combined branching fraction central value of $\mathcal{B}(B^+ \to \tau^+\nu) = (1.7 \pm 0.8(\text{stat}) \pm 0.2(\text{syst})) \times 10^{-4}$ with an overall signal significance of approximately 2.3σ.
Figure 17.10.3. (a) Distribution of E_{extra} reported by *BABAR* using hadronic tags (Lees, 2013a). The points with error bars represent data. The solid histogram shows the background and the dashed component is the best-fit signal excess distribution. (b) The same distribution obtained using semileptonic tagged events (Aubert, 2010a). The points with error bars are data. The gray shaded boxes represent MC simulated backgrounds and the dotted histogram is the signal MC simulation normalized to 10 times the expected branching fraction.

Summary of $B^+ \to \tau^+\nu$ measurements

The branching fractions reported by Belle and *BABAR* using the hadronic and semileptonic tagged samples are summarized in Table 17.10.1 and graphically compared in Figure 17.10.4. The errors for N_{sig} are statistical only. For the semileptonic-tag analysis at *BABAR*, we obtain N_{sig} by taking a difference between the total yield of 583 events and the expected background yield of 509 ± 30 events, where the error is obtained by taking a quadratic sum of the errors for the above two yields assuming a Poisson error for the total yield. The significance Σ_{sig} includes systematic uncertainties. The efficiency ϵ_{sig} includes the branching ratios of the tau decay modes. The first and second errors for $\mathcal{B}$ are the statistical and systematic uncertainties, respectively.

The four results are consistent within the errors. Both Belle and *BABAR* quote average branching fractions from the combination of their own hadronic and semileptonic tag results. Taking the simple weighted average of these two values one obtains

$$\mathcal{B}(B^+ \to \tau^+\nu)_{\text{AVG}} = (1.15 \pm 0.23) \times 10^{-4}. \quad (17.10.10)$$
Figure 17.10.4. Comparison of the branching fractions reported by Belle and *BABAR* using the hadronic and semileptonic tagged samples of data. The error bars indicate the quadratic sums of the statistical and systematic uncertainties.

Interpretation of results

The experimental average for the $B^+ \to \tau^+\nu$ branching fraction is consistent with the SM prediction from Equation (17.10.5). In turn, using the average $B^+ \to \tau^+\nu$ branching fraction, the product of $|V_{ub}|$ and the B meson decay constant f_B is calculated to be,

$$f_B|V_{ub}| = (8.06 \pm 0.81) \times 10^{-4}\,\text{GeV}. \quad (17.10.11)$$

Using the value of f_B above (Section 17.10.2.1), $|V_{ub}|$ is deduced to be,

$$|V_{ub}| = (4.22 \pm 0.47) \times 10^{-3}. \quad (17.10.12)$$

This is consistent, within errors, with the average values of $|V_{ub}|$ obtained from inclusive and exclusive B semileptonic decay data in Eq. (17.1.70). This result is also consistent with the value from inclusive B semileptonic decay data alone, but higher than the value from exclusive B semileptonic decay data by 2.1 σ.

The obtained branching fraction can also be used to constrain the charged Higgs. The ratio r_H, as defined in Eq. (17.10.7), is found to be $r_H = 1.14 \pm 0.40$. Based on this result and Eq. (17.10.6), the charged Higgs can be constrained in the $(\tan\beta, M_H)$ plane, as shown in Figure 17.10.5.
Figure 17.10.5. Constraint on the ratio of the two vacuum expectation values $\tan\beta$ and the charged Higgs mass in the type II of two Higgs doublet model. The green regions indicate the excluded regions at a confidence level of 95%.

17.10.2.3 $B^+ \to \ell^+\nu$ $(\ell = e, \mu)$

Although the $B^+ \to e^+\nu$ and $B^+ \to \mu^+\nu$ branching fractions are substantially suppressed compared to the τ mode, these modes are still of considerable interest at the B Factories. While the electron mode, within the SM, is well beyond reach, the μ mode has a predicted branching fraction of $\sim 5 \times 10^{-7}$, which is potentially detectable by *BABAR* and Belle. It is also notable that the relative

Table 17.10.1. Summary table for the $B^+ \to \tau^+ \nu$ analyses. The number of $B\bar{B}$ pairs in the data sample ($N_{B\bar{B}}$), the signal yield (N_{sig}), the significance (Σ_{sig}), the detection efficiency (ϵ_{sig}), and the branching ratio ($\mathcal{B}$) are shown for each of the hadronic-tag and semileptonic-tag analyses. The combined results reported by Belle and *BABAR* for $\mathcal{B}$ are also shown, where the errors are the sum in quadrature of the statistical and systematic uncertainties.

Experiment	Tagging	$N_{B\bar{B}}$ (10^6)	N_{sig}	Σ_{sig}	ϵ_{sig} (10^{-4})	$\mathcal{B}$ (10^{-4})	Reference
	Hadronic	772	62^{+23}_{-22}	3.0σ	11.2	$0.72^{+0.27}_{-0.25} \pm 0.11$	(Adachi, 2012b)
Belle	Semileptonic	657	143^{+36}_{-35}	3.6σ	14.3	$1.54^{+0.38+0.29}_{-0.37-0.31}$	(Hara, 2010)
	Combined					0.96 ± 0.26	(Adachi, 2012b)
	Hadronic	468	62 ± 17	3.8σ	7.3	$1.83^{+0.53}_{-0.49} \pm 0.24$	(Lees, 2013a)
BABAR	Semileptonic	459	74 ± 39	2.3σ	9.6	$1.7 \pm 0.8 \pm 0.2$	(Aubert, 2010a)
	Combined					1.79 ± 0.48	(Lees, 2013a)

enhancement (or suppression) of the leptonic branching fractions due to the existence of a charged Higgs boson is independent of the final state lepton mass as can be seen from Eq. (17.10.7). Consequently, equally precise determinations of experimental branching fractions in any of the three leptonic modes would yield identical constraints on a postulated charged Higgs boson. Additionally, because the $B^+ \to \mu^+ \nu$ final state contains only a single neutrino and a high momentum μ, there exist sufficient constraints that the search can be performed without the need for exclusive B_{tag} reconstruction and hence with substantially higher signal efficiency than in the case of $B^+ \to \tau^+ \nu$. The higher efficiency and cleaner signature compensates to some degree for the smaller SM branching fraction, however current measurements of $B^+ \to \mu^+ \nu$ are not yet sufficiently sensitive to provide evidence of a non-zero signal. Both *BABAR* (Aubert, 2004ac, 2009as) and Belle (Satoyama, 2007) have published the results of searches for $B^+ \to \mu^+ \nu$ and $B^+ \to e^+ \nu$ using this "inclusive" (*i.e.* un-tagged) approach. These inclusive searches have resulted in branching fraction upper limits that are within about a factor of two of the SM expectation, and that are limited by the finite size of the background event samples. *BABAR* has also performed a search using hadronic B_{tag} reconstruction (Aubert, 2008az) and a search using semileptonic tag reconstruction (Aubert, 2010a).

Inclusive searches

The most stringent limits on $B^+ \to \mu^+ \nu$ and $B^+ \to e^+ \nu$ are obtained from "inclusive" searches from *BABAR* (Aubert, 2009as) and Belle (Satoyama, 2007). These analyses rely on the distinctive signature of the high-momentum lepton (e or μ) resulting from the two-body B decay. The lepton momentum lies well above the kinematic limit for $b \to c\ell\nu$ and close to the endpoint for $b \to u\ell\nu$. Consequently, backgrounds from B decays with real leptons are relatively limited, but continuum background can be large.

Tight particle identification requirements are imposed in order to cleanly identify the signal candidate electron or muon. Although the lepton is expected to be mono-energetic in the signal B rest frame, the $\Upsilon(4S)$ rest frame (*i.e.* the e^+e^- CM frame) is initially used as an approximation since the rest frame of the parent B is not known. Because the two B mesons have momenta of ~ 320 MeV/c in this frame, the signal lepton momentum is smeared out and ranges from 2.4 GeV/c to about 3.2 GeV/c.

Since the only other daughter of the signal B is an undetected neutrino, it is expected that all other particles detected in the $\Upsilon(4S) \to B^+ B^-$ event originate from the non-signal B. Consequently, for signal events, the combination of all particles should yield a four-vector consistent with a B meson, and a total charge that is opposite that of the signal lepton. In order to obtain the best possible resolution for this four-vector, tracks used in this combination are assigned mass hypotheses based on particle identification criteria. Events with any additional identified leptons are vetoed since their presence often implies either additional missing energy from unobserved neutrinos, or that the event is continuum background. Missing energy can also arise due to particles lost outside the detector fiducial acceptance; in particular this can occur for continuum backgrounds, which tend to produce particles in the forward and backward regions of the detector. Belle requires the transverse component of the missing momentum to be greater than 1.75 GeV/c and the cosine of the angle with respect to the beam axis to be less than 0.84 (0.82) for the muon (electron) mode. Continuum background is further suppressed by exploiting the differences in event shapes compared with $B\bar{B}$ events. To this end both *BABAR* and Belle use a Fisher discriminant (see Chapter 4) combining kinematic and angular variables describing the distribution and energies of reconstructed particles in the event.

The four-vector of the non-signal B is obtained by summing the four-vectors of all tracks and clusters in the event other than the signal lepton. The kinematic variables ΔE and m_{ES} are used to characterize the B candidate. Events in which all non-signal B decay daughters, and no additional particles, are correctly identified and included in the four-vector sum are expected to have $\Delta E \approx 0$ and m_{ES} close to the nominal B mass. Due to the "inclusive" nature of the method, the resolution of both of these quantities is relatively poor compared to what is typically obtained for exclusively reconstructed B decays.

The signal B four-vector can be inferred from the non-signal B four-vector and used to refine the estimate of the

B rest frame momentum of the signal lepton. This results in a modest improvement in the resolution of the lepton momentum (see *e.g.* Figure 17.10.6 upper plot), compared with the e^+e^- CM frame.

The signal yield is extracted based on the distributions of the corrected lepton momentum (p_ℓ^B) and the non-signal B m_{ES} and ΔE distributions. *BABAR* and Belle use different methods. Belle requires $2.6 < p_{\mu(e)}^B < 2.84\,(2.80)$ GeV/c and $-0.8\,(-1.0) < \Delta E < 0.4$ GeV for the muon (electron) mode (see Figure 17.10.6 upper plot), then defines a fit region, $5.10 < m_{ES} < 5.29$ GeV/c^2, and a more constrained signal region, $5.26 < m_{ES} < 5.29$ GeV/c^2, which are used for background and signal estimation, respectively. The signal is extracted using an unbinned maximum likelihood fit to m_{ES} in the signal region. The overall signal efficiency is estimated to be $\epsilon_\mu = (2.18 \pm 0.06)\%$ and $\epsilon_e = (2.39 \pm 0.06)\%$ for the muon and electron channels, respectively. Belle observes a total of 12 (15) events with an expected background of 7.4 ± 1.0 (13.4 ± 1.4) events in the muon (electron) channel, yielding branching fraction upper limits of 1.7×10^{-6} (0.98×10^{-6}) at a 90% confidence level (see Table 17.10.2). The SM expectation for the signal yield in the $B^+ \to \mu^+\nu$ channel is 2 – 3 events in this analysis.

In the *BABAR* analysis, ΔE is required to satisfy $-2.25 < \Delta E < 0$ GeV. A Fisher discriminant is then constructed from the two variables, p_ℓ^{CM} and p_ℓ^B, representing the signal lepton momentum in the CM frame and the inferred signal B rest frame, respectively. The signal yield is then determined using an extended maximum likelihood fit to the Fisher discriminant output and m_{ES}. The total signal efficiencies are estimated to be $\epsilon_\mu = (6.1 \pm 0.2)\%$ and $\epsilon_e = (4.7 \pm 0.3)\%$ in the muon and electron channel, respectively. The fit yields 1 ± 15 (18 ± 14) events in the muon (electron) channel. In the absence of significant evidence for signal, *BABAR* obtains branching fraction upper limits of 1.0×10^{-6} (1.9×10^{-6}) at the 90% confidence level (see Table 17.10.2). In a previous inclusive search for $B^+ \to \mu^+\nu$ by *BABAR* (Aubert, 2004ac), a simpler signal extraction method was used in which the signal yield was obtained using a so-called cut-and-count (or rectangular cut) method based on a rectangular signal region defined in the $(m_{ES}, \Delta E)$ plane. The signal efficiency was estimated to be $\epsilon_\mu = (2.09 \pm 0.06(\mathrm{stat}) \pm 0.13(\mathrm{syst}))\%$ with a total background of 5.2 ± 0.5 events in a data sample of 88×10^6 $B\bar{B}$ pairs.

Searches using tag reconstruction

BABAR has also performed searches for $B^+ \to \mu^+\nu$ and $B^+ \to e^+\nu$ using methods based on hadronic (Aubert, 2008az) and semileptonic (Aubert, 2010a) tag B reconstruction, similar to the methods used for $B^+ \to \tau^+\nu$ and described in Section 17.10.2.2 above. The semileptonic tag search is performed simultaneously with the corresponding $B^+ \to \tau^+\nu$ study, essentially representing a special case of the $\tau^+ \to \ell^+\nu\bar{\nu}$ ($\ell = e, \mu$) signal channels in which the final state lepton has a high momentum.

While the signal efficiency in the "tagged" searches is substantially reduced compared with inclusive searches due to the tag reconstruction procedure, an advantage is gained (particularly in the case of hadronic tags) due to increased continuum background suppression and improved knowledge of the signal event kinematics. In particular, the hadronic B_{tag} four-vector permits the signal B four-vector to be precisely determined, with the consequence that the lepton momentum can be precisely determined in the B rest frame. The improved p_μ^B resolution is illustrated in the lower plot of Figure 17.10.6, which can be compared with the "inclusive" distribution from Belle shown in the upper plot. The improved resolution allows for a significantly improved separation between signal events and backgrounds from semileptonic B decays, in particular $b \to u\ell\nu$ events. In the *BABAR* study (Aubert, 2008az), the hadronic tag search is essentially background free in the signal region. However, with the number of events available with the *BABAR* and Belle data samples, the tagged approach is statistically limited and the inclusive approach results in a significantly more stringent branching fraction limit than the tagged analyses. However, both the hadronic tag and inclusive methods yield similar sensitivities for a 5σ signal observation, with the event samples available at the current B Factories, due to the large statistical uncertainty in the background in the inclusive method. It is anticipated that the two methods will provide complementary and precise $B^+ \to \mu^+\nu$ branching fraction measurements with the data expected at future high luminosity B Factories.

17.10.2.4 Radiative decays $B^+ \to \ell^+\nu\gamma$

To date, only a single search for $\mathcal{B}(B^+ \to \ell^+\nu_\ell\gamma)$ has been published (Aubert, 2009a) by the asymmetric B Factories, although CLEO had previously published results using an un-tagged search method (Browder et al., 1997). The *BABAR* result, which is based on a data sample of 465 million $B\bar{B}$ pairs, uses a method based on hadronic-tag reconstruction (see Chapter 7). However, Belle (Abe, 2004d) and *BABAR* (Aubert, 2007aw) have both reported unpublished results using an "inclusive" method similar to that used by CLEO. Although the hadronic-tag technique results in a low signal efficiency (0.3% for signal modes), it compensates by providing a high purity sample of B mesons with comparatively little non-$B\bar{B}$ (continuum) background. This background is very problematic for the inclusive analyses. In addition, by reconstructing the B_{tag} using only detectable hadronic decay modes, the missing four-vector of the signal neutrino is fully determined. Thus the *BABAR* hadronic tag analysis was able to avoid the model-dependent kinematic constraints in the signal selection which had complicated the interpretation of the earlier analyses. However, the inclusive analyses benefit from significantly higher statistical sensitivity. With the available *BABAR* or Belle data it is expected that the inclusive measurements, if they had been published, would have yielded more stringent experimental limits or possibly observation of these decay modes.

Table 17.10.2. $B^+ \to \ell^+ \nu$ and $B^+ \to \ell^+ \nu \gamma$ branching fraction measurements by BABAR and Belle.

Experiment	Decay Mode	Method	$N_{B\bar{B}}$ (10^6)	$\mathcal{B}$ upper limit 90% C.L.	Reference
Belle	$B^+ \to \mu^+ \nu$	inclusive	253 fb^{-1}	1.7×10^{-6}	Satoyama (2007)
	$B^+ \to e^+ \nu$			0.98×10^{-6}

Figure 17.10.6. (Top) Momentum of the reconstructed $B^+ \to \mu^+ \nu$ signal muon in the Belle "inclusive" search (Satoyama, 2007) and (bottom) in the BABAR "hadronic tag" search (Aubert, 2008az).

The hadronic-tag analysis proceeds as follows. After reconstructing a B_{tag}, remaining continuum background is suppressed using a multivariate selector incorporating several event shape variables. From this sample, signal candidate events are required to possess only one "signal-side" track, in addition to those used to reconstruct the B_{tag}. This track is required to satisfy either electron or muon particle identification. In the case of electrons, candidate Bremsstrahlung clusters in the calorimeter are used

to correct the momentum of the electron track. The highest energy remaining calorimeter cluster, not associated with the reconstructed B_{tag}, is assumed to be the radiated signal photon. The energy spectrum of radiated photons in signal candidates is expected to peak at $\sim 1\,\text{GeV}$. The energies of any remaining calorimeter clusters are summed to obtain E_{extra}. A loose requirement of $E_{\text{extra}} < 0.8\,\text{GeV}$ is imposed to reject B backgrounds. To ensure that the signal candidates are consistent with a three-body decay, the lepton momentum and the total missing momentum in the event were required to be back-to-back in the frame recoiling against the photon. As the signal B four-vector can be inferred from the B_{tag} four-vector, the 3-body kinematics can be uniquely determined by combining this information with the signal lepton and photon candidate four-vectors. The most discriminating variable is the reconstructed invariant mass of the neutrino, given as $m_\nu^2 \equiv |p_{\Upsilon(4S)} - p_{B_{\text{tag}}} - p_\ell - p_\gamma|^2$ where p_i is the four-momentum of particle i. Figure 17.10.7 shows that the signal peaks at zero, while the background rises with m_ν^2.

The dominant backgrounds arise from $B^+ \to X_u^0 \ell^+ \nu_\ell$ events, where X_u is a neutral meson containing a u-quark. Events in which the signal photon candidate could be combined with another calorimeter cluster to form an invariant mass consistent with the π^0 or η mass, or combined with a π^0 candidate to form an ω, were rejected. However, $B^+ \to X_u^0 \ell^+ \nu_\ell$ events can mimic the signal decay kinematics. This can occur especially if only one high-energy photon daughter from the X_u decay is present in the signal-side clusters, or if the two photons from a $B^+ \to \pi^0 \ell^+ \nu_\ell$ decay are merged into a single calorimeter cluster containing the full energy of the π^0. Consequently, the combination of this "photon" cluster with the signal lepton results in an m_ν^2 distribution that peaks at zero, mimicking signal. These backgrounds are suppressed by examining the shape of the calorimeter cluster and limiting the lateral moment of the cluster energy deposit.

A cut-and-count method is used to determine the signal yield. The background is divided into two components: events that peak in the m_{ES} signal region are es-
Figure 17.10.7. m_ν^2 distribution in $B^+ \to \ell^+\nu\gamma$, from Aubert (2009a), after all selection criteria are applied, in the electron (top) and muon (bottom) modes. The m_{ES}-peaking (shaded) and non-peaking (solid) background contributions are shown stacked, along with signal MC (dashed) normalized to $\mathcal{B} = 40 \times 10^{-6}$, and data (points). Events to the left of the vertical lines are selected.

timated from various dedicated $B^+ \to X_u^0 \ell^+ \nu_\ell$ MC samples, while non-peaking events are extrapolated directly from the data events in the m_{ES} sideband region in order to reduce the dependence on MC simulations. The largest background uncertainties stem, respectively, from the branching fractions and form factors of the various $B^+ \to X_u^0 \ell^+ \nu_\ell$ decays, and from the limited number of sideband data events.

A measurement of $\mathcal{B}(B^+ \to \ell^+\nu_\ell\gamma) = (6.5^{+7.6}_{-4.7}\,{}^{+2.8}_{-0.8}) \times 10^{-6}$ was obtained with a significance of 2.1σ, along with an upper limit of $\mathcal{B}(B^+ \to \ell^+\nu_\ell\gamma) < 15.6 \times 10^{-6}$ at 90% confidence level. These results are the most stringent published limits, and are close to the theoretical predictions for these modes. Effectively no requirements are applied to the lepton or photon kinematics, thus this analysis is essentially independent of the $B \to \gamma$ form factor models and valid over the full kinematic range.

However, the extraction of λ_B (see Eq. 17.10.9) can be improved by including a minimum energy requirement on the signal photon (Ball and Kou, 2003; Beneke and Rohrwild, 2011). Therefore, additional branching fraction results were reported in specific kinematic regions. A requirement that the signal photon candidate energy is > 1 GeV results in a partial branching fraction of $\Delta\mathcal{B}(B^+ \to \ell^+\nu_\ell\gamma) < 14 \times 10^{-6}$ at a C.L. of 90%. More stringent branching fraction limits were determined by introducing a kinematic requirement on the angles between the three

daughter particles of the signal decay. In a model in which the two $B \to \gamma$ form-factors, f_V and f_A, are equal, the result $\mathcal{B}(B^+ \to \ell^+\nu_\ell\gamma) < 3.0 \times 10^{-6}$ is obtained. In a model with $f_A = 0$, $\mathcal{B}(B^+ \to \ell^+\nu_\ell\gamma) < 18 \times 10^{-6}$ is obtained.

Although a significant $B^+ \to \ell^+\nu_\ell\gamma$ signal has not yet been observed, the sensitivity of the this method is such that it is likely that these decays will be accessible at future high-luminosity B Factories.

17.10.3 $B \to D^{(*)}\tau\nu$

In the SM the branching fractions for the semileptonic decays $B \to D^{(*)}\tau\nu_\tau$, which proceed via a tree-level process with an intermediate $W^\pm$, are predicted to be $(0.69 \pm 0.04)\%$ and $(1.41 \pm 0.07)\%$ for $B^0 \to D^-\tau^+\nu_\tau$ and $B^0 \to D^{*-}\tau^+\nu_\tau$, respectively (Chen and Geng, 2006). However, if a charged Higgs boson exists, the branching fraction may differ significantly due to interference from a tree-level $H^\pm$ exchange contribution similar to that for $B^+ \to \tau^+\nu$ (see Figure 17.10.1). Effects of the charged Higgs on $B \to D^{(*)}\tau\nu$ decays are discussed in a number of theoretical papers (Fajfer, Kamenik, and Nisandzic, 2012; Grzadkowski and Hou, 1992; Itoh, Komine, and Okada, 2005; Kiers and Soni, 1997; Nierste, Trine, and Westhoff, 2008; Tanaka, 1995). From a theoretical point of view, the $B \to D^{(*)}\tau\nu_\tau$ decay has a similar sensitivity to $H^\pm$ as the $B^+ \to \tau^+\nu$ decay, but with different theoretical and parametric uncertainties. While the purely leptonic decay depends only on the relatively well known B meson decay constant f_B, the semileptonic decays depend on form factors. The formulae for the semileptonic rates can be found in Section 17.1. However, for $\ell = e, \mu$ the lepton mass is usually neglected in which case the rates are not sensitive to the "longitudinal" form factors, which are proportional to the momentum transfer $q = (p - p')$

$$\langle D(p')|\bar{c}\gamma_\mu b|B(p)\rangle = (p_\mu - p'_\mu)F_0(q^2) + \cdots \quad (17.10.13)$$

and similarly for the transition $B \to D^*$. These form factors become relevant for $B \to D^{(*)}\tau\nu$, since their contributions to the differential rates are proportional to M_ℓ^2/M_B^2 which is sizable for $\ell = \tau$. Detailed results for the differential rates including lepton mass effects can be found, for example, in (Fajfer, Kamenik, and Nisandzic, 2012; Nierste, Trine, and Westhoff, 2008).

The longitudinal form factors for $B \to D^{(*)}\tau\nu$ are not as well known as the ones appearing in the decays with an e or a μ. Nevertheless, one can apply the heavy quark limit for both the bottom and the charm quark in which case all form factors of the $B \to D^{(*)}$ transitions may be related to a single form factor, the Isgur-Wise function (see Section 17.1). This limit is expected to be valid at the level of (20-30)%, however, in combination with the factor M_ℓ^2/M_B^2 one still arrives at fairly precise predictions for ratios of branching fractions. The ratio

$$\mathcal{R}_{D^{(*)}} = \frac{\mathcal{B}(B \to D^{(*)}\tau\nu)}{\mathcal{B}(B \to D^{(*)}\ell\nu)}, \quad (17.10.14)$$

can provide sensitivity to $H^\pm$. Measurement of this quantity has the additional advantage of using two decay modes with very similar experimental signatures, if only the leptonic decay modes of the tau are considered. This method therefore permits the cancellation of form factor uncertainties as well as many experimental systematic uncertainties.

In contrast, sensitivity to $H^\pm$ in $B^+ \to \tau^+ \nu_\tau$ requires measurement of the absolute branching fraction and comparison with the expected SM prediction, which in turn requires knowledge of the CKM matrix element V_{ub}. Given the current discrepancy between inclusive and exclusive V_{ub} measurements (see Section 17.1), the $B \to D^{(*)}\tau\nu_\tau$ modes currently provide a cleaner interpretation of possible $H^\pm$ contributions. These modes therefore provide complementary approaches to searching for $H^\pm$ signatures in B decays.

The three-body kinematics of the $B \to D^{(*)}\tau\nu_\tau$ decay also potentially permit the study of the τ polarization via the decay distributions of final state particles. These measurements can in principle discriminate between $H^\pm$ and $W^\pm$ exchange, however studies performed to date have not been sensitive to these distributions.

17.10.3.1 Experimental methodology and results

Like $B^+ \to \tau^+\nu$, the $B \to D^{(*)}\tau\nu$ decay has two or more neutrinos in the final state and so cannot be fully reconstructed using only the observable particles. It therefore relies on exclusive reconstruction of the accompanying B ("B_{tag}") to provide the necessary level of background suppression (see Chapter 7). *BABAR* has reported $B \to D^{(*)}\tau\nu$ results using the method of hadronic B tag reconstruction (Aubert, 2008al; Lees, 2012e) while Belle has published results based on another method, referred to as "inclusive tags" (Bozek, 2010; Matyja, 2007), in which B_{tag}'s are reconstructed by calculating the four-vector sum of the tracks inclusively without reconstructing the intermediate mesons. This method is similar to the "inclusive" method used in $B^+ \to \ell^+\nu$ ($\ell = e, \mu$) described in Section 17.10.2.3 above. Belle has also produced a preliminary measurement of $B \to D^{(*)}\tau\nu$ based on hadronic tag reconstruction (Adachi, 2009).

The Belle Collaboration reported the first observation (5.2σ) of a $B^0 \to D^{*-}\tau^+\nu$ using the inclusive tag method with a data sample of 535 M $B\bar{B}$ pairs (Matyja, 2007). The $\tau^+ \to e^+\nu_e\bar{\nu}_\tau$ and $\tau^+ \to \pi^+\bar{\nu}_\tau$ decays were used to reconstruct τ lepton candidates. A follow-up to this analysis for $B^+ \to \bar{D}^{(*)0}\tau\nu_\tau$ was performed using 657 M $B\bar{B}$ pairs (Bozek, 2010). In this analysis, the signal and combinatorial background yields were extracted using an extended unbinned maximum likelihood fit to the distributions of the B_{tag} m_{ES} (referred to as M_{tag}) and the CM frame momentum of the reconstructed D^0, p_{D^0}. The $\tau^+ \to e^+\nu_e\bar{\nu}_\tau$, $\tau^+ \to \mu^+\nu_\mu\bar{\nu}_\tau$ and $\tau^+ \to \pi^+\bar{\nu}_\tau$ decay modes were used to reconstruct the τ^+ lepton candidates. In total, 13 different decay channels, 8 for D^{*0} and 5 for D^0, were considered. The fits were performed simultaneously to all data

subsets. In each of the sub-channels, the data were described as the sum of four components; signal, cross-feed between $\bar{D}^{*0}\tau^+\nu_\tau$ and $\bar{D}^0\tau^+\nu_\tau$, combinatorial and peaking backgrounds. Figure 17.10.8 shows the M_{tag} and p_{D^0} distributions and fit results for the two decay modes. The extracted signal yields (significances) are 446^{+58}_{-56} (8.1 σ) for $B^+ \to \bar{D}^{*0}\tau^+\nu_\tau$ and 146^{+42}_{-41} (3.5 σ) for $B^+ \to \bar{D}^0\tau^+\nu_\tau$. This was the first evidence for the $B^+ \to \bar{D}^0\tau^+\nu_\tau$ decay. Branching fraction results are given in Table 17.10.3.
Figure 17.10.8. The fit projection to M_{tag} and p_{D^0} for $M_{\text{tag}} > 5.26$ GeV/c^2 (a, b) for $\bar{D}^{*0}\tau^+\nu_\tau$ and (c, d) for $\bar{D}^0\tau^+\nu_\tau$, from (Bozek, 2010).

BABAR reported an observation of $B \to D^*\tau\nu$ as well as first evidence of $B \to D\tau\nu$ in Aubert (2008al) using a method based on exclusive hadronic B_{tag} reconstruction and a data sample of 232M $B\bar{B}$ events. This analysis reports measurements of the four modes $B^+ \to \bar{D}^0\tau^+\nu$, $B^+ \to \bar{D}^{*0}\tau^+\nu$, $B^0 \to D^-\tau^+\nu$ and $B^0 \to D^{*-}\tau^+\nu$, as well as the combined modes $B \to D\tau\nu$ and $B \to D^*\tau\nu$. A follow up to this paper, based on the full *BABAR* data sample of 471M $B\bar{B}$ events (Lees, 2012e) uses similar methodology. This more recent analysis reports the first observation of $B \to D\tau\nu$ and measures the ratios, $\mathcal{R}(D^{(*)})$ in a simultaneous measurement of $B \to D^{(*)}\tau\nu$ and $B \to D^{(*)}\ell\nu$ ($\ell = e, \mu$), reporting an excess over SM predictions for both $\mathcal{R}(D)$ and $\mathcal{R}(D^*)$. Several improvements are incorporated into the B_{tag} reconstruction and signal selection, which result in a factor of three improvement of the signal efficiency compared to the earlier analysis.

Since only leptonic decay modes of the tau are considered in this analysis, "signal" $B \to D^{(*)}\tau\nu$ decays have identical final states as the "normalization" $B \to D^{(*)}\ell\nu$ modes, differing only in the kinematics of the observed final state. Consequently, many uncertainties associated

with the signal reconstruction, including charged particle tracking, particle identification and calorimeter-related reconstruction issues, cancel in the ratio. As $\tau^+ \to \ell^+ \nu \bar{\nu}$ results in two additional undetected neutrinos, the missing mass, M_{miss}, computed from the signal B (inferred from the B_{tag}), the reconstructed $D^{(*)}$ and lepton four-vectors, peaks at zero for the normalization modes but not for signal decays. The final state e or μ in the $B \to D^{(*)} \tau \nu$ channel also has a softer momentum distribution than the measured primary lepton in the normalization mode. The two quantities M_{miss} and $|p_\ell^*|$, the magnitude of the lepton momentum in signal B rest frame, are used to extract the signal and normalization mode yields, as described below.

Signal events are further distinguished from normalization events and other backgrounds by requiring that the missing momentum magnitude, $|p_{\text{miss}}|$ and the square of the magnitude of the exchanged four-momentum in $B \to D^{(*)} \tau \nu$, q^2 satisfy $|p_{\text{miss}}| > 200$ MeV and $q^2 > 4$ GeV^2.

The signal $D^{(*)}$ and lepton candidates are reconstructed from tracks and clusters that are not already associated with the B_{tag}. Signal and normalization mode electrons (muons) are required to have laboratory frame momenta greater than 300 MeV (200 MeV) and satisfy particle identification criteria. The D or D^* mesons that are combined with this lepton to form the signal or normalization-mode candidates are reconstructed in the D^0 modes $K^- \pi^+$, $K^- K^+$, $K^- \pi^+ \pi^0$, $K^- \pi^+ \pi^- \pi^+$, $K_s^0 \pi^+ \pi^-$ and the charged modes $D^+ \to K^- \pi^+ \pi^+$, $K^- \pi^+ \pi^+ \pi^0$, $K_s^0 \pi^+$, $K_s^0 \pi^+ \pi^- \pi^+$, $K_s^0 \pi^+ \pi^0$, $K_s^0 K^+$, where $K_s^0 \to \pi^+ \pi^-$. D^* mesons are identified by combining reconstructed D candidates with photons or charged or neutral pions to obtain $D^{*+} \to D^0 \pi^+$, $D^+ \pi^0$ and $D^{*0} \to D^0 \pi^0$, $D^0 \gamma$ candidates. No additional tracks are permitted in the event after reconstruction of the $D^{(*)}$ and lepton, but additional photons are permitted. If multiple candidates are reconstructed in a single event, the candidate with the lowest E_{extra} is selected, where E_{extra} is the sum of the CM energies of any remaining photons in the event.

Four signal channels are analyzed, corresponding to the final states $D^0 \ell$, $D^{*0} \ell$, $D^+ \ell$ and $D^{*+} \ell$. Control samples are constructed by requiring the presence of an additional π^0 in each mode, *i.e.* $D^{(*)} \pi^0 \ell$. These control samples are used to estimate background contributions from decays to higher-mass charm states, such as $B \to D^{**} \ell \nu$, which are relatively poorly understood and not reliably modeled in the MC. Additional event shape requirements are imposed on the control samples to suppress large continuum backgrounds in these samples.

Additional background suppression is obtained by using a set of boosted decision tree multivariate selectors (see Chapter 4) trained and optimized for each of the four signal modes to select signal and normalization modes while rejecting backgrounds including D^{**} contributions and cross-feed from other signal and normalization modes. Eight kinematic variables are used as inputs, including E_{extra}, the invariant masses of the signal and B_{tag} daughter D mesons, the $D^* - D$ mass difference (when a D^* is

present), as well as other quantities related to the quality of the B_{tag} reconstruction and the overall event shape.

The level of agreement between data and MC simulation is verified, and the MC description is improved through use of additional data sideband control samples obtained by requiring $E_{\text{extra}} > 0.5$ GeV, $m_{ES} < 5.26$, or $q^2 < 4$ GeV^2. Conservative systematic uncertainties on signal efficiencies and background estimates are based on these comparisons.

The signal and normalization mode yields are obtained simultaneously for each of the four signal channels using an unbinned extended maximum likelihood fit to the M_{miss} - $|p_\ell^*|$ distribution for the signal and $D^{(*)} \pi^0 \ell$ samples. The fit consists of eight components including signal ($D \tau \nu$, $D^* \tau \nu$), normalization modes ($D \ell \nu$, $D^* \ell \nu$), $D^{**} \ell \nu$, charge cross-feed, other $B\bar{B}$ background and continuum background. The first five of these are allowed to vary in the fit, while the last three are fixed to the values determined from MC and sideband studies. The $D^{**} \ell \nu$ contributions in the signal sample fit are constrained by the fit to the $D^{(*)} \pi^0 \ell$ samples. Even with this method to control the $D^{**} \ell \nu$ contributions, this background imposes the dominant systematic uncertainty on the signal yield extraction.

The branching fraction ratios $\mathcal{R}(D^{(*)})$ are determined from the signal and normalization mode yields and selection efficiencies. Fit projections are shown in Fig. 17.10.9 for the four signal modes. Since most of the uncertainties in the signal and normalization mode efficiencies cancel in the ratio of modes, the dominant uncertainty in the efficiency ratio comes from the form factor model uncertainties for $B \to D^{(*)} \tau \nu$ and $B \to D^{(*)} \ell \nu$. The results are presented in Table 17.10.3. In addition to results for the four individual signal channels, two additional results are obtained by combining charged and neutral B results by imposing isospin constraints.

17.10.3.2 Interpretation of results

Table 17.10.3 summarizes the results of the $B \to D^{(*)} \tau \nu$ branching fraction measurements and $\mathcal{R}(D^{(*)})$ results from Belle and *BABAR*. All results are somewhat high compared with the SM expectations, with averages dominated by the 2012 *BABAR* measurements. *BABAR* (Lees, 2012e) has interpreted the results in the context of the SM and the type-II 2HDM, estimating $\mathcal{R}(D)_{\text{SM}} = 0.297 \pm 0.017$ and $\mathcal{R}(D^*)_{\text{SM}} = 0.252 \pm 0.003$ based on Fajfer, Kamenik, and Nisandzic (2012); Kamenik and Mescia (2008) with updated form factor measurements. The combination of $\mathcal{R}(D)$ and $\mathcal{R}(D^*)$ measurements, including the experimental correlation between the $B \to D \tau \nu$ and $B \to D^* \tau \nu$ measurements, is determined to be inconsistent with the SM at the level of 3.4σ. Interpretation within the context of the 2HDM is shown in Figure 17.10.10. The decay kinematics are sensitive to the presence of a $H^\pm$ contribution, impacting both the momentum spectrum of the final state leptons and the missing mass distribution. This causes the signal efficiency to depend on $\tan \beta / M_H$, with the consequence that the measured value of $\mathcal{R}(D^{(*)})$ also

Table 17.10.3. Summary of measurements of $B \to D^{(*)}\tau\nu$. $N_{B\bar{B}}$: number of $B\bar{B}$ pairs in the data sample used for the analysis, $\mathcal{B}$: branching fraction (the first error is statistical, the second systematic, and the third due to the branching fraction uncertainty in the normalization mode), Σ: significance of the signal including systematic, $\mathcal{R}(D^{(*)})$: the ratio $\mathcal{B}(B \to D^{(*)}\tau\nu)/\mathcal{B}(B \to D^{(*)}\ell\nu)$.

depends on this quantity, as shown in the Figure. In order to correctly estimate the efficiency, BABAR re-weights the kinematics of simulated signal events to correspond to representative $\tan\beta/M_H$ values in the range shown in the Figure and repeats the full fit to arrive at measurements of $\mathcal{R}(D^{(*)})$ as a function of $\tan\beta/M_H$. It should be noted that this has implications for averaging the results of the BABAR and Belle analyses, since the efficiency dependence of the Belle analysis is not available, a simple average can only be correctly interpreted in the context of the SM. Within the context of the 2HDM, the BABAR $\mathcal{R}(D^{(*)})$ measurements imply specific values of $\tan\beta/M_H$ that are incompatible with each other, and hence with the 2HDM type II, at a C.L. of 99.8%.

17.10.4 Discussion and future prospects

Searching for leptonic decays of charged B mesons at the present generation of B Factories has proven to be very challenging, with the light lepton modes $B^+ \to e^+\nu$ and $B^+ \to \mu^+\nu$ remaining beyond the experimental sensitivities and the $B^+ \to \tau^+\nu$ mode observed, but not yet precisely measured. Prior to the most recent Belle hadronic-tag search (Adachi, 2012b), all $B^+ \to \tau^+\nu$ measurements, including previous Belle hadronic-tag studies, had reported branching fractions which were consistently high compared with SM expectations. The most recent BABAR hadronic-tag measurement (Lees, 2013a) determines a branching fraction which is approximately a factor of two higher

than the corresponding Belle result, although the discrepancy between the two is only about 2σ. Other possible points of concern are the modeling of the experimentally crucial E_{extra} variable, which has shown indications of discrepancies in previous measurements, and the internal consistency of $B^+ \to \tau^+\nu$ branching fraction values obtained with different tau decay modes, see for example Lees (2013a). Leptonic and hadronic tau decay signatures have vastly different background sources and rates, hence inconsistencies in signal yields between tau decay modes is a potential red-flag of experimental problems. As both BABAR and Belle have published $B^+ \to \tau^+\nu$ results based on their full data samples, it is unlikely that this situation will be clarified without additional measurements from future B Factory experiments with very large data samples. However, the experimental challenges posed by this decay, in particular low momentum lepton particle identification and modeling of hadronic backgrounds and extra calorimeter energy, will likely be similar (or worse) at high luminosity experiments. Consequently, it is not clear how precisely $B^+ \to \tau^+\nu$ will ultimately be measured. It is notable that precise measurements of $\mathcal{B}(B^+ \to \mu^+\nu)$ at the SM rate will be possible with data samples of $\mathcal{O}(50-100)$ ab^{-1}, using both tagged and un-tagged approaches. As the $B^+ \to \mu^+\nu$ searches utilize a cleanly identifiable high momentum muon and do not rely on E_{extra}, they will provide an independent test of possible new physics in leptonic B decays. If new physics were present in the form of a Type II 2HDM, then $\mathcal{B}(B^+ \to \mu^+\nu)$ would potentially be sensitive to it. This
Figure 17.10.9. Projections of the *BABAR* (Lees, 2012e) $B \to D^{(*)}\tau\nu$ fit for the four signal modes (a) $D^0\ell$, (b) $D^{*0}\ell$, (c) $D^+\ell$ and (d) $D^{*+}\ell$ in M^2_{miss}. Inset figures show the corresponding projection in $|p^*_\ell|$ for $M^2_{\text{miss}} > 1$ GeV^2 in order to exclude the $B \to D^{(*)}\ell\nu$ normalization component. Stacked in order from the bottom the components are: continuum and $B\bar{B}$ background (below dashed line), charge cross-feed (white above dashed line), $B \to \bar{D}^*\ell^+\nu$ (blue hatched), $B \to \bar{D}\ell^+\nu$ (yellow hatched), $B \to \bar{D}^{**}\ell^+\nu$ (black), $B \to \bar{D}^*\tau^+\nu$ (green), $B \to \bar{D}\tau^+\nu$ (red).
Figure 17.10.10. Comparison of the *BABAR* measurements of $\mathcal{R}(D)$ (top) and $\mathcal{R}(D^*)$ (bottom) with the prediction of the Type-II 2HDM (red curves). The $\tan\beta/M_H$ dependence of the *BABAR* $\mathcal{R}(D^{(*)})$ results (blue shaded bands) arises due to changes to the signal kinematics in the case that the process is mediated by a $H^\pm$ rather than a $W^\pm$. The SM case corresponds to the case $\tan\beta/M_H = 0$, and the favored values for $\tan\beta/M_H$ differ for $\mathcal{R}(D)$ and $\mathcal{R}(D^*)$. Plot is taken from Lees (2012e).

role in elucidating any new physics that might be present in $B \to D^{(*)}\tau\nu$.

Measurement of the radiative decay $B^+ \to \ell^+\nu\gamma$ has proven to be problematic at the current generation of B Factories, but the method using hadronic tag B reconstruction (Aubert, 2009a) appears to offer a solution that can permit observation and measurement of this branching fraction at future high-luminosity B Factories. Although these modes do not provide interesting new physics sensitivity, they may be relevant for the interpretation of precision measurements of $B^+ \to \ell^+\nu$ and of $B \to \pi^+\pi^-$ decays.

Future measurements of $B \to D^{(*)}\tau\nu$ will greatly improve our understanding of this process. The recent *BABAR* study of $\mathcal{R}(D^{(*)})$ (Lees, 2012e) provides a conceptually robust experimental method for measuring these decays using the ratio $\mathcal{R}(D^{(*)})$, but this analysis yields results that are incompatible both with the SM and the "preferred" 2HDM scenario that underlies the MSSM. These results have not as of yet been independently confirmed by Belle, but may provide a tantalizing glimpse of new physics coupling to third-generation leptons. In addition to determining $\mathcal{R}(D^{(*)})$, future measurements of $B \to D^{(*)}\tau\nu$ at high luminosity B Factories also have the potential to precisely study the q^2 distributions or angular properties of these decays, providing an additional handle on possible beyond-SM contributions. However, these studies will be confronted with the same experimental challenges as the *BABAR* measurement, in particular the modeling of the missing mass, lepton momentum and E_{extra} distributions, and the understanding of background contributions from semileptonic decays with higher mass open-charm states. All of these issues will need to be addressed with increased precision in order to make substantial improvements to the

scenario is, however, disfavored by $B \to D^{(*)}\tau\nu$ measurements discussed above, so it is not clear what the implications might be for the purely leptonic B decay modes. It is, however, likely that these modes will play an important

existing $\mathcal{R}(D^{(*)})$ measurements at future high luminosity experiments.

17.11 Rare and forbidden B decays

Editors:
Steve Robertson (BABAR)
Youngjoon Kwon (Belle)

Additional section writers:
Matthew Bellis, Fergus Wilson

While many B decay modes are "rare" in the sense that they have small branching fractions, the term usually refers specifically to modes which are suppressed within the SM due to some property of the decay, often related to a symmetry or conserved quantum number. The interest in these modes arises from the possibility that contributions from physics beyond the SM may not be similarly suppressed. In this sense, many of the modes discussed in Sections 17.9 and 17.10 would be considered rare decays as well, since for example the tree-level process $B^+ \to \ell^+ \nu$ is suppressed by helicity conservation when the decay is mediated by a SM W^+ boson. New-physics models permit possible contributions to this process which are mediated by a scalar charged Higgs boson and lead to potentially observable deviations from the SM expectations for the branching fractions. Similarly, the flavor changing neutral current modes in Section 17.9 are suppressed due to the absence of tree-level FCNCs in the SM. Possible new-physics contributions, which also enter at one-loop level, can therefore be comparable in size to the suppressed SM contributions. The decays $B^0 \to \ell^+ \ell^-$ and $B^0 \to \nu\bar{\nu}$, discussed below in Sections 17.11.1 and 17.11.2, are in fact exactly such processes: highly suppressed SM electroweak penguin FCNC processes which can be strongly enhanced in beyond-SM models by neutral Higgs boson contributions or other new physics. The distinction as to which modes are considered "rare" is obviously somewhat arbitrary.

In contrast, "forbidden" modes are those which are expected to proceed primarily through processes beyond the SM, which typically violate quantum numbers that are conserved within the SM such as charged lepton flavor and number, and baryon number. These decays are forbidden in the SM in the absence of neutrino masses. However, lepton flavor is not associated with a fundamental conservation law in the SM and in fact the existence of neutrino mixing explicitly requires that lepton flavor is not conserved in the neutrino sector. This in turn implies lepton flavor violation (LFV) in the charged lepton sector as well, via loop processes which contain neutrinos. However, the expected rate for such processes is many orders of magnitude below current or foreseen future experimental sensitivity to these decay modes. Observation of LFV in B decays would therefore be unambiguous evidence for a new source of LFV beyond the SM. Similarly, lepton number is not protected by any fundamental conservation law and in fact is explicitly violated if neutrinos are of Majorana type, *i.e.* if they are their own antiparticles. Consequently, searches for lepton number violation (LNV), discussed in 17.11.5, can provide insight into the nature of neutrinos.

We discuss $B^0 \to \ell^+ \ell^-$ along with the radiative mode $B^0 \to \ell^+ \ell^- \gamma$ in Section 17.11.1 and the neutrino counterparts to these modes, $B^0 \to \nu\bar{\nu}(\gamma)$, in Section 17.11.2. We describe $B^0_{(s)} \to \gamma\gamma$ in Section 17.11.3. Lepton flavor and lepton number violating modes are presented in Sections 17.11.4 and 17.11.5, respectively, and searches for baryon number violating modes are discussed in Section 17.11.6.

17.11.1 $B^0 \to \ell^+ \ell^- (\gamma)$

$B^0 \to \ell^+ \ell^-$ decays are expected to proceed through the diagrams shown in Figure 17.11.1 within the SM (SM). The branching fraction for the $B^0 \to \ell^+ \ell^-$ decays can be written to good accuracy as

$$
\mathcal{B}(B^0 \to \ell^+ \ell^-) = \frac{G_F^2 \alpha^2}{64\pi^3 \sin^4 \theta_W} \times
$$
$$
|V_{tb}^* V_{td}|^2 \tau_B M_B^3 f_B^2 \sqrt{1 - \frac{4m_\ell^2}{M_B^2}} \cdot \frac{4m_\ell^2}{M_B^2} Y^2(m_t^2/M_W^2) \ .
$$

$$(17.11.1)$$

The equation reveals a high suppression of the decays due to the internal quark annihilation within the B meson involving a $b \to d$ transition (CKM element $|V_{td}|$ and the B meson decay constant f_B) and helicity considerations (helicity suppression factor m_ℓ^2/M_B^2).[93] The SM expected branching fractions are of the order of 10^{-15} and 10^{-10} for the $e^+ e^-$ and $\mu^+ \mu^-$ modes, respectively. In some new-physics models, including those with two Higgs doublets and Z-mediated FCNC, the branching fractions could be enhanced by two orders of magnitude (Babu and Kolda, 2000; Bobeth, Ewerth, Kruger, and Urban, 2001; Chankowski and Slawianowska, 2001; Choudhury and Gaur, 1999; Hewett, Nandi, and Rizzo, 1989).

$B^0 \to \tau^+ \tau^-$ is much less helicity suppressed than $B^0 \to e^+ e^-$ and $B^0 \to \mu^+ \mu^-$ due to the large tau mass, with a predicted branching fraction of order 10^{-7} (Harrison and Quinn, 1998; Grossman, Ligeti, and Nardi, 1997). The large masses of the tau leptons also provide the potential for substantial enhancements due to Higgs couplings in two-Higgs-doublet models (Babu and Kolda, 2000; Logan and Nierste, 2000). However, due to the presence of multiple neutrinos in the experimental final state (between two and four depending on the tau decay modes), the $\tau^+ \tau^-$ final state is considerably more difficult to access experimentally than the $e^+ e^-$ and $\mu^+ \mu^-$ modes. The $e^+ e^-$ and $\mu^+ \mu^-$ searches are described in 17.11.1.1, and the $\tau^+ \tau^-$ decay in 17.11.1.2.

Although $B^0 \to \ell^+ \ell^- \gamma$ ($\ell = e$ or μ) decays can occur by emitting a photon from any of the initial or final-state fermions of $B^0 \to \ell^+ \ell^-$, the dominant contribution is due to photon emission from one of the initial-state quarks, since this process is free from the helicity suppression associated with $B^0 \to \ell^+ \ell^-$. In the SM,

---

[93] The function $Y(m_t^2/M_W^2)$ is known with good accuracy at NLO.
Figure 17.11.1. SM diagrams for $B^0 \to \ell^+\ell^-$.

the expected $B^0 \to \ell^+\ell^-\gamma$ branching fractions are about 10^{-10} (Aliev, Ozpineci, and Savci, 1997; Eilam, Halperin, and Mendel, 1995). Observation of such signals with current sensitivities of *BABAR* and Belle would provide clear evidence for new physics. $B^0 \to \ell^+\ell^-\gamma$ is discussed in Section 17.11.1.3.

17.11.1.1 $B^0 \to \ell^\pm \ell'^\mp$ ($\ell, \ell' = e, \mu$)

Searches for B^0 decays to pairs of light leptons, $\ell = e, \mu$, have been performed at both B Factories and at hadron colliders; the latter are able to probe not only B^0 but also B_s^0 decays. Searches for $B^0 \to e^+e^-$ and $B^0 \to \mu^+\mu^-$ as well as the LFV mode $B^0 \to e^\pm\mu^\mp$ by *BABAR* and Belle provided the most stringent limits on new physics in these modes until around 2008, when they were superseded by results from Run-II at the Tevatron. LHC experiments have now pushed the experimental results considerably beyond the current B Factory sensitivities. The *BABAR* and Belle analyses are described in the following.

BABAR has searched for these decays in a data sample of 384×10^6 $B\bar{B}$ pairs (Aubert, 2008as). The signal candidates are reconstructed by pairing oppositely charged leptons. Leptons are identified with stringent requirements which retain $\sim 93\%$ ($\sim 73\%$) of $e^\pm$ ($\mu^\pm$), while less than $\sim 0.1\%$ ($\sim 3\%$) of pions are misidentified as electrons (muons). The signal candidates are required to satisfy $m_{ES} > 5.2$ GeV/c^2 and $|\Delta E| < 0.15$ GeV. To partially recover the energy lost by electrons due to final-state radiation or bremsstrahlung, photons consistent with originating from the e^+ or e^- track have their 4-momentum added to the track. Using MC simulations, peaking background contributions from $B^0 \to h^+h'^-$ ($h, h' = \pi$ or K) decays are estimated to be of the order of 10^{-4} or less. After applying the lepton ID requirements, other $B\bar{B}$ background is found to be negligible. The backgrounds from non-$B\bar{B}$ events, such as $q\bar{q}$ ($q = u, d, s, c$) continuum and $\tau^+\tau^-$ production, are reduced by using event shape variables which are combined into a single Fisher discriminant $\mathcal{F}$. The signal yields for e^+e^-, $\mu^+\mu^-$ and $e^\pm\mu^\mp$ (see Section 17.11.4 for further discussion of LFV modes) are independently obtained by maximum likelihood (ML) fits to m_{ES}, ΔE and $\mathcal{F}$, where the *p.d.f.*s used in the likelihood function is composed of an uncorrelated product of the *p.d.f.*s of the individual discriminating variables. As an example the distribution of ΔE in the search for $B^0 \to \mu^+\mu^-$ is shown in Fig. 17.11.2. No significant excesses of signal were seen in any modes, and the 90% C.L. upper limits on the corresponding branching fractions are

calculated utilizing a Bayesian approach assuming a flat positive prior and including systematic uncertainties. The obtained upper limit is, at 90% C.L., 11.3 (5.2) $\times 10^{-8}$ for the e^+e^- ($\mu^+\mu^-$) mode (see Table 17.11.1).
Figure 17.11.2. ΔE distribution of selected $B^0 \to \mu^+\mu^-$ candidates (Aubert, 2008as). The solid curve is the background $_s\mathcal{P}lot$ (see Section 11.2.3) and the dashed curve is the expected distribution of signal with an arbitrary normalization.

Using a data sample of 85 million $B\bar{B}$ pairs, Belle has also searched for these modes (Chang, 2003) and obtained 90% C.L. upper limits of 1.9 (1.6) $\times 10^{-7}$ for the e^+e^- ($\mu^+\mu^-$) mode. These upper limits are calculated based on the likelihood ratio ordering (Feldman and Cousins, 1998) and including systematic uncertainties using the POLE program (Conrad, Botner, Hallgren, and Perez de los Heros, 2003). [94]

The Belle analysis included missing-momentum-based quantities in its Fisher discriminant, which significantly reduced the important class of background due to double semileptonic charm decays from the continuum. Using the Pati-Salam model (Kuznetsov and Mikheev, 1994), which predicts a vector leptoquark at a mass associated with the scale of the breaking of an $SU(4)$ gauge group to the usual color $SU(3)$ group, along with the assumption that there are no other colored particles between the t-quark mass and the mass, M_{LQ}, of the Pati-Salam leptoquark, Belle has obtained $M_{LQ} > 46$ TeV/c^2 at the 90% C.L..

17.11.1.2 $B^0 \to \tau^+\tau^-$

BABAR published a search for $B^0 \to \tau^+\tau^-$ (Aubert, 2006b) based on a data sample of $(232 \pm 3) \times 10^6$ $B\bar{B}$ events $(210$ fb$^{-1})$ and using the method of exclusive hadronic

---

[94] The POLE program calculates an upper limit with an extension of the Feldman Cousins method (Feldman and Cousins, 1998) by incorporating systematic uncertainties on the background yields and signal reconstruction efficiency. These uncertainties are incorporated in the calculation by integrating the *p.d.f.*s that parameterize them.

tag reconstruction of the accompanying B meson as described in Section 7.4.1. Evidence for a $B^0 \to \tau^+\tau^-$ decay is sought by considering all charged tracks and clusters which are not associated with a B candidate, "B_{tag}", which has been exclusively reconstructed in one of a large number of hadronic decay modes, as illustrated in Figure 17.11.3. Only events with "one-prong" decays of both taus are considered, so signal events are required to contain exactly two charged tracks on the signal side, each of which is identified as an electron, muon or pion. Each of the two tau leptons can potentially decay to $\tau \to e\nu\bar{\nu}$, $\tau \to \mu\nu\bar{\nu}$, $\tau \to \pi\nu$ or $\tau \to \rho(770)\nu$. Signal topologies are therefore defined corresponding to each combination of $\tau^+\tau^-$ decay modes. Charged pion tracks are considered to be $\rho(770)$ candidates if a π^0 candidate, reconstructed from a pair of photon clusters, can be combined with the π track to give $0.6 < m_{\pi\pi^0} < 1.0$ GeV/c^2. Events with any additional π^0 candidates are rejected, and the sum of any remaining calorimeter energy (E_{extra}) is required to be less than 110 MeV (summing all clusters with energy exceeding 30 MeV).
Figure 17.11.3. Illustration of a $B^0 \to \tau^+\tau^-$ event in which the associated $\bar{B}^0$ is reconstructed as a hadronic B_{tag}. The tau decay modes are depicted as $\tau^- \to e^-\nu\bar{\nu}$ and $\tau^+ \to \pi^+\bar{\nu}$. Since the $\bar{B}^0$ 4-vector is determined by the tag reconstruction, the signal B^0 4-vector can be obtained using the known CM energy, and the event missing energy can be fully attributed to the neutrinos.

Backgrounds from B decays to open charm, which subsequently decay to final states containing a strange quark, are suppressed by vetoing events in which any signal candidate track is identified as a K^+, or if the combination of the two tracks is consistent with originating from a $K^0_S \to \pi^+\pi^-$ decay. Note that this background is large due to the Cabibbo favored $b \to c \to s$ transitions. Similarly, events possessing a calorimeter cluster which is identified as a K^0_L candidate, based on cluster energy and event shape information, are rejected.

Additional background suppression is obtained by exploiting correlations between the momenta and angular distributions of the tau decay daughters in the signal B rest frame, which is estimated from the 4-vector of the reconstructed tag B. A set of neural networks, one for each of the $\tau^+\tau^-$ decay topologies, are trained to discriminate signal from background based on four inputs:

the B rest frame momenta of the positively and negatively charged tau daughters, p_+ and p_-, respectively, $\cos\theta \equiv \boldsymbol{p}_+ \cdot \boldsymbol{p}_- / p_+ p_-$, and E_{extra}.

Substantial backgrounds remain following this selection, primarily arising from $b \to c \to s$ processes with significant missing energy and no identified kaon. Typically these are B decays with an undetected K^0_L, with one or more particles passing outside of the detector acceptance and/or semileptonic B or charm decays. A total of 281 ± 48 background events are expected and 263 ± 19 events are observed in data, distributed across all modes. A 90% C.L. branching fraction limit of $\mathcal{B}(B^0 \to \tau^+\tau^-) < 4.1 \times 10^{-3}$ is obtained. Because of the limited sensitivity imposed by the high backgrounds, this analysis has not been repeated, either by *BABAR* with a larger data sample or by Belle.

17.11.1.3 $B^0 \to \ell^+\ell^-\gamma$ ($\ell = e, \mu$)

BABAR has searched for the radiative decays $B^0 \to \ell^+\ell^-\gamma$ in the $\ell = e, \mu$ modes in an event sample of 320×10^6 $B\bar{B}$ pairs (Aubert, 2008av). Signal MC events are simulated using a leading-order calculation of the Wilson coefficients C_7, C_9, and C_{10} (Dincer and Sehgal, 2001; see also the discussion in Section 17.9.1 of this book). Events are selected by combining a pair of oppositely-charged leptons and an energetic photon yielding B candidates within the region $|\Delta E| \leq 0.5$ GeV and $5.0 \leq m_{\text{ES}} \leq 5.3$ GeV/c^2. Signal candidates are required to lie in the smaller signal region defined by $-0.146(-0.112) \leq \Delta E \leq 0.082$ GeV and $5.270 \leq m_{\text{ES}} \leq 5.289$ GeV/c^2 for the $e^+e^-\gamma$ ($\mu^+\mu^-\gamma$) mode, while the remainder of the larger region is used for background studies. The dominant backgrounds include: (1) un-modelled higher-order QED and two-photon processes for the $e^+e^-\gamma$ mode, (2) B decays where a π^0 produces the photon or a J/ψ (or $\psi(2S)$) produces one or both of the leptons, and (3) continuum processes. Backgrounds of type (1) are suppressed by imposing fiducial constraints on the electrons, cutting on event shape variables, requiring that the photon energy exceeds 0.3 GeV and requiring that there are at least 5 charged tracks and 10 calorimeter clusters in the event. The B decay backgrounds are suppressed by π^0 and J/ψ (or $\psi(2S)$) vetoes. Continuum backgrounds are rejected by using a combination of event shape variables (see Chapter 9). A neural network is constructed using event shape, angular and kinematic variables and trained using MC to discriminate between signal events and remaining background events. After applying all selection requirements, the expected number of background events is estimated from data sideband regions to be $1.75\pm1.38\pm0.36$ and $2.66\pm1.40\pm1.58$ events for $e^+e^-\gamma$ and $\mu^+\mu^-\gamma$, respectively, where the quoted errors are statistical and systematic. The background is dominated by non-B backgrounds and so is estimated by extrapolation from the signal sideband regions. One event is found in the signal region in data for each mode, consistent with the size of the expected backgrounds. The 90% C.L. upper limits on the corresponding branching fractions are determined using a frequentist method (Barlow, 2002): $\mathcal{B}(B^0 \to e^+e^-\gamma) < 1.2 \times 10^{-7}$ and $\mathcal{B}(B^0 \to$

$\mu^+\mu^-\gamma) < 1.6 \times 10^{-7}$. Belle has not reported any results for these decay modes.

All the results described in this subsection are summarized in Table 17.11.1.

17.11.2 $B^0 \rightarrow$ invisible

The decay of a B meson into $\nu\bar\nu$ pairs is similar from a theoretical point of view to the leptonic decays $B^0 \rightarrow \ell^+\ell^-$ described in Section 17.11.1. It is extremely suppressed in the SM due to helicity considerations, and is only permitted, albeit at a rate orders of magnitude below experimental sensitivity, due to the miniscule but non-zero neutrino mass. As is the case with other radiative decays, for example $B^0 \rightarrow \ell^+\ell^-\gamma$ (Section 17.11.1) and $B^+ \rightarrow \ell^+\nu\gamma$ (Section 17.10.2), the radiation of a photon from an initial-state quark can remove this helicity suppression, resulting in a larger branching fraction than the non-radiative process. SM branching fractions for $B^0 \rightarrow \nu\bar\nu$ and $B^0 \rightarrow \nu\bar\nu\gamma$ have been computed to be $\sim 1 \times 10^{-25}$ and 2×10^{-9}, respectively (Badin and Petrov, 2010). In practice, experimental searches for these modes cannot directly detect the neutrinos, and so are more correctly considered to be searches for $B \rightarrow E_{\mathrm{miss}}(+\gamma)$, where E_{miss} represents missing energy from all sources including not only neutrinos, but also possible new-physics particles which do not interact in the detector. As such, they are frequently referred to as "$B^0 \rightarrow$ invisible$(+\gamma)$".

New stable particles which do not interact in the detector are potential dark matter candidates. Consequently, these decay modes are interesting probes of new physics. Decays to pairs of such particles, $B^0 \rightarrow \chi_0\chi_0(\gamma)$ where χ_0 are massive scalars, are not helicity suppressed and hence can occur at rates substantially above the SM rate for $B \rightarrow$ invisible decays. A phenomenological model for $B^0 \rightarrow \bar\chi_1^0$, where χ_1^0 is a neutralino, predicts a branching fraction in the range 10^{-7}–10^{-6} (Dedes, Dreiner, and Richardson, 2001). Since both decay products would be undetected, the experimental signature would be $B \rightarrow$ invisible. Models with large extra dimensions (Agashe, Deshpande, and Wu, 2000; Agashe and Wu, 2001; Davoudiasl, Langacker, and Perelstein, 2002) can also result in significant enhancements to the invisible decay rate.

Because the signature for $B^0 \rightarrow$ invisible(γ) decays is the absence of detector activity (*i.e.* charged tracks and neutral calorimeter clusters) associated with an identified B meson decay, the analysis strategy relies on exclusive tag-B reconstruction (see Section 7.4). Tag reconstruction serves the dual purpose of identifying the event as an $\Upsilon(4S) \rightarrow B^0\bar{B}^0$ transition, and uniquely associating all detector activity with either the tag B or the signal B candidate. Unlike other modes which use this method, for example $B^0 \rightarrow \tau^\pm\ell^\mp$ and $B^+ \rightarrow h^+\tau^\pm\ell^\mp$ discussed in Section 17.11.4, there is no kinematic advantage to be gained from knowledge of the signal B candidate 4-vector (estimated from the tag B 4-vector). Consequently, tag B reconstruction based on semileptonic B decays, which possess additional missing energy due to the un-reconstructed neutrino, is equally viable to hadronic B tagging for these

searches, although signal efficiencies and background rates differ significantly between the two methods.

To date, only Belle has published limits on $B^0 \rightarrow$ invisible using hadronic tag reconstruction (Hsu, 2012), while *BABAR* has only published results based on semileptonic tag reconstruction. A recent *BABAR* paper (Lees, 2012g) updated the results of an earlier analysis (Aubert, 2004y) to include the full *BABAR* data sample. *BABAR* also reports limits on the $B^0 \rightarrow \nu\bar\nu\gamma$ branching fraction for $E_\gamma > 1.2$ GeV and assuming decay kinematics based on a constituent quark model (Lu and Zhang, 1996).

In the *BABAR* analysis, semileptonic B_{tag} candidates are reconstructed in the modes $B^0 \rightarrow D^{(*)-}\ell^+\nu$. Details of the *BABAR* semileptonic tag reconstruction procedure can be found in Section 7.4.2. The $D^{(*)-}$ candidates are combined with identified electrons or muons having lab-frame momentum greater than 800 MeV, and the $\ell^+ - D^{(*)-}$ combination is required to be consistent with a common decay vertex. B^0 candidates are then selected by requiring the $\ell^+ - D^{(*)-}$ combination to be kinematically consistent with a $B^0 \rightarrow D^{(*)-}\ell^+\nu$ event, *i.e.* that the only missing particle is the unobserved neutrino. The quantity $\cos\theta_{B,D^{(*)-}\ell^+}$ is computed as

$$\cos\theta_{B,D^{(*)-}\ell^+} = \frac{2E_B E_{D^{(*)-}\ell^+} - m_B^2 - m_{D^{(*)-}\ell^+}^2}{2|\boldsymbol{p}_B||\boldsymbol{p}_{D^{(*)-}\ell^+}|},$$

(17.11.2)

where $E_{D^{(*)-}\ell^+}$, $\boldsymbol{p}_{D^{(*)-}\ell^+}$ and $m_{D^{(*)-}\ell^+}$ are the CM frame energy, momentum 3-vector and the invariant mass of the ℓ^+-$D^{(*)-}$ combination. The quantity m_B is the nominal B meson mass, while E_B and $|\boldsymbol{p}_B|$ are the expected B energy and momentum magnitude computed from the known CM energy. The quantity $\cos\theta_{B,D^{(*)-}\ell^+}$ represents the cosine of a physical angle only in the case of a correctly reconstructed $B^0 \rightarrow D^{(*)-}\ell^+\nu$ decay. For background events, however, it does not relate to a physical angle, and so $\cos\theta_{B,D^{(*)-}\ell^+}$ can assume values outside of the mathematically allowed region $[-1, 1]$. Lees (2012g) accepts events in the region $-5.5 < \cos\theta_{B,D^{(*)-}\ell^+} < 1.5$ in order to retain high signal efficiency while accounting for detector resolution effects which produce values slightly outside of the allowed region. The larger range for negative values was chosen to implicitly include contributions from higher-mass open charm states in which some of the decay products have not been explicitly reconstructed.

After identifying a well-reconstructed $B^0 \rightarrow D^{(*)-}\ell^+\nu$ candidate (and an energetic photon in the case of $B^0 \rightarrow \nu\bar\nu\gamma$), signal events should have little or no additional detector activity. Consequently, the signal selection requires that no additional tracks are present in the event, there is only limited activity in the calorimeter, and the missing momentum vector of the event is required to point within the detector fiducial acceptance.

Additional background suppression is obtained by using a neural network which includes as inputs the CM-frame lepton momentum, $\cos\theta_{B,D^{(*)-}\ell^+}$, and the angle between the event thrust axis and the $D^{(*)-}\ell^+$ momentum direction. A number of additional inputs are included which are specific to the $B^0 \rightarrow \nu\bar\nu$ and $B^0 \rightarrow \nu\bar\nu\gamma$ searches.

Table 17.11.1. Summary of the results for $B^0 \to \ell^+\ell^-(\gamma)$, $B^0 \to \nu\bar{\nu}(\gamma)$ and $B^0_{(s,d)} \to \gamma\gamma$ modes.

Experiment	Decay Mode	Method	$N_{B\bar{B}}$ (10^6)	$\mathcal{B}$ upper limit (90% C.L.)	Reference

Belle	$B^0 \to \gamma\gamma$	signal recon. only	111	6.2×10^{-7}	Villa (2006)
BABAR	$B^0 \to \gamma\gamma$	signal recon. only	226	3.2×10^{-7}	del Amo Sanchez (2011k)
Belle	$B^0_s \to \gamma\gamma$	signal recon. at $\Upsilon(5S)$	23 fb^{-1}	8.7×10^{-6}	Wicht (2008)

The quantity E_{extra} is constructed by summing the CM-frame energies of any remaining calorimeter clusters with a laboratory-frame energy greater than 30MeV. Signal and background *p.d.f.*s are constructed from MC simulation for E_{extra}, and an extended ML fit is performed on data to extract the signal and background yields. No evidence of signal is seen in either the $B^0 \to \nu\bar{\nu}$ or $B^0 \to \nu\bar{\nu}\gamma$ search. Branching fraction upper limits at are obtained using a Bayesian method which assumes a positive prior distribution (*i.e.* the observed negative signal yield does not result in a more stringent branching fraction limit than if zero signal yield had been obtained). Upper limits of $\mathcal{B}(B^0 \to \nu\bar{\nu}) < 2.4 \times 10^{-5}$ and $\mathcal{B}(B^0 \to \nu\bar{\nu}\gamma) < 1.7 \times 10^{-5}$ are obtained at 90% C.L..

The Belle search (Hsu, 2012) utilizes hadronic B tag reconstruction based on $B^0 \to D^{(*)-}h^+$ decays, where h^+ can be π^+, $\rho(770)^+$, $a_1(1260)^+$, or $D_s^{(*)+}$. Details of the reconstruction procedure can be found in Section 7.4.1. Compared with the semileptonic tag reconstruction method used in the BABAR analysis, the hadronic tag method yields a somewhat lower reconstruction efficiency, but, since it does not have to deal with an unobserved neutrino, it also provides more stringent kinematic constraints on the reconstructed B_{tag}. As a consequence, backgrounds arising from B_{tag} misreconstruction are inherently lower and a simpler signal selection procedure can be used. In the Belle analysis, after hadronic B_{tag} events are selected, $B^0 \to$ invisible candidate events are required to have no additional tracks and no π^0 or K_L^0 candidates in the rest of the event. Continuum backgrounds are suppressed by considering two quantities: the cosine of the angle of the B_{tag} flight direction (in the CM frame) relative to the beam axis, $\cos\theta_B$, and the cosine of the angle of the B_{tag} thrust axis relative to the beam axis, $\cos\theta_T$. Signal decays peak at zero in both of these variables. Events are retained in the region $-0.9 < \cos\theta_B < 0.9$ and $-0.6 < \cos\theta_T < 0.6$. Belle defines the variable E_{ECL} analogously to E_{extra} for BABAR by summing the ener-

gies of remaining calorimeter clusters. However, different cluster energy thresholds are applied in different regions of the calorimeter: 50 MeV in the barrel region, 100 MeV in the forward endcap and 150MeV in the backward endcap. MC modeling of efficiencies and kinematic distributions is verified by studying $B^0 \to D^{(*)-}\ell^+\nu$ decays in events with a hadronic B_{tag}. The signal yield is extracted using a two-dimensional, unbinned ML fit to the E_{ECL} and $\cos\theta_B$ distributions, where the *p.d.f.*s for the two distributions are treated as uncorrelated. A slight excess of signal events is obtained in the fit, with a significance of approximately 1.5σ. A branching fraction upper limit of $\mathcal{B}(B^0 \to \text{invisible}) < 1.3 \times 10^{-4}$ at 90% C.L. is obtained, which is slightly worse than the expected sensitivity of 1.1×10^{-4}. The difference in sensitivity between the BABAR and Belle analyses (2.4×10^{-5} and 13×10^{-5}, respectively), roughly a factor of five, is thought to be primarily due to the difference in tag efficiencies between the hadronic and semileptonic methods, but also reflects different optimizations of the level of background between the two experiments.[95] The observed distributions of E_{extra} (E_{ECL}) are shown in Fig. 17.11.4 for both measurements. It is not clear at this point how the sensitivities of the two tag methods compare for $B^0 \to$ invisible, since neither experiment has performed these searches using both methods. The details of the signal selection, in particular the detector acceptance and extra energy environment, differ sufficiently between BABAR and Belle that it is difficult to draw firm conclusions regarding future B Factory sensitivities.

17.11.3 $B^0 \to \gamma\gamma$ and $B^0_s \to \gamma\gamma$

The $B^0 \to \gamma\gamma$ mode is related to the $b \to d\gamma$ process, as the $\bar{b}$ and d quarks in the initial state B^0 annihilate

---

[95] The BABAR measurement optimizes the selection in order to achieve the most stringent upper limit, assuming no signal events to be found.
Figure 17.11.4. Distribution of E_{extra} in the *BABAR* search for $B^0 \to$ invisible using semileptonic tagged events (Lees, 2012g). Lines represent the result of the fit. Distribution of a similar quantity (bottom, called E_{ECL} at Belle) for the search in the same decay mode using hadronic tagged events (Hsu, 2012). Lines are the result of the fit (lightly hatched yellow region is the background contribution and the solid red line the total).

through a penguin loop. Moreover, it involves radiation of one additional photon. Therefore this mode is highly suppressed in the SM, with a branching fraction which is estimated to be $(3.1^{+6.4}_{-1.6}) \times 10^{-8}$ (Bosch and Buchalla, 2002a).

BABAR (del Amo Sanchez, 2011k) used 226M $B^0\overline{B}^0$ (426 fb^{-1}) to search for $B^0 \to \gamma\gamma$. Two photons with CM energies within $1.15 \leq E^*_\gamma \leq 3.50$ GeV are selected and required to satisfy $m_{\text{ES}} > 5.1$ GeV/c^2 and $|\Delta E| \leq 0.50$ GeV. Background from $e^+e^- \to q\bar{q}$ continuum and $e^+e^- \to \tau^+\tau^-$ events, respectively, are suppressed by using the Fox-Wolfram moment ratio, R_2 (see Section 9.3),

and by requiring the number of reconstructed charged tracks to be larger than two. The dominant sources of background, at this stage, are π^0 and η decays to $\gamma\gamma$. Discrimination against these backgrounds is obtained by combining each of the candidate photons (γ) with other photons in the event (γ'), and using the $\gamma\gamma'$ invariant mass and the energy $E_{\gamma'}$ of the other photon as input variables to a likelihood ratio.

Backgrounds due to merged photons from π^0 decays are suppressed by the energy distribution shape of the photon candidate in the calorimeter. Further suppression of the remaining continuum events is performed with a neural network (see Chapter 4). After all selections are applied, the peaking background contribution from rare B decays is estimated to be 1.18 ± 0.22 events. Using an unbinned extended ML fit to m_{ES} and ΔE, the signal yield N_{sig} is determined to be $N_{\text{sig}} = 21.3^{+12.8}_{-11.8}$ events, with statistical significance of 1.8σ. The systematic error on the branching fraction, 12.1%, is dominated by the fitting uncertainty (9.9%), and is included by convolution with the likelihood function. A branching fraction upper limit $\mathcal{B}(B^0 \to \gamma\gamma) < 3.2 \times 10^{-7}$ (at the 90% C.L.) is obtained.

In an earlier analysis (Villa, 2006) based on data collected prior to 2004, Belle used a limited data sample of 111M $B\overline{B}$ events to search for $B \to \gamma\gamma$. This search set a branching fraction upper limit $\mathcal{B}(B \to \gamma\gamma) < 6.2 \times 10^{-7}$ at the 90% C.L., but the analysis was notable for the fact that it suffered due to calorimeter backgrounds arising from out-of-time signals from previous bunch crossings. As a result of the relatively long decay time of the scintillation light from the CsI(Tl) crystals in the Belle calorimeter, there is a non-negligible probability that a residual calorimeter signal from a previous QED event, typically $e^+e^- \to e^+e^-$, can persist long enough to produce a "fake" photon cluster in a later $\Upsilon(4S) \to B\overline{B}$ event. If two back-to-back clusters from such a Bhabha event are present, and the reduced energy of the pair happens to match the B mass, then it resembles the B signal in the m_{ES} distribution. This background can be mostly removed using the timing information of the calorimeter signals, however, this information was not available in the reduced data format for data processed before summer 2004, and in particular for the sample used for the Villa (2006) analysis. In subsequent reprocessings of this data sample (see Section 3.3), this information was made available however, at the time of writing, the analysis has not been updated. In the existing measurement the background composed of photons from the continuum events (mainly decays of π^0 and η mesons) is suppressed by the selection based on the polar angle of the more energetic photon. The issue of out-of-time calorimeter clusters has also been studied by *BABAR*, as a potential background for other B decay modes which rely on neutral clusters, in particular $b \to s\gamma$ (Section 17.9) and $B^0 \to \pi^0\pi^0$. While this background was not an issue for the *BABAR* $B^0 \to \gamma\gamma$ study, it is potentially a concern for future high-luminosity experiments in which the Bhabha rate is much higher than the present generation of experiments.

In comparison to $B^0 \to \gamma\gamma$, the $B_s^0 \to \gamma\gamma$ decay is favored by $\sim |V_{ts}/V_{td}|^2$, with the SM prediction $\mathcal{B}(B_s^0 \to \gamma\gamma) \sim (0.5-1.0)\times10^{-6}$. Production of B_s mesons does not occur at the $\Upsilon(4S)$, hence a large sample of $\Upsilon(5S)$ events is required. *BABAR* did not collect significant data at this energy. However, Belle obtained a substantial sample (see Table 3.2.1). Using 23.6 fb^{-1} of such data, Belle (Wicht, 2008) performed a search for $B_s^0 \to \gamma\gamma$ decays. Details of the measurement can be found in Section 23.3.6, only the main results are presented at this place. The signal yield is determined by an unbinned extended ML fit to m_{ES} and ΔE. Figure 17.11.5 shows the projections to the fit variables, m_{ES} and ΔE. No signal is observed. Including the systematic error of $^{+21}_{-19}\%$ which is dominated by the uncertainties in the number of B_s^0 events in the $\Upsilon(5S) \to b\bar{b}$ process ($^{+16}_{-13}\%$), the 90% C.L. branching fraction upper limit is determined to be $\mathcal{B}(B_s^0 \to \gamma\gamma) < 8.7 \times 10^{-6}$. This limit is about an order of magnitude larger than the SM prediction.
Figure 17.11.5. m_{ES} (left; called M_{bc} on the plot) and ΔE (right) data yield (points) and fit results for $B_s^0 \to \gamma\gamma$ in the Belle analysis (Wicht, 2008). The solid black curve represents the overall fit, while the dashed red and solid blue curves represent the continuum/combinatorial background and signal components of the fit, respectively. See Chapter 23 for an explanation of the structure of the m_{ES} distribution. On the ΔE projection, $m_{ES} > 5.4$ GeV/c^2 is required to select only the $B_s^*\bar{B}_s^*$ contributions from $\Upsilon(5S)$. The fit returns a slight negative yield, consistent with zero within the data statistical uncertainties.

17.11.4 Lepton flavor violating modes

Lepton flavor violation is permitted within the SM if non-zero neutrino masses are included, since mixing of neutrino generations can then occur. LFV in the charged lepton sector can then occur in processes which contain one or more neutrinos as internal lines in any contributing Feynman diagram. However, the expected rates for LFV B decays via this mechanism are far beyond current or expected future experimental sensitivity. Potentially measurable rates can however result from non-SM contributions, since most models do not explicitly conserve lepton flavor. In models with Higgs-mediated LFV, modes with heavier leptons generally are expected to exhibit larger

LFV than modes with lighter leptons. However, experimental searches for modes containing tau leptons in the final state tend to be more difficult due to the multiple decay modes of the tau and missing energy resulting from the presence of one or more neutrinos. Consequently, experimental limits on μ - e LFV modes tend to be more stringent than τ - e or τ - μ. As many of the proposed mechanisms for LFV tend to have couplings which favor heavier-generation leptons, the experimental limits from LFV modes with tau leptons can still provide interesting constraints on the parameters of these models.

Many lepton flavor violation searches, particularly those containing only first and second generation leptons, are performed as "incidental" studies along with related non-LFV modes. This is the case, for example, for $B^0 \to \mu^\pm e^\mp$ and $B \to K^{(*)}\mu^\pm e^\mp$, which have been published by both *BABAR* and Belle along with the corresponding $B^0 \to \ell^+\ell^-$ modes (discussed in Section 17.11.1) and $B \to K^{(*)}\ell^+\ell^-$ modes (see Section 17.9), respectively, as well as for $D^0 \to e^\pm\mu^\mp$ searched for together with $D^0 \to \ell^\pm\ell^\mp$ decays (Section 19.1.8). In general, these analyses have few unique features which distinguish them from the related non-LFV modes, hence we do not discuss them further in this section. For completeness, we tabulate the results in Table 17.11.2. In several instances however, *BABAR* and Belle have published dedicated searches for specific lepton flavor or lepton number violating decays.

Searches involving final state tau leptons generally require special techniques to overcome the challenges presented by the missing neutrinos and lack of a distinctive tau signature. In particular, tau decays to leptonic final states, $\tau \to \ell\nu\bar{\nu}$, are three-body final states with two unobserved neutrinos, providing essentially no kinematic constraints that can be exploited experimentally. Tau decays to hadronic final states are largely indistinguishable from B and continuum backgrounds containing charged and neutral pions. To overcome these limitations, hadronic tag reconstruction (see Section 7.4.1) has been used in *BABAR* searches for $B^+ \to h^+\tau^\pm\ell^\mp$ (17.11.4.1) and $B^0 \to \tau^\pm\ell^\mp$ (17.11.4.2). As is the case with other studies which use this method, the resulting sensitivity is limited primarily by the very low signal efficiency. Hadronic tag reconstruction provides a number of kinematic advantages for these particular searches, since knowledge of the signal B 4-vector (inferred from the B_{tag} 4-vector) allows the 2-body kinematics of $B^0 \to \tau^\pm\ell^\mp$ to be exploited and, in both $B^0 \to \tau^\pm\ell^\mp$ and $B^+ \to h^+\tau^\pm\ell^\mp$, permits the 4-vector of the daughter tau to be uniquely determined from the observed non-tau decay daughters.

Because they can potentially proceed via a "CKM-favored" b - s FCNC process (see Section 17.9) rather than a b - d FCNC process in which the quarks annihilate, $B^+ \to K^+\tau^\pm\ell^\mp$ are generally predicted to have larger branching fractions in potential new-physics models than $B^0 \to \tau^\pm\ell^\mp$. The primary difference from the experimental point of view is the presence of the additional charged kaon in $B^+ \to K^+\tau^\pm\ell^\mp$. This has two consequences: that the signal has 3-body (rather than 2-body) dynamics, and that the final states all topologically resem-

ble various $b \to c\ell\nu$ modes, resulting in potentially very large backgrounds from these high-branching-fraction processes.

17.11.4.1 $B^+ \to h^+\tau^\pm\ell^\mp$ ($h = K, \pi, \ell = e, \mu$)

Searches for $B^+ \to h^+\tau^\pm\ell^\mp$ (Aubert, 2007au; Lees, 2012b) use a methodology which exploits hadronic tag reconstruction (Section 7.4.1) to enhance the available kinematic constraints and to suppress continuum and combinatorial $B\bar{B}$ backgrounds. Searches for the corresponding neutral modes $B^0 \to h^0\tau^\pm\ell^\mp$ were not performed due to the lower efficiency for K^0 reconstruction via $K_s^0 \to \pi^+\pi^-$ and the fact that the tag reconstruction yield is somewhat higher for charged B mesons than for neutral B^0 mesons due to the branching fractions of the available tag modes. In the more recent study, $h = K, \pi, \ell = e, \mu$ and the decays $B^+ \to h^+\tau^+\ell^-$ and $B^+ \to h^+\tau^-\ell^+$ are considered separately, for a total of eight distinct decay modes (charge conjugate modes are implied, but are not treated as distinct decay modes).

Since details of the specific new physics which could result in a signal for $B^+ \to h^+\tau^\pm\ell^\mp$ are not known *a priori*, a 3-body phase space model is assumed for the signal modes. This is in contrast to studies of the SM $B \to K^+\ell^+\ell^-$ channels described in Section 17.9.

Signal events are required to contain exactly three tracks, with total charge opposite that of the tag B. The primary hadron, h, is required to be one of the two tracks having charge opposite the tag B and can be identified either as a kaon or pion. The two remaining tracks are then inferred to be the primary lepton ℓ and a charged tau decay daughter, which is identified as e, μ or π.

The tau decay 4-vector is uniquely specified using the tag B, primary lepton and primary hadron 4-vectors, independent of the tau decay daughters. The tau invariant mass, m_τ,

$$m_\tau^2 = \left[(E_{CMS}, 0) - (E_{B_{tag}}^*, \mathbf{p}_{B_{tag}}^*) - (E_\ell^*, \mathbf{p}_\ell^*) - (E_h^*, \mathbf{p}_h^*) \right]^2 , \tag{17.11.3}$$

is obtained from this 4-vector and is used to extract the final signal yield as it peaks strongly for signal and is non-peaking for background. In the cases where the primary lepton and the tau daughter are identified as leptons of the same type, vetoes are imposed on the di-lepton invariant mass to reject J/ψ and $\psi(2S)$ decays to $\ell^+\ell^-$: $3.03 < m_{\ell^+\ell^-} < 3.14$ GeV/c^2 and $3.60 < m_{\ell^+\ell^-} < 3.75$ GeV/c^2. In the di-electron case, a photon conversion veto of $m_{e^+e^-} > 0.1$ GeV/c^2 is also applied.

The dominant background sources depend on the relative charge of the primary lepton and the primary hadron in the signal mode. In the case of $B^+ \to h^+\tau^-\ell^+$, the dominant background is from semileptonic B decays, $B^+ \to \bar{D}^{(*)0}\ell^+\nu$ with $\bar{D}^0 \to K^+X^-$ (where X is a hadronic system), in which some or all of the X^- system is incorrectly reconstructed as the signal tau decay daughters.

In the case of $B^+ \to h^+\tau^+\ell^-$ however, the dominant background is from $B^+ \to \bar{D}^{(*)0}X^+$ with the charm system decaying semileptonically. In both cases, the primary

hadron and the track of opposite charge originate from the $\bar{D}^{(*)0}$. The quantity $m(K\pi)$, the invariant mass of the combination of these two tracks computed assuming appropriate kaon and pion mass hypotheses, is required to be greater than 1.95 GeV/c^2, *i.e.* to exceed the D^0 mass, effectively suppressing these decays although with a significant loss of signal efficiency (see Figure 17.11.6). The remaining background is mainly from continuum $q\bar{q}$ production and is further suppressed by using a multivariate likelihood selector based on event shape and PID quality criteria, and the scalar sum of any remaining energy in the calorimeter.

Signal branching fractions are determined relative to high-branching fraction decays with similar topologies, specifically $B^+ \to \bar{D}^{(*)0}\ell^+\nu$ with $\bar{D}^0 \to K^+\pi^-$. Signal yields in each of eight signal modes are determined within a mass window of ± 60 MeV/c^2 in m_τ, centered around the nominal tau mass. For each signal mode, a likelihood function is obtained from the products of the Poisson *p.d.f.*s representing the yields in the e, μ and π decay channels. Since models of LFV can produce signatures in which the charge of the tau is either correlated or uncorrelated with that of the charged hadron, *BABAR* reports results on both the signed (*e.g.* $B^+ \to h^+\tau^-\mu^+$) and unsigned (*e.g.* $B^+ \to h^+\tau^\mp\mu^\pm$) branching fractions. No significant signals were found in any modes and upper limits (see Table 17.11.2) were obtained at the level of a few times 10^{-5}.
Figure 17.11.6. The reconstructed invariant mass, $m(K\pi)$, for the $B^+ \to K^+\tau^-\mu^+$ and $\tau^- \to (n\pi^0)\pi^-\nu_\tau$ (Lees, 2012b). The upper plot shows the full data distribution and the bottom the simulated expectation for the signal. The vertical line denotes the selection requirement just above the D^0 peak at approximately 1.86 GeV/c^2.

17.11.4.2 $B^0 \to \tau^\pm \ell^\mp$ ($\ell = e, \mu$)

BABAR performed a search (Aubert, 2008az) for $B^0 \to \tau^\pm \ell^\mp$ (with $\ell = e, \mu$) based on a data sample of 378×10^6 $B\bar{B}$ pairs using methodology similar to $B^+ \to K^+ \tau^\pm \ell^\mp$ (Section 17.11.4.1). Due to the 2-body kinematics and the large tau mass, the light lepton is expected to possess a momentum (in the signal B rest frame) of ~ 2.34 GeV/c, near the kinematic endpoint for leptons from B decays. Since the B rest frame is inferred from the B_{tag}, the resolution of the signal peak is dictated primarily by the resolution of the B_{tag} 4-vector. This 2-body decay is somewhat similar kinematically to the charged B decay $B^+ \to \ell^+ \nu$ ($\ell = e, \mu$) and hence a search is performed simultaneously (see Section 17.10.2).

The signal and background distribution of the electron momentum in $B^0 \to \tau^\pm e^\mp$, from Aubert (2008az), is shown in Figure 17.11.7. After reconstructing the B_{tag} and high-momentum lepton, all remaining particles in the event are then assumed to be the decay daughters of the tau lepton. Hence there should be either one or three additional tracks with total charge opposite that of the high-p lepton. Six tau decay modes are considered: $e^- \nu \bar{\nu}$, $\mu^- \nu \bar{\nu}$, $\pi^- \nu$, $\rho(770)^- (\to \pi^- \pi^0) \nu$, $a_1(1260)^- (\to \pi^- \pi^0 \pi^0) \nu$ and $a_1(1260)^- (\to \pi^- \pi^+ \pi^-) \nu$, where $\rho(770)$ or $a_1(1260)$ mass constraints are imposed in the latter three cases. In the hadronic tau decay modes only a single neutrino is present. Consequently, the neutrino 4-vector can be uniquely determined from the combination of the reconstructed tag B, the high-p lepton and the hadronic tau daughter 4-vectors. The neutrino mass therefore provides an additional kinematic constraint on these modes. Aubert (2008az) exploits this by defining the quantity ΔE_τ, representing the difference between the expected tau energy and the total energy of the hadronic tau daughters combined with the neutrino (assuming zero mass). Computed in the tau rest frame, this quantity should peak at zero if the missing energy vector is consistent with a single massless neutrino. ΔE_τ is used to select a "best" tau candidate from possible $\pi^\pm$, $\rho(770)^\pm$ and $a_1(1260)^\pm$ candidates in the case that one or more $\pi^0 \to \gamma\gamma$ candidates have been reconstructed.

In signal events, the combination of the high-p lepton with the tau decays daughter(s) should account for all particles in the event which are not associated with the reconstructed tag B, while in background events other particles may be present. A loose E_{extra} (defined as the scalar sum of energies of any remaining tracks or clusters with energy > 50 MeV) requirement is imposed of $E_{\text{extra}} < 1.0$ GeV. Signal yields are extracted from unbinned ML fits to the the high-p lepton momentum spectrum in the signal B rest frame, as shown for $B^0 \to \tau^\pm e^\mp$ in Figure 17.11.7. No significant signal is seen in either mode and limits of $\mathcal{B}(B^0 \to \tau^\pm e^\mp) < 2.8 \times 10^{-5}$ and $\mathcal{B}(B^0 \to \tau^\pm \mu^\mp) < 2.2 \times 10^{-5}$ are obtained. Due to the very low backgrounds, this search is statistically limited.

Interpretation of these results in a new-physics context is model-dependent. However as an example we can consider a SUSY seesaw model with degenerate right-handed neutrino masses $M_N = 10^{14}$ GeV (Babu and Kolda, 2002; Dedes, Ellis, and Raidal, 2002). In such a model $B^0 \to$ $\tau^\pm \mu^\mp$ is mediated by a SUSY neutral Higgs with effective LFV couplings, which would also lead to a potentially observable signal in $\tau^- \to \mu^- \mu^+ \mu^-$ (see Section 20.4). In this model $\mathcal{B}(B^0 \to \tau^\pm \mu^\mp) \propto (\tan^2 \beta / M_A)^4$, leading to a lower bound on the A^0 mass (M_A) of ~ 30 GeV for $\tan \beta = 100$. Although not currently very stringent, improved experimental limits on these modes from future experiments could place significant constraints on new-physics models.
Figure 17.11.7. Signal electron candidate momentum in the signal B rest frame for $B^0 \to \tau^\pm e^\mp$ (Aubert, 2008az). The points with errors are *BABAR* data, the solid blue curve is the fitted background *p.d.f.* and the dashed green curve shows the expected signal shape.

17.11.5 Lepton number violating modes

LNV processes are possible if neutrinos are of the Majorana type. As for the case of neutrino-less double beta decay, lepton number must change by $\Delta L = 2$. Two possible diagrams for such decays are shown in Figure 17.11.8. For a heavy sterile Majorana neutrino with a mass of a few GeV/c^2, the s-channel process (Figure 17.11.8(b)) is expected to give the dominant contribution.

BABAR reports a measurement of the LNV decays $B^+ \to h^- \ell^+ \ell^+$ (where $h = K, \pi$ based on 471×10^6 $B\bar{B}$ decays (Lees, 2012r). The experimental technique is very similar to that used for studies of $B^+ \to h^+ \ell^+ \ell^-$ described in Section 17.9, and the analysis sensitivity is similar. A three-body phase space model is assumed for the signal simulation. Events are required to possess at least four charged tracks, including two same-sign charged leptons each with momentum greater than 0.3 GeV/c. The leptons are required to originate from a common vertex and to satisfy $m_{\ell^+ \ell^+} < 5.0$ GeV/c^2. Leptons from identified photon conversions are not permitted, and a bremsstrahlung recovery procedure is applied to electron and positron tracks to provide the best possible 4-vector for these particles.

For consistency with the $B^+ \to h^+ \ell^+ \ell^-$ studies, mass vetoes are imposed on the J/ψ and $\psi(2S)$ mass regions, rejecting events with $2.85 < m_{\ell^+ \ell^-} < 3.15$ GeV/c^2 and
Figure 17.11.8. Diagrams for a LNV B decay $B^+ \to D^- \ell^+ \ell^+$ in (a) t-channel and (b) s-channel processes.

Figure 17.11.9. Branching fraction upper limits (UL) as a function of the mass $m_{\ell^+ h^-}$ for the BABAR (Lees, 2012r) search modes $B^+ \to \pi^- \mu^+ \mu^+$ (dotted magenta line), $B^+ \to K^- \mu^+ \mu^+$ (dash-dotted red line), $B^+ \to K^- e^+ e^+$ (dashed black line) and $B^+ \to \pi^- e^+ e^+$ (solid blue line).

$3.59 < m_{\ell^+ \ell^-} < 3.77$ GeV/c^2, respectively, although no actual peaking contribution is expected in this case. In the $B^+ \to \pi^- \mu^+ \mu^+$ mode, an additional veto is imposed on the combination of the π^- with each of the two oppositely charged muons in order to reject J/ψ events in which a muon has been misidentified as a pion. Events are rejected if the $\pi^- \mu^+$ combination is within the range $3.05 < m_{\pi^- \mu^+} < 3.13$ GeV/c^2.

The di-lepton pair is then combined with an identified charged kaon or pion track of sign opposite that of the leptons, requiring the combined B candidate to lie within $5.200 < m_{ES} < 5.289$ GeV/c^2 and $-0.10 < \Delta E < 0.05$ GeV. Backgrounds from $q\bar{q}$ and $B\bar{B}$ are suppressed using a set of Boosted Decision Trees based on 18 inputs representing event shape and kinematic variables and trained on MC signal and background samples (see Chapter 4 for a description of Boosted Decision Tree classifiers). A likelihood ratio, $\mathcal{L}_R$, is defined using the Boosted Decision Tree outputs as input $p.d.f.s$. The signal yield in each mode is extracted from an unbinned ML fit to m_{ES} and $\mathcal{L}_R$. No significant signals are observed, and branching fraction upper limits are determined in the range $[2, 11] \times 10^{-8}$ at the 90% C.L. as shown in Table 17.11.2.

If $B^+ \to h^- \ell^+ \ell^+$ is the result of the exchange of a Majorana neutrino, then the reconstructed invariant mass of the hadron h with the opposite-sign lepton, $m_{\ell^+ h^-}$, can be related to the Majorana neutrino mass m_ν (Atre, Han, Pascoli, and Zhang, 2009; Han and Zhang, 2006; Zhang and Wang, 2011). The BABAR results are presented as a function of $m_{\ell^+ h^-}$ in Figure 17.11.9.

Since $b \to c$ decays are in general favored over charmless B decays, it is interesting to extend the search for LNV processes to $B^+ \to X_c^- \ell^+ \ell^+$ decays, where X_c^- is any charmed hadron that has the opposite charge to the leptons. Using a sample of 772×10^6 $B\bar{B}$ pairs, Belle re-

ports a measurement of the $B^+ \to D^- \ell^+ \ell'^+$ decays (Seon, 2011), where $\ell, \ell' = e$ or μ in any combination. Since we have no prior knowledge nor widely accepted model for these decays, a 3-body phase-space model is assumed for the signal simulation. To find signal candidates, first an energetic same-sign lepton pair is chosen. The lepton momentum in the lab frame is required to be greater than $0.5(0.8)$ GeV/c for electrons (muons). Particle identification requirements select electrons (muons) with an efficiency of approximately 90% and a misidentification rate of 0.1% (1%) for pions in the kinematic region of interest. The energy sum of the dilepton system in the CM frame is required to exceed 1.3 GeV: this has minimal effect on the signal efficiency in the phase-space model. The lepton pair is then combined with a $D^- \to K^+ \pi^- \pi^-$ decay candidate. Kaons (pions) are discriminated from pions (kaons) with an efficiency of approximately 91% (95%) and a misidentification rate below 4% (6%) in the kinematic region of interest. The $K^+ \pi^- \pi^-$ invariant mass ($M_{K\pi\pi}$) is required to be within ± 10 MeV/c^2 from the nominal D^- mass. The B candidates are further required to lie within $m_{ES} > 5.2$ GeV/c^2 and $|\Delta E| < 0.3$ GeV (the 'analysis region'). The major background sources are from continuum processes and to a lesser degree from semileptonic B decays such as $B \to D^- \ell^+ \nu_\ell X$, in which a same-sign lepton from the decay products of the other B is combined with the signal B. These backgrounds are suppressed by a single likelihood ratio $\mathcal{R}$ using the four variables: the Fisher discriminant $\mathcal{F}$ of the modified Fox-Wolfram moments (see Section 9.3), the cosine of the polar angle of the B candidate flight direction in the CM frame, $\cos \theta_B$, the missing energy E_{miss} of the event, and the difference δz between the impact parameters of the two leptons in the beam direction. The requirement on $\mathcal{R}$, determined mode-by-mode by a MC study, eliminates

more than 99% of the background while retaining 11–26% of the signal, depending on the mode. Signal yield is estimated in the 'signal region', $5.27 < m_{ES} < 5.29$ GeV/c^2 and $-0.055(-0.035) < \Delta E < 0.035$ GeV for the e^+e^+ and $e^+\mu^+$ modes ($\mu^+\mu^+$ mode). The background region is defined as the complement of the analysis region excluding the signal region. The amount of background is determined by fitting the 2-dimensional (ΔE, m_{ES}) p.d.f. to the data in the background region and then integrating the fitted p.d.f. over the signal region. There was no event observed in the signal region of any mode. Figure 17.11.10 shows the (ΔE, m_{ES}) distribution of selected $B^+ \to D^- \mu^+ \mu^+$ candidates. Upper limits (at the 90% C.L.) are calculated based on a frequentist approach (Feldman and Cousins, 1998) including systematic uncertainties using the POLE program, (Conrad, Botner, Hallgren, and Perez de los Heros, 2003). The results are summarized in Table 17.11.2, and are in the range $[1.1, 2.6] \times 10^{-6}$.

17.11.6 Lepton/baryon number violating modes

Although baryon number is approximately conserved within the SM, it is predicted to be violated in many models of grand unification (Fritzsch and Minkowski, 1975; Georgi and Glashow, 1974), and indeed baryon number violation is one of Sakharov's conditions for cosmological baryogenesis (see Section 16.2). Most GUT models however conserve $\mathcal{B} - L$, the difference of baryon and lepton number, implying that lepton number is also violated. In these models the proton is predicted to be unstable, albeit with a very long lifetime, decaying for example into a positron and π^0. However, the proton decay rates predicted by many of these models have not been observed and very stringent experimental limits have been placed on the proton lifetime (Nakamura et al., 2010). These limits, based on measurements of first-generation quarks, have been used to estimate the potential for baryon number violation in decays involving second- and

Table 17.11.2. Summary of the results for lepton flavor, lepton number and baryon number violating modes.

Decay Mode	$N_{B\bar{B}}$ (10^6)	$\mathcal{B}$ upper limit (90% C.L.)	Reference

del Amo Sanchez (2011l)

third-generation quarks (Hou, Nagashima, and Soddu, 2005). In particular for $B^0 \to \Lambda_c^+ \ell^-$, which violates both lepton number and baryon number, the branching fraction is estimated to be less than 4×10^{-29}. Although this is far beyond any expected experimental sensitivity, searches have still been performed to the precision permitted by current data samples.

BABAR has performed a search for the decays $B^0 \to \Lambda_c^+ \ell^-$, $B^- \to \Lambda \ell^-$, and the $\mathcal{B} - L$ violating mode $B^- \to \overline{\Lambda} \ell^-$, where the lepton is a muon or an electron (del Amo Sanchez, 2011l). This is the first experimental search for these decays, and any positive signal would be evidence of new physics.

B-meson candidates are formed by combining a Λ_c^+, Λ or $\overline{\Lambda}$ candidate with an identified muon or electron. The Λ_c^+ candidates are reconstructed in the decay mode $\Lambda_c^+ \to p K^- \pi^+$, which has a branching fraction of about 5%. The Λ candidates are reconstructed in the decay $\Lambda \to p \pi^-$, which has a branching fraction of about 64%.

The final state hadron (p, K, π) and lepton (μ, e) candidates are all required to be consistent with the candidate particle hypothesis according to PID criteria based on dE/dx, DIRC, EMC and IFR information. The 4-momenta of photons that are consistent with bremsstrahlung radiation from the electron candidate are added to that of the electron.

Λ_c^+ candidates are required to have $p K^- \pi^+$ invariant mass within ± 15 MeV/c^2 of the nominal Λ_c^+ mass. Similarly, Λ candidates must have $p \pi^-$ mass within ± 4 MeV/c^2 of the nominal Λ mass. The final state tracks which form the decay daughters of the the Λ_c^+ (Λ) are constrained to a common spatial vertex, and their invariant mass is constrained to the Λ_c^+ (Λ) mass. This has the effect of improving the 4-momentum resolution for true $B \to \Lambda_{(c)} \ell$ candidates. The baryon and lepton candidates are also constrained to originate from a common vertex.

As the Λ has $c\tau = 7.89$ cm, the purity of the Λ-candidate sample is further improved by selecting candidates for which the reconstructed decay point of the Λ candidate is at least 0.2 cm from the reconstructed decay point of the B candidate in the plane perpendicular to the $e^+ e^-$ beams. Particle mis-ID backgrounds from $e^+ e^- \to e^+ e^- \gamma$ events in which the photon converts to an $e^+ e^-$ pair are eliminated by requiring that there are more than four tracks in the events.

B-meson candidates are selected within the kinematic region $|\Delta E| < 0.2$ GeV and $5.2 < m_{\text{ES}} < 5.3$ GeV/c^2 are fitted to extract the signal yield. The signal yield is extracted using an unbinned extended ML fit in which the total *p.d.f.* is a sum of *p.d.f.*s for signal and background. The signal and background *p.d.f.*s are each a product of *p.d.f.*s describing the dependence on m_{ES} and ΔE. For the $\Lambda_c^+ \ell^-$ modes, additional discriminating power is gained from a three dimensional *p.d.f.*, where the output from a neural network discriminator is used as the third variable.

No significant signal is observed for any of the decay modes, and branching fraction upper limits are determined, ranging from 5.2×10^{-6} to 3.2×10^{-8} at the 90% C.L. (see Table 17.11.2). Less stringent limits are ob-

tained for the $B^0 \to \Lambda_c^+ \ell^-$ modes than the Λ modes due to the relatively low branching fraction for the studied Λ_c^+ decay and a higher level of background compared with the Λ modes.

17.11.7 Summary

Although there is currently no evidence for any of the rare or forbidden decay modes described in this section, they remain useful as probes for physics beyond the SM. In the case of $B_{(s)} \to \ell^+ \ell^-$ and $B \to h \ell^+ \ell^+$ (with $\ell = e, \mu$), experimental results from hadron colliders have already exceeded the current sensitivity from B Factories and it is unlikely that future $e^+ e^-$ facilities will change this situation. In other modes, particularly those with tau leptons or neutrinos, hadron colliders are at a significant disadvantage. It is notable that in some cases, either due to experimental challenges or due to the small size of the expected new-physics effects, current experimental limits on these modes do not yet reach the ranges predicted by most reasonable new-physics models. Consequently, these searches are essentially of the "shot-in-the-dark" variety: essentially probing dark corners of the SM to verify that we see nothing in places where we expect to see nothing. As a rule of thumb one can summarize the achieved sensitivity of B Factories to $\mathcal{O}(10^{-5})$ for $B \to$ invisible and LFV decays with τ's, $\mathcal{O}(10^{-6})$ for $B_{(s)} \to \gamma\gamma$, and $\mathcal{O}(10^{-7})$ for $B \to \ell^+ \ell^-$, LFV decays with light leptons and baryon and/or lepton number violating modes. Improvements in experimental sensitivity with large datasets at the future generation of B Factories could change this picture, with experimental results in some cases directly confronting realistic new-physics models.

17.12 B decays to baryons

Editors:
Roland Waldi (BABAR)
Min-Zu Wang (Belle)
Hai-Yang Cheng (theory)

Additional section writers:
Thomas Hartmann

Baryons and antibaryons have to be produced in pairs in the Standard Model, therefore most mesons cannot decay to baryons for lack of energy. The only baryonic D decay is $D_s^+ \to p\bar{n}$, which has only just enough energy to proceed. But the phase space of the two or four quarks in a purely hadronic weak decay of a B meson is much larger than that of charmed or light mesons, and leaves ample freedom for high multiplicities and for the production of baryon-antibaryon pairs.

That B decays to baryons play an important role became evident by the large proton multiplicities found by ARGUS and CLEO at the $\Upsilon(4S)$ (Albrecht et al., 1989b; Crawford et al., 1992).

The interest in decays to baryons was increased when ARGUS claimed the observation of B decays to $p\bar{p}\pi^\pm$ and $p\bar{p}\pi^+\pi^-$ (Albrecht et al., 1988b). Subsequently, baryonic B decays were studied extensively by theorists around the early 1990s with the focus on the tree-dominated two-body decay modes. Experimental studies were first led by CLEO, but with the accumulating data at the B Factories, BABAR and Belle came to dominate the field.

The features of B decays to baryons reflect the properties of both the weak interaction, and the hadronization of quarks. One or two $q\bar{q}$ pairs have to be produced out of the vacuum to produce a baryon-antibaryon pair, similar to jet fragmentation.

This section presents the inclusive production of baryons in B meson decays (Section 17.12.1), then exclusive two-body decays (Section 17.12.2), followed by the more frequent multibody final states with a baryon-antibaryon pair plus one or more mesons (Section 17.12.3). Complex phenomena are seen in multibody decays, and our treatment includes dedicated discussions of threshold enhancement (Section 17.12.3.3), multiplicity effects (Section 17.12.3.4), and angular correlations (Section 17.12.3.5). Finally, radiative and semileptonic decays with baryons in the final state are discussed (Sections 17.12.4 and 17.12.5 respectively). Theoretical interpretations and model predictions for each of these topics are discussed within the the corresponding section. Baryon number violating decays have been presented in the previous section, 17.11.6.

17.12.1 Inclusive decays into baryons

The inclusive production of protons and antiprotons from $\Upsilon(4S)$ decays, *i.e.*, an admixture of B^+, B^-, B^0, and $\bar{B}^0$, has been measured by ARGUS and CLEO (Albrecht et al., 1993a; Crawford et al., 1992). The combined multiplicity
Figure 17.12.1. Differential $B \to \Lambda_c^+ X$ production rate per $\Upsilon(4S)$ from BABAR (Aubert, 2007p), Belle (Seuster, 2006), and CLEO (Crawford et al., 1992) versus the momentum fraction $x_p = p/p_{\max}$ in the $\Upsilon(4S)$ rest frame. Also shown is the differential Ξ_c^0 production rate normalized to match the peak of the Λ_c^+ rate.

of protons and antiprotons in an average B decay is

$$\langle n_p + n_{\bar{p}} \rangle = 0.080 \pm 0.004. \tag{17.12.1}$$

Some of these protons come from Λ decays; the multiplicity of Λ baryon production has been determined to be $\langle n_\Lambda + n_{\bar{\Lambda}} \rangle = 0.040 \pm 0.005$ (Albrecht et al., 1989b; Crawford et al., 1992).

Inclusive particle spectra in (scaled) momentum are obtained from data at the $\Upsilon(4S)$ energy by subtracting the spectra obtained off resonance, scaled to the on resonance luminosity and cross section. The scaled momentum of a particle of mass m is given by $x_p = p/p_{\max}$ with the maximum center-of-mass momentum $p_{\max} = \sqrt{s/4 - m^2}$. Integration over the extrapolated spectra yields the particle multiplicity.

If protons were the only stable baryons, any baryonic event would have one proton and one antiproton. This would imply a 4% branching fraction into baryon antibaryon + X (ignoring decays with two pairs). But since there are also neutrons, a more sophisticated analysis is required to obtain the total baryonic branching fraction. Such an analysis has been performed by the ARGUS collaboration (Albrecht et al., 1992c) using in addition to the proton and Λ multiplicities the fractions of events at the $\Upsilon(4S)$ with baryon-antibaryon pairs, baryon ℓ^+ pairs, and baryon ℓ^- pairs (where ℓ is an electron or muon). The baryon-antibaryon fraction allows for the elimination of the unknown contribution of neutrons to the final state, while the remaining fractions help to establish baryon-flavor correlations. The result is

$$\mathcal{B}(B \to \mathfrak{B}_1 \overline{\mathfrak{B}}_2 X) = (6.8 \pm 0.5 \pm 0.3)\% \tag{17.12.2}$$

where $\mathfrak{B}$ represents a generic baryon.

Since the dominant weak process in B decays is $b \to cX$, most final states with baryons contain either a meson with charm quarks (like $B^+ \to J/\psi p\bar{\Lambda}$ or $\bar{B}^0 \to D^0 p\bar{p}$) or a charmed baryon. While there are a few charmed baryon decays to charmed mesons and non-charmed baryons (such as $\Lambda_c(2880)^+ \to D^0 p$), most decays are to Λ_c^+, Ξ_c^0, Ξ_c^+, or Ω_c^0. Inclusive production rates for all of these states, except Ω_c^0, have been determined by ARGUS (Albrecht et al., 1988a) and CLEO (Crawford et al., 1992). Inclusive Λ_c production has also been measured at the B Factories (Aubert, 2004m, 2007p,ba; Seuster, 2006): the most precise average multiplicity per B meson has been determined by *BABAR* (Aubert, 2007p),

$$\langle n_{\Lambda_c^+} + n_{\overline{\Lambda}_c^-} \rangle = 0.0456 \pm 0.0009 \pm 0.0031 \pm 0.0118_{\Lambda_c}.$$
$$(17.12.3)$$

The scaled momentum spectrum in the $\Upsilon(4S)$ rest frame is shown in Fig. 17.12.1. As in most measurements where a Λ_c^+ baryon is reconstructed, the decay $\Lambda_c^+ \to pK^-\pi^+$ is used in this analysis. All channels with the Λ_c baryon in the final state suffer from a large systematic uncertainty of 26% since the branching fractions are only poorly known, with $\mathcal{B}(\Lambda_c^+ \to pK^-\pi^+) = 0.050 \pm 0.013$ (Beringer et al., 2012). This value is also used to normalize other Λ_c branching fractions: it is the source of the dominant third uncertainty on the multiplicity in Eq. (17.12.3). A further discussion of this problem is found in Section 19.4.2.3.[96] The situation is even worse for Ξ_c baryons, where no absolute branching fraction measurement is available. For our multiplicity estimate and also for exclusive branching fractions (*e.g.*, Table 17.12.1) we use $\mathcal{B}(\Xi_c^0 \to \Xi^-\pi^+) \approx 1.2\%$, assuming a 50% error. This value is based on the range of theoretical predictions for the partial width (Cheng and Tseng, 1993) and the lifetime of the Ξ_c^0 baryon (Beringer et al., 2012). In the same spirit, we use $\mathcal{B}(\overline{\Xi}_c^- \to \overline{\Xi}^+\pi^-\pi^-) \approx 6.4\%$, assuming a 50% error. This value is obtained from the theoretical prediction $\Gamma(\overline{\Xi}_c^- \to \overline{\Xi}^0\pi^-) \approx 0.8 \times 10^{11}\,\mathrm{s}^{-1}$ derived from Cheng and Tseng (1993), the experimental ratio $\Gamma(\overline{\Xi}_c^- \to \overline{\Xi}^0\pi^-)/\Gamma(\overline{\Xi}_c^- \to \overline{\Xi}^+\pi^-\pi^-) = 0.55 \pm 0.16$, and the lifetime $\tau(\overline{\Xi}_c^-) = (4.42 \pm 0.26) \times 10^{-13}\,\mathrm{s}$ (Beringer et al., 2012).

The multiplicity of charged Ξ_c baryons has only been measured at CLEO (Barish et al., 1997), corresponding to $\langle n_{\Xi_c^+} + n_{\overline{\Xi}_c^-} \rangle \sim 0.007$. For neutral Ξ_c baryons the average from the CLEO (Crawford et al., 1992) and *BABAR* (Aubert, 2005z) measurements is $\langle n_{\Xi_c^0} + n_{\overline{\Xi}_c^0} \rangle \sim 0.016$.

Production of Ω_c^0 baryons in B decays is even more rare, and has been observed by *BABAR* (Aubert, 2007ao), with an average multiplicity of the order 0.0005 assuming $\mathcal{B}(\Omega_c \to \Omega^-\pi^+) \sim 1\%$.

Figure 17.12.2. Candidate events for the decay $\bar{B}^0 \to \Lambda_c^+\bar{p}$ from Belle (Gabyshev, 2003): (a) scatter plot of ΔE versus $m_{\mathrm{ES}} = M_{bc}$, (b) ΔE distribution for $m_{\mathrm{ES}} > 5.270\,\mathrm{GeV}/c^2$, and (c) m_{ES} distribution for $|\Delta E| < 0.030\,\mathrm{GeV}$. The curves indicate the result of a two-dimensional fit.

17.12.2 Two-body decays

One might expect a large fraction of baryonic decays to proceed via two-body decay channels, since the phase space for heavy particles is rather small. However, from the spectrum in Fig. 17.12.1 it is evident that two-body decays are rare, since they would show up as a peak around $x_p = 0.4$. Indeed, it has been found experimentally that decays of B mesons to just a baryon and an antibaryon have very small branching fractions. First measurements of B decays to baryons were made by CLEO, but no two-body decay could be established, and upper limits of those decays were reported (Bornheim et al., 2003; Dytman et al., 2002; Procario et al., 1994).

---

[96] While we were finalising this book Belle submitted an absolute branching fraction measurement for publication, with significantly improved precision: $\mathcal{B}(\Lambda_c^+ \to pK^-\pi^+) = (6.84 \pm 0.24^{+0.21}_{-0.27})\%$ (Zupanc, 2013a). See the discussion in Section 19.4.2.3.

Table 17.12.1. Branching fractions of observed two-body decays of B mesons to baryons. Upper limits are at the 90% C.L. Channels with the Λ_c^+ baryon in the final state have an additional $\pm 26\%$ relative error (not included) from the assumption $\mathcal{B}(\Lambda_c^+ \to pK^-\pi^+) = 0.050 \pm 0.013$ and are marked with †. The same holds for $\mathcal{B}(\Xi_c^0 \to \Xi^-\pi^+) = 0.012$ and $\mathcal{B}(\Xi_c^+ \to \Xi^-\pi^+\pi^+) = 0.064$, both with an additional $\pm 50\%$ taken from the range of theoretical predictions (Cheng and Tseng, 1993). Two daggers indicate that two such errors have to be added (linearly due to correlation).

17.12.2.1 Results from B Factories

An overview of the results from the B Factories for two-body decays is given in Table 17.12.1.

First observation

The first two-body baryonic B decay observed was $\overline{B}^0 \to \Lambda_c^+\overline{p}$ with $\Lambda_c^+ \to pK^-\pi^+$ (Gabyshev, 2003) using a 78.2 fb^{-1} data sample at Belle.

The mass resolution of reconstructed Λ_c is very good. One can just select Λ_c and apply simple continuum suppression (see Chapter 9) to reject most of the background events. Exclusive reconstruction is described in Section 7.1. Fig. 17.12.2 shows the scatter plot of ΔE versus m_{ES} and their projections for selected events. The ΔE projection is shown for $m_{\mathrm{ES}} > 5.270\,\mathrm{GeV}/c^2$ and the m_{ES} projection for $|\Delta E| < 0.030\,\mathrm{GeV}$. A two-dimensional binned

maximum likelihood fit is performed to determine the signal yield. For this fit, the ΔE distribution is represented by a double Gaussian for the signal plus a first order polynomial for the background. The m_{ES} distribution is represented by a single Gaussian for the signal plus the ARGUS function for the background. The signal shapes determined from MC simulation are fixed in the fit. The region $\Delta E < -0.1\,\mathrm{GeV}$ is excluded from the fit to avoid feed-down from modes including extra pions. The measured branching fraction is $(2.19^{+0.56}_{-0.49} \pm 0.32 \pm 0.57) \times 10^{-5}$ where the last error comes from the uncertainty on the sub-decay branching fraction of $\Lambda_c^+ \to pK^-\pi^+$. The branching fraction is thus an order-of-magnitude smaller than that of the three-body decay $B^- \to \Lambda_c^+\overline{p}\pi^-$ (see Table 17.12.6). This suppression is a unique feature of two-body baryonic decays and will be addressed further in Sections 17.12.2.2 and 17.12.3.4. In contrast, the two- and three-body mesonic B decays are comparable.

(a) Belle: *B* signal region (open histogram), fit results (curve) and background from sidebands (hatched).

(b) BABAR: $_s\mathcal{P}lot$ projections of the $\overline{\Sigma}_c(2520)^0 p$ signal (data points) and fits (curves).

(c) BABAR: $_s\mathcal{P}lot$ projections of the $\overline{\Sigma}_c(2800)^0 p$ signal (data points) and fits (curves).
Figure 17.12.3. $m(\Lambda_c^+ \pi^-)$ distributions from (a) Belle (Gabyshev, 2006), and (b,c) BABAR (Aubert, 2008aa); for the $_s\mathcal{P}lot$ technique, see Section 11.2.3. Three Σ_c^0 resonances are visible at $2.455\,\mathrm{GeV}/c^2$ (a), $2.52\,\mathrm{GeV}/c^2$ (a and b, not significant) and $2.80\,\mathrm{GeV}/c^2$ (c).

Quasi-two-body decays

Following the study of $B^- \to \Lambda_c^+ \overline{p} \pi^-$ at CLEO (Dytman et al., 2002) and at Belle (Gabyshev, 2002), an analysis of this final state has been performed using a much larger data sample (containing $\sim 152 \times 10^6$ $B\overline{B}$ pairs) and extending the Λ_c^+ reconstruction to the following five decay modes: $\Lambda_c^+ \to pK^-\pi^+$, $p\overline{K}^0$, $\Lambda\pi^+$, $p\overline{K}^0\pi^+\pi^-$, and $\Lambda\pi^+\pi^+\pi^-$ (Gabyshev, 2006). A clear signal peak is seen from the intermediate two-body $B^- \to \Sigma_c(2455)^0 \overline{p}$ decay, together with a hint of $B^- \to \Sigma_c(2520)^0\overline{p}$, shown in Fig. 17.12.3a. The open histogram is the distribution from the *B* signal region ($|\Delta E| < 0.03\,\mathrm{GeV}$ and $m_{\mathrm{ES}} > 5.27\,\mathrm{GeV}/c^2$). The hatched histogram is the distribution from sideband regions ($-0.10\,\mathrm{GeV} < \Delta E < -0.04\,\mathrm{GeV}$ or $0.04\,\mathrm{GeV} < \Delta E < 0.20\,\mathrm{GeV}$) normalized to the *B* signal region. The curve shows the result of the fit which includes the contributions from $\Sigma_c(2455)^0$ and $\Sigma_c(2520)^0 \to \Lambda_c^+ \pi^-$ decays and the background parameterized with a linear function. The $\Sigma_c(2455/2520)^0$ signal shapes are fixed from MC assuming a Breit-Wigner function convolved with the resolution function.

A subsequent BABAR analysis (Aubert, 2008aa) using $\sim 383 \times 10^6$ $B\overline{B}$ pairs confirms the $\Sigma_c(2455)^0$, but with an even weaker signal from $\Sigma_c(2520)^0$ shown in Fig. 17.12.3b. A broad structure $\Sigma_c(2800)^0$, however, is clearly seen (Fig. 17.12.3c). The $\Sigma_c(2455)^0$ is a spin-$\frac{1}{2}$ baryon, while the $\Sigma_c(2520)^0$ has spin $\frac{3}{2}$. A decay of the spin-0 *B* meson to a spin-$\frac{1}{2}$ antiproton and a spin-$\frac{3}{2}$ Σ_c requires one or two units of orbital angular momentum, and hence its suppression is reasonable.

Final states from weak *B* meson decays $b \to c\overline{u}d$ have three light quarks, therefore the isospin can be $I = \frac{1}{2}$ or $I = \frac{3}{2}$, while the *W* exchange $b\overline{d} \to c\overline{u}$ has only one and therefore $I = \frac{1}{2}$ (see Fig. 17.12.5a and c below). Since hadronization is a strong interaction process, isospin is conserved and we can classify final states according to their isospin. The average branching fraction $\mathcal{B}(B^- \to \Sigma_c(2455)^0\overline{p}) = (4.0 \pm 0.4 \pm 1.0_{\Lambda_c}) \times 10^{-5}$ (pure isospin $I = \frac{3}{2}$) is about twice that of $\overline{B}^0 \to \Lambda_c^+\overline{p}$ (pure isospin $I =$

$\frac{1}{2}$). Using Clebsch-Gordan coefficients, one would expect $\mathcal{B}(\overline{B}^0 \to \Sigma_c(2455)^+\overline{p}) < 2.5 \times 10^{-5}$, compatible with the present limit (Table 17.12.1).

Decays to two charmed baryons

An unexpectedly large rate is found for *B* mesons decaying to two charmed baryons, specifically $B^+ \to \overline{\Xi}_c^0 \Lambda_c^+$ (Chistov, 2006a). In this analysis, the following sub-decays are reconstructed: $\Xi_c^0 \to \Xi^- \pi^+$ and $\Lambda K^- \pi^+$, $\Lambda_c^+ \to pK^-\pi^+$, $\Xi^- \to \Lambda \pi^-$, and $\Lambda \to p\pi^-$. For $\Xi^- \to \Lambda\pi^-$, one can fit the p and π^- tracks to a common vertex in order to get the Λ 4-momenta. Then one can fit the Λ trajectory and the π^- track to a common vertex to reconstruct the long lived Ξ^-. Fig. 17.12.4 shows the projection plots of selected candidate events; the maximum likelihood fit results are overlaid. The product of branching fractions $\mathcal{B}(B^+ \to \overline{\Xi}_c^0\Lambda_c^+) \times \mathcal{B}(\overline{\Xi}_c^0 \to \overline{\Xi}^+\pi^-)$ is measured to be $(4.8^{+1.0}_{-0.9} \pm 1.1 \pm 1.2) \times 10^{-5}$. BABAR found a somewhat smaller branching fraction (Aubert, 2008e), but still about two orders of magnitude larger than that of $\overline{B}^0 \to \Lambda_c^+\overline{p}$. Using our estimate $\mathcal{B}(\Xi_c^0 \to \Xi^-\pi^+) \approx 1.2\%$ described in Section 17.12.1, the average translates to $\mathcal{B}(B^+ \to \overline{\Xi}_c^0\Lambda_c^+) \approx 0.22\%$. This is quite intriguing and offers an important clue to understand the underlying dynamics for baryonic *B* decays.

The decay of the neutral *B* meson $B^0 \to \overline{\Xi}_c^-\Lambda_c^+$ (with $\overline{\Xi}_c^- \to \overline{\Xi}^+\pi^-\pi^-$) has not yet been observed with high significance, however we have averaged the results of Belle and BABAR, using the theoretical estimate (described in Section 17.12.1) $\mathcal{B}(\overline{\Xi}_c^- \to \overline{\Xi}^+\pi^-\pi^-) \approx 6.4\%$, assuming a 50% uncertainty.

Charmless decays

So far, no charmless two-body baryonic *B* decays have been observed. The 90% confidence level upper limits have been pushed below the 10^{-6} level and are listed in Table 17.12.1. The method to determine upper limit yields

Figure 17.12.5. Quark diagrams for two-body baryonic B decay $\overline{B} \to \mathfrak{B}_1 \mathfrak{B}_2$. The waveline represents a W, while gluon lines are omitted. Quark antiquark pairs from the vacuum are denoted as x, y and determine the flavor of the two final baryons. In this and subsequent figures, the colors of the quark lines are significant: see the discussion in Section 17.12.2.2.

Figure 17.12.4. The ΔE (a) and $m_{\mathrm{ES}} = M_{\mathrm{bc}}$ (b) distributions for the $B^+ \to \overline{\Xi}^0_c \Lambda^+_c$ candidates from Belle (Chistov, 2006a). The hatched histograms show the combined $\overline{\Xi}^0_c$ and Λ^+_c mass sidebands normalized to the signal region. Also shown are the $\overline{\Xi}^0_c$ (c) and Λ^+_c (d) mass distributions for the $B^+ \to \overline{\Xi}^0_c \Lambda^+_c$ candidates taken from the B signal region of $|\Delta E| < 0.025\,\mathrm{GeV}$ and $m_{\mathrm{ES}} > 5.272\,\mathrm{GeV}/c^2$. For the $\overline{\Xi}^0_c$ (Λ^+_c) distribution Λ^+_c ($\overline{\Xi}^0_c$) is required to be within $\pm 15\,\mathrm{MeV}/c^2$ of the nominal mass. The overlaid curves are the fit results.

is either based on the Feldman-Cousins approach (Conrad, Botner, Hallgren, and Perez de los Heros, 2003; Feldman and Cousins, 1998) or by integration of the likelihood fit function convolved with a Gaussian error function. Since there is no sign of observation, it will be interesting to know the order of magnitude of the branching fractions of these rare decays, and hopefully they can be determined by the LHCb experiment or future super flavor factories.

17.12.2.2 Theory and interpretation

Since baryonic B decays involve two baryons in the final state, the underlying mechanism is complicated. The quark diagrams for two-body baryonic B decays are shown in Fig. 17.12.5: internal W-emission for $b \to c(u)$ (a), the $b \to s(d)$ penguin transition (b), W-exchange for the neutral B meson (c), and W-annihilation for the charged B (d). As for mesonic B decays, W-exchange and W-annihilation are expected to be helicity suppressed (Chau, 1983) which can be understood in the same way as for leptonic decays (see Eq. 17.10.4 and the accompanying discussion). Therefore, the main contributions to two-body baryonic B decay $B \to \mathfrak{B}_1 \overline{\mathfrak{B}}_2$ are due to either the internal W-emission diagram or the penguin diagram. It should be stressed that, unlike the case of mesonic B decays, internal W emission in baryonic B decays is not

necessarily color suppressed. This is because the baryon wave function is totally antisymmetric in the color indices. One component of this wave function is illustrated in Fig. 17.12.5, where the internal W-emission (a) needs either of two matching colors (blue or green) to produce a baryon, while exactly one matching color (red) would be required to produce a meson. The black quark lines in (d) indicate that any color will do.

In short, the two-body decay proceeds mainly through the nonfactorizable internal W-emission or the $b \to s(d)$ penguin transition. This is why it is difficult to determine theoretical estimates for the rates of two-body decays.

There exist several theoretical models for describing B decays into two baryons: the pole model of Jarfi et al. (1990) and Cheng and Yang (2002a), the diquark model of Ball and Dosch (1991) and the QCD sum rule analysis by Chernyak and Zhitnitsky (1990). The predictions of these models for some selected charmless, singly-charmed and doubly-charmed baryonic B decays are listed in Tables 17.12.2–17.12.4. Evidently, many of the earlier model predictions are either too large compared to or marginally comparable to experiment.

Experimentally, two-body baryonic B decays follow the pattern

$$
\begin{aligned}
\mathcal{B}(\overline{B} \to \mathfrak{B}_{1c} \overline{\mathfrak{B}}_{2c}) &\sim 10^{-3} \\
\gg \mathcal{B}(\overline{B} \to \mathfrak{B}_c \overline{\mathfrak{B}}) &\quad \sim 10^{-5} \\
\gg \mathcal{B}(\overline{B} \to \mathfrak{B}_1 \overline{\mathfrak{B}}_2) &\quad \lesssim 10^{-6} \ .
\end{aligned}
\tag{17.12.4}
$$

where no c subscript indicates a non-charmed baryon.

Since the doubly-charmed baryonic decay $\overline{B} \to \Xi_c \overline{\Lambda}_c$ proceeds via $b \to cs\overline{c}$, while $\overline{B} \to \Lambda_c \overline{p}$ proceeds via a $b \to cd\overline{u}$ quark transition, the CKM matrix elements for the two decays are the same in magnitude but opposite in sign. One may therefore wonder why the $\Xi_c \overline{\Lambda}_c$ mode has a

Table 17.12.2. Branching fractions (in units of 10^{-7}) for some charmless two-body baryonic B decays classified into two categories: tree-dominated (upper) and penguin-dominated (lower). Branching fractions denoted by "†" are calculated only for the parity-conserving part. Experimental limits are taken from Table 17.12.1. Theoretical predictions are taken from the following references — "CZ": Chernyak and Zhitnitsky (1990); "Jarfi": Jarfi et al. (1990); and "CY": Cheng and Yang (2002a).

Decay	CZ	Jarfi	CY	Experiment

$B^- \to \Sigma^-\bar{\Delta}^0$	20		0.87	

Table 17.12.3. Predictions (in units of 10^{-5}) of singly charmed two-body baryonic B decays in various models. Theoretical references are as in Table 17.12.2. Experimental results are taken from Table 17.12.1.

Decay	CZ	Jarfi	CY	Experiment
$\overline{B}^0 \to \Lambda_c^+\bar{p}$	190	110	1.1	1.9 ± 0.2
$B^- \to \Sigma_c^0\bar{p}$	300	1500	6.0	4.0 ± 0.4
$\overline{B}^0 \to \Sigma_c^0\bar{n}$	580	0.06		
$B^- \to \Lambda_c^+\bar{\Delta}^{--}$	20	3600	1.9	5.9 ± 1.2

Table 17.12.4. Predicted branching fractions (in units of 10^{-4}) of doubly-charmed two-body baryonic B decays (Cheng, Chua, and Hsiao, 2009). Experimental results are taken from Table 17.12.1.

Decay	Theory	Experiment
$B^- \to \Xi_c^0\bar{\Lambda}_c^-$	$10.4^{+5.7}_{-5.5}$	$\sim 21.6 \pm 5.4$
$\overline{B}^0 \to \Xi_c^+\bar{\Lambda}_c^-$	$9.4^{+6.3}_{-4.1}$	~ 3
$\overline{B}^0 \to \Lambda_c^+\bar{\Lambda}_c^-$	$0.52^{+0.35}_{-0.19}$	< 0.62
Figure 17.12.6. Quark diagrams for two-body baryonic B decays $\overline{B} \to \Xi_c\bar{\Lambda}_c$ and $\overline{B} \to \Lambda_c^+\bar{p}$. At least two hard gluons are needed for $\Lambda_c^+\bar{p}$ production.

$\sim 1/3$. Hence, two hard gluons are needed to produce an energetic $\bar{p}$: one hard gluon to kick the spectator quark of the B meson to make it energetic and the other to produce the hard $q\bar{q}$ pair (see Fig. 17.12.6b). Therefore, the decay rate of $\overline{B} \to \Lambda_c\bar{p}$ is suppressed with respect to $\overline{B} \to \Xi_c\bar{\Lambda}_c$ due to a dynamical factor $\mathcal{O}(\alpha_s^4) \sim 10^{-2}$. These qualitative statements have been supported by realistic calculations of the decay rates for $\overline{B} \to \Xi_c\bar{\Lambda}_c$ (Cheng, Chua, and Hsiao, 2009) and $\overline{B}^0 \to \Lambda_c^+\bar{p}$ (He, Li, Li, and Wang, 2007).

The charmless decay $\overline{B}^0 \to p\bar{p}$ is suppressed relative to $\overline{B} \to \Lambda_c\bar{p}$ by the CKM matrix elements $|V_{ub}/V_{cb}|^2$ and is also subject to a possible dynamical suppression:

$$\mathcal{B}(\overline{B} \to p\bar{p}) = \mathcal{B}(\overline{B} \to \Lambda_c^+\bar{p}) \left|\frac{V_{ub}}{V_{cb}}\right|^2 \times f_{\mathrm{dyn}}$$

$$\approx 2\times 10^{-7} \times f_{\mathrm{dyn}} . \qquad (17.12.5)$$

In the absence of dynamical suppression f_{dyn}, the predicted rate for two-body charmless decays is on the verge of the experimental upper limit.

If the dynamical suppression is of order 10^{-2} as in the case of $\overline{B} \to \Lambda_c\bar{p}$, then the branching fraction for charmless two-body decays will be of order 10^{-9} and thus beyond the reach even of super flavor factories. In reality, the branching fraction is most likely of order 10^{-8}, between the extreme cases of 10^{-7} and 10^{-9}. Thus far, there is no clear theoretical prediction for charmless two-body decays. Presumably a reliable prediction based on pQCD can be made as the energy release in charmless two-body decay is very large, justifying the use of pQCD (Cheng and Yang, 2002a).

Most of the previous theoretical predictions are not trustworthy: for example, predictions based on the QCD sum rule, the pole model and the diquark model are too large compared to experiment. The most reliable predictions are based on pQCD, which has been successfully applied to $B \to \Lambda_c\bar{p}$ (He, Li, Li, and Wang, 2007). The

rate two orders of magnitude larger than $\Lambda_c\bar{p}$. Indeed, earlier calculations based on QCD sum rules (Chernyak and Zhitnitsky, 1990) or the diquark model (Ball and Dosch, 1991) all predict that $\mathcal{B}(B \to \Xi_c\bar{\Lambda}_c) \approx \mathcal{B}(\overline{B} \to \mathfrak{B}_c\overline{N})$ (see Table 17.12.3), which is in violent disagreement with experiment. The decay pattern (17.12.4) can be understood as follows. In an energetic heavy baryon, the momentum is mostly carried by the constituent heavy quark. Therefore, in $b \to c\bar{c}s$ decays, the energetic c quark will fragment into $\mathfrak{B}_{1c}$, and $\bar{c}$ into $\overline{\mathfrak{B}}_{2c}$. Consequently, no hard gluon is needed to produce the energetic $\Xi_c\bar{\Lambda}_c$ pair in B decays (see Fig. 17.12.6a). In $\overline{B} \to \Lambda_c\bar{p}$ decay, the three quarks of the energetic proton share the same momentum fraction

Table 17.12.5. Branching fractions of observed decays of B mesons to charmless baryons plus charmed mesons. Contributing quark diagrams are given in square brackets following each mode: annihilation type A (Fig. 17.12.5c with an extra $q\bar{q}$ pair), external W-emission type 1 (Fig. 17.12.7), and internal W-emission type 2 (Fig. 17.12.8).

pQCD calculation for charmless modes such as $\Lambda\bar{p}$ and $p\bar{p}$ is much more involved and has not yet been carried out.

17.12.3 Decays to baryon antibaryon plus mesons

Before Belle and BABAR investigated baryonic B decays, there were already observations by CLEO of $B^+ \to \overline{\Lambda}_c p\pi^+$ (Fu et al., 1997) and $B^0 \to D^{*-} p\bar{p}\pi^+, D^{*-} p\bar{n}$ (Anderson et al., 2001). These are all generic $b \to c$ transitions, and many more have since been investigated by the B Factories. Their branching fractions are shown in Table 17.12.5 for cases where a c quark hadronizes into a charmed meson, and in Table 17.12.6 where a c quark hadronizes into a charmed baryon. In the following subsections we consider in turn theoretical issues (Section 17.12.3.1), rare decays (Section 17.12.3.2), the threshold enhancement seen in many multibody baryonic decays (Section 17.12.3.3), the role of final state multiplicity (Section 17.12.3.4), and angular correlations of the final state particles (Section 17.12.3.5); we conclude with brief discussions of the role of Cabibbo suppression (Section 17.12.3.6), isospin relations (Section 17.12.3.7), and the suppression of $s\bar{s}$ pairs (Section 17.12.3.8).

17.12.3.1 Theoretical models and Feynman diagrams

The complexity of quark diagrams increases with the final state multiplicity. For three-body decays of a B meson to the baryonic final state $\mathfrak{B}_1\overline{\mathfrak{B}}_2 M$ there are many distinct quark diagrams: two type-1 or external W-diagrams (Figs 17.12.7a and b), and eight type-2 or internal W-emission

Table 17.12.6. Branching fractions of observed decays of B mesons to final states with a charmed baryon including three or more final state particles. Channels with a Λ_c^+ baryon in the final state have an additional $\pm 26\%$ relative uncertainty (not included) from the assumption $\mathcal{B}(\Lambda_c^+ \to pK^-\pi^+) = 0.050 \pm 0.013$ and are marked with †. Two daggers indicate that two such terms have to be added (linearly due to correlation). Decays via intermediate resonances are marked with •. Contributing quark diagrams are given in square brackets following each three-body mode: annihilation type A (Fig. 17.12.5c with an extra $q\bar{q}$ pair), external W-emission type 1 (Fig. 17.12.7), and internal W-emission type 2 (Fig. 17.12.8).

diagrams (Figs 17.12.8a–h); W-exchange diagrams (basically Fig. 17.12.5c, inserting another $q\bar{q}$ pair) for the neutral B meson; and W-annihilation (Fig. 17.12.5d with another $q\bar{q}$ pair) for the charged B. The various possibilities for inserting the extra $q\bar{q}$ pair are only illustrated for the type-2 decay in Fig. 17.12.8, as the same modification to
Figure 17.12.7. Quark diagrams for three-body baryonic B decay $\bar{B} \to \mathfrak{B}_1 \overline{\mathfrak{B}}_2 M$ corresponding to type 1, factorizable external W-emission contributions.

the annihilation diagrams is straightforward. Penguin diagrams can also contribute: these can be obtained from Fig. 17.12.5b by adding the extra $q\bar{q}$ pair in the same way as for W exchange.

In the Feynman diagrams presented in the figures, the $q\bar{q}$ pairs are shown detached; they can be produced by soft or hard gluons attached to any other quark line in the diagram, and usually involve more than one gluon to accomplish color matching for color neutral mesons and baryons.

It should be stressed that among the internal W-emission diagrams, Figs 17.12.8d and e (where a red $q\bar{q}$ pair is created by the W) are color suppressed while the remaining diagrams in Fig. 17.12.8 are not, since the baryon wave function is antisymmetric in color indices (Cheng and Yang, 2002a). For example, $B^- \to J/\psi \Lambda \bar{p}$ proceeds via Fig. 17.12.8e, while $\bar{B}^0 \to \Sigma_c^0 \bar{p} \pi^+$ receives contributions predominantly from Figs 17.12.8a and b. The experimental observation that $J/\psi \Lambda \bar{p}$ is suppressed by one order of magnitude is due to the color suppression for Fig. 17.12.8e and non-suppression for Figs 17.12.8a and b. The decay to $\Sigma_c^{++} \bar{p} \pi^-$ can also proceed through the (non-suppressed) external W-emission Fig. 17.12.7a, and has a higher branching fraction than the internal W-emission processes for $\Sigma_c^0 \bar{p} \pi^+$. This may be explained by simple color counting: all three colors are possible in color-allowed processes (type 1), only one color in fully color-suppressed processes (type 2d,e) and two colors in the unsuppressed processes (type 2a–c,f–h).

Neglecting the factorizable annihilation contributions, which are helicity suppressed, the factorizable contributions to three-body decays consist of two parts: (i) the transition process with meson emission, $\langle M|(\bar{q}_3 q_2)|0\rangle \times \langle \mathfrak{B}_1 \overline{\mathfrak{B}}_2|(\bar{q}_1 b)|\bar{B}\rangle$ where $(\bar{q}_i q_j) \equiv \bar{q}_i \gamma_\mu (1 - \gamma_5) q_j$ and M denotes a meson, and (ii) the current-induced process in association with a B to meson transition, $\langle \mathfrak{B}_1 \overline{\mathfrak{B}}_2|(\bar{q}_1 q_2)|0\rangle \times \langle M|(\bar{q}_3 b)|\bar{B}\rangle$. The two-body matrix element $\langle \mathfrak{B}_1 \overline{\mathfrak{B}}_2|(\bar{q}_1 q_2)|0\rangle$ in the latter process can be either related to some measurable quantities, or calculated using the quark model. Note that while the form factors in the matrix elements $\langle \mathfrak{B}_1 \overline{\mathfrak{B}}_2|(\bar{q}_1 q_2)|0\rangle$ and $\langle M|(\bar{q}_3 b)|\bar{B}\rangle$ depend on the dibaryon invariant mass squared $t = (p_1 + p_2)^2$, form factors in $\langle \mathfrak{B}_1(p_1) \overline{\mathfrak{B}}_2(p_2)|(\bar{q}_1 b)|\bar{B}(p_B)\rangle$ are functions not only of t but also of one of the other Mandelstam
Figure 17.12.8. Spectator diagrams of type 2, factorizable (d,e) and non-factorizable (a–c,f–h) internal W-emission, for three-body baryonic B decays $\bar{B} \to \mathfrak{B}_1 \overline{\mathfrak{B}}_2 M$.

variables $s = (p_B - p_1)^2$ or $u = (p_B - p_2)^2$. The current-induced contribution to three-body baryonic B decays has been discussed in various publications, *e.g.* Chua, Hou, and Tsai (2002a). By contrast, it is difficult to evaluate the three-body matrix element in the transition process and in this case one can appeal to the pole model (Cheng and Yang, 2002b). Instead of showing various model predictions for three-body decays, we summarize in Table 17.12.7 the references related to the study of doubly-charmed, singly-charmed, and charmless three-body baryonic B decays. The interested reader is referred to the original work for more details.

17.12.3.2 Rare decays

The first charmless baryonic B decay observed was $B^+ \to p\bar{p}K^+$, in an analysis of a 29.4 fb^{-1} data sample (Abe, 2002f). One unexpected feature of this rare decay process is that the observed mass distribution of the baryon-antibaryon pair is peaked near threshold as shown in Fig. 17.12.9. To ensure that the measured events are genuine non-$b \to c$ signals, the regions $2.850 < M(p\bar{p}) < 3.128$ GeV/c^2 and $3.315 < M(p\bar{p}) < 3.735$ GeV/c^2 are excluded to remove background from modes with η_c and J/ψ mesons, and ψ', χ_{c0}, and χ_{c1} mesons, respectively. The mass distribution of vetoed events can be found in the inset plot of Fig. 17.12.9, where a J/ψ peak can be clearly identified. Since the efficiency of particle identification varies with respect to the particle's momentum, the overall reconstruction efficiency is dependent on the mass of the baryon-antibaryon system. The partial branching fractions in bins of baryon-antibaryon mass are then summed to obtain the total branching fraction.
Figure 17.12.9. The fitted yield from Belle (Abe, 2002f) divided by the bin size for $B^+ \to p\bar{p}K^+$ as a function of $p\bar{p}$ mass. A charmonium veto is applied. The distribution from non-resonant $B^+ \to p\bar{p}K^+$ MC simulation is superimposed (shaded). The inset shows the $p\bar{p}$ mass distribution for the $J/\psi K^+$ signal region.

The measured $B^+ \to p\bar{p}K^+$ branching fraction is $\sim 4 \times 10^{-6}$. The decay is difficult to observe due to the large background from continuum events. A good particle identification system is a key for this analysis since both p and K^+ should be positively identified in order to reject the background. Another important point is that a more sophisticated pattern recognition method based on event shape information was adopted to discriminate the more isotropic B events from the jet-like continuum events.

Following this first observation, many other three-body charmless baryonic B decays have been found: $p\bar{\Lambda}\pi^-$, $p\bar{\Lambda}\pi^0$, $p\bar{p}\pi^+$, $p\bar{p}K^0$, $p\bar{p}K^{*0}$, $p\bar{p}K^{*+}$, $\Lambda\bar{\Lambda}K^+$, $\Lambda\bar{\Lambda}K^0$, and $\Lambda\bar{\Lambda}K^{*0}$. Except for $B^+ \to p\bar{\Lambda}\pi^0$, all these modes are reconstructed entirely from charged particles in the final state, *i.e.* $\Lambda \to p\pi^-$, $K_S^0 \to \pi^+\pi^-$, $K^{*0} \to K^+\pi^-$, and $K^{*+} \to K_S^0\pi^+$. The signal shape can be well described by a single Gaussian in m_{ES} and a sum of two Gaussians in ΔE. In the fit to determine signal yield with the ΔE spectrum, there are feed-across events between similar B decays. For example, $B^+ \to p\bar{p}K^+$ events can form a bump at -0.05 GeV in ΔE in the study of $B^+ \to p\bar{p}\pi^+$ when the K^+ is misidentified as a π^+. There are also feed-down events from similar decays with higher multiplicity, *e.g.* $B^0 \to p\bar{p}K^{*0}$ can form a bump below -0.01 GeV in ΔE in the study of $B^+ \to p\bar{p}K^+$. These structures are useful as a sanity check for the measured branching fractions of related modes. The measured branching fractions of the above modes are all $\sim 10^{-6}$, and are summarized in Table 17.12.8.

17.12.3.3 Threshold enhancement

Many of the abovementioned channels also have the special feature that the measured mass spectrum of

Table 17.12.8. Branching fractions of observed decays of B mesons to charmless baryons plus charmless mesons. Decays via intermediate resonances are marked with •.

the baryon-antibaryon pair peaks near threshold. Figure 17.12.10 shows the differential branching fractions in bins of the baryon-antibaryon invariant mass for some representative decays: $B^+ \to p\bar{p}\pi^+$, presumed to proceed via the $b \to u$ tree process, and $B^+ \to p\bar{p} K^+$ and $B^0 \to p\bar{\Lambda}\pi^-$, presumably $b \to s$ strong penguin modes. They will be further discussed below in Section 17.12.3.5 on angular correlations.

Threshold enhancement has also been found in the $b \to c$ process, although the effect is not as pronounced or dominant as in the charmless case. When the available energy is limited to a small amount, say ~ 200 MeV, there is no visible peaking feature. Figure 17.12.11 shows the baryon-antibaryon mass for $\bar{B}^0 \to p\bar{p} D^0$, $B^+ \to J/\psi p\bar{\Lambda}$, $B^+ \to p\bar{\Lambda}_c\pi^+$, $B^+ \to \Lambda_c\bar{\Lambda}_c K^+$, $\bar{B}^0 \to \Lambda_c\bar{\Lambda} K^-$, and

$\bar{B}^0 \to \Sigma_c^0 \bar{p}\pi^+$. There are clear threshold enhancement peaks in $\bar{B}^0 \to p\bar{p} D^0$, $B^+ \to p\bar{\Lambda}_c\pi^+$, and $\bar{B}^0 \to \Lambda_c\bar{\Lambda} K^-$ along with non-negligible phase space components. But not all three-body decays show the threshold behavior. For $B^+ \to J/\psi p\bar{\Lambda}$ and $B^+ \to \Lambda_c\bar{\Lambda}_c K^+$ (Fig. 17.12.11b and d), where the available phase space is small, there is no clear threshold peak visible, but still a slight enhancement can be detected. The threshold peaking effect is totally absent in $\bar{B}^0 \to \Sigma_c^0 \bar{p}\pi^+$ (Fig. 17.12.11f).

The same threshold behavior has also been observed in the baryonic J/ψ decays $J/\psi \to \gamma p\bar{p}$ (Bai et al., 2003) and $J/\psi \to K^- p\bar{\Lambda}$ (Ablikim et al., 2004b). However, it is often argued in the literature (see references in Table 17.12.9 under the item "Final-state interactions") that threshold enhancement in $J/\psi \to \gamma p\bar{p}$ can be explained in terms

(a) $B^+ \to p\bar{p}K^+$ (Wei, 2008b)

(b) $B^+ \to p\bar{p}\pi^+$ (Wei, 2008b)

(c) $B^0 \to p\bar{\Lambda}\pi^-$ (Wang, 2007b)

Table 17.12.9. Various interpretations of threshold effects in baryonic B decays.

Model	Description
1. Pole model	The absence of $1/m_b^2$ suppression of the propagator in pole diagrams and the presence of a Λ_b or Ξ_b intermediate state lead to threshold enhancement (Cheng and Yang, 2002a; Hou and Soni, 2001).
2. $\mathfrak{B}_1\overline{\mathfrak{B}}_2$ bound state	The $p\bar{p}$ pair forms a bound state such as baryonium or $X(1835)$ (Datta and O'Donnell, 2003a; Rosner, 2003).
3. Glueball	An isoscalar $p\bar{p}$ pair forms a gluonic state (Chua, Hou, and Tsai, 2002a; Rosner, 2003).
4. Final-state interactions	Enhancement due to final-state interactions between the baryon pair (Haidenbauer, Meissner, and Sibirtsev, 2006; Kerbikov, Stavinsky, and Fedotov, 2004; Laporta, 2007; Sibirtsev, Haidenbauer, Krewald, Meissner, and Thomas, 2005).
5. Baryon form factors	In some approaches such as factorization, fragmentation, etc., the amplitude is governed by dibaryon form factors which fall off rapidly with dibaryon invariant mass as suggested by QCD counting rules (Chua and Hou, 2003; Chua, Hou, and Tsai, 2002a).

of final-state interactions between the baryon pair, while the same threshold effect in baryonic B decays can be understood in terms of the simple short-distance picture depicted in Fig. 17.12.12.

The so-called "threshold effect" indicates that the B meson prefers to decay into a baryon-antibaryon pair with low invariant mass accompanied by a fast recoil meson. This peaking behavior was quite unexpected, and has lead to various speculations about possible mechanisms, such as a glueball bound state formed by gluons, a baryonium bound state of the baryon-antibaryon pair, etc. Threshold enhancement was first proposed by Hou and Soni (2001), motivated by the CLEO measurement of $B \to D^* p\bar{n}$ and $D^* p\bar{p}\pi$ (Anderson et al., 2001). They argued that in order to enhance baryonic B decay, one has to reduce the energy release and at the same time allow for baryonic ingredients to be present in the final state. In other words, they conjectured that enhanced baryon production is favored by reduced energy release on the baryon side. This is indeed the near threshold effect mentioned above. Hence, the smallness of the two-body baryonic decay $B \to \mathfrak{B}_1\overline{\mathfrak{B}}_2$ has to do with its large energy release.

A heuristic approach to understanding the threshold enhancement in three-body decays can be obtained by looking at the Feynman diagrams in Fig. 17.12.8. In all these diagrams, the weak decay of a B meson produces two quarks and two antiquarks including the spectator. Baryons are formed with additional $q\bar{q}$ pairs produced by strong interaction from the vacuum. The initial arrangement of the primary four quarks determines whether the baryon-antibaryon pair is close in phase space (i.e., at mass threshold) or distant. If the diagram can be converted into a $B \to MM$ diagram by omitting the extra $q\bar{q}$ pairs from the vacuum (as in Figs 17.12.8d and e, the factorizable color-suppressed diagrams) we observe enhancement, while diagrams where the same process leaves a diquark-antidiquark pair would produce no enhancement at threshold. The latter class includes $\bar{B}^0 \to \Sigma_c^0 \bar{p}\pi^+$ (see Fig. 17.12.11f) proceeding through diagrams Fig. 17.12.8a and b.
Figure 17.12.12. Short-distance picture in terms of quarks and antiquarks for (a) two-body baryonic decay and (b) three-body baryonic decay. The slow spectator antiquark is denoted by the short line $\bar{q}_s$.

This idea is illustrated in Fig. 17.12.13. The diagram (a) would produce two mesons; with the extra $q\bar{q}$ pairs in (b) one meson transforms into a $\mathfrak{B}_1\overline{\mathfrak{B}}_2$ pair ($\Lambda_c^+\bar{p}$) with preferentially low invariant mass. This may be related to a meson pole, as described below. The diagram (c), however, produces a diquark-antidiquark pair, which is transformed by the extra $q\bar{q}$ pairs into a $\mathfrak{B}_1 M\overline{\mathfrak{B}}_2$ state $\Sigma_c^0\bar{p}\pi^+$. Here, no meson pole is possible, and no threshold enhancement is observed.

Of course, one has to understand the underlying origin of the threshold peaking effect. Threshold enhancement is closely linked to the behavior of baryon form factors which fall off sharply with t, the invariant mass squared of the dibaryon. While various theoretical ideas, summarized in Table 17.12.9, have been put forward to explain the low mass threshold enhancement, this effect can be understood in terms of a simple short-distance picture illustrated in Fig. 17.12.12 (Suzuki, 2007). To produce a baryon and an antibaryon in the two-body decay, one energetic $q\bar{q}$ pair must be emitted at high invariant mass, i.e., by a hard gluon (high q^2). This hard gluon is far off mass shell and hence the two-body decay amplitude is suppressed by a factor of order α_s/q^2. In three-body baryonic B decays, a possible configuration is that the $\mathfrak{B}_1\overline{\mathfrak{B}}_2$ pair is emitted collinearly against the meson. The
Figure 17.12.13. Spectator diagrams of type 2, illustrating the basic picture for a $\mathfrak{B}_1\overline{\mathfrak{B}}_2$ threshold enhancement: (b) shows one diagram for $B^- \to \Lambda_c^+ \overline{p}\pi^-$ with preferentially low $\mathfrak{B}_1\overline{\mathfrak{B}}_2$ mass related to the meson pair diagram (a), and (d) shows $\overline{B}^0 \to \Sigma_c^0 \overline{p}\pi^+$ with preferentially high $\mathfrak{B}_1\overline{\mathfrak{B}}_2$ mass related to the diquark pair diagram (c).

Figure 17.12.14. Multiplicities for decays $B \to \mathfrak{B}_1\overline{\mathfrak{B}}_2 + \mathrm{n}M$.

quark-antiquark pair emitted from a gluon is moving in nearly the same direction. Since this gluon is close to mass shell, the corresponding configuration is not subject to the short-distance suppression. This implies that the dibaryon pair tends to have a small invariant mass.

All present explanations for the baryon antibaryon threshold enhancement have in common that the partial rate increases at low values of the baryon-antibaryon invariant mass, while other regions of phase space are poorly populated. Decay channels which have a small phase space would be naturally suppressed through the phase space factor, but this is counteracted by the property of the matrix element to cluster in a small phase space volume anyway, resulting in no or a much smaller suppression of those channels. A first test of this idea has been performed by *BABAR* (Grünberg, 2012), looking for the decay $\overline{B}^0 \to \Lambda_c^+ \overline{p}p\overline{p}$, where two baryon-antibaryon pairs are produced within a small overall phase space region. However, no event of this type has been found, yielding the upper limit shown in Table 17.12.6.

17.12.3.4 Multiplicity

There is a noticeable hierarchy in decay rates: three-body decays have substantially larger rates than their two-body counterparts. Likewise, four-body decays are usually more frequent than the three-body ones. For example,

$$\mathcal{B}(B^- \to p\overline{p}\pi^-) \gg \mathcal{B}(\overline{B}^0 \to p\overline{p}),$$
$$\mathcal{B}(\overline{B}^0 \to \Lambda\overline{p}\pi^-) \gg \mathcal{B}(B^- \to \Lambda\overline{p}),$$
$$\mathcal{B}(\overline{B}^0 \to \Lambda_c^+ \overline{p}\pi^+\pi^-) \gg \mathcal{B}(\overline{B}^0 \to \Lambda_c^+ \overline{p}\pi^0)$$
$$\gg \mathcal{B}(\overline{B}^0 \to \Lambda_c^+ \overline{p}),$$
$$\mathcal{B}(\overline{B}^0 \to D^{*+}p\overline{p}\pi^-) \gg \mathcal{B}(\overline{B}^0 \to D^{*0}p\overline{p}), \quad (17.12.6)$$

as shown in Fig. 17.12.14. This phenomenon can be understood in terms of the aforementioned threshold effect, that is, the preference for the invariant mass of the dibaryon to be close to threshold. The configuration of the two-body decay $B \to \mathfrak{B}_1\overline{\mathfrak{B}}_2$ is not favorable since its invariant mass is m_B. In $B \to \mathfrak{B}_1\overline{\mathfrak{B}}_2 M$ decays, the effective mass of the baryon pair is reduced as the emitted meson can carry away energy. This explains why $\mathcal{B}(B \to \mathfrak{B}_1\overline{\mathfrak{B}}_2 M) \gg \mathcal{B}(B \to \mathfrak{B}_1\overline{\mathfrak{B}}_2)$. The same reasoning applies to decays with two or more mesons.

However, it is not always true that a larger rate for three-body decays can be ascribed to threshold enhancement. As an example, consider the three-body doubly-charmed baryonic decay $\overline{B} \to \Lambda_c\overline{\Lambda}_c\overline{K}$ which has been observed at the B Factories with a branching fraction of order 10^{-3} (see Table 17.12.6). Since this mode is color-suppressed and has a very small phase space, the estimate is $\mathcal{B}(\overline{B} \to \Lambda_c\overline{\Lambda}_c\overline{K}) \sim 10^{-6}$ in naïve factorization. This is too small by two to three orders of magnitude compared to experiment. Possibilities for the enhancement of $\Lambda_c\overline{\Lambda}_c\overline{K}$ rates include final-state interactions and some resonances. There are two possible resonant states: a hidden-charm bound state $X_{c\overline{c}}$ with a mass near the $\Lambda_c\overline{\Lambda}_c$ threshold, $4.6 \sim 4.7$ GeV, and a $\Lambda_c\overline{K}$ resonance. Indeed, Belle has reported a peak, called the $X(4630)$, in the $e^+e^- \to \Lambda_c^+\overline{\Lambda}_c^-$ exclusive cross section (Pakhlova, 2008b; see also the discussion in Sections 21.4.6 and 18.3.5), while *BABAR* has found a resonance in the $\Lambda_c\overline{K}$ invariant mass distribution with mass ~ 2930 MeV (Aubert, 2008e; see also Section 19.4.1.3). It is therefore plausible that it is the resonant contribution rather than the threshold effect that renders $\mathcal{B}(\overline{B} \to \Lambda_c^+\overline{\Lambda}_c^-\overline{K}) > \mathcal{B}(\overline{B} \to \Lambda_c^+\overline{\Lambda}_c^-)$.

Also, as has already been pointed out, double charmed two-body decays are enhanced over single charm or charmless decays by the same mechanism: the baryon-antibaryon pair is closer to threshold in the former case. Much softer gluons are employed in double charmed decays. At least two hard gluons are needed for single charm or charmless two-body decays, and they are suppressed by factors of α_S^4 relative to double-charm two-body decays as explained above in Section 17.12.2.2.

17.12.3.5 Baryon-meson angular correlations in three-body decays

The measurement of angular correlations of the outgoing meson in the dibaryon rest frame can provide further insight into the underlying mechanism for three-body decays. From the theoretical point of view, within pQCD it is expected that the meson in $\bar{B} \to \mathfrak{B}_1\overline{\mathfrak{B}}_2 M$ decays has a stronger correlation with the antibaryon than with the baryon in the dibaryon rest frame. Hence, the opposite correlation effect seen in $B^- \to p\bar{p}K^-$ and $\Lambda\bar{p}\pi^-$ is astonishing and entirely unexpected.

Experimental results

After sufficient data was accumulated at the B Factories, there was an effort to study the threshold region by investigating the angular distribution in the baryon-antibaryon rest frame (Chang, 2009; Wang, 2005, 2007b; Wei, 2008b). In these analyses, θ_p is defined as the angle between the (anti)proton direction and the oppositely charged meson direction in the baryon antibaryon rest frame for $B^+ \to p\bar{p}K^+$, $B^+ \to p\bar{p}\pi^+$, and $B^0 \to p\bar{\Lambda}\pi^-$. Figure 17.12.15 shows the differential branching fractions as a function of $\cos\theta_p$ for these representative modes with baryon-antibaryon mass $< 2.85\,\text{GeV}/c^2$. These distributions are not symmetric and have some puzzling features. Since the proton and the antiproton move almost collinearly in the B rest frame due to the threshold constraint, the peaking toward $\cos\theta_p = 1$ for $B^+ \to p\bar{p}K^+$ indicates that the baryon containing the spectator quark of the B meson moves faster in the B rest frame. This is opposite to the pQCD expectation for $b \to sg^*$ decays (see below). Similarly, most of the time the protons in $B^0 \to p\bar{\Lambda}\pi^-$ decays move faster in the $p\bar{\Lambda}$ system. An early attempt to account for the $B^+ \to p\bar{p}K^+$ data within pQCD, based on the preliminary result shown at the International Conference on High Energy Physics held in Beijing in 2004,

predicted a similar correlation for $B^+ \to p\bar{p}\pi^+$ (Geng and Hsiao, 2006; see the curve in Fig. 17.12.15b). Instead, the opposite effect is seen. The difference between these modes may indicate a crucial difference between the $b \to s$ strong penguin and the $b \to u$ tree processes.
Figure 17.12.16. Measured angular asymmetries (A_{θ_p}) as a function of $p\bar{p}$ mass near threshold for $B^+ \to p\bar{p}K^+$ from Belle (Wei, 2008b).

Using 449×10^6 $B\bar{B}$ pairs (Wei, 2008b), enough data is available for a detailed study of $B^+ \to p\bar{p}K^+$ signal events near threshold. The angular asymmetry

$$A_{\theta_p} = \frac{N_+ - N_-}{N_+ + N_-}, \qquad (17.12.7)$$

where N_+ and N_- are the efficiency-corrected B yields with $\cos\theta_p > 0$ and $\cos\theta_p < 0$ respectively, is shown as a function of $m_{p\bar{p}}$ in Fig. 17.12.16. The distribution is not flat, indicating that the relative contributions from differ-

ent decay amplitudes are changing in this near-threshold mass range.

$b \to sg^*$ and other models

In the short-distance $b \to sg^*$ picture, it is expected that the antibaryon produced in penguin-dominated $\bar{B} \to \mathfrak{B}_1\overline{\mathfrak{B}}_2 M$ decays tends to emerge parallel to the outgoing meson, while the baryon moves antiparallel to the meson in the $\mathfrak{B}_1\overline{\mathfrak{B}}_2$ rest frame. This is also true for tree-dominated three-body decays. Intuitively, this can be understood in the following manner. Since in the B rest frame

$$m_{12}^2 = m_1^2 + m_2^2 + 2(E_1 E_2 - |\boldsymbol{p}_1||\boldsymbol{p}_2|\cos\theta_{12}), \quad (17.12.8)$$

threshold enhancement implies that the baryon pair $\mathfrak{B}_1$ and $\overline{\mathfrak{B}}_2$ tends to move collinearly in this frame, *i.e.* $\theta_{12} \to 0$. See Fig. 17.12.5(b) for a comparable penguin diagram, and Fig. 17.12.7a for a comparable three-body decay. From Fig. 17.12.7a we see that the $\mathfrak{B}_1$ is moving faster than $\overline{\mathfrak{B}}_2$ as the former picks up an energetic quark from the b decay. When the system is boosted to the $\mathfrak{B}_1\overline{\mathfrak{B}}_2$ rest frame, $\overline{\mathfrak{B}}_2$ and M are moving collinearly away from the $\mathfrak{B}_1$.

This picture has been tested and confirmed by the measurements of angular correlations in $B^- \to p\bar{p}\pi^-$ (see Fig. 17.12.15b) and $\Lambda_c^+\bar{p}\pi^-$ decays. (For the related $B^- \to \Lambda\bar{p}\gamma$ decay, see Section 17.12.4 and Fig. 17.12.21.) However, from the study of the polar angle distribution of the proton in the $p\bar{p}$ system of $B^- \to p\bar{p}K^-$, it was found by both *BABAR* (Aubert, 2005p) and Belle (Wang, 2004b) that there is a preference for K^- to be collinear with the proton in the $p\bar{p}$ rest frame (see Fig. 17.12.15a, recalling that θ_p is the angle between K^+ and $\bar{p}$ or K^- and p). This is against the theoretical prediction based on a short-distance $b \to sg^*$ picture. The fragmentation model by Rosner (2003) implies a large correlation between K^- and $\bar{p}$ from the penguin annihilation diagram. However, this diagram is suppressed by a factor $1/m_b$ relative to the dominant diagram that leads to the opposite correlation. For a detailed discussion of this model on $B^- \to p\bar{p}K^-$, see Cheng (2006). This puzzle may indicate that (i) some long-distance effect enters and reverses the angular dependence, or (ii) the $p\bar{p}$ pair is produced from some intermediate states such as a baryonium, a $p\bar{p}$ bound state, or a glueball. For example, the angular puzzle for $p\bar{p}K^-$ can be resolved if $p\bar{p}$ is produced via a $^1S_0$ or $^3S_1$ baryonium state. However, the same flip mechanism will modify the correct $(1 - \cos\theta_p)^2$ distribution for $p\bar{p}\pi^-$ to a wrong one, unless one assumes D- and P-waves for $p\bar{p}\pi^-$ (Suzuki, 2007). This is the first big surprise.

The second big surprise arises from the experimental findings by Belle (Wang, 2007b) that the Λ particle is moving slower than the $\bar{p}$ in the decay of $\bar{B}^0 \to \Lambda\bar{p}\pi^+$ (see Fig. 17.12.15c which shows that Λ moves collinearly with π^+ in the $\Lambda\bar{p}$ rest frame, which in turn implies that Λ is moving slower than $\bar{p}$ in the B rest frame). This violates the common idea for $b \to sg^*$ decay since the Λ particle
Figure 17.12.17. B yield distributions from Belle (Chen, 2008a) as a function of $\cos\theta_K$ with a fit curve overlaid for $B^0 \to p\bar{p}K^{*0}$. The fraction of the signal in the helicity zero state is the fit parameter and is denoted by H_0. The asymmetry in the fit curve is due to detection efficiency: the underlying theoretical distribution is symmetric.

(a) $B^0 \to p\bar{p}K^{*0}$ (b) $B^+ \to p\bar{p}K^{*+}$
Figure 17.12.18. Distributions of efficiency corrected signal yields *vs* $\cos\theta_p$ in the proton-antiproton system with $M(p\bar{p}) < 2.85 \,\mathrm{GeV}/c^2$ from Belle (Chen, 2008a).

inherits the energetic s quark from b decay directly. It is naïvely expected that the pion has no preference for its correlation with Λ or $\bar{p}$. The aforementioned baryonium mechanism does not work for this case.

Further measurements, including $B \to p\bar{p}K^*$

The abovementioned correlation enigmas are great challenges to theorists. It appears that these puzzles occur only in the penguin-dominated decays $B^- \to p\bar{p}K^-$ and $\bar{B}^0 \to \Lambda\bar{p}\pi^-$. Experimental studies of the angular distributions in charmed decays such as $\bar{B}^0 \to \Lambda\bar{p}D^{*+}$ may help solve the angular correlation puzzle in $\bar{B}^0 \to \Lambda\bar{p}\pi^+$, as the same vacuum to $\Lambda\bar{p}$ transition form factors appear in both cases (Chen, Cheng, Geng, and Hsiao, 2008). It is also very important to study the angular distributions of the baryon for $p\bar{p}X$ with $X = K^{*+}, K^0, K^{*0}, \pi^-$, and the $\Lambda\bar{\Lambda}K^-$ modes.

Both the $p\bar{p}$ threshold enhancement and baryon-meson correlations have been studied for the the isospin-related

decays $B^+ \to p\bar{p}K^{*+}$ and $B^0 \to p\bar{p}K^{*0}$ (Chen, 2008a); the analysis relies on a measurement of the helicity of the K^* in the decays. Large MC samples with different helicity states, 0 or ± 1, of K^* mesons are generated in order to obtain the corresponding angular $p.d.f.$s in $\cos\theta_K$, where θ_K is the polar angle of the K in the K^* helicity frame. For events with $m_{p\bar{p}} < 2.85\,\mathrm{GeV}/c^2$, the B yield distribution in bins of $\cos\theta_K$ is used to determine the helicity zero fraction: the result is shown in Fig. 17.12.17 for $B^0 \to p\bar{p}K^{*0}$. It is interesting to note that the K^{*0} meson is likely to be fully polarized in the helicity zero state, whereas the K^{*+} produced in $B^+ \to p\bar{p}K^{*+}$ has only a $(32\pm17\pm9)\%$ fraction in this state (Chen, 2008a). If more than one decay amplitude is important, interference between them could lead to sizeable direct CP violation. A theoretical conjecture based on the factorization approach predicts that the CP violation in $B^{\pm} \to p\bar{p}K^{*\pm}$ could be as large as $\sim 22\%$ (Geng, Hsiao, and Ng, 2007). This should be checked experimentally in the future.

With fixed K^* polarization, the $p\bar{p}K^*$ detection efficiency is determined as a function of $M(p\bar{p})$, and the differential cross section is then measured in $M(p\bar{p})$ bins. Threshold enhancements similar to those of $B^+ \to p\bar{p}K^+$ or $p\bar{p}\pi^+$ (Fig. 17.12.10) are seen. Distributions of the efficiency-corrected signal yield as a function of $\cos\theta_p$ are shown in Fig. 17.12.18. For $B^0 \to p\bar{p}K^{*0}$, consistent with a pure helicity state (and presumably dominated by the $b \to s$ penguin transition), the distribution is featureless; for $B^+ \to p\bar{p}K^{*+}$, where the polarization is lower (and both $b \to s$ penguin and external W-emission transitions can contribute) an angular correlation comparable to that in $B^- \to p\bar{p}K^-$ or $\bar{B}^0 \to \Lambda\bar{p}\pi^-$ is seen. The statistical power is limited in both cases.

17.12.3.6 Cabibbo suppression

BABAR measured the Cabibbo suppressed decay $\bar{B}^0 \to \Lambda_c^+\bar{p}\pi^+K^-$ (Aubert, 2009ag) which can be compared to the Cabibbo favored decay $\bar{B}^0 \to \Lambda_c^+\bar{p}\pi^+\pi^-$ (Park, 2007). From a naïve comparison of the matrix elements one would expect a ratio of $|V_{us}/V_{ud}|^2 = 0.054 \pm 0.002$ if the decay mechanisms would be dominated solely by the CKM matrix elements. Comparing the branching ratios, as given in Table 17.12.6, the ratio is

$$\frac{\mathcal{B}\left(\bar{B}^0 \to \Lambda_c^+\bar{p}K^-\pi^+\right)}{\mathcal{B}\left(\bar{B}^0 \to \Lambda_c^+\bar{p}\pi^-\pi^+\right)} = 0.038 \pm 0.009, \qquad (17.12.9)$$

which implies that additional decay amplitudes (similar to 2b and 2h in Fig. 17.12.8) are only present in $\bar{B}^0 \to \Lambda_c^+\bar{p}\pi^+\pi^-$ and their contribution cannot be neglected.

The resonant subchannels have a ratio

$$\frac{\mathcal{B}\left(\bar{B}^0 \to \Sigma_c^{++}(2455)\bar{p}K^-\right)}{\mathcal{B}\left(\bar{B}^0 \to \Sigma_c^{++}(2455)\bar{p}\pi^-\right)} = 0.048 \pm 0.016, \quad (17.12.10)$$

which is in better agreement with the expectation from Cabibbo suppression. This may be understood by the fact that the spectator amplitudes are the same (1a, 2g, see Table 17.12.6) for these decays.

17.12.3.7 Isospin relations

Isospin relations between two-body decays have already been used in Section 17.12.2 for the ratios of $\Sigma_c^0\bar{p}$, $\Lambda_c^+\bar{p}$, and $\Sigma_c^+\bar{p}$. Similar considerations can be applied to three-body states. The isospin restrictions on the final states in $\bar{B}^0 \to \Lambda_c^+\bar{p}\pi^0$ (Aubert, 2010h) and $B^- \to \Lambda_c^+\bar{p}\pi^-$ (Aubert, 2008aa; Gabyshev, 2006) are different: while $B^- \to \Lambda_c^+\bar{p}\pi^-$ can have only a final isospin of $I_{X\pi^-} = 3/2$ (where $X = \Lambda_c^+\bar{p}$) the neutral decay $\bar{B}^0 \to \Lambda_c^+\bar{p}\pi^0$ can have $I_{X\pi^0} = 1/2$, $3/2$. If the decay mechanisms were equivalent in both decays one would expect a ratio of the decay rates $\bar{B}^0 \to \Lambda_c^+\bar{p}\pi^0 : B^- \to \Lambda_c^+\bar{p}\pi^-$ of $2 : 3$ for $I_{X\pi^-} = I_{X\pi^0} = 3/2$. A significant difference would suggest contribution from amplitudes specific to one of the decays, e.g. amplitudes where the π^- originates from the W in $B^- \to \Lambda_c^+\bar{p}\pi^-$ or $\bar{B}^0 \to \Lambda_c^+\bar{p}\pi^0$ contributions with $I_{X\pi^0} = \frac{1}{2}$. BABAR finds the ratio of partial decay widths for all decays to the final state particles

$$\frac{\Gamma\left(\bar{B}^0 \to \Lambda_c^+\bar{p}\pi^0\right)}{\Gamma\left(B^- \to \Lambda_c^+\bar{p}\pi^-\right)} = 0.61 \pm 0.09 \qquad (17.12.11)$$

to be consistent with the expectation of 2/3. When we remove the Σ_c resonant states that are only visible in the charged B decay, the ratio

$$\frac{\Gamma\left(\bar{B}^0 \to \Lambda_c^+\bar{p}\pi^0\right)}{\Gamma\left(B^- \to \Lambda_c^+\bar{p}\pi^-\right)_{\mathrm{nonresonant}}} = 0.80 \pm 0.11 \quad (17.12.12)$$

is found to be in agreement with the assumption of similar processes in both decays.

There are, however, penguin decays for which the isospin relations are violated. Using the average of the results reported in Table 17.12.8, and correcting for the different lifetimes $\tau_+/\tau_0 = 1.071 \pm 0.009$ and the different $\Upsilon(4S)$ branching fraction $\mathcal{B}_{+-}/\mathcal{B}_{00} = 1.066 \pm 0.024$ (Beringer et al., 2012) we obtain

$$\frac{\Gamma(B^+ \to p\bar{p}K^+)}{\Gamma(B^0 \to p\bar{p}K^0)} = 1.91 \pm 0.27$$

and

$$\frac{\Gamma(B^+ \to p\bar{p}K^{*+})}{\Gamma(B^0 \to p\bar{p}K^{*0})} = 2.7 \pm 0.3 \qquad (17.12.13)$$

while a ratio of 1 is expected. Note that the helicities of the K^{*+} and K^{*0} mesons in the latter pair differ, as discussed at the end of Section 17.12.3.5 above.

17.12.3.8 $s\bar{s}$ suppression

In fragmentation, $s\bar{s}$-production is suppressed by a factor of three compared to $u\bar{u}$ or $d\bar{d}$. This is attributed to the tunnelling process leading to additional $q\bar{q}$-pairs from the vacuum. In B meson decays, a similar process occurs in hadronization. This can be investigated using pairs of decays such as $\bar{B}^0 \to D^0\Lambda\bar{\Lambda}$ (Chang, 2009) and $\bar{B}^0 \to D^0 p\bar{p}$
Figure 17.12.19. Pole diagrams for $B^- \to \Lambda \bar{p} \gamma$.

(Abe, 2002g), where both decays can have contributions from the same diagram types (see Table 17.12.5). The ratio

$$\frac{\mathcal{B}\left(\bar{B}^0 \to D^0 \Lambda \bar{\Lambda}\right)}{\mathcal{B}\left(\bar{B}^0 \to D^0 p \bar{p}\right)} = 0.103^{+0.056}_{-0.043} \pm 0.014 \qquad (17.12.14)$$

does not include the additional possible final states $D^0 \Sigma^0 \bar{\Lambda}$, $D^0 \Lambda \bar{\Sigma}^0$, and $D^0 \Sigma^0 \bar{\Sigma}^0$ for the $s\bar{s}$ diagrams. Assuming branching fractions of the same order for each of those, the resulting ratio ~ 0.4 is compatible with the fragmentation picture.

One would expect a similar ratio between the penguin decays $B^0 \to K^0 \Lambda \bar{\Lambda}$ (Chang, 2009) and $B^0 \to K^0 p \bar{p}$ (Wei, 2008b), however more diagrams can contribute to $B^0 \to K^0 \Lambda \bar{\Lambda}$ due to the combinatoric rearrangements of $b \to s + s\bar{s}$ compared to $b \to s + u\bar{u}$ in $B^0 \to K^0 p \bar{p}$. The experimental ratio of

$$\frac{\mathcal{B}\left(\bar{B}^0 \to K^0 \Lambda \bar{\Lambda}\right)}{\mathcal{B}\left(\bar{B}^0 \to K^0 p \bar{p}\right)} = 1.89^{+0.37}_{-0.40} \pm 0.29 \qquad (17.12.15)$$

is larger by a factor of ~ 10 than that for the $D^0 \mathfrak{B}_1 \bar{\mathfrak{B}}_2$ channels.

An $s\bar{s}$ suppression may also be expected between $\bar{B}^0 \to \Lambda_c^+ \bar{p} \pi^+ \pi^-$ and $\bar{B}^0 \to \Lambda_c^+ \bar{p} K^+ K^-$. However, differences are not attributable to $s\bar{s}$ suppression alone since possible contributing diagrams differ: Only $\bar{B}^0 \to \Lambda_c^+ \bar{p} \pi^+ \pi^-$ can have contributions from diagrams of type 1 (Fig. 17.12.7). In decays of type 2 (Fig. 17.12.8) different intermediate resonant states are contributing, and the number of diagrams for $\bar{B}^0 \to \Lambda_c^+ \bar{p} K^+ K^-$ is smaller.

17.12.4 Radiative decays into baryons

It would be very difficult to detect the radiative baryonic B decay $B \to \mathfrak{B}_1 \bar{\mathfrak{B}}_2 \gamma$ if it proceeded only via bremsstrahlung. Fortunately, there is an important short-distance electromagnetic penguin transition $b \to s\gamma$ which is neither Cabibbo nor (due to the large top quark mass) loop suppressed. Moreover, it is considerably enhanced by QCD corrections. At the mesonic level, it is well known that the electromagnetic penguin transition $b \to s\gamma$ is represented by the radiative decays $B \to K^* \gamma$. The measurement of $B^- \to \Lambda \bar{p} \gamma$ using a $449 \times 10^6 B\bar{B}$ sample in 2005 by Belle (Lee, 2005) provided the first observation of $b \to s\gamma$ in baryonic B decays.
Figure 17.12.20. Differential branching fractions for $B^- \to \Lambda \bar{p} \gamma$ as a function of baryon-antibaryon pair mass from Belle (Wang, 2007b). The shaded distribution shows the expectation from a phase-space MC simulation. The theoretical prediction from Geng and Hsiao (2005) is overlaid as a solid line for comparison. The area of the shaded distributions and areas under the theoretical curves are scaled to match the measured branching fractions from data. The uncertainties are statistical only.
Figure 17.12.21. Differential branching fractions $vs \cos\theta_p$ for $B^- \to \Lambda \bar{p} \gamma$ in the region near threshold (baryon-antibaryon mass $< 2.8 \, \text{GeV}/c^2$) from Belle (Wang, 2007b). The uncertainties are statistical only.

Theoretically, radiative baryonic B decays have been studied in the pole model, in which the dominant contributions are assumed to arise from low-lying baryon and meson intermediate states (Cheng and Yang, 2002b). For example, the relevant intermediate states for $B^- \to \Lambda \bar{p} \gamma$ are K^*, $\Lambda_b^{(*)}$ and $\Sigma_b^{(*)0}$ (see Fig. 17.12.19). Predictions for some radiative decay modes are summarized in Table 17.12.10. The model prediction for $\mathcal{B}(B^- \to \Lambda \bar{p} \gamma) =$

Table 17.12.10. Predicted branching fractions for radiative baryonic B decays where A_θ is the angular asymmetry defined in Eq. (17.12.7) and "$\mathcal{B}(\mathrm{tot})$" denotes the sum of the baryon and meson pole contributions (Cheng and Yang, 2006).

Mode	Baryon	Meson	$\mathcal{B}(\mathrm{tot})$	A_θ
$B^- \to \Lambda \bar{p} \gamma$	7.9×10^{-7}	9.5×10^{-7}	2.6×10^{-6}	0.25
$B^- \to \Sigma^0 \bar{p} \gamma$	4.6×10^{-9}	2.5×10^{-7}	2.9×10^{-7}	0.07
$B^- \to \Xi^0 \bar{\Sigma}^- \gamma$	7.5×10^{-7}	1.6×10^{-7}	5.6×10^{-7}	0.43
$B^- \to \Xi^- \bar{\Lambda} \gamma$	1.6×10^{-7}	2.4×10^{-7}	2.2×10^{-7}	0.13

2.6×10^{-6} is in good agreement with the latest measurement (Wang, 2007b)

$$\mathcal{B}(B^- \to \Lambda \bar{p} \gamma) = (2.45^{+0.44}_{-0.38} \pm 0.22) \times 10^{-6} \ . \quad (17.12.16)$$

The measured differential branching fraction as a function of baryon-antibaryon mass for $B^- \to \Lambda \bar{p} \gamma$ is shown in Fig. 17.12.20. This distribution is sharply peaked near threshold and is quite similar to those observed in $B^- \to \Lambda \bar{p} \pi^0$ and $\bar{B}^0 \to \Lambda \bar{p} \pi^+$ (Wang, 2007b; see the discussion in Section 17.12.3.3 above).

Experimentally, the angular correlation in $B^- \to \Lambda \bar{p} \gamma$ is measured by considering the angular asymmetry A_θ defined in Eq. (17.12.7). Figure 17.12.21 shows the differential branching fraction as a function of $\cos \theta_p$ near the $\Lambda \bar{p}$ mass threshold, where θ_p is the angle between the photon and the antiproton in the $\Lambda \bar{p}$ rest frame. From Fig. 17.12.20, we know that Λ and $\bar{p}$ tend to move in parallel. Since the energetic s quark from the $b \to s\gamma$ process will hadronize into Λ, it is expected that Λ will move faster than $\bar{p}$ in the B rest frame. Indeed, after boosting to the baryon-antibaryon rest frame, the antiproton prefers leaning to the photon direction as shown in Fig. 17.12.21. Again, the predicted angular asymmetry $A_\theta = 0.25$ agrees with the measured value of $0.29 \pm 0.14 \pm 0.03$ (Wang, 2007b). We see from Table 17.12.10 that the decay $B^- \to \Xi^0 \bar{\Sigma}^- \gamma$, with an estimated branching fraction of order 6×10^{-7}, should be accessible at the B Factories. Penguin-induced radiative baryonic B decays should be further explored both experimentally and theoretically.

17.12.5 Semileptonic decays with a baryon-antibaryon pair

Semileptonic decays would proceed only through the type 1 (external) diagram shown in Fig. 17.12.7a, when the W decays into a $\ell^- \bar{\nu}_\ell$ pair instead of a quark antiquark pair. The observation of such decays could therefore establish the relevance of this diagram compared to the type 2 (internal) ones. Unfortunately, no semileptonic decay to baryons has been observed so far. The upper limit from

BABAR (Lees, 2012p) is

$$\frac{\mathcal{B}(\bar{B} \to \Lambda_c^+ X \ell^- \bar{\nu}_\ell)}{\mathcal{B}(B/\bar{B} \to \Lambda_c^+ X)} < 0.025 \text{ at } 90\% \text{ CL} \quad (17.12.17)$$

which, using the inclusive $\Lambda_c^\pm$ multiplicity in B decays from Section 17.12.1, translates into an approximate upper limit $\mathcal{B}(\bar{B} \to \Lambda_c^+ X \ell^- \bar{\nu}_\ell) < 1.2 \times 10^{-3}$.

17.12.6 Summary

The observed pattern in two-body baryonic B decays, namely, $\mathcal{B}(B \to \mathfrak{B}_{1c}\overline{\mathfrak{B}}_{2c}) \gg \mathcal{B}(B \to \mathfrak{B}_c\overline{\mathfrak{B}}) \gg \mathcal{B}(B \to \mathfrak{B}_1\overline{\mathfrak{B}}_2)$, can be understood in pQCD, though there is still no clear theoretical prediction for charmless two-body decays. Given the large energy release in such decays, an estimate based on the pQCD approach should be reliable.

The enhancement of the baryon-antibaryon invariant mass near threshold observed in multi-body baryonic B decays indicates that the B meson preferentially decays into a baryon-antibaryon pair with low invariant mass accompanied by a fast recoil meson. Theoretically, the threshold peaking effect is closely linked to the behavior of baryon form factors which fall off sharply with t, the invariant mass squared of the dibaryon. There are two unsolved puzzles in the study of baryon-antibaryon angular correlations. First, the anomalous correlation effect measured in $B^- \to p\bar{p}K^-$ decay is against the theoretical prediction based on the short-distance $b \to sg^*$ picture. Second, the Λ particle in the decay of $\bar{B}^0 \to \Lambda \bar{p} \pi^-$ moves collinearly with π^- in the $\Lambda \bar{p}$ rest frame, whereas it is naïvely expected that the pion has no preference for its correlation with Λ or the antiproton. These correlation enigmas are great challenges to theorists.

The measured branching fraction and the angular correlation in $B^- \to \Lambda \bar{p} \gamma$ are consistent with the theoretical model based on the weak penguin process $b \to s\gamma$. Hence, this radiative baryonic B decay is induced by the electroweak penguin transition. It is important to further explore penguin-mediated radiative baryonic B decays both experimentally and theoretically.

Chapter 18
Quarkonium physics

18.1 Introduction to quarkonium

Editors:
Nora Brambilla, Thomas Mannel (theory)

Heavy quarkonia are systems composed of a heavy quark and antiquark of the same flavor (charm, bottom, or top[97]), with mass m much larger than the "QCD confinement scale" Λ_{QCD}, so that $\alpha_s(m) \ll 1$ holds. Within both the $c\bar{c}$ and $b\bar{b}$ quarkonium spectra, it is evident that the difference in energy levels is much smaller than the quark mass: quarkonia are non-relativistic systems.

Due to the large quark mass and small (relative) quark velocity $|\boldsymbol{v}| = v$ in quarkonia, these states are affected by physical processes at a range of energy scales. They probe all the regimes of QCD, from high energies where an expansion in the coupling constant is possible, to low energies where non-perturbative effects dominate; they also probe intermediate scales. Quarkonium is thus a laboratory where our understanding of non-perturbative QCD and its interplay with perturbative QCD may be tested in a controlled framework. The large mass and the clean and known decay modes also make quarkonia an ideal probes of new physics in some well defined window of beyond Standard Model (BSM) parameters, in particular for some searches for dark matter candidates (Brambilla et al., 2004, 2011; Dermisek, Gunion, and McElrath, 2007; McElrath, 2005; Sanchis-Lozano, 2010).

Belle and *BABAR* have collected a wide range of quarkonium data, including clean samples of charmonia produced in B decays, two-photon fusion, initial state radiation, and e^+e^- annihilation, including the unexpected observation of large associated $(c\bar{c})(c\bar{c})$ production. The final years of datataking have also seen extensive studies of $b\bar{b}$ states. Even if quarkonium studies were not a priority at the start of the running of the B Factories, these facilities have come to function as heavy meson factories, producing many new states and new data on quarkonia, and accumulating large data samples on spectra and decays. In the same period, quarkonia have been studied at BES and BESIII at BEPC and BEPC2, KEDR at VEPP-4M, CLEO-III and CLEO-c at CESR, CDF and DØ at Fermilab, and the PHENIX and STAR experiments at RHIC. New states and exotics, new production mechanisms, new transitions and unexpected states of an exotic nature have been observed. Large new data samples are now being collected at the LHC experiments and new facilities will become operational (PANDA at GSI, a much higher luminosity B Factory at KEK) adding challenges and opportunities to this research field.

In the following, we describe the possible quantum numbers and some features of the spectrum of quarko-

nium states (Section 18.1.1), and briefly review the potential model approach (Section 18.1.2). The hierarchy of scales required to describe quarkonia, and its implications, are then discussed (Section 18.1.3), followed by an extended review of effective field theory (EFT) methods (Section 18.1.4) and a brief discussion of lattice calculations (Section 18.1.5). We conclude this introduction with examples of results obtained from theoretical studies of quarkonia. In the remainder of this chapter, we describe in turn the B Factory results on conventional charmonium states (Section 18.2), the exotic charmonium-like or "XYZ" states (Section 18.3), and bottomonium states (Section 18.4).

18.1.1 Quantum numbers and spectroscopy

The term "quarkonium" was coined because of the similarity of heavy quark-antiquark bound states to those of positronium: the bound states of an e^+ and an e^-. These systems share similar spectroscopy and decays. For example, the parapositronium decays into two photons, while its charmonium analogue η_c decays into two gluons; the orthopositronium decays into three photons, while the "orthocharmonium" (J/ψ) decays into and gluons, as these decays are fixed by quantum numbers and related parity and charge conjugation conservation.

In Fig. 18.1.1 our present knowledge of the bottomonium and charmonium energy levels is illustrated: our current understanding has changed dramatically after the B Factory era and we have acquired information about many new energy levels, both below and above threshold, and among several new decays and transitions.

The spectroscopic notation $n^{2s+1}\ell_J$ (with the J^{PC} number often given in parenthesis) is conventionally used for quarkonium levels, where n is the radial quantum number (equal to the number of nodes in the wavefunction) plus 1, ℓ is the orbital angular momentum between quarks (designated by letters as S, P, D, etc.), $s = 0, 1$ is the total spin of the quarks, and J is the quarkonium spin ($|\ell - s| \leq J \leq \ell + s$). We note, that among the above four quantum numbers, only the spin of a state can be measured; the others are merely assigned based on the measured parity P, and charge-conjugation C. The behavior of a state under parity is dictated by the symmetry of the angular momentum eigenfunctions, the spherical harmonics Y_l^m, for which $P = (-1)^\ell$, and by the opposite parity of the antifermion with respect to the fermion, which finally yields for the quarkonium parity

$$P = (-1)^{\ell+1}. \tag{18.1.1}$$

Charge conjugation exchanges the two constituents. Because of Fermi-Dirac statistics, the exchange of two identical fermions gives a minus sign. On the other hand, this exchange is performed applying the charge conjugation operator (which gives a factor C), exchanging the coordinates (which gives $(-1)^\ell$) and exchanging the spin (which gives a factor $(-1)^{s+1}$). Therefore $C(-1)^\ell(-1)^{s+1} = -1$ and

$$C = (-1)^{\ell+s}. \tag{18.1.2}$$

---

[97] The top quark does not form a proper bound state since it decays weakly on a time scale shorter than that typical of the would-be bound state. However, to calculate the $t\bar{t}$ production cross section, bound state effects have to be taken into account.
Figure 18.1.1. Energy levels of bottomonium (upper plot) and charmonium (lower plot) as known at the end of the *B* Factory era. "Established" states are those predicted in the theory and whose measured properties are in agreement with predictions. "New states" are unpredicted and/or their measured properties are difficult to accommodate in the theory. In the last column we list states with unknown quantum numbers, and the charged quarkonium-like resonances.

Spin, *P* or *C* are often determined from the selection rules both of the production and the decay mechanism. When this is not the case, or if they cannot unambiguously fix ℓ and s, a quarkonium state assignment can be tried relying on theoretical predictions for the mass, width, decay channels, or production mechanisms.

From its non-relativistic nature some specific features of the quarkonium spectrum can be derived. The separation between levels of different n and same l typically

scales like mv^2; the spin separation between pseudoscalar mesons $n\,{}^1S_0(0^{-+})$ and vector mesons $n\,{}^3S_1(1^{--})$, called hyperfine splitting, scales like mv^4; the spin separation between states within the same $\ell \neq 0$ and S multiplets (*e.g.* the splittings in the $1\,{}^3P_j$ multiplet $\chi_c(1P)$ in charmonium), called fine splitting, scales like mv^4; and the hyperfine separation between the spin-singlet state $^1P_1$ and the spin-averaged triplet state $\langle {}^3P_j \rangle$, which again scales like mv^4.

The fact that all splittings are much smaller than the masses implies that all the dynamical scales of the bound state, such as the kinetic energy or the momentum of the heavy quarks, are small compared to the quark mass. Therefore, the heavy quarkonia are to a good approximation non-relativistic systems. For further discussion of the various energy scales relevant for quarkonium system, see Section 18.1.3.

Another important feature of the spectrum is the presence of an "open flavor threshold" (open charm, or open bottom), where a quarkonium state can undergo strong decay to a pair of mesons carrying the corresponding quark flavor. States above threshold are considerably wider than states below. Excited states below threshold decay either by strong interactions or electromagnetically into lower-lying states; the ground states finally decay by an annihilation process of the heavy quark-antiquark pair. This annihilation is controlled by powers of the strong coupling constant evaluated at the quark mass, which gives a large suppression factor, resulting in a small width.

18.1.2 Potential models

To make quantitative predictions of masses and for the the full and partial widths of charmonium states, one has to resort to theory. For many years a phenomenological approach, based on both non-relativistic and relativistic potential model, has been used. Non-relativistic potential models are justified by the fact that the bottom and, to a lesser extent, the charm masses are large in comparison to $\Lambda_{\rm QCD}$, the typical hadronic scale. Hence a quantum mechanical description of the system based on two heavy quarks interacting through a suitable potential appears reasonable. In this approach, the quarks are located in a potential $V(r)$ and the charmonium wave function can be found as a solution of the stationary non-relativistic Schrödinger equation. The potential is usually chosen such that at short distances it coincides with the QCD one-gluon exchange Coulomb potential $-\frac{4}{3}\alpha_S/r$, and at long distances it incorporates confinement by for example including a linearly rising term. Since relativistic effects appear to be sizable for some states, different models incorporate relativistic kinematics appropriately matched to their confinement features. Different models of quark confinement may result in different classes of relativistic corrections. For states close to and beyond the two heavy-light meson threshold, potential models have to be complemented with extra degrees of freedom in order to account for possible mixing effects. Hybrid states which are expected from QCD are also incorporated by hand.

Examples of results obtained for the charmonia in such phenomenological approaches are listed in Table 18.2.1: the states below open flavor threshold are well described.

The problem with this approach is that it is purely phenomenological, with no way to link the model parameters to QCD. In this approach on can neither use the quarkonia to improve our understanding of strong interactions, nor as a tool to extract precise information on the Standard Model and beyond. The modern approach to charmonium physics relies on non-relativistic effective field theories (NRQCD, pNRQCD), discussed in Section 18.1.4, and lattice calculations, discussed in Section 18.1.5 below. These methods are conditioned by the importance of a range of different energy scales in quarkonium physics, to which we now turn.

18.1.3 Quarkonium as a multiscale system

As non-relativistic systems, quarkonia are characterized by the heavy-quark velocity v ($v^2 \sim 0.1$ for the $b\bar{b}$, and ~ 0.3 for the $c\bar{c}$ systems) and by a hierarchy of energy scales: the mass m of the heavy quark (hard scale), the typical relative momentum $p \sim mv$ (in the meson rest frame) corresponding to the inverse Bohr radius $r \sim 1/(mv)$ (soft scale), and the typical binding (or kinetic) energy $E \sim mv^2$ (ultrasoft scale). This is similar to the energy scales for the hydrogen atom, in which case $v \sim \alpha_{\mathrm{EM}}$.

The hierarchy of non-relativistic scales makes the heavy quarkonia qualitatively different from the heavy-light mesons, which are characterized by just two scales: m and Λ_{QCD}. This makes the theoretical description of quarkonium physics more complicated. There are effects at each of these scales in a typical amplitude involving a quarkonium observable. In particular, quarkonium annihilation and production take place at the scale m, quarkonium binding takes place at the scale mv, which is the typical momentum exchanged inside the bound state, while very low-energy gluons and light quarks (also called ultrasoft degrees of freedom) live long enough that a bound state has time to form and, therefore, are sensitive to the scale mv^2. Ultrasoft gluons are responsible for phenomena similar to the Lamb shift in QCD.

The appearance of a hierarchy of scales calls for the application of effective field theory (EFT) methods. However, "heavy quark effective theory" (HQET), where only an ultraviolet mass scale m and an infrared mass scale Λ_{QCD} appear, is not suitable for the description of heavy quarkonia, since HQET is unable to describe the dynamics of binding. The appropriate effective field theories are "non-relativistic QCD" (NRQCD; Section 18.1.4.1) and "potential non-relativistic QCD" (pNRQCD; Section 18.1.4.2) which are far more complicated, since the scales mv and mv^2 are generated by the dynamics of the system which determines the velocity of the quarks in the bound state.

The description of the heavy quark-antiquark systems depends on the relation of Λ_{QCD} to the above-mentioned scales. Clearly for energy scales close to Λ_{QCD} there is no perturbative description and one has to rely
Figure 18.1.2. Energy scales and corresponding effective field theories for quarkonium. The scale μ separates QCD from NRQCD, while μ' separates NRQCD from pNRQCD.

on non-perturbative methods. Regardless of this, the non-relativistic hierarchy $m \gg mv \gg mv^2$ persists below the Λ_{QCD} threshold, as long as v is small. While the hard scale m is always larger than Λ_{QCD}, different situations may arise for the other two scales.

In a case with $\Lambda_{\mathrm{QCD}} \ll mv^2$ both scales are still perturbative and the system is similar to a Coulombic system: for such a quarkonium we would have — as for the hydrogen atom — $v \sim \alpha_s(mv)$. However, none of the $b\bar{b}$ or $c\bar{c}$ states satisfy this condition. In all realistic quarkonia ($b\bar{b}$ and $c\bar{c}$) the ultrasoft scale is non-perturbative. Only for $t\bar{t}$ threshold states may the ultrasoft scale be considered to lie in the perturbative regime.

The soft scale, proportional to the inverse quarkonium radius r, may be either perturbative ($mv \gg \Lambda_{\mathrm{QCD}}$) or non-perturbative ($mv \sim \Lambda_{\mathrm{QCD}}$) depending on the physical system under consideration. Unfortunately, we do not have any direct information on the radius of the quarkonia, and thus the assignment of some of the lowest bottomonium and charmonium states to the perturbative or the non-perturbative soft regime is at the moment still ambiguous, but it is likely that the lowest bottomonium and possibly also the lowest charmonium states have small enough radii that the scale mv is in fact still perturbative.

In Fig. 18.1.2 we schematically show the various scales. The short-range quarkonia are small enough to allow for a perturbative treatment of the scale mv, while for the long range quarkonia already this scale requires a non-perturbative treatment.

The implications of the hierarchy of scales for lattice calculations of quarkonium are outlined in Section 18.1.5 below; effective field theory methods are described in the following section.

18.1.4 Effective Field Theories

Effective field theories for the description of quarkonium processes have recently been developed, providing a unifying description as well as a solid and versatile tool giving well-defined, model-independent and precise predictions. They rely on the one hand on high-order perturbative calculations and on the other hand on lattice simulations, the recent progress in both fields having added significantly to the reach of theory. The progress in our understanding of EFTs has made it possible to move beyond phenomenological models (at least for states below open-flavor threshold) and to provide a systematic description, inside QCD, of heavy-quarkonium physics. On the other hand, the recent progress in the measurement of several heavy-quarkonium observables makes it meaningful to address the problem of their precise theoretical determination. Here we will give a brief introduction to EFTs for heavy quarkonium. For a general introduction to the field of quarkonium, a detailed review of quarkonium theory and experiments and a comparison of theory predictions to experiments with a discussion of the most important open problems, see Brambilla et al. (2004, 2011).

The idea of non-relativistic Effective Field Theories (NR EFTs) was pioneered by Caswell and Lepage (1986) and was later refined and cast into the NRQCD effective theory language by Bodwin, Braaten, and Lepage (1995); subsequently, the EFT at the lowest possible energy scale (the ultrasoft scale), potential NRQCD (pNRQCD), was obtained (Brambilla, Pineda, Soto, and Vairo, 2000; Pineda and Soto, 1998). A recent review can be found in Brambilla, Pineda, Soto, and Vairo (2005). The point is to take advantage of the existence of the different energy scales to substitute QCD with simpler but equivalent NR EFTs. A hierarchy of NR EFTs may be constructed by systematically integrating out modes associated with high-energy scales not relevant for the quarkonium system. Such integration is performed in a matching procedure that enforces the equivalence between QCD and the EFT at a given order of the expansion in v. The EFT Lagrangian is factorized in matching coefficients, encoding the high-energy degrees of freedom, and low-energy operators; relativistic invariance is realized via exact relations among these coefficients (Brambilla, Gromes, and Vairo, 2001, 2003; Manohar, 1997). The EFT displays power counting in the small parameter v, *i.e.* we are able to attach a definite power of v to the contribution of each of the EFT operators to the physical observables.

18.1.4.1 Physics at the scale m: NRQCD

Quarkonium annihilation and production take place at the scale m. The suitable EFT is non-relativistic QCD (Bodwin, Braaten, and Lepage, 1995; Caswell and Lepage, 1986), which follows from QCD after integrating out the scale m. As a consequence, the effective Lagrangian is or-

ganized as an expansion in $1/m$ and $\alpha_s(m)$:

$$\mathcal{L}_{\mathrm{NRQCD}} = \sum_n \frac{c_n(\alpha_s(m), \mu)}{m^n} \times O_n(\mu, mv, mv^2, \ldots),$$

(18.1.3)

where c_n are Wilson coefficients that contain the contributions from the scale m; they can be perturbatively calculated by matching the full QCD result to the effective theory. The O_n are the local operators of NRQCD; the matrix elements of these operators contain the physics of scales below m, in particular of the scales mv and mv^2 and also of the non-perturbative scale Λ_{QCD}. Finally, the parameter μ is the NRQCD factorization scale, which separates the contributions to be described in QCD from the ones to be described in NRQCD. Matrix elements of O_n depend on the scales μ, mv, mv^2 and Λ_{QCD} and the power counting is performed in powers of v. The low-energy operators O_n are constructed out of two or four heavy quark/antiquark fields plus gluons. The operators with a fermion and an antifermion field are the same ones obtained from the non-relativistic reduction of the QCD Lagrangian. This part of the Lagrangian is equal, in the meson rest frame, to the Lagrangian of Heavy Quark Effective Theory (HQET) which is used to treat heavy-light mesons. The power counting is, however, different: while in HQET there is a strict counting in inverse powers of m, in NRQCD the power counting is in powers of v, because the energy scales of heavy-light mesons and quarkonia are different. In particular, in a heavy-light meson, the three-momentum and the energy of the heavy quark are both of order Λ_{QCD}, in contrast with the situation in a heavy quarkonium, in which the three-momentum is of order mv and the energy is of order mv^2.

Annihilation decays

To describe the annihilation decays of heavy quarkonia into light hadrons, we have to consider four-fermion operators with four heavy quark/antiquark fields in the effective interaction. Considering operators up to dimension six we have the following contributions

$$\frac{c_1(^1S_0)}{m^2} O_1(^1S_0) + \frac{c_1(^3S_1)}{m^2} O_1(^3S_1)$$
$$+ \frac{c_8(^1S_0)}{m^2} O_8(^1S_0) + \frac{c_8(^3S_1)}{m^2} O_8(^3S_1),$$

(18.1.4)

where c_j are the matching coefficients: they are calculated as a series in α_s and in this case they acquire also imaginary parts. The dimension-6 operators (*i.e.* the operators containing two quark and two antiquark operators) are

$$O_1(^1S_0) = \psi^\dagger \chi \chi^\dagger \psi, \qquad O_1(^3S_1) = \psi^\dagger \boldsymbol{\sigma} \chi \chi^\dagger \boldsymbol{\sigma} \psi,$$
$$O_8(^1S_0) = \psi^\dagger \mathrm{T}^a \chi \chi^\dagger \mathrm{T}^a \psi, \quad O_8(^3S_1) = \psi^\dagger \mathrm{T}^a \boldsymbol{\sigma} \chi \chi^\dagger \mathrm{T}^a \boldsymbol{\sigma} \psi,$$

(18.1.5)

where ψ and χ are the Pauli fields for the quark and the antiquark, $\boldsymbol{\sigma}$ are the three spin Pauli matrices and T^a are

the $SU(3)$ color matrices. The subscript 1 or 8 indicates the color structure: since we consider states made by a quark and an antiquark, from the point of view of color $SU(3)$ these are $3 \times \bar{3}$ states, 3 being the fundamental color representation of $SU(3)$ and $\bar{3}$ the antifundamental. Therefore, since in $SU(3)$ $3 \times \bar{3} = 1 \oplus 8$, $q\bar{q}$ states behave under color transformation as color singlets or color octets. The arguments $^{2S+1}L_J$ indicate the angular-momentum state of the $Q\overline{Q}$ pair which is annihilated or created by the operator. Then, the annihilation rate can be calculated by recalling that the decay rate is minus two times the imaginary part of the energy of the state, so that we obtain that the inclusive decays of a heavy quarkonium state $|H\rangle$ induced through annihilation of the heavy quarks can be calculated in NRQCD as (Bodwin, Braaten, and Lepage, 1995)

$$\Gamma(H \to \text{light hadrons}) = \sum_n \frac{2\text{Im}\, c_n}{m^{d_n-4}} \langle H | O_n^{\text{4fermions}} | H \rangle,$$

$$(18.1.6)$$

d_n being the dimension of the operator O_n. This formula realizes a factorization between the physics at the hard scale contained in the imaginary parts of the matching coefficients and the low-energy physics contained in the non-perturbative matrix elements of four-fermion operators. The sum, over operators of increasing dimension, has to be truncated at the desired accuracy counting the contribution of each matrix element in powers of v and the suppression factor in α_s coming from the matching coefficient. Electromagnetic annihilation is treated in a similar way.

Color octet contributions

A quarkonium state $|H\rangle$ in NRQCD is expanded in the number of partons

$$|H\rangle = |\overline{Q}Q\rangle + |\overline{Q}Qg\rangle + |\overline{Q}Q\bar{q}q\rangle + \cdots \qquad (18.1.7)$$

where the states including one or more light parton are shown to be suppressed by powers of v. In $|\overline{Q}Qg\rangle$ for example the quark-antiquark are in a color octet state, since the in total the state may not carry any color, and thus the two quarks have to compensate the color of the gluon. Then both color singlet and color octet operators contribute in Eq. (18.1.6).

If one instead assumes that only heavy-quarkonium states with quark-antiquark in a color-singlet configuration can exist, then only color-singlet four-fermion operators can contribute and the matrix elements reduce to heavy-quarkonium wave functions (or derivatives of them) calculated at the origin. This assumption is known as the "color-singlet model".

Explicit calculations show that at higher order the color-singlet matching coefficients c_n develop infrared divergences, e.g. for P-waves this takes place at order α_s. In the color-singlet model, these singularities do not cancel in the expression of the decay widths. The first success of NRQCD (Bodwin, Braaten, and Lepage, 1995) was to

show that the Fock space of a heavy-quarkonium state may contain a small component of quark-antiquark in a color-octet configuration, bound with some gluonic degrees of freedom. Due to this component, matrix elements of color-octet four-fermion operators contribute, and it is exactly these contributions that absorb the infrared divergences of the color-singlet matching coefficients in the decay widths, giving rise to finite results.

Quarkonium production

The relevant scale for direct quarkonium production is also the hard scale m, so this process can be described by a local interaction in NRQCD, as we have done for inclusive decays. As a result, the inclusive cross section for the direct production of a quarkonium state H at large momentum in the center-of-mass frame can be written as a sum of products of NRQCD matrix elements and short-distance coefficients:

$$\sigma[H] = \sum_n \sigma_n \langle \mathcal{K}_n^{\text{4fermions}} \rangle \qquad (18.1.8)$$

where the σ_n are short-distance coefficients, and the matrix elements $\langle \mathcal{K}_n^{\text{4fermions}} \rangle$ are vacuum-expectation values of objects similar to the four-fermion operators in decays, containing both color singlet and color octet contributions. This factorization formula for production however has been proven only at next-to-next-to-leading order in α_s (Nayak, Qiu, and Sterman, 2005). Interesting new developments are coming from defining fragmentation functions in the NRQCD formalism (Kang, Qiu, and Sterman, 2012) and using soft collinear theory (Fleming, Leibovich, Mehen, and Rothstein, 2012). The short-distance coefficients $\sigma_n(\Lambda)$ are essentially the process-dependent partonic cross sections to make a $Q\overline{Q}$ pair (convoluted with parton distributions if there are hadrons in the initial state). The $Q\overline{Q}$ pair can be produced in a color-singlet state or in a color-octet state. Its spin state can be singlet or triplet, and it can also have orbital angular momentum. The matrix elements $\langle \mathcal{K}_n^{\text{4fermions}} \rangle$ contain all of the non-perturbative physics associated with the evolution of the $Q\overline{Q}$ pair into a quarkonium state. An important property of these matrix elements, which greatly increases the predictive power of NRQCD, is the fact that they should be universal, i.e., process independent. However, this is still an object of study. Again, NRQCD power-counting rules allow one to organize the sum over operators as an expansion in powers of v so that through a given order in v, only a finite set of matrix elements contributes.

Aside from NRQCD, which is a QCD-based approach, models have also been used to study quarkonium production. One is the color singlet model, which can be related to NRQCD by retaining in Eq. (18.1.8) only the color singlet contributions at leading order in v. Another is the color evaporation model, where the $Q\overline{Q}$ pair only has to have a certain invariant mass close to the quarkonium mass, but the color of the $Q\overline{Q}$ state is assumed to "evaporate". However, both models lead to inconsistencies: see Brambilla et al. (2004, 2011) for a detailed review.

For a review of applications of NRQCD to quarkonium production at the B Factories see Bodwin (2010, 2012) and Brambilla et al. (2004, 2011); for original calculations see Bodwin, Braaten, Lee, and Yu (2006); Bodwin, Kang, and Lee (2006); Bodwin, Lee, and Yu (2008); He, Fan, and Chao (2010); Li, He, and Chao (2009); Wang, Ma, and Chao (2011).

It is important to relate quarkonium production at B Factories and at hadron colliders. For example, recently NLO order NRQCD calculations for the process $e^+e^- \to J/\psi + X(\text{non}-c\bar{c})$ have been carried out by Zhang, Ma, Wang, and Chao (2010) and by Butenschoen and Kniehl (2011); the latter authors rely on the extraction of the NRQCD production matrix elements obtained from a global fit to all production data. For a note on intepretation of B Factory measurements of such cross sections, see Section 18.2.4.3.

Recently, factorization theorems have been obtained in two exclusive heavy-quarkonium production processes: production of two quarkonia in e^+e^- annihilation and production of a quarkonium and a light meson in B-meson decays (Bodwin, Garcia i Tormo, and Lee, 2010).

18.1.4.2 Physics at the scales mv, mv^2: pNRQCD

Quarkonium formation takes place at the scale mv. The suitable EFT is potential non-relativistic QCD, pNRQCD (Brambilla, Pineda, Soto, and Vairo, 2000, 2005; Pineda and Soto, 1998), which follows from NRQCD by integrating out the scale $mv \sim r^{-1}$. The soft scale mv may be either larger or smaller than the confinement scale Λ_{QCD} depending on the radius of the quarkonium system. When $mv \gg \Lambda_{\text{QCD}}$, we speak about weakly-coupled pNRQCD because the soft scale is perturbative and the matching from NRQCD to pNRQCD may be performed in perturbation theory. When $mv \sim \Lambda_{\text{QCD}}$, we speak about strongly-coupled pNRQCD because the soft scale is nonperturbative and the matching from NRQCD to pNRQCD is non-perturbative and cannot be calculated with an expansion in α_s.

It is generally assumed that the lowest levels of quarkonium, like J/ψ and $\Upsilon(1S)$, may be described by weakly coupled pNRQCD, while the radii of the excited states are larger and presumably need to be described by strongly coupled pNRQCD. All this is valid for states away from open charm (bottom) threshold.

Close to threshold, many additional degrees of freedom become relevant and many more scales, which do not have a clear hierarchy, appear. Hence it will be difficult to devise an effective theory for this situation and thus one has presently to refer to models.

From pNRQCD one can also derive the $Q\overline{Q}$ QCD interaction potentials which may be used as an input for calculations of spectra on the basis of the Schrödinger Equation. In this way one can obtain QCD-based information on the spectra of heavy quarkonium systems.

The case $mv \gg \Lambda_{\text{QCD}}$: weakly-coupled pNRQCD

The effective Lagrangian is organized as an expansion in $1/m$ and $\alpha_s(m)$, inherited from NRQCD, and an expansion in r (Brambilla, Pineda, Soto, and Vairo, 2000):

$$\mathcal{L}_{\text{pNRQCD}} = \int d^3r \sum_n \sum_k \frac{c_n(\alpha_s(m), \mu)}{m^n}$$
$$\times V_{n,k}(r, \mu', \mu) \, r^k \times O_k(\mu', mv^2, ...), \quad (18.1.9)$$

where O_k are the operators of pNRQCD. The matrix elements of these operators depend on the low-energy scale mv^2 and μ', where μ' is the pNRQCD factorization scale. The $V_{n,k}$ are the Wilson coefficients of pNRQCD that encode the contributions from the scale r and are nonanalytic in r. The c_n are the NRQCD matching coefficients as given in Eq. (18.1.3).

The degrees of freedom, which are relevant below the soft scale, and which appear in the operators O_k, are $Q\overline{Q}$ states (a color-singlet S and a color-octet $O = O_a T^a$ state) and (ultrasoft) gluon fields, which are expanded in r as well (multipole expanded). Looking at the equations of motion of pNRQCD, we may identify $V_{n,0} = V_n$ with the $1/m^n$ potentials that enter the Schrödinger equation and $V_{n,k\neq0}$ with the couplings of the ultrasoft degrees of freedom, which provide corrections to the Schrödinger equation. Since the degrees of freedom that enter the Schrödinger description are in this case both $Q\overline{Q}$ color singlet and $Q\overline{Q}$ color octets, both singlet and octet potentials exist. Nonpotential interactions, associated with the propagation of low-energy degrees of freedom are, in general, present as well, and start to contribute at NLO in the multipole expansion. They are typically related to non-perturbative effects.

If the quarkonium system is small ($r \ll \Lambda_{\text{QCD}}$), the soft scale is perturbative and the potentials can be calculated in perturbation theory, *i.e.* no non-perturbative quantities enter the potential (Brambilla, Pineda, Soto, and Vairo, 2005). Being matching coefficients of the effective field theory, the potentials undergo renormalization, develop a scale dependence and satisfy renormalization group equations, which allow the resummation of large logarithms having as arguments ratios of physical scales, such as $\log(\frac{mv^2}{mv}) = \log(v)$.

The case $mv \sim \Lambda_{\text{QCD}}$: strongly-coupled pNRQCD

When $mv \sim \Lambda_{\text{QCD}}$ the soft scale is non-perturbative, and matching cannot be performed in perturbation theory any more. Rather the potential matching coefficients $V_{n,k}$ are obtained as non-perturbative quantities in the form of expectation values of gauge invariant Wilson-loop operators. In this case, under certain assumptions, the quarkonium singlet field $S = \overline{Q}Q$ is the only low-energy dynamical degree of freedom in the pNRQCD Lagrangian which reads (Brambilla, Pineda, Soto, and Vairo, 2001, 2005; Pineda

and Vairo, 2001):

$$\mathcal{L}_{\text{pNRQCD}} = \int d^3r \, S^\dagger \left(i\partial_0 - \frac{\mathbf{p}^2}{2m} - V_S(r) \right) S.$$

(18.1.10)

The singlet potential $V_S(r)$ is a series in the expansion in the inverse of the quark masses; the terms up to $1/m^2$ have been calculated long ago (Brambilla, Pineda, Soto, and Vairo, 2001; Pineda and Vairo, 2001). They involve NRQCD matching coefficients (containing the contribution from the hard scale) and low-energy non-perturbative parts given in terms of static Wilson loops and field strength insertions in the static Wilson loop (containing the contribution from the soft scale).

In this regime, from pNRQCD we recover the quark potential singlet model. However, here the potentials are obtained from QCD by non-perturbative matching and they often appear to have a different form with respect to phenomenological potential models. Their evaluation requires calculations on the lattice or in QCD vacuum models. Recent progress includes new precise lattice calculations of these potentials (Koma, Koma, and Wittig, 2008; Koma and Koma, 2010). Using these potentials, all the masses for heavy quarkonia away from threshold can be obtained by the solution of the Schrödinger equation.

A trivial example of application of this method is the mass of the h_c. The lattice data show a vanishing long-range component of the spin-spin potential so that the potential appears to be entirely dominated by its short-range, delta-like part. This suggests that the $^1P_1$ state should be close to the center-of-gravity of the ^3P_J system. Indeed, the measurements show consistency between data and this expected value (see experimental results in Table 18.2.1).

18.1.5 Lattice calculations

Lattice calculations play a key role for quarkonium physics. For an introduction to the lattice treatment of quarkonia see Brambilla et al. (2004) and for recent results see Brambilla et al. (2011). We already mentioned that the recent progress in this field relies both on high order perturbative calculations and on lattice simulations, the results of the two being often combined inside the EFT framework.

In fact it is difficult to put a multiscale system on the lattice as the lattice step should be smaller than the smallest scale (m^{-1}) and the lattice size should be bigger than the biggest scale of the system $\Lambda_{\text{QCD}}^{-1}$, putting prohibitive requirements on the lattice dimensions. This is true in particular for bottomonium, due to its larger mass. In this case one could use direct anisotropic lattice simulations or EFTs. The Lagrangian of NRQCD can be put on the lattice and used to obtain quarkonium energy levels. Recent results can be found in Daldrop, Davies, and Dowdall (2012), Dowdall et al. (2012), Gregory et al. (2011), and Donald et al. (2012). Charmonium spectra may also be calculated on the lattice with relativistic actions. Very recently new lattice techiques have been introduced that will eventually allow the excited charmonium spectroscopy to

be obtained from the lattice (Bali, Collins, and Ehmann, 2011; Liu et al., 2012). Another possibility is to evaluate on the lattice the potentials of strongly coupled pNRQCD and use them inside a Schrödinger equation to obtain all the quarkonium energy levels. New precise quenched lattice calculations of these potentials obtained using the Lüscher multilevel algorithm have recently become available (Koma, Koma, and Wittig, 2008; Koma and Koma, 2010).

18.1.6 Applications

A large set of phenomenological applications of the EFT framework outlined above to quarkonium spectra, decays, and production has been presented elsewhere (Brambilla, Pineda, Soto, and Vairo, 2005; Brambilla et al., 2004, 2011), and discussed in relation to experimental data. Here we briefly recall some selected results.

In the regime in which the soft scale mv is perturbative the energy levels of quarkonium have been calculated at order $m\alpha_s^5$ (Brambilla, Pineda, Soto, and Vairo, 1999; Kniehl, Penin, Smirnov, and Steinhauser, 2002).

Decay amplitudes (Brambilla, Pineda, Soto, and Vairo, 2005; Brambilla et al., 2011; Kiyo, Pineda, and Signer, 2010) and production and annihilation (Beneke, Kiyo, and Penin, 2007) have been calculated in perturbation theory at high order. Since for systems with a small radius the non-perturbative contributions are power suppressed, it is possible to obtain a good determinations of the masses of the lowest quarkonium resonances with purely perturbative calculations in the cases in which the perturbative series is convergent (after the appropriate subtractions of renormalons have been performed) and large logarithms in the scale ratios are resummed. For example, in Brambilla and Vairo (2000) a prediction of the B_c mass[98] has been obtained: $(6326\,^{+29}_{-9})$ MeV/c^2, to be compared to the experimental value of (6277 ± 6) MeV/c^2 (Beringer et al., 2012). An NNLO calculation with finite charm mass effects (Brambilla, Sumino, and Vairo, 2002) predicts a mass that well matches the Fermilab measurement (Brambilla et al., 2011) and the lattice determination (Allison et al., 2005). The same procedure has been applied at NNLO even for higher states (Brambilla, Sumino, and Vairo, 2002). An NLO calculation reproduces in part the $1P$ fine splitting (Brambilla and Vairo, 2005). Including log resummation at NLL, it is possible to obtain a prediction for the B_c hyperfine separation $\Delta = 50 \pm 17(\text{th})^{+15}_{-12}(\delta\alpha_s)$ MeV/c^2 (Penin, Pineda, Smirnov, and Steinhauser, 2004) and for the hyperfine separation between the $\Upsilon(1S)$ and the η_b the value of $41 \pm 11(\text{th})^{+9}_{-8}(\delta\alpha_s)$ MeV/c^2 (where the second error comes from the uncertainty in α_s; Kniehl, Penin, Pineda, Smirnov,

---

[98] The B_c states constitute a separate class of heavy mesons, distinct both from the quarkonia (*e.g.* in lacking electromagnetic and strong decays) and from the simpler heavy mesons (in lacking light valence quarks). Because of their masses they lie outside the scope of research at the B Factories.

and Steinhauser, 2004). This last value turned out to considerably undershoot the measurements of *BABAR* (Aubert, 2008ak, 2009l) and Belle (Mizuk, 2012).

NRQCD lattice calculations (Gray et al., 2005) obtained a value close to the experimental one but did not include the calculation of the matching coefficient at one loop. Recent lattice calculations (Hammant, Hart, von Hippel, Horgan, and Monahan, 2011) aim at including the NRQCD matching coefficients in the NRQCD lattice calculation and will help to settle this issue, see for example the result contained on the η_b mass in Dowdall et al. (2012). See also the result contained in Meinel (2010). The hyperfine separation of B_c has been calculated on the lattice to be $M_{B_c^*} - M_{B_c} = 54(3)$ MeV/c^2 in Dowdall, Davies, Hammant, and Horgan (2012). In the same paper values for the excited energy levels of B_c have been presented.

An EFT of the magnetic dipole transition has been given in Brambilla, Jia, and Vairo (2006), allowing magnetic dipole transitions between $c\bar{c}$ and $b\bar{b}$ ground states to been considered in pNRQCD at NNLO. The results are: $\Gamma(J/\psi \to \gamma\eta_c) = (1.5 \pm 1.0)$ keV and $\Gamma(\Upsilon(1S) \to \gamma\eta_b)$ $= (k_\gamma/71 \text{ MeV})^3 (15.1 \pm 1.5)$ eV, where the errors account for uncertainties coming from higher-order corrections. The width $\Gamma(J/\psi \to \gamma\eta_c)$ is consistent with the world-average value (Beringer et al., 2012) but bears a large error. Working in the same formalism but exactly incorporating the perturbative static potential in the leading order Hamiltonian and resumming large logarithms in the mass scale in Pineda and Segovia (2013) a number of M1 transitions have been calculated. In particular, the values $\Gamma(J/\psi \to \gamma\eta_c) = 2.12(40)$ keV has been obtained, which is in agreement with the experimental determination with a smaller error, and $\Gamma(\Upsilon(1S \to \gamma\eta_b) = 15.18(51)$ eV and $\Gamma(\Upsilon(2S \to \gamma\eta_b) = 0.668(60)$ eV has been obtained. The transition $\Gamma(J/\psi \to \gamma\eta_c)$ and the J/ψ annihilation constant have been evaluated on the lattice in Becirevic and Sanfilippo (2013) and in Davies et al. (2012). The quarkonium magnetic moment is explicitly calculated in Brambilla, Jia, and Vairo (2006) and turns out to be very small in agreement with a recent lattice calculation (Dudek, Edwards, and Richards, 2006); the M1 transition of the lowest quarkonium states at relative order v^2 turn out to be completely accessible in perturbation theory (Brambilla, Jia, and Vairo, 2006). A theory of electric dipole transitions has been given in Brambilla, Pietrulewicz, and Vairo (2012) and Pietrulewicz (2012), reproducing some of the results of the phenomenological potential models with some important differences.

A description of the η_c line shape has been given in Brambilla, Roig, and Vairo (2011). Using pNRCD and Soft Collinear EFT (SCET) a good description of the $\Upsilon(1S)$ radiative decay has been obtained (Garcia i Tormo and Soto, 2007).

Concerning decays, substantial progress has recently been made in the evaluation of the NRQCD factorization formula for inclusive decays at order v^7 (Brambilla, Mereghetti, and Vairo, 2006, 2009), in the lattice evaluation of the NRQCD matrix elements (Bodwin, Lee, and Sinclair, 2005), and in the higher order perturbative cal-culation of some NRQCD matching coefficients (Guo, Ma, and Chao, 2011; Jia, Yang, Sang, and Xu, 2011; Li, Ma, and Chao, 2013). The data are clearly sensitive to NLO corrections in the Wilson coefficients and presumably also to relativistic corrections. Improved theory predictability would entail the lattice calculation or data extraction of the NRQCD matrix elements and perturbative resummation of large contribution in the NRQCD matching coefficients. The $J/\psi \to 3\gamma$ decay has been studied in NRQCD in Feng, Jia, and Sang (2012). Inclusive decay amplitudes have been calculated in pNRQCD (Brambilla, Eiras, Pineda, Soto, and Vairo, 2003) and the number of non-perturbative correlators appears to be sizeably reduced with respect to NRQCD so that new model-independent predictions have been made possible (Brambilla, Eiras, Pineda, Soto, and Vairo, 2002). Still, the new data on hadronic transitions and hadronic decays pose interesting challenges to the theory. Exclusive decay modes are more difficult to address in theory (He, Lu, Soto, and Zheng, 2011; Soto, 2011; Vairo, 2004).

For excited states with masses away from threshold, phenomenological applications of the QCD potentials obtained in Brambilla, Pineda, Soto, and Vairo (2001) and Pineda and Vairo (2001) are ongoing (Laschka, Kaiser, and Weise, 2011). For a full phenomenological description of the spectra and decays it would be helpful to have updated, more precise and unquenched lattice calculation of the Wilson loop field strength insertion expectation values and of the local and nonlocal gluon correlators (Brambilla, Pineda, Soto, and Vairo, 2005). For recent lattice results on the spectroscopy see Gregory et al. (2011).

In the most interesting region, the region close to threshold where many new (possibly exotic) states have recently been discovered, a full EFT description has not yet been constructed nor the appropriate degrees of freedom clearly identified (Brambilla, Vairo, Polosa, and Soto, 2008; Brambilla et al., 2011). An exception is the $X(3872)$, which displays universal characteristics related to its being so close to threshold, allowing a beautiful EFT description to be obtained (Braaten, 2009; Braaten and Kusunoki, 2004). The light quark mass dependence in quarkonium has been studied in Guo and Meissner (2012).

The threshold region remains troublesome also for the lattice, although several excited state calculations have recently been pioneered.

18.2 Conventional charmonium

Since its discovery in 1974 the charmonium family has served as a laboratory to test strong interactions.

After the discovery of the first charmonium state, the J/ψ, its radial excitation, the $\psi(2S)$, was found just two weeks later, and another eight states were discovered within the subsequent five years. More than half of the charmonium states known by 1980 were observed in e^+e^- annihilation, while the others were found in the decays of J/ψ or $\psi(2S)$. Next, the decays of the ten known charmonia were studied in detail; theoretical frameworks used to compute the masses and widths for charmonium states evolved over the years from purely phenomenological approaches to the effective field and lattice gauge theories that are the current state of the art.

The known conventional charmonium states are listed in Table 18.2.1, together with predictions for their masses from the potential models described in Section 18.1.2 above. For accounts of effective field theory (NRQCD) and lattice approaches to charmonium, see Sections 18.1.4 and 18.1.5 respectively. In the following material, we present the experimental results on charmonia from the B Factories: the observation of four new states (Section 18.2.1), and new decay modes of well known states (Section 18.2.2); more precise determinations of the parameters of some charmonium states (Section 18.2.3); and the various mechanisms of charmonium production at the B Factories (Section 18.2.4). Some concluding remarks are provided in Section 18.2.5.

18.2.1 New conventional charmonium states

18.2.1.1 $\eta_c(2S)$

In the heavy quark potential model the $\eta_c(2S)$, the first radial excitation of the charmonium ground state η_c, is predicted to lie below the $D\bar{D}$ threshold (Buchmüller and Tye, 1981; Ebert, Faustov, and Galkin, 2000; Eichten and Feinberg, 1981; Eichten and Quigg, 1994; Godfrey and Isgur, 1985). Calculations within this model predict a mass splitting $m_{\psi(2S)} - m_{\eta_c(2S)}$ in the range $(42-103)\,\text{MeV}/c^2$.

In 1982 the Crystal Ball Collaboration reported evidence of a signal in $\psi(2S)$ radiative decay attributed to the $\eta_c(2S)$ with a mass of $(3594 \pm 5)\,\text{MeV}/c^2$ (Edwards et al., 1982). This claim remained unconfirmed and unrefuted for about 20 years until the observation of the $\eta_c(2S)$ at the B Factories.

Exclusive observation in B decays

The first modern evidence for the $\eta_c(2S)$ was the observation of a significant peak in the $K_S^0 K^\pm \pi^\mp$ mass spectrum, near the mass $3.65\,\text{GeV}/c^2$, in $B \to K_S^0 K^\pm \pi^\mp K$ decays at Belle (Choi, 2002). In this analysis the B candidates are exclusively reconstructed, and B meson signal events are distinguished from continuum $q\bar{q}$ background by using a likelihood ratio combining event-shape variables (see Chapter 9). To suppress potential backgrounds from $B \to D_{(s)}X$ decays, combinations with any $K\pi$ ($K_S^0 K$) pairs lying near the D (D_s^+) nominal masses are vetoed. To extract the number of signal $B \to K_S^0 K^\pm \pi^\mp K$ decays as a function of $M_{K_S^0 K^\pm \pi^\mp}$, Belle performs fits to the m_{ES} and ΔE distributions in bins of $M_{K_S^0 K^\pm \pi^\mp}$ with $40\,\text{MeV}/c^2$ width. The signal yields obtained from these fits are plotted in Fig. 18.2.1, where in addition to a prominent η_c signal, another significant peak is evident at higher mass. This spectrum is fitted to a sum of η_c and $\eta_c(2S)$ Breit-Wigner signal components and a polynomial background. The signal functions are convolved with a Gaussian representing the detector resolution function. The fitted $\eta_c(2S)$ parameters are reported in Table 18.2.2.
Figure 18.2.1. $K_S^0 K^\pm \pi^\mp$ invariant mass distribution for $B \to K_S^0 K^\pm \pi^\mp K$ signal events with the η_c and $\eta_c(2S)$ mass peaks visible (Choi, 2002). The solid line represents the fit function.

BABAR follows a similar approach in the analysis of B decays to $K\bar{K}\pi K^{(0)}$ final states (Aubert, 2008ba). The $K\bar{K}\pi$ system is reconstructed in $K_S^0 K^\pm \pi^\mp$ and $K^+ K^- \pi^0$ final states, and the sum over these two modes is reported in the results. Signal B mesons are selected by applying a tight ΔE requirement. The $K\bar{K}\pi$ invariant mass distribution from continuum-background events is extrapolated from the m_{ES} sidebands. In the fit to the $K\bar{K}\pi$ background-subtracted distribution the $\eta_c(2S)$ mass and width are fixed to world-average values, $3637\,\text{MeV}$ and $14\,\text{MeV}$ respectively (Yao et al., 2006). The measured $B^+ \to \eta_c(2S)K^+$ yield is 59 ± 12. By using $\mathcal{B}(B^+ \to \eta_c(2S)K^+) = (3.4 \pm 1.8) \times 10^{-4}$ (Aubert, 2006ae; see the details of this analysis under "Inclusive B decays at *BABAR*" below), *BABAR* measures the absolute branching ratio for $\eta_c(2S) \to K\bar{K}\pi$ to be $\mathcal{B}(\eta_c(2S) \to K\bar{K}\pi) = (1.9 \pm 0.4 \pm 0.5 \pm 1.0)\%$, where the first error is statistical, the second systematic

Table 18.2.1. Charmonium masses (MeV/c^2) according to potential models, compared with the observed values (Beringer et al., 2012). The states observed by the B Factories and the CLEO collaboration after 2002 are marked with $*$: see Sections 18.2.1.1 ($\eta_c(2S)$), 18.2.1.2 ($\chi_{c2}(2P)$), and 18.2.1.3 ($\eta_c(3S)$ and $\eta_c(4S)$). The model names are built from the first letters of the authors and the year: GI85 (Godfrey and Isgur, 1985); EG94 (Eichten and Quigg, 1994); F91 (Fulcher, 1991); GJ95 (Gupta and Johnson, 1996); EFG02 (Ebert, Faustov, and Galkin, 2003); ZVR94 (Zeng, Van Orden, and Roberts, 1995); BGS05 (Barnes et al., 2005).

and the third is due to the uncertainty of the branching fractions used in the calculation.

Recently, Belle has updated the $\eta_c(2S)$ measurement in the decays $B^+ \to (K_S^0 K^\pm \pi^\mp) K^+$ by using a much larger data sample (Vinokurova, 2011). Besides improving the statistical accuracy, this analysis accounts for $\eta_c(2S)$ interference with the non-resonant continuum for the first time in a model-independent way, thus providing more reliable measurements of the $\eta_c(2S)$ mass and width, and the branching ratio for the $B^+ \to \eta_c(2S) K^+$ decay. Indeed the decays $B^+ \to K_S^0 K^\pm \pi^\mp K^+$ can occur without proceeding via a charmonium state; the amplitude for such decays can interfere with the $\eta_c(2S)$ signal, which has a non-vanishing width. Different values of the interference phase can result in different $\eta_c(2S)$ resonance line shapes, and can lead to significant variations in the number of $\eta_c(2S)$ events while the total number of observed events in the $\eta_c(2S)$ peak remains the same. In this study Belle jointly analyzes the $M_{K_S^0 K^\pm \pi^\mp}$ spectrum and the distribution of the angle θ between the K_S^0 and K^+ in the rest frame of the $K_S^0 K^\pm \pi^\mp$ system. The angular analysis pro-

vides discrimination between the component of the non-resonant amplitudes that interfere with the signal and the one that does not. As can be seen from Fig. 18.2.2, the interference deforms the Breit-Wigner, making it asymmetric and lengthening its tail; the angular distribution in the $\eta_c(2S)$ signal region is dominated by S-wave,[99] while in the $\eta_c(2S)$ sidebands a sum of S-, P-, and D-waves is visible. The fitted $\eta_c(2S)$ mass and width are listed in Table 18.2.2. Taking interference into account has a dramatic effect on the measured $\eta_c(2S)$ parameters: if interference is ignored, Belle finds a $\sim 10\,\mathrm{MeV}/c^2$ upward mass shift, while the $\eta_c(2S)$ width increases by more than a factor 6. The measured product of branching fractions $\mathcal{B}(B^\pm \to K^\pm \eta_c(2S)) \times \mathcal{B}(\eta_c(2S) \to K_S^0 K^\pm \pi^\mp)$ is equal to $(3.4\,^{+2.2}_{-1.5}\,^{+0.5}_{-0.4}) \times 10^{-6}$.

---

[99] Since the $\eta_c(2S)$ is a pseudoscalar, one expects a uniform distribution in $\cos\theta$ for pure $\eta_c(2S)$ decay (pure S-wave). The signal region also contains non-resonant background, but the $\eta_c(2S)$ component is much larger, so the S-wave contribution here is dominant.
Figure 18.2.2. From the Belle $B \to K_S^0 K^{\pm} \pi^{\mp} K$ analysis Vinokurova (2011): Projections of a 2D-fit onto the $M_{K_S^0 K^{\pm} \pi^{\mp}}$ axis (left) and onto the $\cos\theta$ axis in the $\eta_c(2S)$ signal (center) and sideband (right) regions. The combinatorial background is subtracted. In the mass plot, the change in binning between the signal ($16 \,\mathrm{MeV}/c^2$) and sideband regions ($130 \,\mathrm{MeV}/c^2$) is evident; the gap near $3.5 \,\mathrm{GeV}/c^2$ is due to a veto of the χ_{c1} region, $M_{K_S^0 K^{\pm} \pi^{\mp}} \in [3.48, 3.54] \,\mathrm{GeV}/c^2$.

Exclusive observation in two-photon fusion

The $\eta_c(2S)$ decay into the $K_S^0 K^{\pm} \pi^{\mp}$ final state has also been studied by *BABAR* in the two-photon production process (Aubert, 2004s; del Amo Sanchez, 2011h). In the latter analysis the $\eta_c(2S)$ signal has also been observed in the $K^+ K^- \pi^+ \pi^- \pi^0$ final state. Events produced via two-photon fusion (see Chapter 22) are selected with requirements on the total number of charged and neutral particles in the event, and transverse momentum p_T of the reconstructed hadronic final state. In addition, to suppress ISR background the missing mass squared is required to be greater than $2 \,\mathrm{GeV}^2/c^4$ ISR events are expected to show a peak at $m_{\mathrm{miss}}^2 \sim 0 \,\mathrm{GeV}^2/c^4$, while in two-photon events the missing mass should be large due to the large momentum taken away by the outgoing $e^+ e^-$. The invariant mass distributions are fitted to a sum of non-relativistic Breit-Wigner functions to model η_c, χ_{c0}, χ_{c2}, and $\eta_c(2S)$ signals plus a polynomial shape to describe combinatorial background. In the $K_S^0 K^{\pm} \pi^{\mp}$ fit a χ_{c0} component is not included, since a $J^P = 0^+$ resonance cannot decay to this final state, due to angular momentum and parity conservation.[100] The signal shapes are convolved with the detector resolution function obtained from MC simulation. The width of the $\eta_c(2S)$ in the fit to the $K^+ K^- \pi^+ \pi^- \pi^0$ invariant mass distribution is fixed to the value found in the $K_S^0 K^{\pm} \pi^{\mp}$ decay mode. Results of the fit are reported in Table 18.2.2 and shown in Fig. 18.2.3. Although the interference of the $\eta_c(2S)$ state with the non-resonant $\gamma\gamma \to K_S^0 K^{\pm} \pi^{\mp} (K^+ K^- \pi^+ \pi^- \pi^0)$ continuum may shift the measured parameters, this effect can not be determined in this analysis due to the small signal to back-

ground ratio. The p_T distribution is found to be consistent with that expected for two-photon production.
Figure 18.2.3. Fit to (a) the $K_S^0 K^{\pm} \pi^{\mp}$ and (c) the $K^+ K^- \pi^+ \pi^- \pi^0$ mass spectra in two-photon fusion events (del Amo Sanchez, 2011h). The solid curves represent the total fit functions and the dashed curves show the combinatorial background contributions. The background-subtracted distributions are shown in (b) and (d), where the solid curves indicate the signal components. The prominent peak is the η_c, while the small peak above $3 \,\mathrm{GeV}/c^2$ is due to residual ISR J/ψ production. The peaks in the insets are (left to right) χ_{c0}, χ_{c2}, and $\eta_c(2S)$. The χ_{c0} peak is not present in (a) and (b), since the decay to $K_S^0 K^{\pm} \pi^{\mp}$ is not allowed for this state.

---

[100] The decay proceeds via the strong interaction, so P is conserved. In the $K_S^0 K^{\pm} \pi^{\mp}$ system, let l_1 be the angular momentum between K_S^0 and $K^{\pm}$, and l_2 the angular momentum between $\pi^{\mp}$ and the $K_S^0 K^{\pm}$ system. The final state has $P = (-1)^{1+l_1+l_2}$. Since the final state spin is equal to 0, $\boldsymbol{J} = \boldsymbol{l_1} + \boldsymbol{l_2}$. Thus $J = 0$ implies $l_1 = l_2$ and $P = -1$.

Angular analysis of the $\eta_c(2S) \rightarrow K_S^0 K^\pm \pi^\mp$ decay (Aubert, 2004s) confirms that the observed events are consistent with the two-photon production mechanism and inconsistent with production via ISR. This analysis also restricts the allowed J^{PC} values for the final state (Yang, 1950) to be 0^{-+} or $J \geq 2$. The measured mass and the probable $J^{PC} = 0^{-+}$ assignment support the interpretation of the observed signal as the $\eta_c(2S)$ resonance. These results are consistent with those previously obtained by CLEO with a similar analysis of the $\gamma\gamma \rightarrow K_S^0 K^\pm \pi^\mp$ process (Asner et al., 2004a). BABAR has also measured the product of the two-photon coupling, $\Gamma_{\gamma\gamma}$, and the final state branching fractions, $\mathcal{B}$. This quantity is related to the ratio of the resonance signal yield and the detection efficiency. In order to reduce the systematic uncertainty due to the unknown resonant substructure of the decays, a weighted fit to the efficiency-corrected mass distribution is performed, taking into account the dependence of the efficiency on the $K_S^0 K^\pm \pi^\mp (K^+ K^- \pi^+ \pi^- \pi^0)$ decay kinematics. The values $\Gamma_{\gamma\gamma}(\eta_c(2S)) \times \mathcal{B}(\eta_c(2S) \rightarrow K\bar{K}\pi) = (41 \pm 4 \pm 6) \text{ eV}$ and $\Gamma_{\gamma\gamma}(\eta_c(2S)) \times \mathcal{B}(\eta_c(2S) \rightarrow K^+ K^- \pi^+ \pi^- \pi^0) = (30 \pm 6 \pm 5) \text{ eV}$, and the ratio between the $\eta_c(2S)$ branching fractions to the final states $\frac{\mathcal{B}(\eta_c(2S) \rightarrow K^+ K^- \pi^+ \pi^- \pi^0)}{\mathcal{B}(\eta_c(2S) \rightarrow K_S^0 K^\pm \pi^\mp)} = 2.2 \pm 0.5 \pm 0.5$ are found (del Amo Sanchez, 2011h).

BABAR has also searched for the $\eta_c(2S)$ in the process $\gamma\gamma \rightarrow \eta_c \pi^+ \pi^-$, with the η_c decaying to $K_S^0 K^\pm \pi^\mp$ (Lees, 2012t). The analysis uses a two-dimensional fit in the variables $m(K_S^0 K^\pm \pi^\mp)$ and $m(K_S^0 K^\pm \pi^\mp \pi^+ \pi^-)$. Signal events peak in both of these quantities. The combinatorial background is expected to be distributed smoothly, with significant correlation between the distributions over these two variables. The correlation, studied with η_c sidebands, is found to be consistent with being due to phase space. Utilizing this enables precise determination of the combinatorial background shape from the data. The analysis also accounts for backgrounds that peak in either $m(K_S^0 K^\pm \pi^\mp)$ or $m(K_S^0 K^\pm \pi^\mp \pi^+ \pi^-)$. The fit yields the ratio $\frac{\mathcal{B}(\eta_c(2S) \rightarrow \eta_c \pi^+ \pi^-)}{\mathcal{B}(\eta_c(2S) \rightarrow K_S^0 K^\pm \pi^\mp)} = 4.9 \pm 3.5(\text{stat}) \pm 1.3(\text{syst}) \pm 0.8(\mathcal{B})$, where the third error is due to the uncertainty on $\mathcal{B}(\eta_c \rightarrow K_S^0 K^\pm \pi^\mp)$ (Beringer et al., 2012). No significant signal is found, and an upper limit of 10.0 is set on this ratio of branching fractions at the 90% confidence level.

Inclusive observation in double charmonium production

The $\eta_c(2S)$ has also been observed in the process $e^+ e^- \rightarrow J/\psi \eta_c(2S)$ by both Belle (Abe, 2002j, 2004g, 2007f) and BABAR (Aubert, 2005n): see Section 18.2.4.2. The $\eta_c(2S)$ is not reconstructed in these analyses, but inferred from the reconstructed J/ψ by using energy-momentum conservation. The $\eta_c(2S)$ signal is identified as a peak in the mass spectrum of the system recoiling against the reconstructed J/ψ; $M_{\text{recoil}}(J/\psi)$ is defined in Eq. (18.2.3), and the technique is discussed in the surrounding text. We illustrate these measurements using the BABAR analysis as a representative. The recoil mass spectrum is fitted with
Figure 18.2.4. The $M_{\text{recoil}}(J/\psi)$ distribution for the $e^+ e^- \rightarrow J/\psi X$ process (Aubert, 2005n). The solid line represents the total fit function and the dashed line is the background contribution. The histograms represent different sources of backgrounds. Signals from η_c, χ_{c0}, and $\eta_c(2S)$ are visible.

signal line shapes determined from MC simulation, taking into account phase space suppression due to the variation of the virtual photon energy in ISR (Fig. 18.2.4). The $J/\psi \eta_c(2S)$ system is assumed to be produced in P-wave as required by parity conservation. The combinatorial background contribution is estimated from J/ψ sidebands. The $\psi(2S)$ ISR background is estimated by using MC simulations; the other feed-down from $\psi(2S) \rightarrow J/\psi X$ is estimated by using $\psi(2S)$ events reconstructed in the data. The M_{recoil} distributions for such backgrounds are structureless and are described by a smooth function in the fit. The main sources of systematic uncertainty in the mass measurement are the uncertainty on the signal lineshape, selection procedure, and mass scale calibration. BABAR and Belle results are summarized in Table 18.2.2.

Inclusive B decays at BABAR

A search for $\eta_c(2S)$ has also been performed by BABAR in inclusive B-meson decays to $X_{c\bar{c}} K^\pm$ (Aubert, 2006ae). The analysis is carried out by fully reconstructing one B meson (B_{tag}), so the signal B-meson (B_{sig}) momentum is known from the B_{tag} and beam momenta. In events with one charged kaon not associated with B_{tag}, its momentum is calculated in the B_{sig} rest frame. The mass of $X_{c\bar{c}}$ is $m_X = \sqrt{m_B^2 + m_K^2 - 2E_K m_B}$, where m_B and m_K are the $B^\pm$ and $K^\pm$ masses and E_K is the $K^\pm$ energy in the B rest frame. The resulting m_X spectrum is fitted with a sum of signal and combinatorial background components, to obtain the $\eta_c(2S)$ signal yield. An excess of events with a statistical significance of 1.8σ is observed at the expected position for the $\eta_c(2S)$ peak. Results of the fit are reported in Table 18.2.2.

Summary

In conclusion, the $\eta_c(2S)$ has been measured in several production processes and final states at the B Factories. The mass values measured in different processes show quite

Table 18.2.2. $\eta_c(2S)$ mass and width as measured by BABAR and Belle. The first three rows refer to measurements performed by using B meson decays, the fourth and fifth rows to two-photon collisions, and the last rows to double charmonium production. These results are discussed in the summary at the end of Section 18.2.1.1. Limits are at 90% C.L.

Experiment	Process	Luminosity (fb^{-1})	Mass (MeV/c^2)	Width (MeV)	Reference

BABAR	$\gamma\gamma \to K_S^0 K^{\pm} \pi^{\mp}$	520	$3638.5 \pm 1.5 \pm 0.8$	$13.4 \pm 4.6 \pm 3.2$	del Amo Sanchez (2011h)
BABAR	$\gamma\gamma \to K^+ K^- \pi^+ \pi^- \pi^0$	520	$3640.5 \pm 3.2 \pm 2.5$	$-$	del Amo Sanchez (2011h)
BABAR	$e^+ e^- \to J/\psi\,\eta_c(2S)$	112	$3645.0 \pm 5.5\,^{+4.9}_{-7.8}$	22 ± 14	Aubert (2005n)
Belle	$e^+ e^- \to J/\psi\,\eta_c(2S)$	357	$3626 \pm 5 \pm 6$	$-$	Abe (2007f)

a large spread ranging from 3626 to 3654 MeV/c^2. The large spread among the mass values measured in various processes does not indicate an actual discrepancy: its size is marginally consistent with the experimental uncertainties, and the interference of the $\eta_c(2S)$ resonance with the underlying background is neglected in all but one measurement (Vinokurova, 2011). In that analysis a 10 MeV mass shift due to this effect is estimated. Similar shifts with different values or signs are expected for the various $\eta_c(2S)$ production processes (B decays, two-photon fusion, and double charmonium production). Nonetheless, all the B Factory measurements are in contradiction with the previous result reported by the Crystal Ball Collaboration (Edwards et al., 1982).

Hadronic branching fractions of the $\eta_c(2S)$ are expected to be similar to those of η_c (Chao, Gu, and Tuan, 1996). However, the measured branching fraction $\mathcal{B}(\eta_c(2S) \to K\bar{K}\pi) = (1.9 \pm 1.2)\%$ (Aubert, 2008ba) is significantly smaller than the corresponding $\mathcal{B}(\eta_c \to K\bar{K}\pi) = (7.0 \pm 1.2)\%$ (Beringer et al., 2012). Furthermore, the η_c is observed to decay into $h^+ h^- h'^+ h'^-$ (with $h^{(\prime)} = K, \pi$) with a branching fraction $\sim 1.6\%$ (Beringer et al., 2012), while the corresponding decays for $\eta_c(2S)$ were searched for, but not observed (e.g. $\mathcal{B}(\eta_c(2S) \to 4\pi) < 4.5 \times 10^{-3}$ at 90% C.L.; Uehara, 2008b). The only exclusive $\eta_c(2S)$ decays observed to date are to $K\bar{K}\pi$ and $K^+ K^- \pi^+ \pi^- \pi^0$.

18.2.1.2 $\chi_{c2}(2P)$

Although the lowest ^3P_J charmonium states (the χ_{cJ}) are well established, no experimental information existed about their radial excitations $\chi_{cJ}(2P)$ before the B Factory era. Theory predicts that the masses of these states lie in the region $3.9 - 4.0$ GeV/c^2 (Godfrey and Isgur, 1985), which places them well above the $D\bar{D}$ threshold. The $\chi_{c0}(2P)$ and $\chi_{c2}(2P)$ mesons would then decay primarily into $D\bar{D}$; the decay $\chi_{c1}(2P) \to D\bar{D}$ is forbidden by parity conservation, but the $\chi_{c1}(2P)$ could decay into $D\bar{D}^*$, if energetically allowed.

In 2006, the Belle Collaboration reported the observation of a new resonance, provisionally called $Z(3930)$,

based on analysis of a data sample of 395 fb^{-1} (Uehara, 2006). The resonance is observed in two-photon production, a mechanism providing a clean environment for studying resonances in direct formation (see Chapter 22 for the details), both in $\gamma\gamma \to D^0\bar{D}^0$ and $\gamma\gamma \to D^+ D^-$ (see Fig. 18.2.5 (a) and (b), respectively). The final state charmed mesons are fully reconstructed. Two-photon events are separated from $e^+ e^-$ annihilation and ISR events by requiring that the transverse momentum of the $D\bar{D}$ system be small, as expected for two-photon events in the no-tag mode (i.e., where neither the outgoing electron nor the positron are detected). The resulting combined invariant mass distribution is fitted with a relativistic Breit-Wigner signal function (taking the mass resolution and reconstruction efficiency into account) and a background component (Fig. 18.2.5 (c)). The statistical significance of the $Z(3930)$ peak is $5.3\,\sigma$. The measured mass and total width of the resonance are listed in Table 18.2.3. The systematic uncertainties are dominated by uncertainties in the D mass and the choice of the signal function lineshape.

Belle performs an angular analysis to identify the spin of the observed resonance. If one defines θ as the angle of a D meson relative to the beam axis in the $\gamma\gamma$ frame (equivalent to the $D\bar{D}$ frame), the $\cos\theta$ distribution for a scalar particle will be flat, while for a spin-2 resonance produced with helicity 2 along the incident axis, a distribution proportional to $\sin^4\theta$ is expected. Spin-1 is largely suppressed in two-photon events with quasi-real photons (Yang, 1950), thus this assignment is not considered. The Belle data significantly favor spin-2 over spin-0 assignment, while the production and decay mechanisms require positive parity and C-parity. The resulting quantum numbers, $J^{PC} = 2^{++}$, suggest identifying this particle with the previously unobserved $\chi_{c2}(2P)$ charmonium state. Assuming production of a spin-2 state, Belle calculated the product of its two-photon width and the branching fraction into $D\bar{D}$ (Table 18.2.3). The systematic errors are primarily due to uncertainties in tracking and particle identification efficiencies, the choice of fit lineshapes and the errors of D branching fractions.

Figure 18.2.6. The $\cos\theta$ distribution (see the text) for $\chi_{c2}(2P)$ signal candidates in $D\bar{D}$ events produced in two-photon fusion at *BABAR* (Aubert, 2010g). The results of a fit to the $J = 2$ hypothesis are shown with the solid curve; the dashed curve corresponds to the $J = 0$ hypothesis.

Figure 18.2.5. (a) $D^0\bar{D}^0$, (b) D^+D^-, and (c) combined $D\bar{D}$ invariant mass distributions in two-photon fusion events (Uehara, 2006). The open histogram shows the combinatorial background distribution estimated from D sidebands. The solid line represents the total fit function, the dashed line the fit without any resonant structure.

Similar results have been obtained by *BABAR*, using a 384 fb^{-1} data sample (Aubert, 2010g). The $D^0\bar{D}^0$ and D^+D^- final states are fully reconstructed, selecting two-photon events (in the no-tag mode) by requiring a large missing mass ($\sqrt{(p_{e^+e^-} - p_{D\bar{D}})^2}$) and a small transverse momentum of the $D\bar{D}$ system. Additionally, the energy deposited in the calorimeter unmatched to any charged-particle track should not exceed 400 MeV. A peak in the $D\bar{D}$ invariant mass distribution near 3.93 GeV/c^2 is also clearly seen in *BABAR* data. The combined efficiency-corrected $D\bar{D}$ invariant mass spectrum is fitted with a relativistic Breit-Wigner signal function convolved with a mass-dependent Gaussian resolution function and a background lineshape taking the $D\bar{D}$ threshold into account.

The significance of the $\chi_{c2}(2P)$ observation is 5.8 σ; the fitted mass and width are listed in Table 18.2.3. The angular distribution for signal entries is obtained from fits to data in 10 bins of $\cos\theta$, with θ being the angle of a D in the $D\bar{D}$ system relative to the $D\bar{D}$ lab momentum (Fig. 18.2.6). As in the Belle study, the expected distribution for spin-2 is significantly favored over spin-0; taking the production and decay processes into account, $J^{PC} = 2^{++}$ is therefore preferred. The calculated product of the two-photon width and the branching fraction into the $D\bar{D}$ final state is in good agreement with the Belle value (Table 18.2.3). Systematic errors in this analysis address the choice of signal and background lineshapes, tracking and particle identification issues, and uncertainties in D mass and branching fractions.

In summary, the $\chi_{c2}(2P)$ has been observed in two-photon production at both B Factory experiments, decaying into $D^0\bar{D}^0$ and D^+D^-. The parameters reported by *BABAR* and Belle are in good agreement. The measured $\chi_{c2}(2P)$ mass is 50 MeV/c^2 lower than potential model predictions (Table 18.2.1); other parameters including the two-photon width are consistent with the model expectations for the $\chi_{c2}(2P)$ state. This state has so far not been seen in any other production mechanism or decay mode. For example, *BABAR* has obtained a 90% C.L. upper limit $\Gamma_{\gamma\gamma}(\chi_{c2}(2P)) \times \mathcal{B}(\chi_{c2}(2P) \rightarrow \eta_c\pi^+\pi^-) < 18$ eV (del Amo Sanchez, 2011h). Only two other reported charmonium-like states in the predicted mass region are observed to decay into $D\bar{D}$ or $D\bar{D}^*$: the $X(3872)$, the structure of which is controversial (see Section 18.3.2), and the $X(3940)$, which is likely an excitation of the η_c (see

Table 18.2.3. Summary of $\chi_{c2}(2P)$ mass and width measurements obtained by Belle and *BABAR* in $\gamma\gamma \to D\bar{D}$.

Experiment	Luminosity (fb^{-1})	Mass (MeV/c^2)	Width (MeV)	Spin J^{PC}	$\Gamma_{\gamma\gamma}(\chi_{c2}(2P))\times$ $\mathcal{B}(\chi_{c2}(2P)\to D\bar{D})$ (keV)	Reference
Belle	395	$3929 \pm 5 \pm 2$	$29 \pm 10 \pm 2$	2^{++}	$0.18 \pm 0.05 \pm 0.03$	Uehara (2006)
BABAR	384	$3926.7 \pm 2.7 \pm 1.1$	$21.3 \pm 6.8 \pm 3.6$	2^{++}	$0.24 \pm 0.05 \pm 0.04$	Aubert (2010g)

Sections 18.2.1.3 and 18.3.3). The $\chi_{c2}(2P)$ remains the only confirmed radial excitation of the ^3P_J charmonium states.

18.2.1.3 $X(3940)$ and $X(4160)$ as candidates for higher radial excitations of η_c

Double charmonium production in e^+e^- annihilation, first observed in 2002 by Belle (Abe, 2002j) and confirmed by *BABAR* (Aubert, 2005n), can be regarded as a mini-factory of charmonium production. This process, described in detail in Section 18.2.4.2, provides opportunities both to search for new charmonia, and to study the decays of known states. Using two-body kinematics, exclusive final states can be identified by reconstructing a state such as the J/ψ, and then studying the spectrum of the recoil mass ($M_{\rm recoil}(J/\psi)$, as defined in Eq. 18.2.3, Section 18.2.4.2). Both known and new states produced in association with J/ψ appear as peaks in this spectrum.[101] Studies of various double charmonium final states have demonstrated that scalar and pseudoscalar charmonia are copiously produced in recoil against J/ψ or $\psi(2S)$, and there is no significant suppression of the production of radially excited states (Abe, 2004g; Aubert, 2005n).

In the study by Abe (2007f) of the $M_{\rm recoil}(J/\psi)$ distribution, in addition to previously reported peaks at the η_c, χ_{c0}, and $\eta_c(2S)$ masses, a fourth enhancement around 3940 MeV/c^2 was found (Fig. 18.2.7). The new state was called $X(3940)$. A fit to this spectrum that includes the three previously seen charmonium states plus a fourth state finds the significance of the new state to be 5.0σ including systematics. However, in this study it is not possible to prove that the observed peak is due to a single resonance.

The $X(3940)$ mass is above both the $D\bar{D}$ and $D\bar{D}^*$ thresholds, so it is natural to search for $X(3940)$ decays into these final states. Because of the small product of $D^{(*)}$ reconstruction efficiencies and branching fractions, it is not feasible to reconstruct fully the chain $e^+e^- \to J/\psi X(3940)$, $X(3940) \to D\bar{D}^{(*)}$. To increase the efficiency, only the J/ψ and one D meson are reconstructed, detecting the other $\bar{D}^{(*)}$ as a peak in the $M_{\rm recoil}(J/\psi D)$ spectrum. The instrumental resolution allows the $\bar{D}$ and $\bar{D}^*$ peaks to be clearly resolved, thus effectively tagging the processes $e^+e^- \to J/\psi\, D\bar{D}$ and $e^+e^- \to J/\psi\, D\bar{D}^*$. A clear

---

[101] Only states with charge conjugation $C = +1$ can be produced in association with the J/ψ, due to the conservation of this quantum number in $e^+e^- \to \gamma^* \to J/\psi X$ and to the fact that both the γ^* and the J/ψ have $C = -1$.
Figure 18.2.7. From the Abe (2007f) analysis: The distribution of $M_{\rm recoil}(J/\psi)$ in inclusive $e^+e^- \to J/\psi\, X$ events (points with error bars). The cross-hatched histogram shows the scaled J/ψ sideband distribution; the open histogram corresponds to the feed-down from $\psi(2S)$ decay. The solid curve is the fit result; the dashed curve shows the background and non-resonant contribution.

$X(3940)$ signal is seen only in the latter process, with 5.0σ significance. We illustrate the method, and present the measured parameters of both the $X(3940)$ and another new state, using the results of the latest Belle study.

Using a dataset twice as large, Pakhlov (2008) performed a detailed study of the processes $e^+e^- \to J/\psi\, D\bar{D}$, $J/\psi\, D\bar{D}^*$, and $J/\psi\, D^*\bar{D}^*$. After reconstruction of a $J/\psi D$ combination, signals for all three processes are evident in the spectrum of recoil mass $M_{\rm recoil}(J/\psi D)$ (Fig. 18.2.8 (a)), at the $\bar{D}$ mass, the $\bar{D}^*$ mass, and at $\sim 2.2\,\text{GeV}/c^2$ respectively. The latter peak is shifted and widened due to the missing pion or photon from $\bar{D}^*$ decay. The processes $e^+e^- \to J/\psi\, D\bar{D}^*$ and $J/\psi\, D^*\bar{D}^*$ are also clearly seen following $J/\psi D^*$ reconstruction, in the spectrum of recoil mass $M_{\rm recoil}(J/\psi D^*)$ (Fig. 18.2.8 (b)), as distinct peaks around the $\bar{D}$ and $\bar{D}^*$ masses. Selecting $J/\psi D$ or $J/\psi D^*$ combinations from the proper interval of $M_{\rm recoil}(J/\psi D^{(*)})$, events can be effectively divided into non-overlapping samples corresponding to each of the studied processes. In particular, only the process $e^+e^- \to D\bar{D}$ (and combinatorial background) contributes in the interval $|M_{\rm recoil}(J/\psi D) - M_{\bar{D}}| < 70\,\text{MeV}/c^2$. Events from the adjacent interval $|M_{\rm recoil}(J/\psi D) - M_{\bar{D}^*}| < 70\,\text{MeV}/c^2$ are dominated by the process $e^+e^- \to J/\psi D\bar{D}^*$; a small feed-down from the process $e^+e^- \to J/\psi D\bar{D}$ appears in this interval due to initial state radiation. $J/\psi D^*$ combinations from the interval $|M_{\rm recoil}(J/\psi D^*) - M_{\bar{D}}| < 70\,\text{MeV}/c^2$ provide a very clean sample of the same pro-
Figure 18.2.8. From Pakhlov (2008): The distribution of (a) $M_{\mathrm{recoil}}(J/\psi\,D)$ and (b) $M_{\mathrm{recoil}}(J/\psi\,D^*)$ in $e^+e^- \to J/\psi\,D^{(*)}X$ events (points with error bars). The histograms show the scaled $D^{(*)}$ sideband distribution. The solid curve is the fit result; the dashed curve shows the background contribution.

cess $e^+e^- \to J/\psi\,D\overline{D}^*$, with very small background and free of feed-down. However, as this sample is a small subsample of the previous case, it is used only as a cross check. Finally, $J/\psi\,D^*$ combinations from the interval $|M_{\mathrm{recoil}}(J/\psi\,D^*) - M_{\overline{D}^*}| < 70\,\mathrm{MeV}/c^2$ tag the process $e^+e^- \to J/\psi\,D^*\overline{D}^*$.

The spectra of $M(D^{(*)}\overline{D}^{(*)}) \equiv M_{\mathrm{recoil}}(J/\psi)$ are shown in Figs 18.2.9 (a), (b), (c), and (d) for the four selected cases in turn. Enhancements near threshold are evident in each distribution. A fit to the $M(D\overline{D})$ distribution finds a broad resonance-like structure near the threshold, tentatively denoted $X(3880)$. However the significance of the broad peak is low ($3.8\,\sigma$), and the fit is not stable under variation of the background parameterization. Therefore, with the existing sample the resonant structure in this process cannot be reliably determined. The significance of the $X(3940)$ signal found by the fit to the $M(D\overline{D}^*)$ spectrum is $5.7\,\sigma$ (including systematic uncertainties). The $X(3940)$ mass and width are $M = (3942\,^{+\,7}_{-\,6} \pm 6)\,\mathrm{MeV}/c^2$ and $\Gamma = (37\,^{+\,26}_{-\,15} \pm 8)\,\mathrm{MeV}$. The insets in Figs 18.2.9 (a) and (b) show the background subtracted spectra with the signal functions superimposed.

The $M(D^*\overline{D}^*)$ spectrum has a clear broad enhancement near threshold, which is seen above the small combinatorial background and the $X(3940)$ reflection. The observed enhancement, which has a significance of $5.1\,\sigma$ (including systematics), was interpreted as a new resonance and denoted $X(4160)$. The $X(4160)$ parameters are $M = (4156\,^{+\,25}_{-\,20} \pm 15)\,\mathrm{MeV}/c^2$ and $\Gamma = (139\,^{+\,111}_{-\,61} \pm 21)\,\mathrm{MeV}$. Although the masses and widths of the $X(4160)$ and $\psi(4160)$ are not inconsistent, the latter cannot be produced in e^+e^- annihilation via a single virtual photon due to C-parity conservation, as explained above; annihilation
Figure 18.2.9. From Pakhlov (2008): The spectra of $M(D^{(*)}\overline{D}^{(*)}) \equiv M_{\mathrm{recoil}}(J/\psi)$ for events tagged and constrained as (a) $e^+e^- \to J/\psi\,D\overline{D}$, (b,c) $e^+e^- \to J/\psi\,D\overline{D}^*$, and (d) $e^+e^- \to J/\psi\,D^*\overline{D}^*$ in the data (points with error bars). Hatched histograms show the combinatorial background distributions and open histograms show the feed-down contribution (see text). The solid lines represent the fit results; the dashed lines are background functions.

via two virtual photons is strongly suppressed, as demonstrated by the non-observation of $e^+e^- \to J/\psi\,J/\psi$ (Abe, 2004g).

If the $X(3940)$ has spin equal to 0, like other states produced together with the J/ψ, the absence of a $D\overline{D}$ decay mode strongly favors $J^P = 0^-$, for which the most likely charmonium assignment is the $\eta_c(3S)$ (see Table 18.2.1).[102] The fact that the lower-mass η_c and $\eta_c(2S)$ are also produced in double charmonium production supports this assignment. However, there is the problem that the measured $X(3940)$ mass is below potential model estimates for the $\eta_c(3S)$ mass of $\sim 4050\,\mathrm{MeV}/c^2$ or higher (Barnes et al., 2005). A further complication is the observation of the $X(4160)$, which could also be attributed to the $^1S_0$ state, using similar arguments. But the $X(4160)$ mass is well above expectations for the $\eta_c(3S)$ and well be-

---

[102] The decay of the pseudoscalar state, 0^-, into two pseudoscalar mesons is forbidden by parity conservation, as only S-wave is allowed. On the contrary, for the scalar state, 0^+, this decay is allowed and should be dominant.

low those for the $\eta_c(4S)$, which is predicted to be near 4400 MeV/c^2 (Barnes et al., 2005). Although either the $X(3940)$ or the $X(4160)$ or both might conceivably fit a charmonium assignment, the final identification of these states will be possible only after angular analysis of the $e^+e^- \to J/\psi\, D^*\overline{D}^{(*)}$ processes has been performed, allowing quantum numbers to be fixed. Such a study requires much larger samples than those collected by the B Factories.

18.2.2 New decay modes of known charmonia

It is difficult for the B Factories to compete with the charm factories (BES and CLEO-c) in searching for new decay modes of the charmonium states below $D\overline{D}$ threshold, as the charm factories have collected large datasets at the J/ψ and $\psi(2S)$ peaks. Automatically, large samples of tagged η_c, χ_{cJ}, and h_c events are also collected through radiative or hadronic transitions. Nonetheless, one new η_c decay mode was observed by the B Factories.

For the states above $D\overline{D}$ threshold the B Factories are competitive: for a study of wide ψ resonances charm factories need to perform an energy scan, with relatively low luminosity at each point, whereas the B Factories can see the whole energy region in many open charm exclusive final states. Here we present the observed new decay mode of the η_c (Section 18.2.2.1) and first measurements of the exclusive decays of ψ states above open charm threshold (Section 18.2.2.2).

18.2.2.1 $\eta_c \to \Lambda\overline{\Lambda}$

Belle has studied decays of η_c and J/ψ to both $p\overline{p}$ and $\Lambda\overline{\Lambda}$, using two-body B decays $B \to \eta_c K$ and $J/\psi K$ (Wu, 2006). The primary goal was to study anisotropy parameters in the decays of J/ψ to baryon-antibaryon pairs (Murgia and Melis, 1995). In addition to a clear $\eta_c \to p\overline{p}$ signal, a significant excess has also been observed in $\eta_c \to \Lambda\overline{\Lambda}$ for the first time.

In this analysis B mesons are reconstructed using the standard procedure, with ΔE and m_{ES} as discriminating variables (see Section 7.1). The dominant background, continuum events, is suppressed using a Fisher discriminant that combines seven event shape variables (Section 9.3). The $\Lambda\overline{\Lambda}$ mass spectrum from the B meson signal window is presented in Fig. 18.2.10. An unbinned maximum likelihood fit to this spectrum is performed using a relativistic Breit-Wigner function for the η_c peak, a Gaussian for the J/ψ peak, and a linear function for the non-resonant background. The Breit-Wigner function is convolved with the detector resolution function, which is taken from the Gaussian width of the J/ψ peak. The fit result is shown in the Fig. 18.2.10 inset. The measured η_c mass and width are $(2974 \pm 7 \,{}^{+2}_{-1})$ MeV/c^2 and $(40 \pm 19 \pm 5)$ MeV, respectively. The signal yield is (18.2 ± 4.8) η_c events.

A fit to the m_{ES} spectrum from the η_c signal window yields $(19.5 \,{}^{+5.1}_{-4.4})$ events, consistent with the result of the
Figure 18.2.10. From Wu (2006): The $\Lambda\overline{\Lambda}$ mass spectrum in $B \to \Lambda\overline{\Lambda}K$ events from the B meson signal window. The η_c and J/ψ region is shown inset, with the fit results as a solid line. No significant signal is visible in the $\eta_c(2S)$ region.

former fit. The statistical significance of the observation of the new η_c decay mode is estimated to be 7.9 standard deviations. Taking into account reconstruction efficiency, the branching fraction of the $\eta_c \to \Lambda\overline{\Lambda}$ decay is calculated to be $\mathcal{B} = (0.87\,{}^{+0.24}_{-0.21}(\text{stat})\,{}^{+0.09}_{-0.14}(\text{syst}) \pm 0.27\,(\mathcal{B})) \times 10^{-3}$, where the third uncertainty term is due to the poorly known absolute branching fractions of η_c. This term cancels in the ratio $\mathcal{B}(\eta_c \to \Lambda\overline{\Lambda})/\mathcal{B}(\eta_c \to p\overline{p})$, measured to be $0.67\,{}^{+0.19}_{-0.16} \pm 0.12$, consistent with the theoretical expectations.

18.2.2.2 Open charm decays of $J^{CP} = 1^{--}$ charmonium states

The process with a photon radiated from the initial state (ISR), $e^+e^- \to \gamma_{\text{ISR}} V$ (see Fig. 21.2.2 for the Feynman diagram), generates a state V coupled to the virtual photon, and therefore with the same quantum numbers, $J^{PC} = 1^{--}$. Such events represent an excellent laboratory to study exclusive decays of the vector V, with very clean signals observed in most studied final states (see Chapter 21 for a detailed description of the process). The ISR method has been successfully used to measure charmonium decays into open charm final states: their high multiplicity allows for efficient reconstruction with the ISR method, while the small branching fractions of charmed mesons to modes convenient for reconstruction make them difficult to detect in exclusive B decays. The B Factories have provided measurements of the branching fractions of various vector charmonium states for the first time. Here we describe only the procedure that was used to extract the branching fractions, and summarize the results.

Both BABAR (Aubert, 2009n) and Belle (Abe, 2007d; Pakhlova, 2008a) have studied the processes $e^+e^- \to$
Figure 18.2.11. From Aubert (2009n): The (a) $D\bar{D}$, (b) $D\bar{D}^*$, and (c) $D^*\bar{D}^*$ mass spectra in the $e^+e^- \to \gamma_{\text{ISR}} D^{(*)}\bar{D}^{(*)}$ process. The curves represent the fitted functions as described in the text. The shaded histogram corresponds to the smoothed incoherent background. The second smooth solid line represents the non-resonant contribution.

Figure 18.2.12. From del Amo Sanchez (2010d): The observed (a) $D_s^+D_s^-$, (b) $D_s^{*+}D_s^-$, and (c) $D_s^{*+}D_s^{*-}$ mass spectra in the processes $e^+e^- \to \gamma_{\text{ISR}}D_s^{(*)}\bar{D}_s^{(*)}$ (del Amo Sanchez, 2010d). The shaded areas show the background contribution. The dashed lines indicate the sum of this background and the coherent background. The solid lines are the results from the fit as described in the text.

$\gamma_{\text{ISR}} D^{(*)}\bar{D}^{(*)}$; their results are in good agreement. The measured cross-sections for these processes around threshold exhibit many structures, which could be attributed to the various ψ states. *BABAR* has performed fits to the measured mass spectra including interference between the resonant terms ($c_i W_i(m)e^{i\phi_i}$, where $W_i(m)$ is a P-wave relativistic Breit-Wigner) and the non-resonant contribution. The fitting functions for each channel are computed with their own thresholds, efficiencies, purities, and backgrounds. The fits, summed over the charged and neutral final states, provide a good description of all the data (Fig. 18.2.11). The fraction for each resonant contribution i is defined by

$$f_i = \frac{|c_i|^2 \int |W_i(m)|^2 dm}{\sum_{j,k} c_j c_k^* \int W_j(m)W_k^*(m)dm};$$ (18.2.1)

the fractions f_i do not necessarily add up to 1 because of interference between amplitudes. The error for each fraction has been evaluated by propagating the full covariance

matrix obtained by the fit. The resulting relative branching fractions are listed in Table 18.2.4, and compared with the predictions of theoretical models.

A similar fit was performed by *BABAR* to the $D_s^+D_s^-$, $D_s^{*+}D_s^-$, and $D_s^{*+}D_s^{*-}$ mass spectra (del Amo Sanchez, 2010d). In the fit the mass and width of the $\psi(4040)$, $\psi(4160)$, $\psi(4415)$, and the exotic state $Y(4260)$ (see Section 18.3) are fixed to the PDG values (Amsler et al., 2008); interference with the coherent non-resonant contribution is taken into account. The fit results are shown in Fig. 18.2.12 and measured fit fractions are given in Table 18.2.5.

Table 18.2.4. From Aubert (2009n): Ratios of branching fractions for the three ψ resonances. The first error is statistical, the second systematic. Theoretical expectations are from the $^3P_0$ model (Barnes et al., 2005), C^3 model (Eichten, Lane, and Quigg, 2006), and $\rho K \rho$ model (Swanson, 2006).

Ratio	Measurement	$^3P_0$	C^3	$\rho K \rho$

$\psi(4160)$	23 ± 26	53 ± 8	
$\psi(4415)$	6 ± 11	4 ± 2	5 ± 12
$Y(4260)$	0.5 ± 3.0	18 ± 24	11 ± 16
non-resonant	11 ± 5	27 ± 5	71 ± 20
Sum	103 ± 36	102 ± 26	87 ± 28

Figure 18.2.13. From Pakhlova (2008c): Mass distributions for $D^0 D^- \pi^+$ in $e^+e^- \to \gamma_{\mathrm{ISR}} D^0 D^- \pi^+$ events. Fit results are shown by the solid curve. (a) The $M_{D^0 D^- \pi^+}$ spectrum for the $D\bar{D}_2^*(2460)$ signal region; the dashed curve corresponds to the non-$\psi(4415)$ contribution. (b) The $M_{D^0 D^- \pi^+}$ spectrum outside the $D\bar{D}_2^*(2460)$ signal region; the dashed curve shows the upper limit on the $\psi(4415)$ yield at the 90% C.L. In both plots, shaded histograms show the normalized contributions from M_{D^0} and M_{D^-} sidebands.

In similar studies of two-body charmed mesons states produced via ISR, Belle does not perform fits to the obtained cross-sections, motivating their choice by the difficulty of taking coupled channel effects into account. However, a fit is performed to the prominent $\psi(4415)$ peak found in the process $e^+e^- \to \gamma_{\mathrm{ISR}} D^0 D^- \pi^+$ (Pakhlova, 2008c). As this peak is observed far from other ψ states, and $\psi(4415)$ decay to this final state turns out to be large, a naïve one-resonance fit is justified in this case. A study of invariant masses of the $D^-\pi^+$ and $D^0\pi^+$ combinations demonstrates that the decay $\psi(4415) \to D^0 D^- \pi^+$ is dominated by the $D^0\bar{D}_2^*(2460)^0$ and $D^-\bar{D}_2^*(2460)^+$ intermediate states. Because of their positive interference (due to $C = -1$ of the $\psi(4415)$) Belle does not study them separately, but divides the selected sample into $D\bar{D}_2^*(2460) +$ c.c. and non-resonant $D^0 D^- \pi^+$ regions. A $\psi(4415)$ peak is seen only in the former region; no sign of $\psi(4415)$ is seen in the second case (Fig. 18.2.13). A fit to the $M_{D^0 D^- \pi^+}$ spectrum in the $D\bar{D}_2^*(2460) +$ c.c. regions yields 109 ± 25(stat) signal events, and the significance for the $\psi(4415)$ signal is $\sim 10\sigma$. The measured peak mass $M_{\psi(4415)} = (4.411 \pm 0.007(\mathrm{stat}))\,\mathrm{GeV}/c^2$ and total width $\Gamma_{\mathrm{tot}} = (77 \pm 20(\mathrm{stat}))\,\mathrm{MeV}$ are in good agreement with the BES results (Ablikim et al., 2007). Belle measures $\mathcal{B}(\psi(4415) \to D\bar{D}_2^*(2460)) \times \mathcal{B}(D_2^*(2460) \to D\pi^+) = (10.5 \pm 2.4 \pm 3.8)\%$ and sets an upper limit on the ratio of the branching fractions of $\psi(4415)$ decays to non-resonant $D^0 D^- \pi^+$ and $D\bar{D}_2^*(2460) +$ c.c. to be 0.22 at the 90% C.L.

In the study of the process $e^+e^- \to D^0 D^{*-}\pi^+$ Belle found only a hint for the $\psi(4415)$ signal with statistical significance 3.1σ (Pakhlova, 2009) and set an upper limit on the branching fraction $\mathcal{B}(\psi(4415) \to D^0 D^{*-}\pi^+) < 10.6\%$ at the 90% C.L.

18.2.3 Measurements of parameters

B Factory analyses have contributed to the precision with which various charmonium parameters are known: studies have been performed for the η_c (Section 18.2.3.1), J/ψ (Section 18.2.3.2), χ_{c0} and χ_{c2} (Section 18.2.3.3), and $\psi(3770)$ (Section 18.2.3.4). The treatment of interference effects is important in a number of these analyses, as discussed below.

Table 18.2.6. Summary of η_c mass and width measurements obtained by *BABAR* and Belle in different production processes as marked in the second column.

Experiment	Process	Decay	Mass (MeV/c^2)	Width (MeV)	Reference
Belle	$B \to K\eta_c$	hadrons	$2979.6 \pm 2.3 \pm 1.6$	$29 \pm 8 \pm 6$	Fang (2003)
BABAR	$B \to K\eta_c$	inclusive	2982 ± 5	—	Aubert (2006ae)
Belle	$B \to K\eta_c$	$p\bar{p}$	$2971 \pm 3^{+2}_{-1}$	$48^{+8}_{-7} \pm 5$	Wu (2006)
Belle	$B \to K\eta_c$	$\Lambda\bar{\Lambda}$	$2974 \pm 7^{+2}_{-1}$	$40 \pm 19 \pm 5$	Wu (2006)
BABAR	$B \to K^{(*)}\eta_c$	$K\bar{K}\pi$	$2985.8 \pm 1.5 \pm 3.1$	$36.3^{+3.7}_{-3.6} \pm 4.4$	Aubert (2008ba)
Belle	$B \to K\eta_c$	$K^0_S K\pi$	$2985.4 \pm 1.5^{+0.5}_{-2.0}$	$35.1 \pm 3.1^{+1.0}_{-1.6}$	Vinokurova (2011)
BABAR	$\gamma\gamma \to \eta_c$	$K\bar{K}\pi$	$2982.5 \pm 1.1 \pm 0.9$	$34.3 \pm 2.3 \pm 0.9$	Aubert (2004s)
Belle	$\gamma\gamma \to \eta_c$	hadrons	$2986.1 \pm 1.0 \pm 2.5$	$28.1 \pm 3.2 \pm 2.2$	Uehara (2008b)
BABAR	$\gamma\gamma \to \eta_c$	$K^0_S K\pi$	$2982.2 \pm 0.4 \pm 1.6$	$31.7 \pm 1.2 \pm 0.8$	Lees (2010b)
Belle	$\gamma\gamma \to \eta_c$	$\eta'\pi^+\pi^-$	$2982.7 \pm 1.8 \pm 2.2 \pm 0.3$	$37.8^{+5.8}_{-5.3} \pm 2.8 \pm 1.4$	Zhang (2012)
Belle	$e^+e^- \to J/\psi\eta_c$	inclusive	$2970 \pm 5 \pm 6$	—	Abe (2007f)

18.2.3.1 η_c mass, width, and transition form factor

The η_c is the lightest S-wave spin-singlet charmonium state. In spite of a long history of studies, the η_c parameters are still not well defined. As detailed in Section 18.1, the η_c mass and total width are of particular importance for QCD tests in the charmonium sector, where a set of QCD complications are partially removed due to the large quark mass. While the spin-independent part of the $c\bar{c}$ potential is well-fixed by experimental data, for the study of the spin-dependent part exact knowledge of the η_c mass plays an important role. There is a relatively large spread in the η_c mass and total width values obtained in different experiments (in Beringer et al., 2012, the fourteen measurements have $\chi^2 = 36$), and no definitive explanation for the discrepancy between the η_c parameters measured in J/ψ and $\psi(2S)$ radiative decays, in $\gamma\gamma$ and $p\bar{p}$ production, and in B decays has been suggested to date.

One of the critical issues for the correct measurement of η_c parameters in the decays $J/\psi(\psi(2S)) \to \eta_c\gamma$ may be the theoretical understanding of the η_c line shape in $M1$ radiative transitions. For example, the effect of a distorted η_c line shape in these decays was discussed by CLEO (Mitchell et al., 2009b). In other processes where η_c parameters are measured, there is another source of systematic uncertainty which was only recently recognized as of possible significance: interference of the η_c, which is commonly exclusively reconstructed in a multihadron final state, with a non-resonant (continuum) substrate. It is not an easy task to take the effect of interference into account. If the final state contains more than two particles, the resonant structure and the orbital angular momentum between final state hadrons may differ for η_c decay and the continuum. Hence the interference may be partial or even absent, and simply adding a coherent continuum amplitude to the η_c Breit-Wigner amplitude in the fit does not guarantee results more correct than those obtained when interference is ignored. Over the past decade, both *BABAR* and Belle have carried out many measurements of η_c parameters, as summarized in Table 18.2.6. Below we briefly review some recent analyses where the effect of interference has been considered.

In a study of η_c production in $\gamma\gamma$ fusion *BABAR* estimates the uncertainty on the η_c mass and width due to interference effects (Lees, 2010b). In the baseline fit to the measured $K^0_S K\pi$ mass spectra for the selected $\gamma\gamma$ events the interference term is ignored. To estimate the possible mass shift a fit assuming the maximum (full) interference with the continuum $\gamma\gamma \to K^0_S K\pi$ background is performed. The η_c mass value changes by $1.5\,\text{MeV}/c^2$, which is the dominant contribution to the systematic uncertainty. Belle observes a clear η_c signal in the mass spectrum of $\eta'\pi^+\pi^-$ combinations produced in two-photon collisions (Zhang, 2012), and measures its mass and width. As in the *BABAR* analysis above, the effect of interference can only be estimated: the differences in the η_c parameters with and without interference, $\Delta M = 0.3\,\text{MeV}/c^2$ and $\Delta\Gamma = 1.4\,\text{MeV}$, are taken as model-dependent uncertainties of the measurement. In the Belle study of $B \to K\eta_c$ followed by $\eta_c \to K^0_S K\pi$ (Vinokurova, 2011) an angular analysis is used to distinguish the contributions from the coherent and noncoherent $K^0_S K\pi$ continuum amplitudes from $B \to K(K^0_S K\pi)$ decays, mediated by the penguin diagram. This analysis takes interference into account with no assumptions on its phase or absolute value. If interference is turned off, the fitted mass and width do not vary significantly. Finally, a recent BES paper (Ablikim et al., 2012a) has presented a high statistics measurement of the interference: considering such results in future measurements would help to reduce systematic uncertainties.

Another important η_c property, the transition form factor, has been measured by *BABAR* (Lees, 2010b). Such a measurement allows the shape of the charmonium wave function to be probed, and provides a test of the predictions of pQCD as well as calculations that use the lattice QCD approach. *BABAR* studies the process $e^+e^- \to e^+e^-\gamma\gamma^* \to e^+e^-\eta_c$ for the momentum transfer range from 2 to $50\,\text{GeV}^2$. To ensure high virtuality of one of the photons, either the electron or positron is required to be detected, while the other is scattered at a small an-
Figure 18.2.14. From Lees (2010b): The $F(Q^2)/F(0)$ distribution for the η_c (points with error bars). The solid curve shows the fit to the simple monopole shape. The dotted curve shows the leading order pQCD prediction from Feldmann and Kroll (1997).

gle and hence escapes detection. The transition form factor $F(Q^2)$ (Fig. 18.2.14) is extracted from the measured differential cross section $d\sigma/dQ^2$, where the squared momentum transfer is calculated from the measured (p') and known (p) four-momenta of the final and initial state electrons respectively: $Q^2 = -(p'-p)^2$. The obtained distribution is well described by the simple monopole form

$$\left|\frac{F(Q^2)}{F(0)}\right| = \frac{1}{1+Q^2/\Lambda}, \quad \Lambda = (8.5\pm0.6\pm0.7)\,\text{GeV}^2, \quad (18.2.2)$$

and in fair agreement with the QCD prediction (Feldmann and Kroll, 1997).

18.2.3.2 Electronic and total width of the J/ψ

The electronic width of 1^{--} charmonium resonances is an important characteristic that measures the charmonium wavefunction $\psi(0)$ and helps to fix potential model parameters. Lattice QCD calculations of Γ_{ee}, which are gradually approaching experimental results in precision, will also soon be put to the test.

Experimentally Γ_{ee} can be derived from the resonance peak cross section. This either requires a dedicated energy scan of the resonance at a charm factory, or can be achieved at B Factories via ISR. The latter process provides significant cancellation of systematic uncertainties, as an energy range including both the resonance and nearby regions is simultaneously available. *BABAR* pioneered this method for determination of the J/ψ electronic

and total widths (Aubert, 2004d). In this analysis the J/ψ is reconstructed in the dimuon channel only, because the e^+e^- final state has much larger backgrounds from radiative Bhabha events. The directly measured quantity is $\Gamma_{ee} \times \mathcal{B}(J/\psi \to \mu^+\mu^-)$,[103] which is found to be equal to $(0.3301 \pm 0.0077 \pm 0.0073)\,\text{keV}$. Then using the known leptonic branching fractions it is possible to derive both the electronic width $\Gamma_{ee} = (5.61 \pm 0.20)\,\text{keV}$, and the total width $\Gamma_{\text{tot}} = \Gamma_{ee}/\mathcal{B}(J/\psi \to e^+e^-) = (94.7 \pm 4.4)\,\text{keV}$. The statistical and systematic uncertainties are combined in quadrature. The *BABAR* $\Gamma_{ee} \times \mathcal{B}(J/\psi \to \mu^+\mu^-)$ result is one of three measurements contributing to the current world average, which is $(0.334\pm0.005)\,\text{keV}$ (Beringer et al., 2012).

18.2.3.3 χ_{c0} and χ_{c2}

The B Factories have also made a moderate contribution to the precision measurement of the P-wave charmonium masses and widths. Belle has measured charmonium production in two-photon collisions (Uehara, 2008b), observing signals for the three C-even charmonia η_c, χ_{c0}, and χ_{c2} in the $\pi^+\pi^-\pi^+\pi^-$, $K^+K^-\pi^+\pi^-$, and $K^+K^-K^+K^-$ decay modes. The invariant mass distributions in the vicinity of each charmonium peak are fitted to the sum of charmonium and background components. The combined results for the three decay modes yield a χ_{c0} mass of $(3414.2 \pm 0.5 \pm 2.3)\,\text{MeV}/c^2$ and a width of $(10.6 \pm 1.9 \pm 2.6)\,\text{MeV}$. The measured χ_{c2} mass is $(3555.3 \pm 0.6 \pm 2.2)\,\text{MeV}/c^2$.

BABAR has also searched for resonances decaying to $\eta_c\pi^+\pi^-$ in two-photon collisions (Lees, 2012t). In this analysis η_c is reconstructed in the $K_S^0 K\pi$ decay mode, and searches for several known charmonium states, including the χ_{c2}, are performed in the reconstructed $\eta_c\pi^+\pi^-$ mass spectrum. The fit in the χ_{c2} region yields a central value for the ratio of branching fractions $\frac{\mathcal{B}(\chi_{c2}\to\eta_c\pi^+\pi^-)}{\mathcal{B}(\chi_{c2}\to K_S^0 K\pi)} = 14.5 \pm 9.8(\text{stat}) \pm 7.3(\text{syst}) \pm 2.5\,(\mathcal{B})$, where the last uncertainty is due to the uncertainty on $\mathcal{B}(\eta_c \to K_S^0 K\pi)$. No significant signal is found, and an upper limit of 31.4 is set on this ratio of branching fractions at the 90% C.L.

18.2.3.4 $\psi(3770)$ mass and width

The $\psi(3770)$ is thought to be a D-wave state with a small admixture of S-wave, and as it is above $D\bar{D}$ threshold, it is expected to decay mostly to $D\bar{D}$. The $\psi(3770)$ has been investigated in direct formation in e^+e^- annihilation by numerous experiments since its observation by MARK I (Rapidis et al., 1977). Precise measurements of its mass and width have been obtained from energy scans near the resonance. However, as the accuracy of measurements has increased, an anomalous deviation of

---

[103] The peak Born cross section, which can be extracted from the fit to the data spectrum, is equal to $\sigma_{\text{Born}}^{\text{peak}} = \frac{12\pi^2}{ms}\Gamma_{ee}\mathcal{B}(J/\psi \to \mu^+\mu^-)$

the $\psi(3770)$ peak lineshape from the Breit-Wigner function has appeared (Ablikim et al., 2008a), and remained puzzling until recently.

At the B Factories one can use the process with initial state radiation to study $\psi(3770)$ formation, and both *BABAR* and Belle have observed the $\psi(3770)$ in their analysis of $e^+e^- \to \gamma_{\mathrm{ISR}} D\bar{D}$ (Pakhlova, 2008a and Aubert, 2009n; see Section 21.4.2). Only *BABAR* has fitted its $D\bar{D}$ mass spectrum to measure $M = (3778.8 \pm 1.9 \pm 0.9)$ MeV/c^2 and $\Gamma = (23.5 \pm 3.7 \pm 0.9)$ MeV. Although the electromagnetic suppression of ISR processes results in small data samples[104] and does not allow the study of the $\psi(3770)$ peak in detail, the access to the large energy range provided by ISR turns out to be extremely important for understanding the $\psi(3770)$ lineshape. Both *BABAR* and Belle observe a structure in the ISR cross section at ~ 3.9 GeV/c^2 (Fig. 21.4.3), known as $G(3900)$,[105] which must be taken into account to describe the cross section in the region below 4 GeV. This observation suggests that resonance-continuum interference is essential for determination of the $\psi(3770)$ parameters. A recent KEDR analysis of e^+e^- scan data (Anashin et al., 2012), which includes interference with the tail of the $\psi(2S)$ resonance, concludes that the interference causes a significant shift in the fitted $\psi(3770)$ peak and can explain the nontrivial $\psi(3770)$ lineshape. The Particle Data Group (Beringer et al., 2012), when determining the $\psi(3770)$ mass, now uses only those analyses which take interference into account.

The B Factories have also observed the $\psi(3770)$ in B decays (Brodzicka, 2008; Chistov, 2004; Aubert, 2008bd). The measured mass and width are in good agreement with the parameters obtained from the direct formation analysis that accounts for interference.

18.2.4 Production

The B Factories also provide useful information on charmonium production mechanisms. Measurement of the charmonium production rates in different processes, as well as kinematic characteristics of produced charmonia, help to test models numerically and to determine charmonium properties. At the B Factories charmonia are produced in $\gamma\gamma$ fusion, via resonant direct production in e^+e^- annihilation with initial state radiation, in the decays of B mesons, and in the fragmentation of $c\bar{c}$ pairs produced in e^+e^- annihilation.

The former two processes provide a direct measurement of important charmonium parameters, namely the two-photon and dielectron widths. Both are related to the charmonium wave function, and are used to fix the parameters of the potential models that describe charmonium

---

[104] Note that the emission of the ISR photon is suppressed by the electromagnetic coupling constant α_{EM}.

[105] The $G(3900)$ is not considered to be a real resonance, as the appearance of a bump in this region is qualitatively consistent with predictions of the coupled-channel model of Eichten, Gottfried, Kinoshita, Lane, and Yan (1980).

spectroscopy. Chapters 21 and 22 describe in detail the numerous experimental results obtained at the B Factories, in ISR and two-photon physics respectively.

When describing charmonium formation from $c\bar{c}$ pairs produced either in B decays or in e^+e^- annihilation, effective field theories are used. The EFT most often exploited is non-relativistic QCD (NRQCD), which assumes factorization of the production of charmonium partons (*e.g.* a $c\bar{c}$ pair) in the given process, and the formation of charmonium from those partons (Bodwin, Braaten, and Lepage, 1995; Caswell and Lepage, 1986; Thacker and Lepage, 1991). The former part contains a partonic level cross section generally calculated in perturbative QCD, in which the $c\bar{c}$ pair may be produced in a color singlet or color octet state (Braaten and Fleming, 1995; Cho and Leibovich, 1996a). The latter part, which describes the evolution of the $c\bar{c}$ pair with the quantum numbers of the final charmonium state, cannot be calculated in perturbation theory, and the relevant parameters are usually extracted from the data. A signature of the NRQCD approach is the universality of the long distance production matrix elements, which are assumed to be independent of the hard process of parton production. For a more extensive account of EFTs and quarkonia, see Section 18.1.4.

Before presenting the experimental results it is worth emphasizing that the B Factories provide the cleanest processes for calculation of charmonium production, as $c\bar{c}$ pairs in B decays (Section 18.2.4.1) and e^+e^- annihilation (Section 18.2.4.2) are produced via weak and electromagnetic processes, which can be calculated exactly. However in some cases, the test of such predictions requires a careful treatment of the details of the experimental measurements (Section 18.2.4.3).

18.2.4.1 B decays

B mesons can decay into almost all possible charmonium states, with typical inclusive branching fractions $\sim 1\%$, although some states are dynamically suppressed. The first example of charmonium production in B decays, $B \to J/\psi X$, was discovered in 1985 by the ARGUS and CLEO collaborations (Albrecht et al., 1985b; Haas et al., 1985). At present, the Particle Data Group lists branching ratios for 31 charmonium modes, while upper limits are set for a further 26 modes. Although the B Factories have made a formidable contribution to the majority of these measurements, in this section we limit ourselves to the first observations of inclusive and exclusive B to charmonium decays that are interesting for the theory of charmonium production.

Inclusive decays

Two-body B-decays

Inclusive B decays to charmonia provide a very good opportunity to test charmonium production models. The
Figure 18.2.15. Mass difference between $J/\psi\gamma$ and J/ψ candidates in B decays (Abe, 2002i).

well measured inclusive J/ψ production rate (after subtraction of the contribution from cascade decays $\psi(2S)$ and $\chi_c \to J/\psi X$) is a factor $5-10$ larger than the predicted color singlet contribution: inclusion of the color octet mechanism to resolve this discrepancy therefore makes the octet the dominant contribution. One of the cleanest ways to check whether this conclusion is correct is to measure the χ_{c2}-to-χ_{c1} production ratio in B decays: the only contribution to χ_{c2} production comes from the color octet model, which favors χ_{c2} over χ_{c1} production, the rate being proportional to $2J+1$, the number of spin states.[106] Experimentally, $B \to \chi_{c1} X$ was measured many years ago by ARGUS (Albrecht et al., 1992b), while only an upper limit had been set on χ_{c2} production before the B Factories began operation (Chen et al., 2001c).

Inclusive $B \to \chi_{c2} X$ decays were first observed by Belle in 2002 using $29.4\,\mathrm{fb}^{-1}$ of data (Abe, 2002i). χ_c candidates are reconstructed in the $J/\psi\gamma$ mode. In addition to the prominent χ_{c1} peak, a χ_{c2} signal is clearly seen in the $J/\psi\gamma - J/\psi$ mass difference spectrum (Fig. 18.2.15). Signal yields are extracted by fitting the distribution with the sum of two Crystal Ball functions representing the χ_{c1} and χ_{c2} contributions, and a third-order Chebyshev polynomial parameterizing the background. After subtraction of the $\psi(2S) \to \chi_{cJ}\gamma$ feed-down the direct branching fractions are found to be $\mathcal{B}(B \to \chi_{c1} X) = (3.32 \pm 0.22 \pm 0.34) \times 10^{-3}$ and $\mathcal{B}(B \to \chi_{c2} X) = (1.80^{+0.23}_{-0.28} \pm 0.26) \times 10^{-3}$. A similar analysis was performed by *BABAR* (Au-

bert, 2003n), with results in good agreement with those of Belle: $\mathcal{B}(B \to \chi_{c1} X) = (3.41 \pm 0.35 \pm 0.42) \times 10^{-3}$ and $\mathcal{B}(B \to \chi_{c2} X) = (1.90 \pm 0.45 \pm 0.29) \times 10^{-3}$. As can be seen, the ratio of production rates of χ_{c2} and χ_{c1} is roughly $1:2$, between the pure color singlet and pure color octet predictions ($0:1$ and $5:3$ respectively).

Two-body decays of the type $B \to (c\bar{c})_{\mathrm{res}}K^{(*)}$ have been extensively studied, because of their extremely clean experimental environment and their importance for *CP*-violation measurements. Theoretical calculations for these decays are more difficult than those for inclusive charmonium production, as they have to include the fragmentation of light quarks into $K^{(*)}$ mesons, introducing an additional uncertainty. However, for such decays it is justified to use the factorization hypothesis, since a charmonium state (which does not pick up the spectator quark from the B meson) is an object of small size and escapes the decay region; only the kaon partner is affected by soft-gluon exchange. The factorization approach predicts large suppression in the production of χ_{c0}, h_c, and χ_{c2} in comparison with χ_{c1} in $B \to (c\bar{c})_{\mathrm{res}}K$ decays (Beneke and Vernazza, 2009). By the start of B Factory data taking, only the $B \to \chi_{c1}K$ decay had been observed.

The decay $B \to \chi_{c0}K$ was seen for the first time at the B Factories; this process was difficult to observe, due to the small χ_{c0} branching fractions to modes suitable for reconstruction. In 2001 Belle (Abe, 2002e) observed a $B^+ \to \chi_{c0}K^+$ signal in two χ_{c0} decay modes: $\pi^+\pi^-$ and K^+K^-. A more substantial study of this decay, that takes into account interference of the χ_{c0} resonance with a large variety of possible intermediate hadron resonances in the $K^+\pi^-$, $\pi^+\pi^-$, and K^+K^- systems, was performed by Belle (Garmash, 2005) with a larger data set using the Dalitz analysis technique (see Chapter 13). In this analysis, signal events are selected from an ellipse around the nominal ΔE and m_{ES} values in the $\Delta E - m_{\mathrm{ES}}$ plane. The regions with dipion mass around the J/ψ or $\psi(2S)$ nominal masses contain a large background from $B^+ \to J/\psi\,(\psi(2S))K^+$ decays followed by $J/\psi\,(\psi(2S)) \to \mu^+\mu^-$, where both muons are misidentified as pions. Similarly, the region in the $K^+\pi^-$ mass corresponding to $\bar{D}^0 \to K^+\pi^-$ decay is contaminated by the $B^+ \to \bar{D}^0 K^+$ process. These three regions are excluded from further analysis. The Dalitz plot for the signal region is shown in Fig. 18.2.16 (a) and (b) for $B^+ \to \pi^+\pi^-K^+$ and $K^+K^-K^+$ decays respectively. The $B^+ \to \chi_{c0}K^+$ signal can be seen as a horizontal band at $M^2(\pi^+\pi^-)$ and $M^2(K^+K^+) \sim 11.6\,\mathrm{GeV}^2/c^4$. The χ_{c0} signal yield in $B^+ \to \pi^+\pi^-K^+$ is extracted by an unbinned maximum-likelihood fit to the Dalitz distribution with a coherent sum of all known intermediate quasi-two-body processes ($\chi_{c0}K^+$, $K^*(892)^0\pi^+$, $K_0^*(1430)^0\pi^+$, $\rho(770)^0K^+$, $f_0(980)K^+$, $f(1300)K^+$, $\kappa\pi^+$), a non-resonant three-body $K^+\pi^+\pi^-$ contribution, and a background shape fixed from sideband studies. A similar procedure is used for the $K^+K^-K^+$ final state. Significant signals for χ_{c0} are observed in both modes, and the combined branching fraction is found to be $\mathcal{B}(B^+ \to \chi_{c0}K^+) = (1.96 \pm 0.35 \pm 0.33^{+1.97}_{-0.26}) \times 10^{-4}$, where the first error is statistical, the second is systematic, and the third is the model error

---

[106] If the $c\bar{c}$ pair is produced in the singlet state, it can directly form a meson, but this one can only have $J = 0, 1$. In order to be able to produce the χ_{c2} state, which has $J = 2$, a gluon needs to be emitted; gluon emission is also necessary when the $c\bar{c}$ is produced in a color octet state. Note also that in the naïve factorization approach $\Gamma(B \to \chi_{c0(2)}P)$ is expected to vanish as explained in Section 17.3.5.4.

Figure 18.2.16. From Garmash (2005): Dalitz plot for events in the signal region for the (a) $B^+ \to \pi^+\pi^- K^+$ and (b) $B^+ \to K^+K^-K^+$ processes.

due to Dalitz plot parameterization. Subsequent, similar measurements based on larger samples by Belle ($\mathcal{B}(B^+ \to \chi_{c0}K^+) = (1.12 \pm 0.12 \, {}^{+0.30}_{-0.20}) \times 10^{-4}$; Garmash, 2006) and *BABAR* ($\mathcal{B}(B^+ \to \chi_{c0}K^+) = (1.23 \, {}^{+0.27}_{-0.25} \pm 0.06) \times 10^{-4}$; Aubert, 2008j) are in good agreement.

Two-body B decay into χ_{c2} (such as $B \to \chi_{c2}K^{(*)}$) has not yet been observed with high statistical significance. The upper limit obtained by *BABAR* is $\mathcal{B}(B^+ \to \chi_{c2}K^+) < 1.8 \times 10^{-5}$ at 90% C.L. (Aubert, 2009m). Belle has found 3.6σ evidence for the $B^+ \to \chi_{c2}K^+$ decay, with $\mathcal{B}(B^+ \to \chi_{c2}K^+) = (1.11 \, {}^{+0.36}_{-0.34} \pm 0.09) \times 10^{-5}$ (Bhardwaj, 2011), *i.e.* almost 40 times smaller than the branching fraction for the $B^+ \to \chi_{c1}K^+$ decay. There is also an upper limit from Belle $\mathcal{B}(B^+ \to h_cK^+) < 3.8 \times 10^{-5}$ (Fang, 2006). Such a large suppression of production of χ_{c2} and h_c with respect to χ_{c1} in two-body B decays is anticipated by theory, as discussed above.

18.2.4.2 e^+e^- annihilation

Prompt charmonium production in e^+e^- annihilation was first observed in 1990 by the CLEO collaboration (Alexander et al., 1990), which found 15.2 ± 4.9 events with reconstructed J/ψ above the kinematical limit for B-decays ($p_{J/\psi} > 2\,\mathrm{GeV}/c$) in the $\Upsilon(4S)$ data. In the first analysis this observation was misinterpreted as non-$B\bar{B}$ decays of $\Upsilon(4S)$, but later a J/ψ signal was also seen in the CLEO continuum data.

For more than ten years after this observation, there were attempts by theoreticians to explain the estimated cross section ($\sigma \sim 2\,\mathrm{pb}$) without new experimental inputs. Due to the lack of experimental information, all possible production mechanisms had to be considered. The

dominant contribution to prompt J/ψ production was expected to be due to color singlet and color octet diagrams $e^+e^- \to c\bar{c}\,g(g)$. In the color singlet $e^+e^- \to c\bar{c}\,gg$ process, two hard gluons are emitted, pushing the mass of the $c\bar{c}$ pair into the charmonium region. Although the radiation of two gluons is suppressed by α_s^2, the contribution of this diagram is comparable with single gluon production because it provides a colorless $c\bar{c}$ pair, which can be directly projected into a physical charmonium state, *e.g.* J/ψ (Fig. 18.2.17 (a)). NRQCD, based on leading-order perturbative QCD calculations, predicted that the cross section of the color singlet process $e^+e^- \to c\bar{c}gg \to J/\psi X$ might be as high as $0.8\,\mathrm{pb}$ (Cho and Leibovich, 1996b; Yuan, Qiao, and Chao, 1997b). The color octet $e^+e^- \to c\bar{c}g$ diagram leads to the formation of a color $(c\bar{c})^8$ state, which is required to be "decolorized" by emission of another soft gluon before it can be transformed into a physical charmonium state (Fig. 18.2.17 (b)). Due to the large value of α_s at low energy, such emission is both large and impossible to compute perturbatively. According to theoretical estimates, the color singlet and color octet contributions may be of the same order (Schuler, 1999; Yuan, Qiao, and Chao, 1997a,b), although the uncertainty of this estimate is large due to poorly-constrained color octet matrix elements. Another color singlet diagram $e^+e^- \to c\bar{c}\,c\bar{c}$ (Fig. 18.2.17 (c)) that can contribute to prompt charmonium production was estimated to be so small ($\sim 0.05\,\mathrm{pb}$; Kiselev, Likhoded, and Shevlyagin, 1994), that detection of this process was considered hardly possible.

Initial cross section measurements

In 2001 both *BABAR* and Belle performed much more precise measurements of the $e^+e^- \to J/\psi X$ cross section
Figure 18.2.17. Feynman diagrams describing J/ψ production in e^+e^- annihilation: see the text for details.

Figure 18.2.18. From Abe (2004g): the mass of the system recoiling against the reconstructed (top) J/ψ and (bottom) $\psi(2S)$ in inclusive $e^+e^- \to J/\psi(\psi(2S)) X$ events. The solid curve is the result of a fit that includes η_c, χ_{c0}, and $\eta_c(2S)$; the dashed curve is the background contribution.

using the data sets obtained in the first year of their operation ($\mathcal{L} \sim 20\,\text{fb}^{-1}$). In both collaborations the J/ψ production was studied in the full momentum interval: the region below $2\,\text{GeV}/c$ was studied using continuum data. *BABAR* obtained $(2.52 \pm 0.21 \pm 0.21)\,\text{pb}$ (Aubert, 2001b), while Belle obtained $(1.47 \pm 0.10 \pm 0.13)\,\text{pb}$ (Abe, 2002n). The discrepancies between the two measurements are likely due to differences in the selection criteria for J/ψ events that were used to suppress contributions from the huge QED background. Corrections for the selection efficiency are model dependent and may result in poorly controlled systematic uncertainty. (See also the discussion in Section 18.2.4.3 below.) While the measured cross section is not in contradiction with the NRQCD predictions (color singlet + color octet) of 1.1–$1.6\,\text{pb}$ (Yuan, Qiao, and Chao, 1997a,b), the expected sole color singlet contribution is too small to describe the data. On the other hand, the J/ψ momentum spectrum measured by Belle and *BABAR* does not show any indication of the sizable color octet contribution, that was expected to result in an enhancement at the maximum momentum value. *BABAR* and Belle also measured the J/ψ production and helicity angle distributions, which roughly agree with NRQCD expectations.

Belle and *BABAR* performed searches for other charmonium states produced in e^+e^- annihilation. In addition to the J/ψ production study, Belle also measured $\sigma(e^+e^- \to \psi(2S) X) = (0.67 \pm 0.09^{+0.09}_{-0.11})\,\text{pb}$ (Abe, 2002n) and set upper limits on the production of χ_{c1} and χ_{c2}. Later *BABAR*, using a much larger data sample, improved these limits: $\sigma^{\text{prompt}}_{N_{ch}\geq 3}(e^+e^- \to \chi_{c1(2)} X) < 77(79)\,\text{fb}$ at the 90% confidence level (Aubert, 2007at). Upper limits were set for events where the charmonium momentum exceeds $2.0\,\text{GeV}/c$ and there are at least three additional charged tracks. These limits are consistent with NRQCD predictions.

The recoil mass analyses

In 2002, contrary to NRQCD expectations, Belle observed that most of the prompt J/ψ's are accompanied
by charmed hadrons (Abe, 2002j). The J/ψ is reconstructed in its $\ell^+\ell^-$ ($\ell = e, \mu$) decays, with its mass constrained to the nominal value to improve the momentum resolution. $B\bar{B}$ background is suppressed by requiring $p^*_{J/\psi} > 2\,\text{GeV}/c$, where $p^*_{J/\psi}$ is the J/ψ momentum in the CM system. Backgrounds from QED $e^+e^- \to \ell^+\ell^-(\gamma)$ processes are suppressed by requiring the number of tracks in each event to be larger than 4. Unexpectedly, Belle found that a significant fraction of J/ψ's are produced together with another charmonium state in two-body reactions of the type $e^+e^- \to J/\psi\,\eta_c$ (Fig. 18.2.17 (d)). More often, charmed mesons are found in the events with reconstructed J/ψ (Fig. 18.2.17 (c)). To identify the first type of process (with the double charmonium final state) it is not necessary to reconstruct both mesons, which inevitably leads to substantial efficiency loss. Relying on four-momentum conservation, the mass of the system produced together with J/ψ can be calculated using only the measured J/ψ momentum. The mass of the system recoiling against the J/ψ candidate—the "recoil mass"— is defined as

$$M_{\text{recoil}}(J/\psi) = \left[(\sqrt{s} - E^*_{J/\psi})^2 - p^{*\,2}_{J/\psi} \right]^{1/2}, \quad (18.2.3)$$

where $E^*_{J/\psi}$ is the J/ψ energy in the CM system. A clear peak was observed around the η_c mass; two more peaks were seen around the masses of χ_{c0} and $\eta_c(2S)$.

Table 18.2.7. Comparison of experimental cross sections ($\sigma \times \mathcal{B}_{>2}$ in fb, see text for symbol definition) with theoretical expectations that do not include the $\mathcal{B}_{>2}$ factor.

$J/\psi\, c\bar{c}$	η_c	χ_{c0}	$\eta_c(2S)$	Reference
Belle	$25.6 \;\pm 2.8 \pm 3.4$	$6.4 \;\pm 1.7 \pm 1.0$	$16.5 \;\pm 3.0 \pm 2.4$	Abe (2004g)
BABAR	$17.6 \;\pm 2.8^{+1.5}_{-2.1}$	$10.3 \;\pm 2.5^{+1.4}_{-1.8}$	$16.4 \;\pm 3.7^{+2.4}_{-3.0}$	Aubert (2005n)
NRQCD	3.78 ± 1.26	2.40 ± 1.02	1.57 ± 0.52	Braaten and Lee (2003)
NRQCD	5.5	6.9	3.7	Liu, He, and Chao (2003)
Light cone	$14.4 \;^{+11.2}_{-9.8}$	$-$	$13.0 \;^{+12.2}_{-11.0}$	Braguta (2009)
NLO NRQCD	$17.6 \;^{+10.7}_{-8.3}$	$-$	$-$	Bodwin, Lee, and Yu (2008)

This observation was later confirmed by subsequent Belle (Fig. 18.2.18; Abe, 2004g) and *BABAR* analyses (Fig. 18.2.4; Aubert, 2005n) using larger samples. The most recent results are summarized in Table 18.2.7. Because of the selection criteria applied by both collaborations the results are given in terms of the product of the cross section and the branching fraction of the recoil charmonium state into more than 2 charged tracks, $\sigma \times \mathcal{B}_{>2}$. The similar process involving $\psi(2S)$ was also observed by Belle (Fig. 18.2.18; Abe, 2004g). Surprisingly, the cross sections of double charmonium production with $\psi(2S)$ are close to those with J/ψ.

Following the observation of double charmonium production, the corresponding cross sections were calculated using NRQCD to be an order of magnitude smaller than experimental values (Braaten and Lee, 2003; Liu, He, and Chao, 2003). Later the importance of relativistic corrections was recognized by Ma and Si (2004) and Bondar and Chernyak (2005); the relative momentum of the heavy quarks in the charmonium was taken into account using the light cone approximation. As a result, the calculated cross sections are now close to the experimental values though within a large uncertainty (Braguta, 2009). Alternatively, other authors (Bodwin, Lee, and Yu, 2008; He, Fan, and Chao, 2007) suggested to resolve the discrepancy within the NRQCD approach by the resummation of the corrections of next-to-leading order (NLO) in α_s, relativistic corrections, and contributions from pure QED diagrams. The theoretical expectations (not including the $\mathcal{B}_{>2}$ factor) are summarized in comparison with the Belle and *BABAR* measurements in Table 18.2.7.

Measuring the large double-$c\bar{c}$ fraction

In 2002 Belle also observed that J/ψ's are often accompanied by D^{*+} and D^0-mesons (Abe, 2002j). Scatter plots of the invariant mass of J/ψ candidates versus masses of D^{*+} and D^0 candidates are shown in Fig. 18.2.19 (a), (c). The charmed meson mass projections for the J/ψ signal and sideband regions are shown in Fig. 18.2.19 (b), (d). A significant excess of D^{*+} ($N_{D^{*+}J/\psi} = 10.1\,^{+3.6}_{-3.0}$, with significance $5.3\,\sigma$), and D^0 mesons ($N_{D^0 J/\psi} = 14.9\,^{+5.4}_{-4.8}$, with significance $3.7\,\sigma$) in the events with J/ψ's above the kinematical limit for $\Upsilon(4S)$ decays demonstrates that another $c\bar{c}$ pair is present. To calculate the $e^+e^- \to J/\psi\, c\bar{c}$ cross
Figure 18.2.19. Results of a search for associated production of J/ψ and charm mesons (Abe, 2002j): (a) the scatter plot $M(\ell^+\ell^-)$ vs $M(D^0\pi^+)$; (b) projection onto the $M(D^0\pi^+)$ axis; (c) the scatter plot $M(\ell^+\ell^-)$ vs $M(K^-\pi^+(K^+K^-))$; (d) projection onto the $M(K^-\pi^+(K^+K^-))$ axis. Points with error bars show the J/ψ signal region and the hatched histograms show the scaled sidebands.

section, one needs to know how often the second $c\bar{c}$-pair fragments into D^{*+} or D^0-mesons. Using the Lund fragmentation model (Sjöstrand, 1994) Belle calculated the ratio of the $J/\psi\, c\bar{c}$ and inclusive $J/\psi\, X$ production cross sections to be equal to $0.59\,^{+0.15}_{-0.13}\pm 0.12$. This result clearly demonstrates that, contrary to NRQCD predictions, the dominant diagram for J/ψ production is $e^+e^- \to J/\psi\, c\bar{c}$.

In 2009, using an order of magnitude larger data sample ($673\,\text{fb}^{-1}$) Belle measured the cross sections for the processes $e^+e^- \to J/\psi\, c\bar{c}$ in a model-independent way (Pakhlov, 2009). In the study of associated production of a J/ψ with charmed hadrons, all the ground state charmed mesons (D^0, D^+, D_s^+) and the Λ_c-baryon were used. As two charmed hadrons are produced in $c\bar{c}$ fragmentation, the $e^+e^- \to J/\psi\, c\bar{c}$ cross section is given by the sum of double-charmonium $e^+e^- \to J/\psi\, (c\bar{c})_{\text{res}}$ cross
Figure 18.2.20. From Pakhlov (2009): (a) Differential cross section for the $e^+e^- \to J/\psi\, c\bar{c}$ (open squares) and $e^+e^- \to J/\psi$ non-$c\bar{c}$ processes (filled triangles). The curves represent a fit to the Peterson fragmentation function (Peterson, Schlatter, Schmitt, and Zerwas, 1983). Angular distributions (b) $|\cos\theta_{\text{helicity}}|$ and (c) $|\cos\theta_{\text{production}}|$ for inclusive (open circles), $e^+e^- \to J/\psi\, c\bar{c}$ (open squares), and $e^+e^- \to J/\psi$ non-$c\bar{c}$ processes (filled triangles).

sections (for $(c\bar{c})_{\text{res}}$ states below open-charm threshold) plus half the sum of the cross sections for production of J/ψ with any of ground state charmed hadrons. Production of the J/ψ via mechanisms other than $e^+e^- \to J/\psi\, c\bar{c}$ was also studied: the $e^+e^- \to J/\psi$ non-$c\bar{c}$ cross section was calculated as the difference between inclusive $e^+e^- \to J/\psi\, X$ and $e^+e^- \to J/\psi\, c\bar{c}$ cross sections. Belle found $\sigma(e^+e^- \to J/\psi\, c\bar{c}) = (0.74 \pm 0.08\,^{+0.09}_{-0.08})$ pb and $\sigma(e^+e^- \to J/\psi$ non-$c\bar{c}) = (0.43 \pm 0.09 \pm 0.09)$ pb, respectively, thus confirming the dominance of the $e^+e^- \to J/\psi\, c\bar{c}$ production mechanism. It should be noted that in this analysis (unlike that of Abe, 2002n) no correction for the charged track multiplicity ($N_{\text{ch}} > 4$) requirement was applied for any of the processes. For $e^+e^- \to J/\psi$ non-$c\bar{c}$, such corrections are only possible by relying on a model, while for $e^+e^- \to J/\psi\, c\bar{c}$ they are close to unity. A note on the interpretation of these results follows in Section 18.2.4.3.

With the same technique Belle measured the J/ψ momentum (Fig. 18.2.20 (a)) and J/ψ helicity and production angle distributions (Fig. 18.2.20 (b) and (c), respectively) for both $e^+e^- \to J/\psi\, c\bar{c}$ (open squares) and $e^+e^- \to J/\psi$ non-$c\bar{c}$ (filled triangle) processes. For the $e^+e^- \to J/\psi$ non-$c\bar{c}$ process, the J/ψ momentum spectrum is significantly softer than that for $e^+e^- \to J/\psi\, c\bar{c}$, and the production angle distribution peaks along the beam axis.

Recently, both $e^+e^- \to J/\psi\, gg$ and $J/\psi\, c\bar{c}$ cross sections have been recalculated including NLO corrections (Gong, Wang, and Zhang, 2011; He, Fan, and Chao, 2010; Li, Song, Zhang, and Ma, 2011) and are in better agreement with the experimental data than the first leading-order calculations. A complete discussion can be found in Brambilla et al. (2011).

18.2.4.3 Special note: the $e^+e^- \to J/\psi\, X$ cross section

It is both important and difficult to compare measurements of the $e^+e^- \to J/\psi\, X$ cross section with theory. This is especially true in the case where the recoil system X does not include open or hidden charm ("$e^+e^- \to J/\psi$ non-$c\bar{c}$"), as this allows the NRQCD framework— with universal matrix elements describing production in e^+e^-, $p\bar{p}$, and other environments—to be tested (Section 18.1.4.1). The measurements are described in detail in Section 18.2.4.2; here we treat problems of interpretation.

The main pitfall is the selection requiring more than four reconstructed tracks. As described above, B Factory $e^+e^- \to J/\psi\, X$ analyses impose such a requirement to suppress low-multiplicity events of QED origin, which are numerous and poorly understood. While the physics of QED events is straightforward, practical measurement requires control of cases where tracks are missed or misreconstructed, and where beam-background tracks are added to the event, together with photon conversions and bremsstrahlung. The lack of coverage close to the beamlines, and the trigger conditions, are key limitations: see Chapter 2 for the design of the experiments; for the forward-peaked cross-section of QED processes, in a simple case (initial state radiation), see the discussion in Section 21.2.1.

The requirement of more than four reconstructed tracks must be taken into account when comparing measurements with theoretical predictions:

1. For double charmonium production, $e^+e^- \to J/\psi\, c\bar{c}$, this is straightforward: both collaborations quote results for $\sigma \times \mathcal{B}_{>2}$ (Table 18.2.7), where the factor $\mathcal{B}_{>2}$ describes the fraction of $c\bar{c}$ decays to final states with more than two charged particles. (J/ψ is reconstructed only in the decay to a lepton pair $\ell^+\ell^-$.)

2. The first B Factory measurements of $e^+e^- \to J/\psi\, X$ quoted the cross section directly, attempting to correct for the effect of track requirements. The initial *BABAR* analysis (Aubert, 2001b) required more than four tracks in the $J/\psi \to e^+e^-$ case (*i.e.* not for $J/\psi \to \mu^+\mu^-$), with additional selections to suppress $e^+e^- \to \gamma_{\text{ISR}} J/\psi$ and $\gamma_{\text{ISR}}\psi(2S)$. The initial Belle analysis (Abe, 2002n) required more than four tracks in all events (the same condition used by more recent analyses), with additional selections to suppress $e^+e^- \to \gamma\psi(2S)(\to \pi^+\pi^- J/\psi)$. Both experiments incorporated these requirements into their efficiency calculations, making assumptions about the angular distribution and polarization of these events, the fraction of recoil systems X containing charm, and the mix of hadronic final states within the system X in the light-quark case. All of these were poorly known at the time;

in the case of the fraction containing charm, prevailing assumptions were incorrect. These early measurements are thus subject to a significant and poorly-controlled model dependence.

3. The latest Belle measurement (Pakhlov, 2009) seeks to minimize such problems, reconstructing a list of states that exhausts most of the possibilities for X systems containing charm: the omissions are systems including the Ξ_c, Ω_c, and their excitations. There is thus only weak dependence on modelling of the system X. Because the intrinsic reliance on models is so low, Belle quotes cross-sections *without* correcting for the number-of-tracks cut. As noted above, this has little impact on the $e^+e^- \to J/\psi\, c\bar{c}$ measurement: the correction approaches unity. For the important $e^+e^- \to J/\psi$ non-$c\bar{c}$ cross-section, however, the Belle result is an *underestimate* of the true value.

The remaining issue is the comparison of Belle and *BABAR* results. The disagreement between the initial measurements was much larger than their reported uncertainties (Aubert, 2001b; Abe, 2002n); while the Belle result has been superseded by Pakhlov (2009), there has been no update of the *BABAR* cross section. (The successor analysis Aubert, 2005n concentrated on the then-controversial production of double $c\bar{c}$ final states.) The systematic limitations of the early measurements have been listed at point 2 above: while the two collaborations' results formally disagree, experimentalists do not interpret Aubert (2001b) as casting doubt on the Pakhlov (2009) cross sections.

18.2.5 Concluding remarks

The last decade saw both an experimental and a theoretical revival in charmonium physics due to the B Factories, with their large enriched charm sample, playing a leading role with the observation and study of dozens new charmonium-like states. For most of them a charmonium assignment has not been found so far: these states are reviewed in Section 18.3. Only a few of the new states match the conventional charmonium level scheme and have been discussed in this section. However even this selection of new states reveals problems in the quantitative description of the charmonium spectrum, since potential models can not accurately predict masses above the $D\bar{D}$ threshold. This suggests that the coupling between the charmonium and two-charmed-meson sectors is not well described, and B Factory measurements provide a stimulating input for the development of theoretical models. In a complementary development, rigorous work at the B Factories on accurate description of broad charmonium states in their interference with non-resonant background has helped to measure properly their masses and widths, which are also of great importance for theory.

The majority of the results presented in this section are illustrated by Fig. 18.2.21, which shows with colors the significant contribution of the B Factories to the study of the charmonium spectrum.

Charmonium production is another case where the B Factories managed to obtain surprising results. Observa-
Figure 18.2.21. The charmonium spectrum and scheme of charmonium transitions and decays. The red bands correspond to states newly observed at the B Factories, blue bands show states where the B Factories have made a substantial contribution to the accurate measurement of parameters, while the white bands represent yet unobserved states. The arrows show charmonium transitions and decays: decay modes newly observed at the B Factories are shown in red.

tion of unexpectedly large double $c\bar{c}$ continuum production stimulated new methods to calculate charmonium production. The importance of relativistic corrections and large NLO contributions were recognized in attempts to resolve this puzzling discrepancy.

In conclusion, the numerous results obtained by the B Factories in the charmonium sector have triggered theoretical developments for better descriptions of the spectroscopy, decay and production of charmonium states.

18.3 Exotic charmonium-like states

As discussed in Section 18.1, the theory of bound states of heavy quarks, such as charmonium, provides quantitative predictions for masses and other properties of the physically observable states with minimal ambiguity, primarily because the velocities of the heavy quarks in these bound states are low enough for relativistic effects to be treated as small perturbations to non-relativistic calculations. The quantum numbers that are most appropriate to characterize a realizable state are, in decreasing order of the energy-splitting among eigenstates: the radial excitation n, the orbital angular momentum ℓ, the spin s, and the total angular momentum J. Given this set of quantum numbers, the parity and charge conjugation of $c\bar{c}$ states[107] are given by $P = (-1)^{\ell+1}$ and $C = (-1)^{\ell+s}$. States are designated by the usual spectroscopic notation: $n\,^{2s+1}\ell_J$. Figure 18.1.1 shows the mass and quantum number assignments of the experimentally well established charmonium states (see also Table 18.2.1).

All of the predicted $c\bar{c}$ states with mass below the open-charm threshold (*i.e.*, $M < 2m_D$) have been observed with measured masses and other properties that are in good agreement with theoretical predictions. This suggests that the charmonium system is a good environment to search for "exotic" states, *i.e.* states containing a $c\bar{c}$ quark pair, as evidenced from its decay products, but with properties that deviate from theoretical expectations for $c\bar{c}$ spectroscopy. Before the advent of the B Factories no evidence for deviations from standard charmonium expectations was found.

In this section, we first summarize the existing models that describe possible exotic states, then review the experimental observations, reporting both the final states where the states have been observed and those where they have not. Since the easiest quantum number to assign is the charge-conjugation parity C, which is uniquely determined either by the production method or decay final state (see Section 18.2), we first examine the $C = +1$ states (Sections 18.3.2, 18.3.3, and 18.3.4) and then discuss the $J^{PC} = 1^{--}$ states (Section 18.3.5). In addition, we discuss the evidence for candidates for states with non-zero electric charge that contain a $c\bar{c}$ pair among their constituents. These play a crucial role since they can by no means be regular charmonium states, which, by definition, contain only a $c\bar{c}$ pair and are, therefore, electrically neutral. We conclude by summarizing the observations and the remaining open issues (Section 18.3.7).

---

[107] A complete discussion of quantum numbers can be found in Section 18.1.1.

18.3.1 Theoretical models

Although the Standard Model is well established, QCD, the fundamental theory of strong interactions, is only amenable to analytic computation at very high energy scales, where perturbation theory is effective due to asymptotic freedom. Lattice gauge theory has recently reached the level where it is able to provide precision predictions of simple hadronic properties (Durr et al., 2008; see also the discussion in Section 18.1.5). Nevertheless, a comprehensive understanding of low energy phenomena remains elusive.

Systems that include heavy quark-antiquark pairs (quarkonia) are a unique and, in fact, ideal laboratory for probing both the high energy regime of QCD and the low energy regime, where non-perturbative effects dominate. For this reason, quarkonia have been the subject of detailed experimental study for several decades. The accuracy of current models of quarkonia is such that a particle which mimics quarkonia but does not fit in the model spectrum is a likely candidate for a nonconventional, "exotic" state.

Indeed, in the past years the B Factories and the Tevatron have provided evidence for states that do not admit a conventional mesonic interpretation and that instead could be made of a larger number of constituents. While this possibility has been considered since the beginning of the quark model (Gell-Mann, 1964), the actual identification of such states would represent a major revolution in our understanding of elementary particles. It would also imply the existence of a possibly large number of additional states that have not yet been observed.

Finally, the study of strong bound states could be of relevance to understanding the Higgs boson. It could transpire, for example, that the Higgs is a bound state, as predicted by several technicolor models, with or without extra dimensions (Contino, Kramer, Son, and Sundrum, 2007; Dietrich, Sannino, and Tuominen, 2005).

A short list of possible "exotic" bound states is:

hybrids: bound states of a quark-antiquark pair and a number of constituent gluons. A signature of such states is that they can have quantum numbers that cannot be assumed by quarkonium states (*e.g.* $J^{PC} = 0^{+-}$ or 1^{-+}). Model and lattice computations indicate that the 1^{-+} states are the lightest hybrid states and thus should be easy to distinguish from conventional quarkonia. Additional signatures are the predicted preference for decays to either a pair of open-charm mesons, one S- and one P-wave (Kokoski and Isgur, 1987) or to quarkonium plus pions; see *e.g.* Kou and Pene (2005) and Close and Page (2005).

molecules: bound states of two mesons, usually represented as $[Q\bar{q}][q'\bar{Q}]$, where Q is the heavy quark. The system would be stable if the binding energy were sufficient to place the mass below all meson-meson continua that couple to the molecule. It is expected that this can happen readily when $Q = b$. For $Q = c$ model computations indicate that resonant states are possible in certain channels. These states can decay strongly

via configuration mixing (Braaten and Kusunoki, 2004; Braaten and Lu, 2009; Close and Page, 2004; Fleming, Kusunoki, Mehen, and van Kolck, 2007; Swanson, 2006; Tornqvist, 2004; Voloshin, 2006).

tetraquarks: a bound quark pair, neutralizing its color with a bound antiquark pair, usually represented as $[Qq][\bar{q}'\bar{Q}]$. A full nonet of states is predicted for each spin-parity, *i.e.* a large number of states are expected. There is no need for these states to be close to any threshold (Maiani, Piccinini, Polosa, and Riquer, 2006).

In addition, before the panorama of states is fully clarified, there is always the lurking possibility that some of the observed states are misinterpretations of threshold effects: a given amplitude might be enhanced when new hadronic final states become energetically possible, even in the absence of resonances.

18.3.2 The X(3872)

The $X(3872)$ was the first exotic charmonium-like state discovered. As shown in Fig. 18.3.1, it was initially observed decaying into $J/\psi\pi^+\pi^-$ by the Belle experiment in $B \to XK$ decays (Choi, 2003), and subsequently confirmed both in B decays (Aubert, 2005af) and in inclusive $p\bar{p}$ production (Abazov et al., 2004; Acosta et al., 2004). Far more information is available on the $X(3872)$ than on any other state; this information will be reviewed here by topic: quantum numbers, mass and width, and production and decay.

18.3.2.1 Quantum numbers

The exotic nature of this state was initially signalled by the narrowness of its width, $\Gamma_{X(3872)} < 2.3 \,\mathrm{MeV}/c^2$ at 90% confidence (Choi, 2003), despite being above threshold for decay to a pair of charmed mesons. Furthermore, the $\pi^+\pi^-$ invariant mass distribution first (Choi, 2003; Abulencia et al., 2006a), and a detailed angular analysis next (Abulencia et al., 2007), showed that the dominant decay is $X(3872) \to J/\psi\rho$, which would be isospin violating if the $X(3872)$ were a conventional charmonium state.[108]

The above-mentioned angular analysis from the CDF experiment (Abulencia et al., 2007) was able to discriminate among the possible J^{PC} assignments, excluding all except $J^{PC} = 1^{++}$ and 2^{-+}. Positive intrinsic charge conjugation had already been established, with the evidence for the decay $X \to J/\psi\gamma$ (Abe, 2005a; Aubert, 2006an) and an upper limit on the branching fraction of the decay $X \to \chi_{c1}\gamma$ (Choi, 2003), thus confirming positive intrinsic charge conjugation.[109]

---

[108] In this case, an isosinglet particle (the $X(3872)$) would be decaying into an isovector state: the combination of an isosinglet (J/ψ) and an isovector (ρ) particle.

[109] The χ_{c1} has $C = +1$, while the γ has $C = -1$: the final state therefore has $C = -1$. If the X has positive charge conjugation it cannot decay via electromagnetic interactions into a $C = -1$ final state.
Figure 18.3.1. Invariant mass spectrum of the $J/\psi\pi^+\pi^-$ system in $B \to J/\psi\pi\pi K$ decays as observed by Belle (Choi, 2003; upper plot) and of the $\bar{D}^{*0}D^0$ system in $B \to \bar{D}^*DK$ decays as published by *BABAR* (Aubert, 2008bd; lower plot).

For years the most favored option has been to assume that the X has $J^{PC} = 1^{++}$; a $D^{*0}\bar{D}$ molecule with $L = 0$ would have these quantum numbers. Such a deuteron-like state, bound by pion exchange, was discussed by Tornqvist (1994), and proposed as a model of the $X(3872)$ structure by Swanson (2004b), and many subsequent investigators. However, definitive arguments against the 2^{-+} assignment have been lacking.

The spin-2 hypothesis has been considered implausible from early studies onwards: the 2^{-+} decay to $\gamma J/\psi$ is not an electric dipole transition, and so should be suppressed;[110] for the charmonium state with these quantum numbers, the $1\,^1D_2$ or η_{c2}, the isospin-violating transition $\eta_{c2} \to \pi^+\pi^- J/\psi$ would be expected to have a small rate, relative to isospin-conserving $\eta_{c2} \to \pi^+\pi^-\eta_c$ (Olsen, 2005). However the *BABAR* study of $X(3872) \to J/\psi\omega$ (del Amo Sanchez, 2010c) reported a (relatively weak) preference for $J^{PC} = 2^{-+}$, and there has since been a renewed discussion of this possibility (*e.g.* Burns, Piccinini, Polosa, and Sabelli, 2010; Faccini, Pilloni, and Polosa, 2012; Hanhart, Kalashnikova, Kudryavtsev, and Nefediev, 2012). If the $X(3872)$ has quantum numbers $J^{PC} = 2^{-+}$, it should be produced by two-photon fusion (see Chapter 22).

---

[110] This straightforward point is part of the commonly-accepted wisdom about the $X(3872)$. We are not aware of who first brought it to general attention.

BABAR has searched for $\gamma\gamma \to X(3872) \to \eta_c(1S)\pi^+\pi^-$ with the $\eta_c(1S)$ decaying to $K^0_S K^\pm \pi^\mp$ (Lees, 2012t). No signal events were found, and a 90% confidence-level upper limit $\sigma(\gamma\gamma \to X(3872)) \times \mathcal{B}(X(3872) \to \eta_c(1S)\pi^+\pi^-) < 48$ fb was set on the product of the $\gamma\gamma \to X(3872)$ cross section and $X(3872) \to \eta_c(1S)\pi^+\pi^-$ branching fraction. CLEO has searched for $\gamma\gamma \to X(3872) \to J/\psi\pi^+\pi^-$ and has found no significant signal (Dobbs et al., 2005).

The updated Belle analysis of $X(3872) \to \pi^+\pi^- J/\psi$, using the full 711 fb^{-1} $\Upsilon(4S) \to B\bar{B}$ data sample (Choi, 2011), confirmed two key CDF results: the $M(\pi^+\pi^-)$ spectrum is consistent with $X(3872) \to \rho^0 J/\psi$ with either $L = 0$ or $L = 1$, consistent with $J^{PC} = 1^{++}$ and 2^{-+} respectively (*cf.* Abulencia et al., 2006a); and the angular distribution of the decay allows both 1^{++} and 2^{-+} interpretations (*cf.* Abulencia et al., 2007). Decays $B \to KX(3872)[\to \pi^+\pi^- J/\psi \{\to \ell^+\ell^-\}]$ are described in general by a five-dimensional angular distribution; under certain assumptions, the 1^{++} distribution is fixed, while there are two free parameters for 2^{-+}: the relative magnitude and phase of two complex amplitudes.[111] Due to this extra freedom for 2^{-+}, and complementary limitations of the Belle and CDF analyses, it is not possible to exclude 2^{-+}. The Belle analysis, due to the limited size of the sample, considers three different one-dimensional projections of the full distribution; CDF works with a binned three-dimensional distribution, as the other two quantities are unmeasurable on the sample used (inclusive $X(3872)$ production from $p\bar{p}$, without requiring $B \to KX$).

While we were preparing this book, LHCb published an analysis of a large and clean $B^+ \to K^+ X(3872)$ sample (313 ± 26 events), based on an event-by-event likelihood ratio test of 1^{++} and 2^{-+} hypotheses on the full five-dimensional angular distribution (Aaij et al., 2013a). This study favored 1^{++} over 2^{-+} by more than eight standard deviations; the complex ratio of amplitudes for the 2^{-+} hypothesis, which is treated as a nuisance parameter, is found to be consistent with both the Belle result (Choi, 2011) and with the expectation for decays of a 1^{++} state. It therefore appears that the $J^{PC} = 1^{++}$ assignment has finally been established.

18.3.2.2 Mass, width, and hypothetical partner states

Measurements of the mass and width of the $X(3872)$ have been complicated by discussion of two further questions: is the X a single particle, or a pair of neutral states; and, even in the case of a single state, what lineshape do we expect to observe in any given decay mode? These questions have been particularly important for the analysis and interpretation of the decays $X(3872) \to \pi^0 D^0 \bar{D}^0$ and

---

[111] A publicly available LHC note (Mangiafave, Dickens, and Gibson, 2010), cited by Belle (Choi, 2011), lists the various angular distributions but incorrectly represents the normalized ratio of amplitudes for the 2^{-+} hypothesis, $\alpha = B_{11}/(B_{11} + B_{12})$, as a real number with $0 \le \alpha \le 1$. The corresponding LHCb thesis (Mangiafave, 2011) notes that α is complex in general.

$\gamma D^0 \bar{D}^0$; at the time of writing, the default approach is to exclude results of these decays from averages of mass and width measurements (see for example Beringer et al., 2012). In the following, we will briefly sketch the history, before presenting a summary of the results from the B Factories and other experiments.

Partner states, and nontrivial lineshape

Models in which the $X(3872)$ is a compact four-quark state (a "tetraquark"; see Section 18.3.1) predict partner states, in particular an additional neutral state. The discovery process $B^+ \to K^+ X(3872)$ and the isospin-related decay $B^0 \to K^0_S X(3872)$ in general produce both states with different branching ratios, see for example Maiani, Piccinini, Polosa, and Riquer (2005). However, it could happen that each B decays into a different X mass eigenstate. Both *BABAR* (Aubert, 2006ax, 2008d) and Belle (Adachi, 2008c; Choi, 2011) have performed analyses that distinguish the two samples, in order to test this idea. The most recent results (Aubert, 2008d and Choi, 2011; see Fig. 18.3.2) set the mass difference of the states produced in B^+ and B^0 decay at

$$\delta M \equiv M(X \mid B^+ \to K^+ X) - M(X \mid B^0 \to K^0 X)$$
$$= (+2.7 \pm 1.6 \pm 0.4)\,\text{MeV}/c^2 \ (BABAR),$$
$$= (-0.7 \pm 1.0 \pm 0.2)\,\text{MeV}/c^2 \ (\text{Belle}),$$
$$= (+0.2 \pm 0.8)\,\text{MeV}/c^2 \quad (\text{mean}). \quad (18.3.1)$$

A complementary analysis by CDF (Aaltonen et al., 2009c), fitting the inclusive $\pi^+\pi^- J/\psi$ spectrum, yields no evidence for any other neutral state and sets a limit on the mass difference of 3.6 MeV/c^2 at the 95% C.L., to be compared to the expectation

$$\delta M = (7 \pm 2)/\cos(2\theta)\,\text{MeV}/c^2 \quad (18.3.2)$$

from Maiani, Piccinini, Polosa, and Riquer (2005), where θ is a (small) angle describing mixing between flavor eigenstates.

The same analyses provide measurements of the ratio of product branching fractions,

$$R \equiv \frac{\mathcal{B}(B^0 \to K^0 X) \times \mathcal{B}(X \to \pi^+\pi^- J/\psi)}{\mathcal{B}(B^+ \to K^+ X) \times \mathcal{B}(X \to \pi^+\pi^- J/\psi)},$$

finding

$$R = 0.41 \pm 0.24 \pm 0.05 \ (BABAR),$$
$$= 0.50 \pm 0.14 \pm 0.04 \ (\text{Belle}). \quad (18.3.3)$$

The expectation in the case of molecular models of the X has been a source of confusion: an extensively-cited study by Braaten and Kusunoki (2005) predicted $R < 0.1$, and together with δM measurements prior to Choi (2011), this led to a widespread interpretation that B Factory B^+-versus-B^0 production results favored the tetraquark picture. Other estimates of R for $D^{*0}\bar{D}^0$ molecules exist: for
Figure 18.3.2. Events from the $B^0 \to K^0_S \pi^+ \pi^- J/\psi$ analysis of Belle (Choi, 2011), with the results of a three-dimensional fit to $M_{bc} \equiv m_{ES}$, $M(J/\psi \pi^+ \pi^-)$, and ΔE shown (blue solid curve); the fitted contributions of combinatorial background (red dotted), and combinatorial plus peaking background (green dashed) are also shown.

example, Swanson (2006) found 0.06–0.29. Braaten and Lu (2008) subsequently described the $R < 0.1$ prediction as the result of a "conceptual error" and found that in the molecular model R could be studied only together with the lineshapes of $X(3872)$ decays.

As no significant separation is seen between the masses of the peaks in the $K^+ \pi^+ \pi^- J/\psi$ and $K^0_S \pi^+ \pi^- J/\psi$ final states, we assume in what follows that both are due to the decay of a single $X(3872)$ state. In the mass and width measurements presented below, the results from $K^+ \pi^+ \pi^- J/\psi$ dominate.

Belle observed the decay $X(3872) \to D^{*0} \overline{D}^0$ in the $\pi^0 D^0 \overline{D}^0$ final state at the higher mass $M = (3875.2 \pm 0.7^{+0.3}_{-1.6} \pm 0.8)$ MeV/c^2 (Gokhroo, 2006; the final error reflects the then-current uncertainty in the D^0 mass). Subsequent analyses by both *BABAR* (Aubert, 2008bd) and Belle (Aushev, 2010) confirmed the observation, also adding the $\gamma D^0 \overline{D}^0$ final state, and finding a mass of $M = (3873.8 \pm 0.5)$ MeV/c^2 if the two results are averaged. As this is significantly larger than the value observed in the discovery mode $\pi^+ \pi^- J/\psi$ (see below) there has been some speculation that $D^{*0} \overline{D}^0$ and $\pi^+ \pi^- J/\psi$ are produced by the decay of two distinct parent particles (see for example the discussion in Aubert, 2008bd). While this is possible *a priori*, there are two related problems with using this model to interpret the data:

– *Expected lineshape:* In a decay $X(3872) \to D^{*0} \overline{D}^0$ the D^{*0} will in general be off-shell, because of the proximity of the $D^{*0} \overline{D}^0$ threshold. The effect on the decays is pronounced if the X is below threshold, and study of the $\pi^0 D^0 \overline{D}^0$ and $\gamma D^0 \overline{D}^0$ lineshapes (which can have a complicated structure in general) is required to distinguish between an X state which is below threshold and an above-threshold "virtual state" (see for exam-

ple the discussions by Artoisenet, Braaten, and Kang, 2010, and Hanhart, Kalashnikova, and Nefediev, 2010, 2011).

– *Analysis technique:* The mature analyses of both collaborations impose a D^* mass constraint on one of the $\pi^0 D^0$ (or γD^0) combinations, to improve the resolution of the resulting $B \to KX$ candidates, and hence the suppression of the background. This yields a reconstructed $X(3872)$ mass that is above threshold by construction, and complicates the task of extracting the $\pi^0 D^0 \overline{D}^0$ (or $\gamma D^0 \overline{D}^0$) lineshape.

Within a model where a state above threshold is decaying to on-shell D^{*0} and $\overline{D}^0$, both collaborations resolve a nonzero width for that state, with an average of $\Gamma = (3.4 \pm 1.5)$ MeV/c^2. Some care is taken with the simulation and fitting in both measurements, including (in the Aubert, 2008bd analysis for example) simulations of $X(3872)$ with a range of masses and widths, rather than relying on parameterization of the reconstructed mass. Aubert (2008bd) also finds $\delta M = (0.7 \pm 1.9 \pm 0.3)$ MeV/c^2 for the difference between masses observed in B^+ and B^0 decays to $D^{*0} \overline{D}^0$.

For the reasons quoted above, and in common with other recent reviews (*e.g.* Beringer et al., 2012), we exclude these $D^{*0} \overline{D}^0$ results from averages of the $X(3872)$ mass and width below.

Searches for charged partner states have also been conducted by both *BABAR* (Aubert, 2005aa) and Belle (Choi, 2011). No evidence for such a state is seen, with limits from Belle (*BABAR*) on the product branching fractions of

$$\mathcal{B}(\overline{B}^0 \to K^- X^+) \times \mathcal{B}(X^+ \to \rho^+ J/\psi) < 4.2(5.4) \times 10^{-6},$$
$$\mathcal{B}(B^+ \to K^0 X^+) \times \mathcal{B}(X^+ \to \rho^+ J/\psi) < 6.1(22) \times 10^{-6},$$
$$(18.3.4)$$

to be compared with

$$\mathcal{B}(B^+ \to K^+ X) \times \mathcal{B}(X \to \rho^0 J/\psi)$$
$$= (8.4 \pm 1.5 \pm 0.7) \times 10^{-6} \ (BABAR),$$
$$= (8.6 \pm 0.8 \pm 0.5) \times 10^{-6} \ (Belle)$$
$$(18.3.5)$$

for the discovery mode, from Aubert (2008d) and Choi (2011) respectively. This excludes models in which the $X(3872)$ is the neutral member of an isospin triplet, where decays to the charged states would be favored by a factor of two. However, the tetraquark model of Maiani, Piccinini, Polosa, and Riquer (2005) provides lower limits for the rates in Eq. (18.3.4) which are still allowed by the $X(3872)$ rate in Eq. (18.3.5).

Mass measurements in J/ψ final states

A summary of all available mass measurements is shown in Fig. 18.3.3. The current world average, considering only $X(3872)$ decays to final states including the J/ψ, is $M = (3871.68 \pm 0.17)\,\text{MeV}/c^2$ (Beringer et al., 2012). The most precise measurements are those of CDF (Aaltonen et al., 2009c), Belle (Choi, 2011), the new measurement from LHCb (Aaij et al., 2012k), and $BABAR$ (Aubert, 2008d), all effectively $\pi^+\pi^- J/\psi$ measurements; the hadron machines measure inclusive production in $p\bar{p}$ and pp respectively, while the B Factory measurements are dominated by $B^+ \to K^+ \pi^+ \pi^- J/\psi$.

The $D^{*0}\bar{D}^0$ threshold is at $(3871.84 \pm 0.27)\,\text{MeV}/c^2$ (using the D^0 mass and $m_{D^{*0}} - m_{D^0}$ difference values from Beringer et al., 2012). If the $X(3872)$ is interpreted as a $D^{*0}\bar{D}^0$ "molecule" (see Section 18.3.1), bound by pion exchange, then the binding is exceptionally weak, $m_X - m_{D^{*0}} - m_{D^0} = (0.16 \pm 0.31)\,\text{MeV}$, to be compared to $2.2\,\text{MeV}$ for the deuteron. Although the B Factory (and

LHCb) mass measurements for the $X(3872)$ are statistically limited, the precision of the comparison with $D^{*0}\bar{D}^0$ threshold will only significantly improve with better measurements of the D^0 mass, the D^{*0} mass (or $m_{D^{*0}} - m_{D^0}$ difference), or the use of some new techniques.

Width measurements in J/ψ final states

The $X(3872)$ was known to be relatively narrow from the discovery analysis, with a limit $\Gamma < 2.3\,\text{MeV}/c^2$ at 90% C.L. (Choi, 2003). The confirmations by $BABAR$ (Aubert, 2005af), CDF (Acosta et al., 2004), and DØ (Abazov et al., 2004) each found a peak width consistent with the measurement resolution, but did not present explicit width measurements; subsequent analyses by $BABAR$ (Aubert, 2006ax, 2008d) set upper limits on the width ($4.1\,\text{MeV}/c^2$ and $3.3\,\text{MeV}/c^2$ respectively). The CDF analysis that set limits on the two-neutral-state hypothesis, and provides the best single measurement of the mass, used an $X(3872)$ intrinsic width of $\Gamma = 1.34\,\text{MeV}/c^2$ (Aaltonen et al., 2009c), based on an average of the central values of the (not statistically significant) width measurements from Belle (Choi, 2003) and $BABAR$ (Aubert, 2008d); no independent determination of the width was performed.

The best current estimate of the width comes from the recent Belle analysis (Choi, 2011), which finds $\Gamma < 1.2\,\text{MeV}/c^2$ at 90% C.L. based on a three-dimensional fit to m_{ES}, ΔE, and $M(\pi^+\pi^- J/\psi)$. This is below the experimental resolution. Simulation studies show that natural widths in this range can be recovered; Belle attributes this to constraints on the area of the peak in $M(\pi^+\pi^- J/\psi)$ provided by the distributions in m_{ES} and ΔE, which make the peak height in $M(\pi^+\pi^- J/\psi)$ sensitive to the natural width. Improved precision will presumably be possible if this technique is applied in the future.

18.3.2.3 Production and decay

The $X(3872)$ has been sought in a range of possible decays $B \to KX$, $X \to f$: these are listed, together with the measured product branching fractions (or upper limits) in Table 18.3.1. Plots from a number of important decay modes have been shown above in Figs 18.3.1 and 18.3.2; results in two modes where no signal is seen are shown in Fig. 18.3.4

The most important unresolved case is $X(3872) \to \gamma\psi(2S)$, shown in Fig. 18.3.5, where $BABAR$ (Aubert, 2009m) finds a signal with

$$\mathcal{B}(B^+ \to K^+ X) \times \mathcal{B}(X \to \gamma\psi(2S))$$
$$= (9.5 \pm 2.7 \pm 0.6) \times 10^{-6}, \quad (18.3.6)$$

while Belle (Bhardwaj, 2011) sees no significant signal and finds

$$= (0.8^{+2.0}_{-1.8} \pm 0.4) \times 10^{-6}. \quad (18.3.7)$$

Belle $KJ/\psi\pi^+\pi^-$	$3871.85 \pm 0.27 \pm 0.19$
$BABAR$ $KJ/\psi\omega$	$3873^{+1.8}_{-1.6} \pm 1.3$
$BABAR$ $K^+J/\psi\pi^+\pi^-$	$3871.4 \pm 0.6 \pm 0.1$
$BABAR$ $K^0_S J/\psi\pi^+\pi^-$	$3868.7 \pm 1.5 \pm 0.4$
LHCb $J/\psi\pi^+\pi^-X$	$3871.95 \pm 0.48 \pm 0.12$
CDF $J/\psi\pi^+\pi^-X$	$3871.61 \pm 0.16 \pm 0.19$
DØ $J/\psi\pi^+\pi^-X$	$3871.8 \pm 3.1 \pm 3.0$
Average	3871.68 ± 0.17
Figure 18.3.3. Measured mass of the $X(3872)$. We show the measurements which contribute to the average in Beringer et al. (2012).

(a) $\gamma\chi_{c1}(1P)$ at Belle (Choi, 2003).

(b) $\eta J/\psi$ at BABAR (Aubert, 2004v).
Figure 18.3.4. Invariant mass plots for representative $X(3872)$ searches where no signal is seen.

This is in contrast to the $X(3872) \to \gamma J/\psi$ decay, where the same two analyses both find a signal, with consistent product branching fractions

$$\mathcal{B}(B^+ \to K^+ X) \times \mathcal{B}(X \to \gamma J/\psi)$$
$$= (2.8 \pm 0.8 \pm 0.1) \times 10^{-6} \; (BABAR),$$
$$= (1.8^{+0.5}_{-0.4} \pm 0.1) \times 10^{-6} \; (\text{Belle}).$$
$$(18.3.8)$$

The radiative decays are crucial for understanding the structure of the $X(3872)$: while the $\gamma J/\psi$ decay is expected, the $\gamma\psi(2S)$ decay should be heavily suppressed for a molecular state; by contrast, decays of the $2\,^3P_1$ charmonium state (χ'_{c1}) to $\gamma\psi(2S)$ should be enhanced over those to $\gamma J/\psi$ (Barnes and Godfrey, 2004; Suzuki, 2005; Swanson, 2004a, 2006). And unlike other disputed exotic charmonium measurements, where the two experiments disagree on the significance of a signal but make statistically compatible measurements of the rate, the measurements in Eqs (18.3.6) and (18.3.7) are in apparent contradiction. During the final editing of this book, LHCb found evidence for this decay (Aaij et al., 2014a), with $\mathcal{B}(X \to \gamma\psi(2S))/\mathcal{B}(X \to \gamma J/\psi) = 2.46 \pm 0.64 \pm 0.29$. Critical study of the radiative decay modes will therefore be an urgent priority for a super flavor factory.

Measured product branching fractions can be translated into absolute branching fractions of the $X(3872)$ by exploiting the upper limit on $B \to KX(3872)$ measured by BABAR from the spectrum of the kaons recoiling against fully reconstructed B mesons (Aubert, 2006ae), $\mathcal{B}(B^\pm \to K^\pm X(3872)) < 3.2 \times 10^{-4}$ at 90% C.L.. Such an analysis has been performed by Drenska et al. (2010), who combine likelihoods for the various product branching fractions (using results available up to mid-2010), the $B \to KX(3872)$ upper limit, and the X width measure-

(d) $\gamma\psi(2S)$ at Belle
Figure 18.3.5. Invariant mass plots for radiative decays of the $X(3872)$: (a,c) $B^+ \to K^+X[\to \gamma J/\psi]$ and (b,d) $B^+ \to K^+X[\to \gamma\psi(2S)]$, at (a,b) BABAR (Aubert, 2009m) and (c,d) Belle (Bhardwaj, 2011). See the discussion in the text. The BABAR analyses in (a,b) use the $_s\mathcal{P}lot$ technique (Pivk and Le Diberder, 2005) to extract the number of signal events. The curves in the Belle plots show: in (c,d) the fit to data (blue solid) and fitted yields for the signal (red dashed); in (c) the background component (blue dotted); and in (d) the combinatorial background (black dotted), and background from $B \to K^*\psi(2S)$ and $B \to K\psi(2S)$ (pink dot-dashed).

ment in the $D^{*0}\overline{D}^0$ channel of Aubert (2008bd) using a Bayesian procedure. The resulting 68% confidence intervals are summarized in Table 18.3.1 for each of the decay modes. The same analysis finds a $B \to KX(3872)$ branching fraction in the range $(0.1$–$0.2) \times 10^{-3}$, to be compared to the corresponding branching fractions for conventional charmonium states, which are at least 5×10^{-3}.

As far as other production mechanisms are concerned, $B^0 \to K^+\pi^- X(3872)$ decays have also been studied. Such decays are seen, but with a smooth distribution in $K^+\pi^-$ invariant mass; an upper limit is set on $\mathcal{B}(B^0 \to K^*(892)^0 X(3872))$ (Adachi, 2008c; see the results in Table 18.3.1). This is in contrast to other charmonium states, where $B \to K^*c\bar{c}$ and $Kc\bar{c}$ branching fractions are comparable, and K^* dominates over nonresonant $K\pi$.

18.3.2.4 Summary

In summary, the $X(3872)$ is the most studied of the exotic hidden-charm states, and the only one observed in several

Table 18.3.1. Measured $X(3872)$ product branching fractions, separated by production and decay mechanism. The combined results and fitted values are taken from Drenska et al. (2010); see the text. When more than one publication is present, the combination is performed assuming Gaussian uncorrelated errors. The last two columns report the results in terms of absolute $X(3872)$ branching fraction (B_{fit}) and in terms of the branching fraction normalized to $J/\psi\pi\pi$ (R_{fit}) as obtained from the global likelihood fit described in the text. Ranges and limits are provided at 68% and 90% C.L., respectively. Averages marked with a dagger[†] include Belle results that have been superseded by subsequent publications: those from Adachi (2008c) by Choi (2011); those from Gokhroo (2006) by Aushev (2010); and those from Abe (2005a) by Bhardwaj (2011). The $\gamma\psi(2S)$ results in particular are controversial: see the text. Concerning $\pi\pi\pi^0$ results (marked with a double dagger[‡]): the B Factories find that the $X(3872) \to \pi\pi\pi^0 J/\psi$ process is dominated by $\omega J/\psi$, but set no limits on the nonresonant $\pi\pi\pi^0 J/\psi$ rate; the unpublished Belle result Abe (2005a) quotes only the ratio of $\pi\pi\pi^0 J/\psi$ and $\pi\pi J/\psi$ branching fractions.

decay modes; estimates of its width and absolute branching fractions are also available. Some of the early questions about the state — such as its quantum numbers, and whether charged or neutral partners exist — seem to have been resolved. However the structure of the $X(3872)$ is still not fully understood. Outstanding experimental questions are whether the disputed decay $X(3872) \to \gamma\psi(2S)$ takes place (and if so at what rate), and whether the $X(3872)$

lies above or below the $D^{*0}\overline{D}^0$ threshold. For the latter, large and clean $B^+ \to K^+\pi^0 D^0\overline{D}^0$ and $K^+\gamma D^0\overline{D}^0$ samples will be required; a super flavor factory provides some hope of performing these measurements.

Table 18.3.2. Measured J^{PC}, masses, and widths of the "3940 family" of states. The first error is statistical, the second systematic.

State	Reference	J^{PC}	Mass (MeV)	Width (MeV)	conventional assignment
$X(3940)$	(Pakhlov, 2008)	$0^{\pm+}$	$3942^{+7}_{-6} \pm 6$	$37^{+26}_{-15} \pm 8$	$\eta_c(3S)$
$Y(3940)$	(Abe, 2005g)	$[0,1,2]^{\pm+}$	$3943 \pm 11 \pm 13$	$87 \pm 22 \pm 26$	$\chi_{c0}(2P)$?
$Y(3940)$	(Aubert, 2008am)	$[0,1,2]^{\pm+}$	$3914.6^{+3.8}_{-3.4} \pm 1.9$	$33^{+12}_{-8} \pm 5$	$\chi_{c0}(2P)$?
$Y(3915)$	(Uehara, 2010b)	$[0,1,2]^{\pm+}$	$3915 \pm 3 \pm 2$	$17 \pm 10 \pm 3$	$\chi_{c0}(2P)$?
$Y(3915)$	(Lees, 2012ad)	0^{++}	$3919 \pm 2 \pm 2$	$13 \pm 6 \pm 3$	$\chi_{c0}(2P)$?
$Z(3930)$	(Uehara, 2006)	2^{++}	$3929 \pm 5 \pm 2$	$29 \pm 10 \pm 2$	$\chi_{c2}(2P)$
$Z(3930)$	(Aubert, 2010g)	2^{++}	$3926 \pm 2.7 \pm 1.1$	$21.3 \pm 6.8 \pm 3.6$	$\chi_{c2}(2P)$

18.3.3 The 3940 family

A number of resonances have been reported by the Belle Collaboration with masses near $3940 \, \mathrm{MeV}/c^2$: the $X(3940)$, $Y(3940)$, $Z(3930)$, and $Y(3915)$. These states have some possible, albeit not certain, interpretations as regular charmonium states and are discussed in Section 18.2. We concentrate here on aspects related to possible exotic assignments. The measured masses and widths of these states are summarized in Table 18.3.2 and Fig. 18.3.6.
Figure 18.3.6. Measured masses and widths of the "3940 family" of states; the boxes represent $\pm 1\sigma$ ranges of the measurements.

18.3.3.1 The $X(3940)$

The $X(3940)$ state was observed in association with a J/ψ meson in double-charmonium production events (*i.e.* not in $\Upsilon(4S)$ decays) (Abe, 2007f; Pakhlov, 2008). Subsequently, by applying a partial reconstruction technique

to the same production channel, Belle measured the absolute production rate and established that $X(3940) \rightarrow D^*\bar{D}$ is a prominent decay mode; searches were made for $X(3940) \rightarrow D\bar{D}$ and $J/\psi\omega$ without evidence for any signals. The lower and upper limits on the branching fractions for these modes set in Abe (2007f) were withdrawn by Belle in Pakhlov (2008), as the inclusive peak in the earlier analysis, used to provide the denominator of the fraction, may have contributions from more than one state. Since the $X(3940)$ is a candidate for a conventional charmonium state, it is also discussed in Section 18.2.1.3. The production mechanism constrains it to have positive charge conjugation since this is an electromagnetic process and the initial state virtual photon and the accompanying J/ψ have the same C. Furthermore, all of the known states that are observed via this production mechanism have $J = 0$. Although the reason for this is not understood, it is plausible that this state also has $J = 0$. Thus, the most likely quantum numbers of the $X(3940)$ are $J^{PC} = 0^{++}$ or 0^{-+}; the apparent absence of the $D\bar{D}$ decay channel favors 0^{-+}.

18.3.3.2 The $Y(3940)$ and $Y(3915)$

A second state, named $Y(3940)$, was observed as a near-threshold peak in the $J/\psi\omega$ invariant mass spectrum in $B \rightarrow J/\psi\omega K$ decays (Abe, 2005g). The $Y(3940)$ state is not seen in $B \rightarrow D^*\bar{D}K$ decays and a lower limit has been set on the ratio $\mathcal{B}(Y(3940) \rightarrow J/\psi\omega)/\mathcal{B}(Y(3940) \rightarrow D^*\bar{D}) > 0.71$ at 90% C.L. (Aushev, 2010); as the $X(3940)$ (discussed above) is seen in $D^*\bar{D}$ but not in $J/\psi\omega$, this strongly suggests that these two states are not the same. The $Y(3940)$ must have positive charge conjugation, while $J = 0, 1, 2$ with either sign parity are possible. The *BABAR* Collaboration confirmed the $Y(3940) \rightarrow J/\psi\omega$ observation in $B \rightarrow J/\psi\omega K$ decays (Aubert, 2008am), but measure a lower mass and narrower width, which are only marginally consistent with the Belle results (see Table 18.3.2); there are various differences between the two analyses, *e.g.* in the assumptions made about the shape of the background. A Belle study of the $\gamma\gamma \rightarrow J/\psi\omega$ reaction (Uehara, 2010b) observed a state, named the
Figure 18.3.7. The $J/\psi\omega$ distribution in $\gamma\gamma$ events as measured by Belle (Uehara, 2010b). The black curve is the result of a fit to the data to determine the $Y(3915)$ mass and width. The dot-dashed curve (brown) represents the result of the fit without the resonant contribution.

$Y(3915)$, with mass and width values consistent with those for the $Y(3940)$ measured by *BABAR* (see Fig. 18.3.7). This observation was confirmed by a *BABAR* analysis of $\gamma\gamma \to J/\psi\omega$ events in which a peak with similar mass and width is seen and an angular correlation study favors a $J^{PC} = 0^{++}$ assignment (Lees, 2012ad).

A likely hypothesis is that the $Y(3940)$ and $Y(3915)$ states coincide, in which case this is the only candidate for an exotic state other than the $X(3872)$ to be seen in two different production mechanisms. The weighted averages of the mass and width measurements listed for $Y(3940)$ and $Y(3915)$ in Table 18.3.2 are $M_{Y(3915)} = (3918.4 \pm 1.9)\,\mathrm{MeV}/c^2$ and $\Gamma_{Y(3915)} = (20 \pm 5)\,\mathrm{MeV}/c^2$. A *BABAR* search for $\gamma\gamma \to Y(3915) \to \eta_c\pi^+\pi^-$ with $\eta_c \to K_S^0 K^\pm\pi^\mp$ found no signal events and established an upper limit of $\Gamma_{\gamma\gamma}(Y(3915)) \times \mathcal{B}(Y(3915) \to \eta_c\pi^+\pi^-) < 91$ eV (Lees, 2012t).

18.3.3.3 The $Z(3930)$

Another state, named $Z(3930)$, was seen by Belle in $\gamma\gamma$ fusion into $D\overline{D}$ (Uehara, 2006). This state has been confirmed by the *BABAR* Collaboration (Aubert, 2010g), which has also performed an angular analysis of the decay products that favors a $J^{PC} = 2^{++}$ assignment. This state is generally accepted as the χ'_{c2}, the $2\,^3P_2$ charmonium state. Details of the relevant analyses can be found in Section 18.2.1.2.

18.3.3.4 Charmonium assignments for the $X(3940)$, $Y(3915)$ and $Z(3930)$?

The $X(3940)$'s prominent decay to $D^*\overline{D}$ taken together with the lack of any evidence for $D\overline{D}$ is strongly suggestive of $J^{PC} = 0^{-+}$ quantum numbers, which implies that the most likely charmonium assignment is the $3\,^1S_0$, commonly known as the $\eta_c(3S)$. This assignment is somewhat problematic because the hyperfine partner state, the $3\,^3S_1$, or $\psi(4040)$, has already been established with a measured mass of $(4040 \pm 4)\,\mathrm{MeV}/c^2$ (Ablikim et al., 2007);

this would imply an $n = 3$ hyperfine splitting of $(98 \pm 8)\,\mathrm{MeV}/c^2$, almost twice as large as the $n = 2$ splitting of $(47 \pm 1)\,\mathrm{MeV}/c^2$.

The *BABAR* study of the $Y(3915)$ state favors a 0^{++} quantum number assignment, for which the closest charmonium level is the $2\,^3P_0$ state, the so-called χ'_{c0}. In this case, its $2\,^3P_2$ multiplet partner is likely the $Z(3930)$ with a measured mass of $(3927\pm3)\,\mathrm{MeV}/c^2$, implying an anomalously small $^3P_2$-$^3P_0$ fine splitting of only $\simeq 10\,\mathrm{MeV}/c^2$ for the $n = 2$ triplet P-wave multiplet (an order of magnitude smaller than the corresponding $n = 1$ splitting). Moreover, the χ'_{c0} is expected to have a partial decay width to $D\overline{D}$ of order $30\,\mathrm{MeV}/c^2$ (Barnes et al., 2005), which, by itself, is substantially wider than the measured total width of the $Y(3915)$. Even though no experimental limits on $\mathcal{B}(Y(3915) \to D\overline{D})$ have been reported to date, no signs of a signal for $Y(3915) \to D\overline{D}$ are evident in the measured $D\overline{D}$ invariant mass distributions for $B \to D\overline{D}K$ decays published by *BABAR* (Aubert, 2008bd) or Belle (Brodzicka, 2008), even though both studies see prominent signals for $B \to \psi(3770)K$, $\psi(3770) \to D\overline{D}$.

The $Z(3930)$ has measured properties that match well to the expectations for the $2\,^3P_2$ charmonium state and has no need for an exotic interpretation.

18.3.4 Other $C = +1$ states

We review now the remaining $C = +1$ resonances. The first is called $X(4160)$, and was discovered by Belle in double charmonium events. It is produced in association with a J/ψ meson and decays into $D^{*+}D^{*-}$ (Pakhlov, 2008; see top panel of Fig. 18.3.8). The fitted mass and width are $M = (4156^{+25}_{-20}\pm15)\,\mathrm{MeV}/c^2$ and $\Gamma = (139^{+111}_{-61} \pm 21)\,\mathrm{MeV}/c^2$. The charge conjugation $C = +1$ is constrained by the production mechanism, which favors also $J = 0$. Hence, this state is a good candidate for a radial excitation of the pseudoscalar charmonium, a $\eta_c(nS)$ state. The identification is discussed in Section 18.2.1.3.

The CDF experiment announced a resonance close to threshold in $J/\psi\phi$ invariant mass, in the channel $B \to J/\psi\phi K$ (Aaltonen et al., 2009a). This state is called $Y(4140)$, and has mass and width $M = (4143.0 \pm 2.9 \pm 1.2)\,\mathrm{MeV}/c^2$ and $\Gamma = (11.7^{+8.3}_{-5.0} \pm 3.7)\,\mathrm{MeV}/c^2$. The natural quantum number would be $J^{PC} = 0^{++}$, but the exotic assignment $J^{PC} = 1^{-+}$ is not excluded. If the latter hypothesis were confirmed, this could be the hybrid ground state. The measured mass is indeed close to lattice calculations for the lightest hybrid meson (for instance, see Bernard et al., 1997). The search for states in this production mechanism at the B Factories suffers from poor acceptance, and thus does not have sufficient statistical power to be conclusive. Some models (Branz, Gutsche, and Lyubovitskij, 2009) predict a copious production of such state in $\gamma\gamma$ fusion. Belle searched in this channel, but found no evidence for a $Y(4140)$. A limit $\Gamma_{\gamma\gamma} \times \mathcal{B}(\phi J/\psi) < 41$ (6) eV for $J^P = 0^+$ (2^+) was set at 90% C.L. for the $Y(4140)$ (Shen, 2010a).

(a) $X(4160) \rightarrow D^{*+} D^{*-}$ from Belle (Pakhlov, 2008)

(b) $X(4350) \rightarrow J/\psi\phi$ from Belle (Shen, 2010a).
Figure 18.3.8. Invariant mass distributions of the most significant observations of states with $C = +1$ and mass above 4 GeV.

During the search for $\gamma\gamma \rightarrow X \rightarrow J/\psi\phi$, Belle found instead a 3.2σ peak with $M = (4350.6^{+4.6}_{-5.1} \pm 0.7)\,\mathrm{MeV}/c^2$ and $\Gamma = (13^{+18}_{-9} \pm 4)\,\mathrm{MeV}/c^2$ (see Fig. 18.3.8, bottom plot). This is possibly another state called $X(4350)$, with $C = +1$ and close in mass to one of the vector states we will discuss in Section 18.3.5.

18.3.5 The 1^{--} family

The most unambiguous way to assign J^{PC} quantum numbers a particle is when it is produced in e^+e^- annihilation, so that its quantum numbers must be the same as the photon ones: $J^{PC} = 1^{--}$. The B Factories can investigate a large range of masses for such particles by looking for events where the emission of an energetic photon by the initial state reduces the e^+e^- center-of-mass energy down to the particle's mass (so-called "ISR" events). Such analyses are discussed in more detail in Chapter 21. Alternatively, dedicated e^+e^- machines, like CESR and BEPC scan directly the center-of-mass energies of interest.

The first new state to be observed via these processes was the $Y(4260) \rightarrow J/\psi\pi^+\pi^-$ resonance seen by *BABAR* (Aubert, 2005y) and promptly confirmed by CLEO both in ISR events (He et al., 2006) and in direct production (Coan et al., 2006). The latter paper also reported evidence for $Y(4260) \rightarrow J/\psi\pi^0\pi^0$ and some events of $Y(4260) \rightarrow J/\psi K^+K^-$.

A *BABAR* search for the $Y(4260)$ in the $\psi(2S)\pi^+\pi^-$ decay channel found no evidence of a signal (Aubert, 2007m),

but, instead, saw a peak at a different mass, the $Y(4350)$. While the absence of $Y(4260) \rightarrow \psi(2S)\pi^+\pi^-$ decays might be understood if the pion pair in the $J/\psi\pi^+\pi^-$ decay were concentrated in an intermediate state (such as $f_0(980) \rightarrow \pi\pi$) that is too massive to be produced with a $\psi(2S)$, the absence of any sign of the $Y(4350) \rightarrow J/\psi\pi^+\pi^-$ is not so easily understood. Cotugno, Faccini, Polosa, and Sabelli (2010) have shown this absence to be significant: $\mathcal{B}(Y(4350) \rightarrow J/\psi\pi^+\pi^-)/\mathcal{B}(Y(4350) \rightarrow \psi(2S)\pi^+\pi^-) < 3.4 \times 10^{-3}$ at the 90% C.L..

Belle subsequently confirmed both of these 1^{--} states (Wang, 2007c; Yuan, 2007), and observed another state in the $\psi(2S)\pi^+\pi^-$ channel that was not visible in *BABAR* data due to the size of the data sample: the $Y(4660)$. Figure 18.3.9 shows Belle's published invariant mass spectra for both the $J/\psi\pi^+\pi^-$ and the $\psi(2S)\pi^+\pi^-$ channels.

An important question is whether or not the pion pair comes from one or more resonant states. Figure 18.3.10 shows the di-pion invariant mass spectra from Belle for events in the $J/\psi\pi^+\pi^-$ and $\psi(2S)\pi^+\pi^-$ invariant mass peaks that correspond to each of the three resonances. Although a subtraction of the continuum background has not been performed, there is some indication that only the $Y(4660)$ has a well defined intermediate state (most likely the $f_0(980)$); the other two peaks have a more complex structure. In addition, the *BABAR* analysis of the $J/\psi\pi^+\pi^-$ channel (Lees, 2012ab) finds some evidence of a $J/\psi f_0(980)$ component. The observation of decays involving an f_0 is particularly interesting because the scalar mesons have long been considered tetraquark candidates (Jaffe, 1977a).

The relative decay rate of these new states into lower-mass charmonium states and into two charm mesons can be used to distinguish between identifications as regular charmonium states and other possibilities. Searches for $Y \rightarrow D^{(*)}\overline{D}^{(*)}$ decay channels carried out by Belle (Abe, 2007d; Pakhlova, 2008a) and *BABAR* (Aubert, 2007u) found no evidence for a signal; 90% C.L. limits from *BABAR* are:

$$\mathcal{B}(Y(4260) \rightarrow D\overline{D})/\mathcal{B}(Y(4260) \rightarrow J/\psi\pi^+\pi^-) < 1.0,$$
$$\mathcal{B}(Y(4260) \rightarrow D^*\overline{D})/\mathcal{B}(Y(4260) \rightarrow J/\psi\pi^+\pi^-) < 34,$$
$$\mathcal{B}(Y(4260) \rightarrow D^*\overline{D}^*)/\mathcal{B}(Y(4260) \rightarrow J/\psi\pi^+\pi^-) < 40.$$
$$(18.3.9)$$

BABAR also set 90% C.L. limits for the $Y \rightarrow D_s^{(*)+} D_s^{(*)-}$ decay channels (del Amo Sanchez, 2010d):

$$\mathcal{B}(Y(4260) \rightarrow D_s^+ D_s^-)/\mathcal{B}(Y(4260) \rightarrow J/\psi\pi^+\pi^-) < 0.7,$$
$$\mathcal{B}(Y(4260) \rightarrow D_s^- D_s^{*-})/\mathcal{B}(Y(4260) \rightarrow J/\psi\pi^+\pi^-) < 44,$$
$$\mathcal{B}(Y(4260) \rightarrow D_s^{*+} D_s^{*-})/\mathcal{B}(Y(4260) \rightarrow J/\psi\pi^+\pi^-) < 30.$$
$$(18.3.10)$$

Analogously, Belle studied $Y \rightarrow D^0 D^{*-}\pi^+$ decays in ISR events as described in Section 21.4.5. The significances for the $Y(4260)$, $Y(4350)$, $Y(4660)$, and $X(4630)$ signals are 0.9σ, 1.4σ, 0.1σ, and 1.8σ, respectively, and the corresponding upper limits on the peak cross sections for
Figure 18.3.9. Distributions of $J/\psi\pi^+\pi^-$ (left; Yuan, 2007) and $\psi(2S)\pi^+\pi^-$ (right; Wang, 2007c) invariant masses in ISR production. The data points (left) and open histogram (right) show the data while the green histograms show the normalized sidebands of the charmonium candidates. The curves show the best fit with two coherent resonances together with a background term; the dashed curve shows the contribution from each component. The interference between the two resonances is not shown. In both cases the likelihood fits to the spectra return two solutions of equally good quality as indicated by the two dashed curves.
Figure 18.3.10. The di-pion invariant mass distribution in $Y(4260) \to J/\psi\pi^+\pi^-$ (left; Yuan, 2007), $Y(4350) \to \psi(2S)\pi^+\pi^-$ (center; Wang, 2007c), and $Y(4660) \to \psi(2S)\pi^+\pi^-$ decays (right; Wang, 2007c). Points are pure signal events, histograms are MC simulations of phase space distributions.

$e^+e^- \to X(Y) \to DD^{*-}\pi^+$ processes are presented in Table 18.3.3. The upper limits presented in the Table are at the 90% C.L. and include systematic uncertainties.

A distinctive signature of tetraquarks would be the observation of 1^{--} states decaying into two baryons since it is easier to form two baryons starting from four constituent quarks than from two (see Cotugno, Faccini, Polosa, and Sabelli, 2010 for details). This motivated a Belle search for the ISR production of resonant structures decaying into $\Lambda_c\bar\Lambda_c$ (Pakhlova, 2008b). A structure is seen near threshold (see Fig. 18.3.11) that, when fitted with a Breit-Wigner line shape, has $M = (4634^{+8+5}_{-7-8})$ MeV/c^2 and $\Gamma_{tot} = (92^{+40+10}_{-24-12})$ MeV/c^2, values that are close to those of the $Y(4660)$. An analysis performed by using the same model for the line-shape of the two measured spectra concluded that the two structures are consistent with the hypothesis that they are the same state with a strong preference for the baryonic decay mode: $\mathcal{B}(Y(4660) \to$

$\Lambda_c\bar\Lambda_c)/\mathcal{B}(Y(4660) \to \psi(2S)\pi\pi) = 25 \pm 7$ (Cotugno, Faccini, Polosa, and Sabelli, 2010).

18.3.5.1 Charmonium assignments for the $Y(4260)$, $Y(4350)$ and $Y(4660)$?

The reasons that at least some of the $Y(4260)$, $Y(4350)$, and $Y(4660)$ are considered as exotic candidates are the lack of unassigned 1^{--} charmonium levels below 4500 MeV/c^2, and the large apparent partial widths of these states in $\pi^+\pi^-$ transitions to the J/ψ or $\psi(2S)$. A comparison of the measured cross section for $e^+e^- \to Y(4260) \to J/\psi\pi^+\pi^-$ with limits on resonance production in the hadron cross section at the same mass leads to the 90% C.L. lower limit $\Gamma(Y(4260) \to J/\psi\pi^+\pi^-) > 1$ MeV/c^2 (Mo et al., 2006). This is much larger than the typical for 1^{--} charmonium states: for instance, the corresponding partial width for the $\psi(3770)$ is 52 ± 8 keV/c^2.

Table 18.3.3. Upper limits on the peak cross section for the processes $e^+e^- \to Y \to D^0D^{*-}\pi^+$, $\mathcal{B}_{ee} \times \mathcal{B}(Y \to D^0D^{*-}\pi^+)$ and $\mathcal{B}(Y \to D^0D^{*-}\pi^+)/\mathcal{B}(Y \to \pi^+\pi^- J/\psi(\psi(2S)))$ at the 90% C.L., where $Y = Y(4260)$, $Y(4350)$, $Y(4660)$, $X(4630)$. From Pakhlova (2009); this analysis is also briefly discussed in Section 21.4.5 (especially Fig. 21.4.9) and Section 18.2.2.2.

		$Y(4260)$	$Y(4350)$	$Y(4660)$	$X(4630)$

The histograms in each case show normalized contributions from Λ_c sidebands. The superimposed curve is the result of the fit reported in the text.

18.3.6 Charged charmonium-like States

A significant turning point in the quest for states beyond the standard charmonium model would be the observation of charged states decaying into charmonium plus accompanying charged hadrons. There is no way to explain such an observation without at least four bound quarks (e.g. $c\bar{c}d\bar{u}$). There is evidence for three such charged states, seen by Belle but not by BABAR: the $Z(4430)^+$ state decaying into $\psi(2S)\pi^+$ (Choi, 2008; see Section 18.3.6.1), and the $Z_1(4050)^+$ and $Z_2(4250)^+$ states decaying into $\chi_{c1}\pi^+$ (Mizuk, 2008; see Section 18.3.6.2).

These states have been observed in B decays in association with a charged kaon, i.e. in three-body $B \to X_{c\bar{c}}\pi K$ decays, where $X_{c\bar{c}} = \psi(2S)$ or χ_{c1}. Three-body decays suffer from interference terms between strong amplitudes mediated by different resonances. In these particular cases the $K\pi$ system has several known resonances that could cause significant reflection effects. Namely, the

decays $B \to X_{c\bar{c}}K^*(892)$, $B \to X_{c\bar{c}}K^*(1410)$, and, in particular, their mutual interference constitute irreducible sources of background which are difficult to estimate.

Further developments on charged states (as this book was being finalised), and some possible future studies, are briefly discussed in Section 18.3.6.3

18.3.6.1 $Z(4430^+) \to \psi(2S)\pi^+$

In the original Belle paper on the observation of the $Z(4430)^+ \to \psi(2S)\pi^+$ resonance in $B \to \psi(2S)\pi^+K$ decays (Choi, 2008), they report the distinct peak in the $M(\psi(2S)\pi^+)$ invariant mass distribution near $4430\,\mathrm{MeV}/c^2$ that is shown in the upper panel of Fig. 18.3.12. Belle argued that this peak could not be due to interference effects in the $K\pi$ channel because in $B \to \psi(2S)\pi^+K$ decays, events with $M(\psi(2S)\pi^+)$ near $4430\,\mathrm{MeV}/c^2$ correspond to $K\pi$ systems with a decay angle $\theta_{K\pi}$ in the region $\cos\theta_{K\pi} \simeq 0.25$, an angular region where interfering S-, P- and D-waves cannot create a peak without other, much larger structures elsewhere.

The Belle analysis was the subject of scrutiny by the BABAR Collaboration, which investigated the same final state by studying in detail the efficiency corrections and the shape of the background, relying for the latter on the data as much as possible (Aubert, 2009at). The search resulted in hints of a structure close to Belle's reported peak, but after estimates of the background they reported an 95% C.L. upper limit on the product branching fraction:

$$\mathcal{B}(B \to Z^+K^-) \times \mathcal{B}(Z^+ \to \psi(2S)\pi^+) < 3.1 \times 10^{-5},$$
(18.3.11)

to be compared with Belle's non-zero value (Choi, 2008)

$$\mathcal{B}(B \to Z^+K^-) \times \mathcal{B}(Z^+ \to \psi(2S)\pi^+) = (4.1^{+1.0}_{-1.4}) \times 10^{-5}.$$
(18.3.12)

Subsequent to the BABAR analysis, Belle made a detailed Dalitz-plot analyses of $B \to \psi(2S)\pi^+K$ events that included interfering amplitudes for all known resonances in the $K\pi$ channel, both with and without a coherent amplitude for a resonance in the $\psi(2S)\pi^+$ channel (Mizuk, 2009). The results of this Belle analysis confirm those from the original report of a significant resonant structure in
Figure 18.3.12. Invariant mass distributions from (top) $\psi(2S)\pi^{\pm}$ (Choi, 2008), and (bottom) $\chi_{c1}\pi^{\pm}$ (Mizuk, 2008), superimposed with fit result showing the charged resonances. In both figures, events with $M(K\pi)$ in the region of the $K^*(890)$ and $K^*(1410)$ peaks are removed. The solid red histogram in the lower figure shows the results of the fit that includes coherent Z_1 and Z_2 amplitudes; the dashed blue curve is the result of the fit using $K\pi$ amplitudes only.

the $\psi(2S)\pi^+$ channel near 4430 MeV/c^2. Although both statistical and systematic uncertainties on the $Z(4430)^+$ resonance parameters increased, the significance of the observed resonance signal remained the same; for the default Dalitz distribution model it was found to be 6.4σ; the fitted mass and width of the $Z(4430)^+ \rightarrow \psi(2S)\pi^+$ from the Dalitz analysis are $M_{Z(4430)^+} = (4443^{+15+19}_{-12-13})$ MeV/c^2 and $\Gamma_{Z(4430)^+} = (109^{+86+74}_{-43-56})$ MeV/c^2.

While we were preparing this book, LHCb performed a four-dimensional fit of the decay amplitude (Aaij et al., 2014b). The $Z(4430)^+$ is confirmed with a significance of 13.9 σ at least; the fitted mass and width are $M_{Z(4430)^+} = (4475 \pm 7^{+15}_{-25})$ MeV/c^2 and $\Gamma_{Z(4430)^+} = (172 \pm 13^{+37}_{-34})$ MeV/c^2, consistent with Belle measurements. Moreover, an analysis of the Argand diagram confirms the resonant character of the $Z(4430)^+$.

18.3.6.2 States decaying to $\chi_{c1}\pi^+$

In a Dalitz-plot analysis of three-body $B \rightarrow \chi_{c1}\pi^+ K$ decays, Belle was unable to get an acceptable fit using only resonances in the $K\pi$ channel (Mizuk, 2008). The inclusion of a single $\chi_{c1}\pi^+$ resonance improved the fit substantially, but still did not reproduce the observed features very accurately. Belle finally settled on a fit that included two resonances in the $\chi_{c1}\pi$ channel: the $Z_1(4050)^+$ and $Z_2(4250)^+$. The $\chi_{c1}\pi^+$ invariant-mass distribution for events in the Dalitz-plot region between the $K^*(980)$ and $K^*(1410)$ bands is shown as data points with the projected final fit shown as a red histogram in the lower panel of Fig. 18.3.12. The fitted masses and widths of the two $\chi_{c1}\pi^+$ resonances are $M_{Z_1^+} = (4051 \pm 14^{+20}_{-41})$ MeV/c^2, $M_{Z_2^+} = (4248^{+44+180}_{-29-35})$ MeV/c^2, $\Gamma_{Z_1^+} = (82^{+21+47}_{-17-22})$ MeV/c^2 and $\Gamma_{Z_2^+} = (177^{+54+316}_{-39-61})$ MeV/c^2, respectively.

BABAR investigated $B \rightarrow \chi_{c1}\pi^+ K$ decays using an analysis that carefully studied the effects of interference between resonances in the $K\pi$ system (Lees, 2012w). They report adequate fits to the data using interfering resonances only in the $K\pi$ channel. They set 95% C.L. upper limits on the product branching fractions to the Z_1^+ and Z_2^+ states by studying the effects of adding incoherent resonant amplitudes for these two states to their fitting model:

$$\mathcal{B}(B \rightarrow Z_1^+ K^-) \times \mathcal{B}(Z_1^+ \rightarrow \chi_{c1}\pi^+) < 1.8 \times 10^{-5},$$
$$\mathcal{B}(B \rightarrow Z_2^+ K^-) \times \mathcal{B}(Z_2^+ \rightarrow \chi_{c1}\pi^+) < 4.0 \times 10^{-5}.$$
$$(18.3.13)$$

For comparison, the non-zero values from Belle for the same quantities are

$$\mathcal{B}(B \rightarrow Z_1^+ K^-) \times \mathcal{B}(Z_1^+ \rightarrow \chi_{c1}\pi^+) = (3.0^{+1.2+3.7}_{-0.8-1.6}) \times 10^{-5},$$
$$\mathcal{B}(B \rightarrow Z_2^+ K^-) \times \mathcal{B}(Z_2^+ \rightarrow \chi_{c1}\pi^+) = (4.0^{+2.3+19.7}_{-0.9-0.5}) \times 10^{-5}.$$
$$(18.3.14)$$

Part of the discrepancy between the two experiments may be due to the fact that in the Belle analysis, the Z_1^+, Z_2^+ and $K\pi$ amplitudes are all coherent and mutually interfere, while in the *BABAR* analysis the Z_1^+ and Z_2^+ terms are added incoherently and do not interfere with the $K\pi$ amplitudes. In the Belle results shown in Fig. 18.3.12 (lower), significant constructive and destructive interference between the Z_1^+ and Z_2^+ amplitudes with the $K\pi$ terms is evident (see the dips and peaks of the solid red curve, relative to the dashed blue curve showing the $K\pi$ amplitude fit result).

18.3.6.3 Other candidates for charged charmonium-like states

Both Belle (Liu, 2013) and BESIII (Ablikim et al., 2013a) have claimed the observation of another charged resonance, $Z(3900)^+$, as a peak in the $J/\psi\pi^+$ invariant mass distribution in $Y(4260) \to \pi^+\pi^- J/\psi$ decay; the Belle peak has Breit-Wigner parameters $M = (3894.5 \pm 6.6 \pm 4.5)\,\mathrm{MeV}/c^2$ and $\Gamma = (63 \pm 24 \pm 26)\,\mathrm{MeV}/c^2$. A structure with similar parameters has also been seen by BESIII in $e^+e^- \to (D\bar{D}^*)^+\pi^-$ (Ablikim et al., 2014b). As this book was being finalised, BESIII also presented evidence for a structure $Z(4020)^+$ in the $h_c\pi^+$ invariant mass distribution in $e^+e^- \to \pi^+\pi^- h_c$ (Ablikim et al., 2013b), with parameters similar to those of a structure $Z(4025)^+$ seen in $e^+e^- \to (D^*\bar{D}^*)^\pm\pi^\mp$ (Ablikim et al., 2014a). Note that charged states $Z_b(10610)^+$ and $Z_b(10650)^+ \to h_b\pi^+$ have been seen by Belle in $\Upsilon(5S) \to h_b\pi^+\pi^-$ (see Section 18.4.5).
Figure 18.3.13. The $D^{*0}D^{*-}$ invariant mass spectrum from $B \to D^{*0}D^{*-}K$ decays from BABAR (Aubert, 2003f). The hatched histograms show the contribution expected from the combinatorial background. The open histograms show the contribution expected for the three-body decay generated with a phase-space model.

A further step in the study of the currently-claimed charged states would be to search for these, or other similar states, in $D^{(*)}\bar{D}^{(*)}$ systems produced in three-body $B \to D^{(*)}\bar{D}^{(*)}K$ decays. For these the experimental efficiencies are lower and detailed three-body amplitude analyses are of limited use with the currently available BABAR and Belle data samples. Nevertheless, results based on existing data samples are intriguing, as can be seen, for example, in the $M(D^{*0}D^{*-})$ invariant-mass distribution for $B \to D^{*0}D^{*-}K$ decays in BABAR (shown in Fig. 18.3.13). Here signs of structure can be seen, but with limited statistical significance. This will be a promising area of research at future flavor factories.

18.3.7 Summary and outlook

The status of experimental studies of exotic charmonium-like states is shown below in tabular form, for the various production mechanisms: B decay (Table 18.3.4), initial state radiation in e^+e^- annihilation (so-called radiative return events; Table 18.3.5), double charmonium production (Table 18.3.6), and two-photon production (Table 18.3.7); studies of charged states are summarized in Table 18.3.8.

As can be seen from the tables, our knowledge is quite fragmentary, despite the large B Factory datasets. Apart from the $X(3872)$ (by far the best-studied state) and the $Y(3915)$, all of the candidate exotic mesons have been observed in only one production mechanism. Most have been observed in only one final state, and none has been the object of a systematic study in a range of final states. Analyses of particular combinations of production mechanism and final state are variously missing, or not performed in the relevant range of invariant mass ("**N**" in the tables), or lacking a fit to the data to test for the presence of exotic states ("**MF**"). To give some examples: the $M(J/\psi\gamma)$ spectra in Fig. 18.3.5 are focussed on the $X(3872)$ region and no information is provided for other masses; the $J/\psi\eta$ invariant mass spectrum in Fig. 18.3.4(b) is published, but not fitted for all the candidate new states. To obtain a more complete picture for any candidate would require either an observation or a limit in many final states, allowing quantitative tests of different models to be performed. For a number of particles where the current data is statistically limited, new decay modes would also add to the evidence for the existence of a new state, as opposed to (say) a final state interaction effect.

States produced in B decays (Table 18.3.4) have been the most studied, although many fits are missing, especially of the baryonic final states $p\bar{p}$ and $\Lambda\bar{\Lambda}$ which are predicted to be important for tetraquark states. Among the decays that have never been studied, $B \to \psi(2S)\pi\pi K$ should be relatively clean, whereas $D_s^{(*)+}D_s^{(*)-}$ modes suffer from the low branching fractions of the usable decays of the final-state D_s mesons.

Analysis of states produced in conjunction with an initial state radiation (ISR) photon (Table 18.3.5) is relatively straightforward, due to the unambiguous $J^{PC} = 1^{--}$ assignment, although the original exotic candidate of this kind, the $Y(4260)$, is still by far the best studied. A complementary set of states, exclusively $C = +1$, is accessible in recoil from a J/ψ in e^+e^- annihilation (Table 18.3.6) an in production via $\gamma\gamma$ fusion (Table 18.3.7). Many of these analyses are challenging, however, due to large backgrounds and (in the case of $\gamma\gamma$ decays) large missing momentum; as a result, the $C = +1$ states seen only through these production mechanisms are relatively poorly studied. Concerning the recoil analyses, production in recoil against particles other than the J/ψ has not been systematically investigated: the available samples in B Factory data are small. Studies of the system recoiling against the χ_{c0} and/or the χ_{c2} would be particularly interesting, given the selection rules.

Table 18.3.4. Status of searches for the new states in the process $B \to XK$, $X \to f$, for several final states f, adapted from Drenska et al. (2010). Following the discussion in Section 18.3.3.2 we treat the state $Y(3940)$ seen in B decay as a different state to the $X(3940)$ seen in $e^+e^- \to X\,J/\psi$ (see Table 18.3.6 below). Final states where each exotic states were observed (**S**: "seen") or excluded (**NS**: "not seen") are indicated. A final state is marked as **N** ("not performed") if the analysis has not been performed in a given mass range and with **MF** ("missing fit") if the spectra are published but a fit to a given state has not been performed. Finally "—" indicates that, although no search has been performed in this mode, the known quantum numbers or available energy forbid the decay; and "hard" that an analysis is experimentally too challenging. The same labels are used in subsequent tables (18.3.5–18.3.8). In the headings, ψ denotes the J/ψ; $\psi' = \psi(2S)$, $2D^* = D^*\bar{D}^*$, and $2D_s^{(*)} = D_s^{(*)+}D_s^{(*)-}$.

Relatively few searches for charged exotic states — the most striking signature of states made of more than two quarks — have been conducted in B decays; as shown in Table 18.3.8, searches have been accomplished for only five combinations of final states and exotic candidates. Ideally, a search for charged partner states should be performed for each neutral exotic meson. A general spectrum of four-quark bound states would also include mesons containing a single s quark, with distinctive strong decays to charmonium plus a charged kaon. Searches for such states could be conducted in B decays in association with an $s\bar{s}$ state, or inclusively at a hadron collider.

In conclusion, a systematic study of the exotic spectrum is required to form a global and definite picture of these states and their structure. As well as finalizing studies with existing B Factory and Tevatron data, results from newer, even higher luminosity machines such as the LHC and the super flavor factories are needed. The apparent confirmation of the $Z(4430)^+$ by LHCb, just as this book was being completed (Aaij et al., 2014b), is both a welcome clarification of the experimental picture, and a reminder that the exotic charmonium-like states — an unexpected product of the bounty of data from the B Factories— must be studied in larger data samples if they are to be more fully understood.

18.4 Bottomonium

18.4.1 Introduction

At the advent of the B-factory experiments, measurements of the spectrum of the bottomonium system were limited to only a few states — the $\Upsilon(nS)$ and $\chi_b(nP)$ resonances. However, the theoretical predictions for this spectrum were abundant and the bottomonium system offered open territory for scientific exploration. The spectrum of the bottomonium system is illustrated in Fig. 18.4.1. Of particular interest were the bottomonium ground state, the $\eta_b(1S)$, and its excitations (the S-wave singlet states, *e.g.* $\eta_b(2S)$), the discovery of the $h_b(nP)$ P-wave singlet states, measurements of their properties and of transitions between bottomonium states as tests of various theoretical frameworks (Lattice QCD, NRQCD, pNRQCD, QCD potential models, etc.). In addition, these measurements allowed for searches for physics beyond the Standard Model (such as violation of universal couplings to leptons, dark matter, and low-mass Higgs bosons).

The bottomonium programs at *BABAR* and Belle yielded a rich assortment of both discoveries and measurements. The ground state of the bottomonium system was first discovered by *BABAR* and later confirmed by Belle, yielding multiple independent mass and branching fraction measurements (Section 18.4.4.2). In addition, Belle discovered the $\eta_b(2S)$ and measured its mass. The *BABAR* Collaboration was the first to show evidence of the existence of the P-wave singlet state, $h_b(1P)$, and the Belle Collaboration demonstrated clear discovery of this state and also of its partner, the $h_b(2P)$ (Section 18.4.4.3). Discovery of these states required in parallel the measurement of transitions between states, and these are detailed in the aforementioned sections. Independent measurements (unconnected with searches for new resonances) of transitions between bottomonium states, as well as decays to hadronic final states, are detailed in Section 18.4.6.

The bottomonium system yielded many surprises, however, when compared to the expectations from theoretical predictions. The Belle confirmation of the $\eta_b(1S)$ and discoveries of the $\eta_b(2S)$ and $h_b(1P, 2P)$ were all made possible in part by apparently large and anomalous $\pi^+\pi^-$ transition rates from the $\Upsilon(5S)$ resonance. This is discussed in Section 18.4.4.3. In addition, as a result of their investigations of these anomalous transition rates, two new states were discovered by the Belle Collaboration just above the open-bottom threshold (Fig. 18.4.1) - the charged Z_b states (Section 18.4.5).
Figure 18.4.1. The bottomonium spectrum. Solid lines correspond to observed states while dashed lines indicate the location of predicted ones. See also the upper plot of Fig. 18.1.1, and the accompanying discussion.

Both collaborations pursued physics beyond the Standard Model using their bottomonium samples. The Belle Collaboration, followed by the *BABAR* Collaboration, both searched for invisible decays of the $\Upsilon(1S)$ meson; these searches, and the theoretical work that motivated them, are discussed in Section 18.4.7.2. The *BABAR* Collaboration also searched for evidence of a low-mass Higgs boson (Section 18.4.7.1), as well as lepton-flavor-violating decays (Section 18.4.7.3) and violation of the universality of couplings to leptons (Section 18.4.7.4).

18.4.2 Common techniques

18.4.2.1 Transition Recoil Method

The use of transition particles between two resonances to "tag" the presence of one of the resonances is a common technique in the bottomonium analyses. Here, we describe the method and its application.

Consider two resonances with masses M_1 and M_2, and a transition between them involving the emission of one or more transition particles, $M_1 \rightarrow (trans) + M_2$. If the transition particles can be reconstructed, and the mass of either the parent or daughter resonance is known, then the remaining mass, which may be said to "recoil" against the transition particles, can be determined from four-momentum conservation:

$$P(M_1) = P(\text{tr}) + P(M_2) \qquad (18.4.1)$$

where $P(\text{tr})$ is the four-vector describing the entire transition-particle energy and momentum. The mass recoiling against the transition particles, defined here as "recoil mass" (though sometimes the term "missing mass" is also used for the same quantity) is then determined by

$$M_{\text{recoil}}^2 \equiv (P(M_1) - P(\text{tr}))^2 = P(M_2)^2 = M_2^2 \quad (18.4.2)$$

where M_{recoil} is defined as the "recoil mass." This expression is valid in any reference frame. It is usually convenient to then choose a reference frame that simplifies the computation while still giving access to the invariant quantity in question.

The most common use of this technique is to determine the mass of a daughter resonance using the four-momentum of the reconstructed transition particles and that of the parent resonance, in the rest frame of the parent resonance. In this case, the equation simplifies to:

$$M_{\text{recoil}}^2 = M_1^2 + m_{\text{tr}}^2 - 2M_1 E_{\text{tr}} \quad (18.4.3)$$

where E_{tr} is the total energy of the transition particles in the parent resonance rest frame and m_{tr}^2 is the total invariant mass-squared of the transition particles.

In many instances, the parent resonance is produced at rest in the center-of-mass (CM) frame of the collider, and when this is true, the above calculation holds exactly. When this is not true, the calculated recoil mass using the transition particles' four-momentum in the CM frame will be shifted due to the presence, for instance, of another intermediate resonance before the transition particles are produced. For instance, if the transition particles are produced in the second of two transitions, e.g. $M_1 \rightarrow (undetected) + M_2$ followed by $M_2 \rightarrow (trans) + M_3$, then Lorentz boosting into the CM frame - the frame of the original parent resonance - will yield a shifted recoil mass.

Most often, sequential transitions in which a shifted recoil mass is observed are transitions in which each of states 1, 2 and 3 is a bottomonium state, and as such the emitted transition particles have small masses and momenta. In such cases transition particle energies and momenta are small compared to the masses M_1, M_2, and M_3. In these cases the amount of the shift is nearly equal to $M_1 - M_2$. When one calculates the recoil mass assuming the transition particles, which were emitted in the second transition, were emitted from the initial state, then the shifted recoil mass obtained is given by

$$M_{\text{shifted}}^2 = (P(M_1) - P(\text{tr}))^2. \quad (18.4.4)$$

This is not equal to M_3^2, which is properly calculated as $(P(M_2) - P(\text{tr}))^2$, assuming both four-momenta are boosted into the CM frame. In our approximation, then, we find (E_i and p_i are the energies and the spatial components of the four momenta $P(M_i)$ and $P(\text{tr})$)

$$\begin{aligned}
M_{\text{shifted}} &= \sqrt{(E_1 - E_{tr})^2 - (p_1 - p_{tr})^2} \\
&= \sqrt{(M_1 - E_{tr})^2 - (p_{tr})^2} \\
&= (M_1 - E_{tr})\sqrt{1 - (p_{tr})^2/(M_1 - E_{tr})^2}
\end{aligned}$$

$$\approx (M_1 - E_{tr}) - p_{tr}^2/2(M_1 - E_{tr}) \quad (18.4.5)$$

and

$$\begin{aligned}
M_3 &= \sqrt{(E_2 - E_{tr})^2 - (p_2 - p_{tr})^2} \\
&= (E_2 - E_{tr})\sqrt{1 - (p_2^2 - p_{tr})^2/(E_2 - E_{tr})^2} \\
&\approx (E_2 - E_{tr}) - (p_2^2 - p_{tr})^2/2(E_2 - E_{tr}). \; (18.4.6)
\end{aligned}$$

We then calculate the shift, $\Delta M = M_{\text{shifted}} - M_3$,

$$\begin{aligned}
\Delta M &= (M_1 - E_2) + (p_2 - p_{tr}^2)/2(M_1 - E_{tr}) \\
&\quad - p_{tr}^2/2(E_2 - E_{tr}) \\
&\approx (M_1 - M_2), \quad (18.4.7)
\end{aligned}$$

since in the cases we are discussing, $E_2 \approx M_2$ and p_2, E_2, and p_{tr} are all much smaller than either M_1 or M_2. Shifted recoil masses of this kind will be observed in the plot of the $M_{\text{recoil}}(\pi^+\pi^-)$ distribution in Figure 18.4.9.

18.4.3 e^+e^- energy scans

As is discussed in Section 18.3, the discovery of non-baryonic charmonium states that behave in ways not predicted by two-quark-system models has yielded a renaissance of experimental and theoretical interplay in quarkonium. The observation of such exotic charmonium states suggests that a similar search for exotic bottomonium states is experimentally warranted. Such searches can be conducted in at least a couple of ways: energy scans of the accelerator across a range of center-of-mass energies, or searches at specific center-of-mass energies. The former will be discussed here, while a discussion of the latter approach can be found in Section 18.4.5.

An energy scan can be used to look for anomalous features in the ratio of the $b\bar{b}(\gamma)$ and $\mu^+\mu^-$ production cross-sections. Exotic charmonium states with quantum numbers $J^{PC} = 1^{--}$ have been observed and named the $Y(4260)$, $Y(4350)$, and $Y(4660)$. One can make naïve predictions for the bottomonium system by taking their masses and scaling them up by the mass difference between the J/ψ and the $\Upsilon(1S)$, yielding predicted masses above the $\Upsilon(4S)$ mass and below $11.2 \, \text{GeV}/c^2$.

During the final two weeks of data taking by the *BABAR* experiment, March 28 – April 7, 2008, the experiment collected $3.9 \, \text{fb}^{-1}$ of data at more than 300 different center-of-mass energies above the $\Upsilon(4S)$ resonance, with typical spacing of 5 MeV. This is a factor of 30 more data than earlier scans (Besson et al., 1985; Lovelock et al., 1985; Aubert, 2009x). An additional $7.8 \, \text{fb}^{-1}$ sample recorded at 10.54 GeV was used to study continuum background.

The quantity of interest is $R_b(s) \equiv \sigma_b(s)/\sigma_{\mu\mu}^0(s)$, the ratio of the total cross section for $e^+e^- \rightarrow b\bar{b}(\gamma)$ divided by the lowest order cross section for $e^+e^- \rightarrow \mu^+\mu^-$. Note that σ_b includes Initial State Radiation (ISR) production of Υ states.

The experimental quantities used to calculate $R_b(s)$ are the number of hadronic events and muon pairs at
Figure 18.4.2. Measured R_b as a function of $\sqrt{s}$ with the position of the opening thresholds of the $e^+e^- \to B_{(s)}^{(*)}\bar{B}_{(s)}^{(*)}$ processes indicated by dotted lines (Aubert, 2009x).
Figure 18.4.3. A zoom of Fig. 18.4.2 with the result of the fit superimposed (Aubert, 2009x). The errors on the data represent the statistical and uncorrelated systematic errors added in quadrature.

center-of-mass energy $\sqrt{s}$ and in the continuum sample. Hadronic events are selected using criteria that preferentially select events with open bottom (B) mesons. Muon pairs are cleanly and efficiently selected using the tracking system and calorimeter only; the muon identification system is not required.

The 10.54 GeV data includes all event types that satisfy the hadronic selection, other than open bottom: continuum $e^+e^- \to q\bar{q}$ (the dominant background), ISR production of Υ, and two photon events. The ISR contribution is calculated using simulated events. The two-photon component, 2% of the continuum sample, is estimated from the direction of the missing-momentum vector. The continuum component is obtained from the 10.54 GeV data by subtracting the other two components.

The efficiency for open bottom events to satisfy the criteria is obtained from simulation. It is taken to be the average of all possible two-body final states. Half the spread is taken as a systematic error.

The resulting values of $R_b(s)$ are shown in Fig. 18.4.2. Note that radiative corrections have not been applied. Not shown in the figure are correlated systematic errors totaling 2.6%, with equal contributions from hadronic event and muon pair efficiencies and $\mu^+\mu^-$ radiative corrections.

The region 10.80–11.20 GeV is fit with a model containing two interfering relativistic Breit Wigner resonances representing the $\Upsilon(10860)$ and the $\Upsilon(11020)$, a flat interfering component, plus an addition flat component representing $b\bar{b}$ continuum not interfering with the resonances (Fig. 18.4.3). The resulting mass and widths are 10.876 ± 0.002 GeV/c^2 and 43 ± 4 MeV for the $\Upsilon(10860)$ and 10.996 ± 0.002 GeV/c^2 and 37 ± 3 MeV for the $\Upsilon(11020)$ (Aubert, 2009x). These widths are considerably narrower than the previous PDG values.

The results are sensitive to the details of the fit model. For example, using a threshold function instead of the flat non-resonant component gives a slightly different mass and a significantly larger width (74 ± 4 MeV) for the $\Upsilon(10860)$. A proper coupled channel approach including

the effects of the various thresholds would undoubtedly modify the results.

Finally it is noted that no evidence for exotic states has been found in the scans.

The Belle Collaboration also conducted a scan above the $\Upsilon(4S)$ resonance, in part in order to investigate possible causes for the anomalously large rates for the processes $\Upsilon(10860) \to \Upsilon(nS)\pi^+\pi^-$ with ($n = 1, 2, 3$) that they had observed (Chen, 2008b). These rates, if the $\Upsilon(10860)$ is interpreted as the fourth radial excitation of the 1^{--} $\Upsilon(1S)$ state, were up to two orders of magnitude larger than expectations.

Belle undertook a scan similar to that conducted by the *BABAR* Collaboration of the cross section for $e^+e^- \to \Upsilon(nS)\pi^+\pi^-$ ($n = 1, 2, 3$) in the vicinity of the known mass of the $\Upsilon(10860)$, taking data at center-of-mass energies between 10.83 and 11.02 GeV (Chen, 2010). In this study, they observed a peak in $\sigma(e^+e^- \to \Upsilon(nS)\pi^+\pi^-)$ ($n = 1, 2, 3$) at an energy of $(10888^{+2.7}_{-2.6}\pm1.2)$ MeV with a width of $(30.7^{+8.3}_{-7.0} \pm 3.1)$ MeV. The measured cross section with the result of the fit using the Breit Wigner function for the signal is shown in Figure 18.4.4 (top).

The important thing to note is that this peak differs substantially in mass from the observed maximum in the overall hadronic cross section (shown in the lower pannel of Fig. 18.4.4), and led to the suggestion that the peak in the $\Upsilon(nS)\pi^+\pi^-$ ($n = 1, 2, 3$) cross section may not, in fact, be due to the $\Upsilon(10860)$ but rather some exotic state (Liu and Ding, 2012).

18.4.4 Spectroscopy

18.4.4.1 Introduction to Bottomonium Spectroscopy

As discussed in Section 18.4.1, the *BABAR* and Belle Collaborations advanced significantly the experimental measurements of states within the predicted bottomonium
Figure 18.4.4. Top: The energy dependence of the cross section for $e^+e^- \to \Upsilon(nS)\pi^+\pi^-$ $(n = 1, 2, 3)$ normalized to the leading order $e^+e^- \to \mu^+\mu^-$ cross section (Chen, 2010). The dashed line shows the energy at which the hadronic cross section is maximal. Bottom: R_b as a function of the energy.

spectrum. At the time that the first $\Upsilon(3S)$ data samples were collected by the Belle and then the *BABAR* Collaborations, predictions of the mass splitting between the lowest-mass S-wave pseudoscalar spin-singlet, $\eta_b(1S)$, and the lowest-mass S-wave vector spin-triplet, $\Upsilon(1S)$, ranged from 36 MeV/c^2 to 100 MeV/c^2 (Godfrey and Rosner, 2001). A measurement of this splitting was clearly critical in establishing which theoretical frameworks more accurately predicted the properties of the bottomonium spectrum and to help inform further developments in those frameworks; a discussion on the theoretical framework of quarkonium physics can be found in Section 18.1. For instance, a measurement of the hyperfine mass splitting would further our understanding of non-relativistic QCD bound states and shed light on the contribution of spin-spin interactions in models of the bottomonium system (Burch and Ehmann, 2007; Gray et al., 2005)

This line of argument also extended to the P-wave spin-singlet states, the $h_b(nP)$, and their properties as predicted in various theoretical frameworks. Prior to their discovery, it was recognized that measuring the hyperfine splitting for the P-wave states was similarly important for assessing the role of spin-spin interactions in potential models for heavy quarks. Treating the bottomonium system non-relativistically, the splitting can be determined from the square of the wave function for the system at the origin. This is expected to be a non-zero quantity for states with $L = 0$; for the P-wave states $(L = 1)$, the splitting between the $h_b(1P)$ and the spin-

averaged triplet state $\langle \chi_{bJ}(1P) \rangle$ is expected to be approximately zero; therefore, one can approximate the mass of the $h_b(1P)$ as the spin-weighted center-of-gravity of the $\chi_{bJ}(1P)$ system: $M(h_b(1P)) = (9899.87 \pm 0.27)\,\mathrm{MeV}/c^2$ (Beringer et al., 2012). If one takes into account higher-order corrections to this approximation, one would expect to observe deviations from this prediction; however, measured deviations from the prediction that correspond to a hyperfine splitting larger than a few MeV/c^2 would indicate a vector component to the confinement potential (Rosner et al., 2005).

In addition to measuring the masses of these states, measuring the branching fractions for the corresponding transitions to and from these states is important for testing theoretical frameworks of heavy quarkonium. The branching fraction for the isospin-violating transition $\Upsilon(3S) \to \pi^0 h_b(1P)$ was expected to be about 0.1% (Godfrey, 2005a; Voloshin, 1986). The branching fraction for the transition $\Upsilon(3S) \to \pi^+\pi^- h_b(1P)$ was expected to range between $\sim 10^{-4}$ (Godfrey, 2005a) and $\sim 10^{-3}$ (Kuang, Tuan, and Yan, 1988; Kuang and Yan, 1981, 1990; Tuan, 1992). The branching fraction for the favored E1 transition $h_b(1P) \to \gamma\eta_b(1S)$ was expected to be large, 41.4% (Godfrey and Rosner, 2002).

18.4.4.2 Observation of the $\eta_b(1S)$ and $\eta_b(2S)$

In the thirty years following the first discovery of the $\Upsilon(nS)$ bottomonium states (Herb et al., 1977), no evidence for the spin-singlet $\eta_b(nS)$ states had been found. The previous best limits for the decays $\Upsilon(3, 2S) \to \gamma\eta_b$ were set by the CLEO experiment (Artuso et al., 2005b). *BABAR* first observed the η_b in 2008 via the $\Upsilon(3S) \to \gamma\eta_b$ decay channel (Aubert, 2008ak). The discovery was confirmed in 2009 in the *BABAR* $\Upsilon(2S)$ data in decays of $\Upsilon(2S) \to \gamma\eta_b$ (Aubert, 2009l). The CLEO experiment subsequently verified the discovery in a re-analysis of its own $\Upsilon(3S)$ data sample (Bonvicini et al., 2010).

These analyses performed fits to the inclusive photon CM energy (E_γ^*) spectrum, searching above the smooth, non-peaking background for evidence of a monochromatic photon associated with a radiative transition to the η_b. Two other peaking components were expected in the energy region close to this signal: one from photons from $\Upsilon(1S)$ production in ISR $(e^+e^- \to \gamma_{ISR}\Upsilon(1S))$, and a merged triplet from the decays $\Upsilon(nS) \to \gamma\chi_{bJ}(mP)$, $\chi_{bJ}(mP) \to \gamma\Upsilon(1S)$, where $m = n - 1$. The photons that result from the decay $\chi_{bJ}(mP) \to \gamma\Upsilon(1S)$ have energies in the range of the searches and thus serve to contribute background photon energy peaks.

The data samples used in the *BABAR* analyses included 28 (14) fb^{-1} collected the $\Upsilon(3S)$ $(\Upsilon(2S))$ resonance, with approximately 9 (7)% of this data (refered to here as the "test sample") used for preliminary studies and later discarded. A total number of $(109 \pm 1) \times 10^6$ $\Upsilon(3S)$ events and $(91.6 \pm 0.9) \times 10^6$ $\Upsilon(2S)$ events were used in the final analysis. Additionally, "off-resonance" samples of 43.9 (2.4) fb^{-1} were taken approximately 40 (30) MeV below

Table 18.4.1. Summary of the optimized variables used in the η_b analyses (Aubert, 2008ak, 2009l).

Variable	$\Upsilon(3S)$	$\Upsilon(2S)$
γ_{LAT}	< 0.55	
$\cos(\theta_{\gamma,LAB})$	$-0.762 < \cos(\theta_{\gamma,LAB}) < 0.890$	
N_{TRK}	> 3	
$\lvert \cos\theta_T \rvert$	< 0.7	< 0.8
$\lvert m_{\gamma\gamma2} - m_{\pi^0} \rvert$	> 15 MeV	
$E_{\gamma2}$	> 50 MeV	> 40 MeV
Efficiency	37%	35.8%

the $\Upsilon(4S)$ ($\Upsilon(3S)$) resonance energies for studies of ISR production.

Candidate photons were single electromagnetic calorimeter (EMC) bumps not matched to any track, with a minimum lab energy of 30 MeV and a lateral moment (Section 15.1.4) less than 0.8. The selection criteria for this analysis were optimized by maximizing the figure of merit $S/\sqrt{B}$, where S represents the number of signal events from $\Upsilon(nS) \rightarrow \gamma\eta_b$ Monte Carlo (MC), and B represents the number of background events taken from the test sample. For optimization purposes, the signal region was restricted to $850 < E_\gamma^* < 950$ ($500 < E_\gamma^* < 700$) MeV for $\Upsilon(3S)$ ($\Upsilon(2S)$). A summary of the optimized selection criteria is given in Table 18.4.1, with the individual variables described below.

To improve photon candidate quality, $\gamma_{LAT} < 0.55$ was required, where "LAT" refers to the lateral moment of the electromagnetic energy deposit. Furthermore, by requiring the photon angle in the lab frame to satisfy $-0.762 < \cos(\theta_{\gamma,LAB}) < 0.890$, only photon candidates with fully-contained electromagnetic showers detected within the barrel of the EMC were used in this analysis. To select hadronic decays of the η_b, the number of charged tracks (N_{TRK}) in the event was required to be greater than or equal to 4, and the ratio of the second to zeroth Fox-Wolfram moments to be less than 0.98. This is typical of the way in which high-multiplicity hadronic final states of B meson decay are selected in the B factories, c.f. Section 9. Background from continuum events was rejected by imposing requirements on $\lvert \cos\theta_T \rvert$, the cosine of the angle in the CM frame between the photon momentum and the thrust axis of the rest of the event. The optimal requirement was found to be $\lvert \cos\theta_T \rvert < 0.7$ (0.8). The dominant background to this analysis, $\pi^0 \rightarrow \gamma\gamma$ decays, was reduced by vetoing photon candidates that, when paired with another photon in the event with a lab energy ($E_{\gamma2}$) greater than 50 (40) MeV, formed an invariant mass ($m_{\gamma\gamma2}$) within 15 MeV/c^2 of the nominal π^0 mass (Beringer et al., 2012). The values for the thrust angle and π^0 veto were optimized simultaneously. The signal efficiency resulting from these selection criteria was 37% (35.8%). The efficiency and selection criteria values were independently verified using the signal yield of the nearby $\chi_{bJ} \rightarrow \gamma\Upsilon(1S)$ signal peaks as a cross-check.

To extract the η_b signal, a binned maximum likelihood fit of the E_γ^* spectrum was performed over the range $0.5 <$

$E_\gamma^* < 1.1$ ($0.27 < E_\gamma^* < 0.80$) GeV for the $\Upsilon(3S)$ ($\Upsilon(2S)$) dataset. The fit contained four components: non-peaking background, $\chi_{bJ} \rightarrow \gamma\Upsilon(1S)$, $\gamma_{ISR}\Upsilon(1S)$, and the η_b signal.

For the $\Upsilon(3S)$ analysis, the non-peaking background was parameterized with a smooth lineshape defined as $f(E_\gamma^*) = A(C + \exp[-\alpha E_\gamma^* - \beta E_\gamma^{*2}])$, where A, C, α, and β were empirically-determined variables. The probability density functions ($p.d.f.$s) for the $\chi_{bJ}(2P) \rightarrow \gamma\Upsilon(1S)$ transitions were parameterized using the Crystal Ball (CB) function (Gaiser, 1982), a Gaussian distribution with an extended, power-law tail on the low side. The relative rates and peak positions for these three decays were fixed to their PDG values (Beringer et al., 2012). The values of the CB parameters were determined from a fit to the background-subtracted data in $840 < E_\gamma^* < 960$ MeV, and are common to all three peaks. Based on MC-simulated events, the ISR $p.d.f.$ was parameterized by a CB function. The $\Upsilon(1S)$ production yield from ISR was measured in the off-resonance $\Upsilon(4S)$ sample, confirmed in $\Upsilon(3S)$ off-resonance data, and extrapolated to fix the size of the contribution in the $\Upsilon(3S)$ on-resonance sample. The η_b signal $p.d.f.$ was a non-relativistic Breit-Wigner function convolved with a CB function to account for the experimental E_γ^* resolution. The CB parameters were fixed from MC events generated with a width of zero, but a natural width of 10 MeV (within the range of theoretical predictions based on expectations for two-photon widths was assumed for the final fit to the data. In the fit, the free parameters were the η_b peak position and yield, the total $\chi_{bJ}(2P)$ yield and peak position, and values of the non-peaking background $p.d.f.$ parameters.

A similar approach was taken for the analysis of the $\Upsilon(2S)$ decay modes. In this case, the non-peaking background was parameterized using the function $g(E_\gamma^*) = D\exp\left(\Sigma_{i=1}^4 c_i E_\gamma^{*i}\right)$, where D and c_i were determined in the fit. A more sophisticated parameterization was used for the $\chi_{bJ}(1P)$ transition peaks. A CB function was analytically convolved with a rectangular function with a width accounting for the Doppler broadening due to the motion of the $\chi_{bJ}(1P)$ relative to the CM frame. The values of the half-width of the rectangular functions were 6.6, 5.5, and 4.9 MeV for the $J = 0, 1, 2$ states, respectively. The CB tail parameters, taken as a free parameter in the final fit, were common to all three peaks, and relative peak positions were fixed to the nominal values (Beringer et al., 2012). The relative yields were fixed to values determined from a control sample of exclusive $\chi_{bJ}(1P) \rightarrow \gamma\Upsilon(1S)$, $\Upsilon(1S) \rightarrow \mu^+\mu^-$ decays. The ISR $p.d.f.$ was determined from MC-simulated events, with the extrapolated yield from the $\Upsilon(4S)$ off-resonance data used only as a cross-check. The η_b signal $p.d.f.$ was parameterized in a fashion identical to $\Upsilon(3S)$ analysis. For the final fit, the free parameters were the η_b peak position and yield, the ISR yield, the total $\chi_{bJ}(1P)$ yield, the $\chi_{b1,2}(1P)$ CB resolutions, the $\chi_{bJ}(1P)$ CB transition point value, an overall energy scale offset based on the $\chi_{bJ}(1P)$ and ISR peak positions, and the power law components for the non-peaking background. The fits to the E_γ^* spectrum for both datasets are shown in Fig. 18.4.5 and 18.4.6.
Figure 18.4.5. (a) Inclusive photon spectrum from $\Upsilon(3S)$ decays in the region $0.50 < E_\gamma^* < 1.1$ GeV (Aubert, 2008ak). The solid line indicates the total fit to the data; the dotted line indicates the non-peaking background component. (b) The same spectrum after the non-peaking background component has been subtracted, with the $\chi_{bJ}(2P)$, ISR, and η_b signal components of the fit indicated from left to right on the plot.

Figure 18.4.6. (a) Inclusive photon spectrum from $\Upsilon(2S)$ decays in the region $0.27 < E_\gamma^* < 0.80$ GeV (Aubert, 2009l). The solid line indicates the total fit to the data. (b) The same spectrum after the non-peaking background component has been subtracted, with the $\chi_{bJ}(1P)$ (cyan), ISR (red), and η_b (blue) signal components from the fit indicated from left to right on the plot.

In the $\Upsilon(3S)$ dataset, systematic uncertainties on the yield due to varying the assumed η_b Breit-Wigner width, the extrapolated ISR yield, and varying the *p.d.f.* parameters were estimated to produce an 11% effect. By far the largest uncertainty (10%) was due to the η_b width assumption. In the $\Upsilon(2S)$ dataset, the largest systematic uncertainties on the yield arise from varying the assumed η_b width and the background shape ($\approx 17\%$ total).

The total systematic uncertainty due to assumptions made on the efficiency calculation was estimated to be 5.5%(6.7%) at the $\Upsilon(3S)$ ($\Upsilon(2S)$).

Combining the two *BABAR* results gave a ratio of branching fractions

$$\frac{\mathcal{B}(\Upsilon(2S) \to \gamma\eta_b)}{\mathcal{B}(\Upsilon(3S) \to \gamma\eta_b)} = 0.89^{+0.25+0.12}_{-0.23-0.16}. \quad (18.4.8)$$

A new, unpredicted pathway to access the $\eta_b(1S)$ and $\eta_b(2S)$ states from $\Upsilon(5S)$ energies allowed Belle to improve substantially the $\eta_b(1S)$ mass measurement, perform the first measurement of its width, and discover the $\eta_b(2S)$.

This progress followed the discovery of the $h_b(nP)$ and Z_b states, which will be described in the following sections, and allowed Belle to access the $\eta_b(1S)$ and $\eta_b(2S)$ states via E1 transitions from the $h_b(nP)$ states. One key development in Belle's ability to study these transitions was the discovery that the $h_b(nP)$ production in e^-e^- collisions at the $\Upsilon(5S)$ resonance is essentially saturated by charged pion cascades through the Z_b states, By requiring that the single charged pion missing mass be consistent with the mass of the Z_b states, significant improvement in the signal to background ratio for the inclusive $M_{\text{miss}}(\pi^+\pi^-) \equiv M_{recoil}(\pi^+\pi^-)$ spectrum was realizable. Using the resulting cleaner $h_b(nP)$ signals and adding the observation of a photon, Belle was able to report the first evidence for the $\eta_b(2S)$ produced in the $h_b(2P) \to \eta_b(2S)\gamma$ transition and the first observation of the $h_b(1P) \to \eta_b(1S)\gamma$ and $h_b(2P) \to \eta_b(1S)\gamma$ transitions (Mizuk, 2012). The $\eta_b(1S)$ samples obtained via this transition chain enabled to improve the mass measurement with respect to the one obtained via M1 transitions, and enabled the $\eta_b(1S)$ width to be measured for the first time.

In this analysis, Belle used a slightly larger data sample than was used in the two analyses which led to the

Figure 18.4.7. The $h_b(1P)$ yield *vs.* $M_{\mathrm{miss}}^{(1)}(\pi^+\pi^-\gamma)$ (a), and $h_b(2P)$ yield *vs.* $M_{\mathrm{miss}}^{(2)}(\pi^+\pi^-\gamma)$ in the $\eta_b(1S)$ region (b) and in the $\eta_b(2S)$ region (c). The solid (dashed) histogram presents the fit result (background component of the fit function). From (Mizuk, 2012).

$M_{recoil}(\pi^+\pi^-\gamma) - M_{recoil}(\pi^+\pi^-) + m_{h_b(nP)}$, and the yield of $h_b(nP)$ radiative decays to $\eta_b(mS)$ was obtained by determining the yield of $h_b(nP)$ as a function of $M_{\mathrm{miss}}^{(n)}(\pi^+\pi^-\gamma)$.

Fits to the $M_{\mathrm{miss}}(\pi^+\pi^-)$ spectra for each $M_{\mathrm{miss}}^{(n)}(\pi^+\pi^-\gamma)$ bin were done using peak shapes for the transitions observed in the inclusive study, keeping the masses of the peaking components fixed at the values given in Table 18.4.5. The combinatorial background was fitted using a polynomial with parameters fixed to the values found in the overall fit, multiplied by a lower-order polynomial with floating coefficients. The resulting $h_b(1P)$ and $h_b(2P)$ yields as a function of $M_{\mathrm{miss}}^{(n)}(\pi^+\pi^-\gamma)$ are presented in Fig. 18.4.7. Clear peaks in $M_{\mathrm{miss}}^{(n)}(\pi^+\pi^-\gamma)$ at 9.4 GeV/c^2 and 10.0 GeV/c^2 were identified as signals for the $\eta_b(1S)$ and $\eta_b(2S)$, respectively.

The branching fraction for these radiative transitions was obtained by fitting the $h_b(nP)$ yield as a function of $M_{\mathrm{miss}}^{(n)}(\pi^+\pi^-\gamma)$ to the sum of the $\eta_b(nS)$ signal components described by the convolution of a non-relativistic Breit-Wigner function with the resolution function and a background parameterized as $e^{f(x)}$, where $f(x)$ is a first- [second-] order polynomial, in the $\eta_b(1S)$ [$\eta_b(2S)$] region. The two $M_{\mathrm{miss}}^{(n)}(\pi^+\pi^-\gamma)$ spectra [from the $h_b(1P)$ and $h_b(2P)$] with $\eta_b(1S)$ signals were fitted simultaneously. In this fit, the width of the $\eta_b(1S)$ Breit-Wigner function was a variable parameter; the width of the $\eta_b(2S)$ was fixed to a value obtained in perturbative calculations (Kwong, Mackenzie, Rosenfeld, and Rosner, 1988):

$$\Gamma_{\eta_b(2S)} = \Gamma_{\eta_b(1S)} \frac{\Gamma_{ee}^{\Upsilon(2S)}}{\Gamma_{ee}^{\Upsilon(1S)}} = (4.9^{+2.7}_{-1.9}) \text{ MeV,} \qquad (18.4.10)$$

discovery of the $h_b(nP)$ and of the Z_b states, described in the next sections: 121.4 fb^{-1} at the $\Upsilon(5S)$ resonance and 12.0 fb^{-1} of energy-scan data collected nearby. A pair of charged pions, selected according to the same criteria as described by Adachi (2012a), and then subject to the requirement that the single charged pion missing mass satisfies the relation:

$$10.59 \text{ GeV}/c^2 < M_{recoil}(\pi^\pm) < 10.67 \text{ GeV}/c^2. \qquad (18.4.9)$$

This cut resulted in a reduction of the combinatorial background by a factor of 5 [1.6] for the $h_b(1P)$ [$h_b(2P)$] without any significant loss of the signal.

Clusters in the electromagnetic calorimeter unassociated with any charged track and which could not be paired with another photon in the event to form a π^0 were identified as photon candidates. The missing mass against $\pi^+\pi^-\gamma$ was then used to form the variable $M_{\mathrm{miss}}^{(n)}(\pi^+\pi^-\gamma) \equiv$

where the uncertainty is due to the experimental uncertainty in $\Gamma_{\eta_b(1S)}$. If the $\eta_b(2S)$ width was allowed to float in the fit, a value of $\Gamma_{\eta_b(2S)} = (4^{+12}_{-20})$ MeV or $\Gamma_{\eta_b(2S)} < 24$ MeV at 90% C.L. using the Feldman-Cousins approach (Feldman and Cousins, 1998) was obtained. Results are given in Tables 18.4.2 and 18.4.3.

Systematic uncertainties in the $\eta_b(nS)$ parameters were evaluated due to the background fit function choice, fit range and binning choice, as well as signal shape and contributions from the experimental $h_b(nP)$ mass uncertainties and photon energy resolution. The various contributions in quadrature to estimate the total systematic uncertainty.

The efficiencies used to normalize the above radiative transition yields were determined using a combination of Monte Carlo and data-driven studies (Mizuk, 2012)

18.4.4.3 Observation of the $h_b(1P, 2P)$

Both the *BABAR* and Belle Collaborations pursued searches for the lowest *P*-wave spin-singlet state, the $h_b(1P)$ (Lees, 2011c) (Adachi, 2012a). These searches and their results are described below.

The *BABAR* Collaboration searched for this state using the experimentally favored transition, $\Upsilon(3S) \to \pi^0 h_b(1P)$, with subsequent decay $h_b(1P) \to \gamma \eta_b(1S)$. This search leveraged the measurement of the η_b mass to constrain the expected energy of the photon. The invariant mass of the system recoiling against the π^0, $M_{\mathrm{recoil}}(\pi^0)$ was then used to search for evidence of a resonance consistent with the h_b. The distribution of $M_{\mathrm{recoil}}(\pi^0)$ was binned, and in each bin a fit was performed to the π^0 mass spectrum to determine the yield. This resulted in a $M_{\mathrm{recoil}}(\pi^0)$ spectrum due only to the recoil against real π^0 mesons. This distribution was then modeled using a combination of a smooth combinatoric background and a peaking distribution resulting from resonance like the h_b (Fig. 18.4.8). The fit to the data determined that there was 3.3σ evidence for a resonance recoiling against the π^0. The mass of this resonance was determined to be $(9902 \pm 4 \pm 2)\,\mathrm{MeV}/c^2$, which is consistent with the prediction of the h_b mass from the spin-weighted average of the $\chi_{bJ}(1P)$ states. The product of the branching fractions $\mathcal{B}(\Upsilon(3S) \to \pi^0 h_b(1P)) \times \mathcal{B}(h_b(1P) \to \gamma \eta_b(1S))$ was determined to be $(4.3 \pm 1.1(\mathrm{stat}) \pm 0.9(\mathrm{syst})) \times 10^{-4}$. This measurement established the first evidence for the existence of the $h_b(1P)$ (Lees, 2011c).

Soon thereafter, the Belle Collaboration announced first observations of both $h_b(1P)$ and its radial excitation $h_b(2P)$ in the reaction $e^+e^- \to h_b(nP)\pi^+\pi^-$ using their $121.4\,\mathrm{fb}^{-1}$ data sample collected at energies near the $\Upsilon(5S)$ resonance (Adachi, 2012a). Among the observations that prompted this search in $\Upsilon(5S)$ data were two anomalous results in data taken above open flavor threshold in both charmonium and bottomonium. First was the observation by CLEO of the process $e^+e^- \to h_c\pi^+\pi^-$ at a rate comparable to that for $e^+e^- \to J/\psi\pi^+\pi^-$ in data taken above open charm threshold (Pedlar et al. (2011)). Such a large rate was unexpected because the production
Figure 18.4.8. The π^0 recoil mass spectrum used by the *BABAR* Collaboration (Lees, 2011c) to search for $\Upsilon(3S) \to \pi^0 h_b(1P)$, shown after subtracting the smooth combinatoric background (black points). The green histogram represents the best-fit value from modeling the data with a signal component. The red-colored square points represent the h_b signal region, and the blue-shaded area indicates the uncertainty in that region due to the background.

of h_c requires a *c*-quark spin-flip, while production of J/ψ does not. Secondly, Belle had previously observed anomalously high rates for $e^+e^- \to \Upsilon(nS)\pi^+\pi^-$ ($n = 1, 2, 3$) at energies near the $\Upsilon(5S)$ mass (Chen, 2008b). These observations motivated Belle to undertake a search for the $h_b(nP)$ states in data taken above open-bottom threshold at and near the $\Upsilon(5S)$ resonance.

Belle undertook an inclusive search for the $h_b(nP)$ states using the distribution of the mass recoiling against $\pi^+\pi^-$, denoted $M_{\mathrm{miss}}(\pi^+\pi^-)$ in what follows. Rather than relying upon Monte Carlo simulations to determine the shape of the $M_{\mathrm{miss}}(\pi^+\pi^-)$ spectrum for signal events, Belle used the $\pi^+\pi^-$ transitions between $\Upsilon(nS)$ states, reconstructed using $\mu^+\mu^-\pi^+\pi^-$ combinations from well-reconstructed four-track events having positively identified $\mu^+\mu^-$ and $\pi^+\pi^-$ pairs. These $\mu^+\mu^-\pi^+\pi^-$ events revealed peaks corresponding to transitions to (and among) the three $\Upsilon(nS)$ states below open-flavor threshold, and masses obtained for each of the $\Upsilon(nS)$ states were consistent within $\pm 1\,\mathrm{MeV}/c^2$ with the world averages for those states.

The search for the $h_b(nP)$ states was performed inclusively on hadronic events, wherein only $\pi^+\pi^-$ candidate pairs were considered. The inclusive $M_{\mathrm{miss}}(\pi^+\pi^-)$ spectrum is dominated by combinatoric $\pi^+\pi^-$ pairs and also, in the region near $M_{\mathrm{miss}}(\pi^+\pi^-) = M(\Upsilon(3S))$ a step increase in the $\pi^+\pi^-$ spectrum which occurs because of the opening up of the threshold for K_s^0 production. This second background shape was obtained by fitting the $\pi^+\pi^-$ invariant mass corresponding to bins of $M_{\mathrm{miss}}(\pi^+\pi^-)$. The fit to the inclusive $M_{\mathrm{miss}}(\pi^+\pi^-)$ spectrum included a polynomial term for the combinatoric background, the K_s^0 shape as just described, and signal shapes for each of
Figure 18.4.9. The spectrum of recoil mass $M_{\text{miss}} \equiv M_{\text{recoil}}(\pi^+\pi^-)$, used by the Belle Collaboration (Adachi, 2012a) to search for $\Upsilon(5S) \to \pi^+\pi^- h_b(nP)$, shown after subtracting the smooth combinatoric background (black points).

the peaks seen in the $\mu^+\mu^-\pi^+\pi^-$ data as well as those arising from $\pi^+\pi^-$ transitions to $h_b(nP)$ and $\Upsilon(1D)$. The $M_{\text{miss}}(\pi^+\pi^-)$ spectrum, after subtraction of both the combinatoric and $K_S^0 \to \pi^+\pi^-$ contributions is shown with the fitted signal functions overlaid in Fig. 18.4.9. The yields and masses obtained in the fits are listed in Table 18.4.4.

Table 18.4.4. Yield and mass obtained in the fit (Adachi, 2012a) to the inclusive $M_{\text{miss}}(\pi^+\pi^-)$ distribution displayed in Fig. 18.4.9. The first uncertainty is statistical, while the second, if present, is the sum of all systematic uncertainties.

	Yield, 10^3	Mass, MeV/c^2
$\Upsilon(1S)$	$105.0 \pm 5.8 \pm 3.0$	$9459.4 \pm 0.5 \pm 1.0$
$h_b(1P)$	$50.0 \pm 7.8^{+4.5}_{-9.1}$	$9898.2^{+1.1+1.0}_{-1.0-1.1}$
$3S \to 1S$	55 ± 19	9973.01
$\Upsilon(2S)$	$143.8 \pm 8.7 \pm 6.8$	$10022.2 \pm 0.4 \pm 1.0$
$\Upsilon(1D)$	22.4 ± 7.8	10166.1 ± 2.6
$h_b(2P)$	$84.0 \pm 6.8^{+23.}_{-10.}$	$10259.8 \pm 0.6^{+1.4}_{-1.0}$
$2S \to 1S$	$151.3 \pm 9.7^{+9.0}_{-20.}$	$10304.6 \pm 0.6 \pm 1.0$
$\Upsilon(3S)$	$45.5 \pm 5.2 \pm 5.1$	$10356.7 \pm 0.9 \pm 1.1$

Systematic uncertainties on the mass and yield of the $h_b(nP)$ states included contributions from the background fit polynomial order, range and bin size used in the fit, variation of selection criteria, and the signal shapes used. By far the most significant source of uncertainty on the yield arose from the choice of signal shape - a relative uncertainty of $^{+9.0\%}_{-18.2\%}$ and $^{+27\%}_{-12\%}$ on the $h_b(1P)$ and $h_b(2P)$ yields, respectively. The most significant source of systematic uncertainty on the $h_b(nP)$ masses (± 1.0 MeV) is estimated from the differences between the fitted masses of the known $\Upsilon(nS)$ states and the world average values. The

signal for the $\Upsilon(1D)$ is marginal ($\sim 2.4\sigma$ statistical significance) and therefore systematic uncertainties on its yield and mass were not evaluated.

The identity of the observed peaks as the $h_b(nP)$ states is established as follows. The observed masses for the $h_b(nP)$ are more than 3σ from the $\chi_{b1}(nP)$ states, and the J^{PC} for the $h_b(nP)$ candidates can be inferred from two observations. The observation by Belle of the $h_b(nP) \to \eta_b(1S)\gamma$ decays (Section 18.4.4.2) establishes the $C-$parity of the states as odd, while the $\chi_{b1}(nP)$ states have even $C-$parity. Similarly, angular analysis of the $\Upsilon(5S) \to h_b(1P)\pi^+\pi^-$ transition (Adachi, 2011) is consistent with the $h_b(1P)$ candidate having $J^P = 1^+$, as required for $h_b(1P)$ states.

The significances of the $h_b(1P)$ and $h_b(2P)$ signals, with systematic uncertainties accounted for, were, in this measurement, 5.5σ and 11.2σ, respectively. The measured masses of $h_b(1P)$ and $h_b(2P)$, $M = (9898.2^{+1.1+1.0}_{-1.0-1.1})$ MeV/c^2 and $M = (10259.8 \pm 0.6^{+1.4}_{-1.0})$ MeV/c^2, respectively, correspond to hyperfine splittings of $\Delta M_{HF} = (+1.7 \pm 1.5)$ MeV/c^2 and $(+0.5^{+1.6}_{-1.2})$ MeV/c^2, respectively, where statistical and systematic uncertainties are combined in quadrature. As expected, then, the hyperfine splittings for both the 1P and 2P levels are consistent with zero.

The ratios $R \equiv \frac{\sigma(h_b(nP)\pi^+\pi^-)}{\sigma(\Upsilon(2S)\pi^+\pi^-)}$ were determined to be $R = 0.45 \pm 0.08^{+0.07}_{-0.12}$ for the $h_b(1P)$ and $R = 0.77 \pm 0.08^{+0.22}_{-0.17}$ for the $h_b(2P)$. Thus $\Upsilon(5S) \to h_b(nP)\pi^+\pi^-$ and $\Upsilon(5S) \to \Upsilon(2S)\pi^+\pi^-$ proceed at similar rates, despite the fact that the production of $h_b(nP)$ requires a spin-flip of a b quark. The measured rates for $\Upsilon(5S) \to h_b(nP)\pi^+\pi^-$ are much larger than the upper limit for that of $\Upsilon(3S) \to h_b(nP)\pi^+\pi^-$ obtained by the *BABAR* Collaboration (Lees, 2011l). This is consistent with the similarly anomalously high rates for $\Upsilon(5S) \to \Upsilon(mS)\pi^+\pi^-$ with $m = 1, 2, 3$.
Figure 18.4.10. The $M_{\mathrm{miss}}(\pi^+\pi^-)$ spectrum with the combinatorial background and K_S^0 contribution subtracted (points with errors) and signal component of the fit function overlaid (smooth curve) in the $h_b(1P)$ (a) and $h_b(2P)$ (b) regions (Mizuk, 2012).

Subsequent studies on this anomaly lead to the discovery of the charged Z_b states, which will be described later in this chapter, and which mediate 100% of the $\pi^+\pi^-$ transitions to the $h_b(nP)$ states. This observation allowed a further reduction of the combinatorial background by a factor of 5 [1.6] for the $h_b(1P)$ [$h_b(2P)$], by imposing the requirement:

$$10.59\,\mathrm{GeV}/c^2 < M_{recoil}(\pi^+\pi^-) < 10.67\,\mathrm{GeV}/c^2$$

$$(18.4.11)$$

on the mass recoiling against the single pion.

The $M_{\mathrm{miss}}(\pi^+\pi^-)$ spectra in the $h_b(1P)$ and $h_b(2P)$ regions, defined as $9.8\,\mathrm{GeV}/c^2 - 10.1\,\mathrm{GeV}/c^2$ and $10.1\,\mathrm{GeV}/c^2 - 10.4\,\mathrm{GeV}/c^2$, are shown in Fig. 18.4.10. The fit procedure was essentially identical to that described before, using a fit function that is the sum of peaking

Table 18.4.5. The yield and mass of peaking components from the fits to the $M_{\mathrm{miss}}(\pi^+\pi^-)$ (Mizuk, 2012). The first quoted uncertainty is statistical (unless stated otherwise) and the second (if present) is systematic. Parameters without uncertainties were fixed in the fit.

	N, 10^3	Mass, MeV/c^2
$\Upsilon(5S) \to h_b(1P)$	$70.3 \pm 3.3^{+1.9}_{-0.7}$	$9899.1 \pm 0.4 \pm 1.0$
$\Upsilon(3S) \to \Upsilon(1S)$	13 ± 7	9973.0
$\Upsilon(5S) \to \Upsilon(2S)$	61.3 ± 4.1	10021.3 ± 0.5
$\Upsilon(5S) \to \Upsilon(1D)$	14 ± 7	10169 ± 3
$\Upsilon(5S) \to h_b(2P)$	$89.5 \pm 6.1^{+0.0}_{-5.8}$	$10259.8 \pm 0.5 \pm 1.1$
$\Upsilon(2S) \to \Upsilon(1S)$	97 ± 12	10305.6 ± 1.2
$\Upsilon(5S) \to \Upsilon(3S)$	58 ± 8	10357.7 ± 1.0

components, a background shape due to the threshold for K_S^0 production, and a combinatorial background. The resulting masses and yields are listed in Table 18.4.5.

Systematic uncertainties in the $h_b(nP)$ parameters arise from the fitting procedure, including polynomial order, fit interval and signal shape. An additional ± 1 MeV/c^2 uncertainty in the mass measurements is added, based on the observed deviations of the masses obtained for previously known vector bottomonium states, as in Adachi (2012a).

These updated mass measurements correspond to hyperfine splittings of $\Delta M_{\mathrm{HF}}(1P) = (+0.8 \pm 1.1)$ MeV/c^2 and $\Delta M_{\mathrm{HF}}(2P) = (+0.5 \pm 1.2)$ MeV/c^2, where statistical and systematic uncertainties in mass are added in quadrature.

18.4.4.4 $\Upsilon(1D)$

The existence of the bottomonium D-wave states has been established. The CLEO Collaboration reported observation of the D-wave triplet bottomonium state, $\Upsilon(1\,^3D_J)$, where $J = 1, 2, 3$ (Bonvicini et al., 2004). They report observation of a single member of the triplet, $\Upsilon(1\,^3D_2)$, using the decay $\Upsilon(1\,^3D_2) \to \gamma\gamma\Upsilon(1S)$. They identify the state in their analysis as corresponding to the $\Upsilon(1\,^3D_2)$ based on the fact that the mass and branching fractions in question correspond well to the theoretical predictions; however, they were not able to experimentally verify the assignment of quantum numbers L and J.

The BABAR Collaboration reported in 2010 the observation of the $J = 2$ state of the $\Upsilon(1\,^3D_J)$ triplet using instead the hadronic decay transition $\Upsilon(1\,^3D_2) \to \pi^+\pi^-\Upsilon(1S)$, with subsequent leptonic decay of the $\Upsilon(1S)$ state, $\Upsilon(1S) \to \ell^+\ell^-$ (where $\ell = e, \mu$) (del Amo Sanchez, 2010k). The analysis was performed using a sample of $(121.8 \pm 1.2) \times 10^6$ $\Upsilon(3S)$ mesons. The parent $\Upsilon(3S)$ was then subsequently observed to decay to the D-wave state via a two-photon radiative transition, $\Upsilon(3S) \to \gamma\gamma\Upsilon(1\,^3D_J)$. An intermediate $\chi_{bJ'}(2P)$ state is produced between the radiation of the first and second photon, where $J' = 0, 1, 2$. The presence of these intermediate resonances implies a pattern of energies that one can use in
Figure 18.4.11. The mass spectrum of the $\Upsilon(1\,^3D_J)$ candidates, and the unbinned maximum likelihood fit to the spectrum. Background peaks from several sources are evident in the spectrum and modeled in the fit. A clear signal from the D-wave triplet is also evident (del Amo Sanchez, 2010k).

Figure 18.4.12. The dipion mass spectrum for the background-subtracted data in the region $10.155 < m_{\pi^+\pi^-\ell^+\ell^-} < 10.68\,\text{GeV}/c^2$. The shapes expected from S-wave, D-wave, and $1P_1$ states are shown (del Amo Sanchez, 2010k).

the search to reject background and identify candidates for the signal processes in question.

Events are required to contain exactly four good charged tracks. Two of the tracks must be identified as same-flavor, opposite-charge leptons. The pion candidates are taken to be the remaining two tracks and must fail an electron requirement. Radiative Bhabha events, a background to this event topology, are rejected by requiring that the electron satisfy a laboratory polar angle requirement, $\cos(\theta) < 0.8$.

The $\Upsilon(1S)$ candidate is selected by making flavor-dependent mass requirements on the lepton pairs: $-0.35 < m_{e^+e^-} - m_{\Upsilon(1S)} < 0.2\,\text{GeV}/c^2$ or $|m_{\mu^+\mu^-} - m_{\Upsilon(1S)}| < 0.2\,\text{GeV}/c^2$. The mass of the dilepton pair is then constrained to the nominal $\Upsilon(1S)$ mass. The pions can be faked by a photon conversion in material. To reject this background, the opening angle between the pions must satisfy $\cos\theta_{\pi^+\pi^-} < 0.95$ if $m_{\pi^+\pi^-} < 0.050\,\text{GeV}/c^2$; for any dipion mass, the angle between the dipion system and either of the leptons must satisfy $\cos\theta_{\pi^+\pi^-,\ell^\pm} < 0.98$.

The events are also required to contain at least two photons, with minimum energy requirements (one with CM energy $> 0.070\,\text{GeV}$ and the other with CM energy $> 0.060\,\text{GeV}$) consistent with the typical energies expected from the transition photons. Final-state radiation photons are rejected by requiring that $\cos\theta_{\gamma,\ell} < 0.98$. If there is more than one photon pair combination that satisfies these requirements, the pair whose energies minimize a χ^2 constructed from the measured and expected photon energies is chosen as the best pair.

The $\Upsilon(1\,^3D_J)$ candidate is combined with the photon pair to form the $\Upsilon(3S)$ candidate, whose momentum must be $< 0.3\,\text{GeV}/c$. The $\Upsilon(3S)$ candidate mass is then constrained to the nominal mass value.

An extended unbinned maximum likelihood fit is then performed on the mass of the $\pi^+\pi^-\ell^+\ell^-$ system (Fig. 18.4.11). The fit includes components for several expected backgrounds, which were studied using MC simulation: $\Upsilon(3S)$ decays to $\gamma\chi_b(2P_{J'}) \to \gamma\omega\Upsilon(1S)$, $\pi^+\pi^-\Upsilon(1S)$,
$\eta\Upsilon(1S)$, and $\gamma\gamma(\pi^0\pi^0)\Upsilon(2S)$. The models for these and signal are obtained from MC simulation. A clear excess exists in the region where $\Upsilon(1\,^3D_J)$, and is fitted with the signal model.

Large data control samples of dipion transitions to $\Upsilon(1S)$ and $\Upsilon(2S)$ final states, directly from the parent $\Upsilon(3S)$, are used to validate the *p.d.f.*s used in the fit to the spectrum. Where shifts are present between the *p.d.f.* parameters determined from MC or data, the shifts are applied as corrections. Only a small shift in the reconstructed mass of the $\Upsilon(2S)$ is observed.

The yield of D-wave triplet states is as follows (determined from the fit to the data): $10.6^{+5.7}_{-4.9}\ \Upsilon(1\,^3D_1)$, $33.9^{+8.2}_{-7.5}\ \Upsilon(1\,^3D_2)$, and $9.4^{+6.2}_{-5.2}\ \Upsilon(1\,^3D_1)$. Fit biases for the yield of signal events are determined by applying the data model to 2000 data-sized MC samples with events randomly drawn from the simulation subsamples. The biases are found to typically be at the level of 1-2 events in the signal region, and these biases are subtracted from the signal yields.

Multiplicative systematic uncertainties arise from various sources, with the largest of them being the photon reconstruction efficiency (3.0%) and particle identification (2.0%). Additive systematic uncertainties arise from the *p.d.f.* shapes, and total 1.5-2.0 events in the signal yields.

The statistical significance of the signal yield for the $J = 2$ D-wave triplet state is 6.5σ (5.8σ) including statistical (statistical and systematic) uncertainties.

The quantum numbers of the state are determined by studying the $\pi^+\pi^-$ mass distribution after subtracting the backgrounds in the region $10.155 < m_{\pi^+\pi^-\ell^+\ell^-} < 10.68\,\text{GeV}/c^2$. The dipion mass distribution is shown in Fig. 18.4.12, compared to the shapes expected from an S-

wave, D-wave, and $1P_1$ state. The data are observed to be most consistent with the D-wave hypothesis.

18.4.5 Discovery of charged Z_b states

In an effort to explain the large rate of dipion transitions to $\Upsilon(nS)$ and $h_b(nP)$ states in e^+e^- annihilation at energies near $\Upsilon(5S)$, which suggest that exotic mechanisms contribute to $\Upsilon(5S)$ decays, Belle searched for evidence of resonant substructures in these decays (Bondar, 2012). For the analysis of $\pi^+\pi^-$ transitions to $\Upsilon(nS)$ states, the $\Upsilon(nS)$ states were observed in their $\mu^+\mu^-$ decays, which led to a relatively background-free sample for investigation. Transitions to $h_b(nP)$ states were investigated inclusively by examining only the $\pi^+\pi^-$ transition pairs.

$\Upsilon(nS)$ samples were obtained using four-track events, positively identified as a $\pi^+\pi^-$ and $\mu^+\mu^-$ pair, subject to the requirement that $|M_{\text{miss}}(\pi^+\pi^-) - M(\mu^+\mu^-)| < 0.2\,\text{GeV}/c^2$, where $M_{\text{miss}}(\pi^+\pi^-)$ is the missing mass recoiling against the $\pi^+\pi^-$ system, and that $|M_{\text{miss}}(\pi^+\pi^-) - m_{\Upsilon(nS)}| < 0.05\,\text{GeV}/c^2$. Sideband regions for the study of background were defined as $0.05\,\text{GeV}/c^2 < |M_{\text{miss}}(\pi^+\pi^-) - m_{\Upsilon(nS)}| < 0.10\,\text{GeV}/c^2$. The $h_b(nP)$ samples utilized events in which only the $\pi^+\pi^-$ system was selected.

Amplitude analysis of the three-body $\Upsilon(5S) \rightarrow \Upsilon(nS)\pi^+\pi^-$ employed unbinned maximum likelihood fits to the two-dimensional $M^2[\Upsilon(nS)\pi^+]$ vs. $M^2[\Upsilon(nS)\pi^-]$ Dalitz distributions. Signal events were found to make up more than 90% of the events in the signal region, and the efficiency-corrected distribution of background events (from $\Upsilon(nS)$ sidebands) was found to be featureless across the Dalitz plot. As an example, the Dalitz distributions of events in the $\Upsilon(2S)$ sidebands and signal regions are shown in Fig. 18.4.13 where, for ease of visualization, the square of the larger of the two $\Upsilon(nS)\pi$ masses is plotted vs. the square of the dipion invariant mass. One-dimensional invariant mass projections for events in each $\Upsilon(nS)$ signal region are shown in Fig. 18.4.14, where two peaks are observed in the $\Upsilon(nS)\pi$ system near 10.61 GeV/c^2 and 10.65 GeV/c^2, and are subsequently referred to as $Z_b(10610)$ and $Z_b(10650)$, respectively.

The parameterization of the $\Upsilon(5S) \rightarrow \Upsilon(nS)\pi^+\pi^-$ three-body decay amplitude includes terms corresponding to the Z_b states as well as $f_0(980)$, $f_2(1270)$ and a non-resonant contribution:

$$M = A_{Z_1} + A_{Z_2} + A_{f_0} + A_{f_2} + A_{\text{nr}}. \quad (18.4.12)$$

In performing the fit, it was assumed that the dominant contributions come from amplitudes that preserve the orientation of the spin of the heavy quarkonium state and, thus, both pions in the cascade decay $\Upsilon(5S) \rightarrow Z_b\pi \rightarrow \Upsilon(nS)\pi^+\pi^-$ are emitted in an S-wave with respect to the heavy quarkonium system. Subsequent angular studies, as outlined in Bondar (2012), support this assumption.

The $Z_b(10610)$ and $Z_b(10650)$ peaks were parameterized with an S-wave Breit-Wigner function, and, to allow for the $\Upsilon(5S)$ decay to both $Z_b^+\pi^-$ and $Z_b^-\pi^+$, the amplitudes A_{Z_1} and A_{Z_2} were symmetrized with respect to π^+
Figure 18.4.13. Dalitz plots for $\Upsilon(2S)\pi^+\pi^-$ events in the $\Upsilon(2S)$ sidebands (upper); $\Upsilon(2S)$ signal region (lower). Events to the left of the vertical line are excluded. From (Bondar, 2012).

and π^- transposition:

$$A_{Z_k} = a_{Z_k}e^{i\delta_{Z_k}}(BW(s_1, M_k, \Gamma_k) + BW(s_2, M_k, \Gamma_k)), \quad (18.4.13)$$

where $s_1 = M^2[\Upsilon(nS)\pi^+]$, $s_2 = M^2[\Upsilon(nS)\pi^-]$. Results of the fits to $\Upsilon(5S) \rightarrow \Upsilon(nS)\pi^+\pi^-$ signal events are shown in Fig. 18.4.14, and numerical results are summarized in Table 18.4.6, where the relative normalization is defined as the ratio of amplitudes a_{Z_2}/a_{Z_1} and the relative phase as $\delta_{Z_2} - \delta_{Z_1}$. The systematic uncertainties on the parameters in Table 18.4.6 includes all evaluated sources - the greatest of which is related to the parameterization of the decay amplitude, and was studied by fitting the data with several modifications of the nominal model (Eq. 18.4.12).

For the study of $\Upsilon(5S) \rightarrow h_b(nP)\pi^+\pi^-$ resonant substructure (which is naturally a much more background-dominated study given the inclusive nature of the $\pi^+\pi^-$
Figure 18.4.14. Comparison of fit results (open histogram) with experimental data (points with error bars) for events in the $\Upsilon(1S)$ (upper), $\Upsilon(2S)$ (middle), and $\Upsilon(3S)$ (lower) signal regions. The hatched histogram shows the background component. From (Bondar, 2012).

Figure 18.4.15. The (a) $h_b(1P)$ and (b) $h_b(2P)$ yields as a function of $M_{\mathrm{recoil}}(\pi)$ (points with error bars) and results of the fit (histogram). From (Bondar, 2012).

detection) the yield of Z_b states contributing to $h_b(nP)$ production is measured as a function of the $h_b(1P)\pi^\pm$ invariant mass by fitting the $M_{\mathrm{miss}}(\pi^+\pi^-)$ spectra in bins of $M_{\mathrm{miss}}(\pi^\mp)$, the mass recoiling against $\pi^\mp$ (which is equivalent to the $h_b(1P)\pi^\pm$ invariant mass). The yields of $\Upsilon(5S) \rightarrow h_b(nP)\pi^+\pi^-$ $(n = 1, 2)$ decays as a function of the $M_{\mathrm{recoil}}(\pi)$ (both signs of π are included) are shown in Fig. 18.4.15. The distributions for the $h_b(nP)$ exhibit a clear two-peak structure without a significant non-resonant contribution. To fit the $M_{\mathrm{recoil}}(\pi)$ distributions for Z_b yields, a combination of P-wave Breit-Wigner amplitudes is used:

$$|BW_1(s, M_1, \Gamma_1) + ae^{i\phi}BW_1(s, M_2, \Gamma_2) + be^{i\psi}|^2 \frac{qp}{\sqrt{s}}.$$

$$(18.4.14)$$

where $\sqrt{s} \equiv M_{\mathrm{recoil}}(\pi)$; the variables M_k, Γ_k $(k = 1, 2)$, a, ϕ, b and ψ are free parameters; $\frac{qp}{\sqrt{s}}$ is a phase-space factor, where p (q) is the momentum of the pion originating from the $\Upsilon(5S)$ (Z_b) decay measured in the rest frame of the corresponding mother particle. The P-wave Breit-Wigner amplitude is expressed as $BW_1(s, M, \Gamma) = \frac{\sqrt{M\,\Gamma}\,F\,(q/q_0)}{M^2 - s - iM\,\Gamma}$. Here F- is the P-wave Blatt-Weisskopf form factor $F = \sqrt{\frac{1 + (q_0 R)^2}{1 + (qR)^2}}$, q_0 is a daughter momentum calculated with pole mass of its mother, $R = 1.6$ GeV^{-1}.

The function (Eq. 18.4.14) is convolved with the detector resolution function ($\sigma = 5.2$ MeV/c^2), integrated over the 10 MeV/c^2 histogram bin and corrected for the reconstruction efficiency. The fit results are shown as solid histograms in Fig. 18.4.15 and the numerical results are summarized in Table 18.4.6. The non-resonant contribution to $h_b(nP)$ production is consistent with zero [significance is $0.3\,\sigma$ both for the $h_b(1P)$ and $h_b(2P)$], while the default fit hypothesis is favored over the phase-space fit hypothesis at the $18\,\sigma$ [$6.7\,\sigma$] level for the $h_b(1P)$ [$h_b(2P)$].

Systematic uncertainies were studied by evaluating contributions from the background function used in fits to the $M_{\mathrm{miss}}(\pi^+\pi^-)$ spectra, effects of finite bin size in the fits, model uncertainties, and data-MC comparisons. An additional 1 MeV/c^2 uncertainty in mass measurements was applied, as in the previous analysis, based on the difference between the observed $\Upsilon(nS)$ peak positions and their world averages (Adachi, 2012a). The total systematic uncertainty presented in Table 18.4.6 is the sum in quadrature of contributions from all sources. After inclusion of systematic uncertainties, the significance of the $Z_b(10610)$ and $Z_b(10650)$ including systematic uncertainties was $16.0\,\sigma$ [$5.6\,\sigma$] for the $h_b(1P)$ [$h_b(2P)$].

The two charged bottomonium-like resonances $Z_b(10610)$ and $Z_b(10650)$ are hence firmly established with signals in five different decay channels, $\Upsilon(nS)\pi^\pm$ $(n = 1, 2, 3)$ and $h_b(nP)\pi^\pm$ $(m = 1, 2)$. The weighted averages over all five channels give $M = 10607.2 \pm 2.0$ MeV/c^2, $\Gamma = 18.4 \pm 2.4$ MeV for the $Z_b(10610)$ and $M = 10652.2 \pm 1.5$ MeV/c^2, $\Gamma = 11.5 \pm 2.2$ MeV for the $Z_b(10650)$, where statistical and systematic errors are added in quadrature. The $Z_b(10610)$ production rate is similar to that of the $Z_b(10650)$ for each of the five decay channels. Their relative phase is consistent with zero for the final states with the $\Upsilon(nS)$ and consistent with 180 degrees for the final states with $h_b(nP)$. Production of the Z_b's saturates the $\Upsilon(5S) \rightarrow h_b(nP)\pi^+\pi^-$ transitions and accounts for the high inclusive $h_b(mS)$ production rate reported in Adachi (2012a). Analyses of charged pion angular distributions (Bondar, 2012) favor the $J^P = 1^+$ spin-parity assignment for both the $Z_b(10610)$ and $Z_b(10650)$. Since the $\Upsilon(5S)$ has negative G-parity, the Z_b states have positive G-parity due to the emission of the pion.

Table 18.4.6. Comparison of results on $Z_b(10610)$ and $Z_b(10650)$ parameters obtained from $\Upsilon(5S) \to \Upsilon(nS)\pi^+\pi^-$ ($n = 1, 2, 3$) and $\Upsilon(5S) \to h_b(nP)\pi^+\pi^-$ ($m = 1, 2$) analyses (Bondar, 2012).

Final state	$\Upsilon(1S)\pi^+\pi^-$	$\Upsilon(2S)\pi^+\pi^-$	$\Upsilon(3S)\pi^+\pi^-$	$h_b(1P)\pi^+\pi^-$	$h_b(2P)\pi^+\pi^-$
$M[Z_b(10610)]$, MeV/c^2	$10611 \pm 4 \pm 3$	$10609 \pm 2 \pm 3$	$10608 \pm 2 \pm 3$	$10605 \pm 2^{+3}_{-1}$	10599^{+6+5}_{-3-4}
$\Gamma[Z_b(10610)]$, MeV	$22.3 \pm 7.7^{+3.0}_{-4.0}$	$24.2 \pm 3.1^{+2.0}_{-3.0}$	$17.6 \pm 3.0 \pm 3.0$	$11.4^{+4.5+2.1}_{-3.9-1.2}$	13^{+10+9}_{-8-7}
$M[Z_b(10650)]$, MeV/c^2	$10657 \pm 6 \pm 3$	$10651 \pm 2 \pm 3$	$10652 \pm 1 \pm 2$	$10654 \pm 3^{+1}_{-2}$	10651^{+2+3}_{-3-2}
$\Gamma[Z_b(10650)]$, MeV	$16.3 \pm 9.8^{+6.0}_{-2.0}$	$13.3 \pm 3.3^{+4.0}_{-3.0}$	$8.4 \pm 2.0 \pm 2.0$	$20.9^{+5.4+2.1}_{-4.7-5.7}$	$19 \pm 7^{+11}_{-7}$
Rel. normalization	$0.57 \pm 0.21^{+0.19}_{-0.04}$	$0.86 \pm 0.11^{+0.04}_{-0.10}$	$0.96 \pm 0.14^{+0.08}_{-0.05}$	$1.39 \pm 0.37^{+0.05}_{-0.15}$	$1.6^{+0.6+0.4}_{-0.4-0.6}$
Rel. phase, degrees	$58 \pm 43^{+4}_{-9}$	$-13 \pm 13^{+17}_{-8}$	$-9 \pm 19^{+11}_{-26}$	187^{+44+3}_{-57-12}	$181^{+65+74}_{-105-109}$

The minimal quark content of the $Z_b(10610)$ and $Z_b(10650)$ is a four-quark combination. The masses of these new states are a few MeV/c^2 above the thresholds for the open beauty channels $B^*\overline{B}$ (10604.6 MeV/c^2) and $B^*\overline{B}^*$
(10650.2 MeV/c^2), which suggests a "molecular" nature of these new states, which might explain most of their observed properties (Bondar, Garmash, Milstein, Mizuk, and Voloshin, 2011), although other possible interpretations have also been offered (Bugg, 2011; Cui, Liu, and Huang, 2012; Danilkin, Orlovsky, and Simonov, 2012; Guo, Cao, Zhou, and Chen, 2011).

18.4.6 Transitions and decays

18.4.6.1 Introduction to transitions and decays

Measuring the transitions between bottomonium states, independent of trying to discover new states, also provides important information for theoretical predictions of heavy quarkonium systems. These transitions can be predicted by effective potential models, and for existing measurements of transitions in the bottomonium system the data appeared well described (cf. Brambilla et al., 2004; Eichten, Godfrey, Mahlke, and Rosner, 2008). At leading order, the dominant radiative decays (those involving emission of a photon) are expected to be electric (E1) or magnetic (M1) transitions. If the bottomonium system is treated as a non-relativistic bound state, the predictions are relatively straight-forward and well-characterized. The picture is complicated, however, in transitions such as $\Upsilon(nS) \to \gamma\eta_b(mS)$, where $n > m$, which are referred to as "hindered" M1 transitions between the S-wave bottomonium states. In the case of $\Upsilon(3S) \to \gamma\chi_{bJ}(1P)$, there is an overlap between the wave functions of the initial state and the final state; this makes the calculation of such transitions more complex. One experimental goal in measuring such transitions is to improve our understanding of the non-relativistic effects in heavy quarkonium systems, which should in turn inform and improve the theoretical calculations.

Charmonium spectroscopy is a field revived after the operation of the two B Factories. States with $J^{PC} = 1^{--}$ may be studied using ISR in the large $\Upsilon(4S)$ data samples.

For a study of charge-parity-even charmonium states, radiative decays of the Υ states below open-bottom threshold may be used.

The production rates of the lowest-lying P-wave spin-triplet (χ_{cJ}, $J=0$, 1, or 2) and S-wave spin-singlet (η_c) states in $\Upsilon(1S)$ radiative decays are calculated (Gao, Zhang, and Chao, 2007), where the former is at the part per million level, and the latter is about 5×10^{-5}. The rates in $\Upsilon(2S)$ decays are estimated to be at the same level.

We know that the OZI-suppressed decays of J/ψ and $\psi(2S)$ to hadrons occur by annihilation of the charm quarks into three gluons or a photon. In either case, pQCD predicts (Appelquist and Politzer, 1975; De Rujula and Glashow, 1975)

$$Q_\psi = \frac{\mathcal{B}_{\psi(2S)\to h}}{\mathcal{B}_{J/\psi\to h}} = \frac{\mathcal{B}_{\psi(2S)\to e^+e^-}}{\mathcal{B}_{J/\psi\to e^+e^-}} \approx 12\% \quad (18.4.15)$$

This relation is referred to as the "12% rule" which is expected to hold to a reasonably good degree for both inclusive and exclusive decays. But the measured experimental data do not follow this rule. The prediction by Eq. 18.4.15 is severely violated in the $\rho\pi$ and several other decay channels. This is the so-called "$\rho\pi$ puzzle". It was first observed by Mark-II Collaboration in 1983 (Franklin et al., 1983). From then on many experimental studies and theoretical explanations have been put forth to decipher this puzzle (Mo, Yuan, and Wang, 2006).

As this so-called "12% rule" in ψ decays is derived from the pQCD and potential models, it is expected to be valid for the bottomonium family, namely, the Υs. Since there are three narrow Υ states below the bottom meson threshold, we expect, using PDG average values of the branching fractions:

$$Q_{21} = \frac{\mathcal{B}_{\Upsilon(2S)\to h}}{\mathcal{B}_{\Upsilon(1S)\to h}} = \frac{\mathcal{B}_{\Upsilon(2S)\to e^+e^-}}{\mathcal{B}_{\Upsilon(1S)\to e^+e^-}} = 0.77 \pm 0.07,$$

$$Q_{31} = \frac{\mathcal{B}_{\Upsilon(3S)\to h}}{\mathcal{B}_{\Upsilon(1S)\to h}} = \frac{\mathcal{B}_{\Upsilon(3S)\to e^+e^-}}{\mathcal{B}_{\Upsilon(1S)\to e^+e^-}} = 0.88 \pm 0.09,$$

$$Q_{32} = \frac{\mathcal{B}_{\Upsilon(3S)\to h}}{\mathcal{B}_{\Upsilon(2S)\to h}} = \frac{\mathcal{B}_{\Upsilon(3S)\to e^+e^-}}{\mathcal{B}_{\Upsilon(2S)\to e^+e^-}} = 1.14 \pm 0.15.$$

$$(18.4.16)$$

These "pQCD rules" should hold better than the 12% rule in ψ decays, since the bottomonium states have higher
Figure 18.4.16. The converted-photon energy spectrum, after subtracting the smooth background (Lees, 2011m). These data were taken at the $\Upsilon(2S)$ resonance.

masses, and pQCD and the potential models should work better, as has been the case for calculations of the bottomonium spectrum.

18.4.6.2 Radiative transitions between bottomonium states

The radiative transitions between Υ and χ_{bJ} states were a background to the discovery of the bottomonium ground state (c.f. Section 18.4.4.2). These transition rates are generally precisely predicted (Section 18.1); however, more precise experimental measurements were needed to determine the accuracy of the methods used to make those predictions. The method used to discover the η_b used photons reconstructed using only the *BABAR* electromagnetic calorimeter. The resolution of the χ_{bJ} transitions is limited by the energy resolution of the calorimeter, which was insufficient to convincingly separate the transitions to and from the three χ_{bJ} states.

For the *BABAR* Collaboration measurement discussed in this section, photon transitions were reconstructed using photons that had converted in material. This results in a much-improved photon energy resolution, reducing it from 25 MeV using calorimeter-only photons to 5 MeV using converted photons. The improved resolution allows for the separation of many radiative transitions. The photon energy spectrum was analyzed (Lees, 2011m) using data taken at the $\Upsilon(3S)$ in three different energy regions: $E^* = [180, 300]$ MeV, $[300, 600]$ MeV, and $[600, 1100]$ MeV. This was done so that regions expected to contain different kinds of transitions could be separately studied. The data taken at the $\Upsilon(2S)$ resonance was analyzed in a single bin, $E^* = [300, 800]$ MeV. Besides studying prominent transitions, a goal of this approach was to "re-discover" the η_b and make an additional measurement of its using an independent technique.

The primary background in these measurements arises due to using a randomly chosen converted photon as the candidate photon from a bottomonium transition. This
Figure 18.4.17. The converted-photon energy spectrum, after subtracting the smooth background (Lees, 2011m). These data were taken at the $\Upsilon(3S)$ resonance. In the lower plot, χ denotes $\chi_{b2}(2P)$.

background is again modeled using a smooth function, and is subtracted (as in Fig. 18.4.16 and 18.4.17). The contributions from monochromatic photons are modeled using functions that describe both their peak location and detector resolution effects.

The $\Upsilon(3S)$ data in the range $[180, 300]$ MeV were expected to contain three monochromatic peaks due to the transitions $\chi_{bJ}(2P) \rightarrow \gamma\Upsilon(2S)$ and six monochromatic peaks due to the transitions $\Upsilon(1D_J) \rightarrow \gamma\chi_{bJ}(1P)$. Due to the very low rates for these latter transitions, the properties of the models describing these transitions are fixed from existing measurements of the masses of the involved states. The branching fractions for the $\chi_{bJ}(2P) \rightarrow \gamma\Upsilon(2S)$ transitions are determined from the data and shown in Table 18.4.7.

The $\Upsilon(3S)$ data in the range $[300, 600]$ MeV were expected to contain photons from the six transitions $\Upsilon(3S) \rightarrow \gamma\chi_{bJ}(1P)$ and $\chi_{bJ}(1P) \rightarrow \gamma\Upsilon(1S)$. The photons from these transitions are all comparable in energy and were expected to overlap. In addition, this region could also contain photons from the $h_b(1P) \rightarrow \gamma\eta_b(1S)$ transition. No evidence was seen for this latter transition, and the measured rates for the transition $\Upsilon(3S) \rightarrow \gamma\chi_{bJ}(1P)$ are given in Table 18.4.7. The pattern of these transitions is unusual for quarkonium, with the pattern for the relative rates to the different $J = 0, 1, 2$ χ_{bJ} states being $J = 2 > 0 > 1$.

A comment on the non-observation of $h_b(1P) \rightarrow \gamma\eta_b(1S)$ in this search may be helpful, since in Section 18.4.4.3 a discussion was made of the discovery by the Belle Collaboration of the transition $h_b(1P) \rightarrow \gamma\eta_b(1S)$. From Table 18.4.7, we can see that the smallest branching fraction to which this search method had sensivity at the $\Upsilon(3S)$ resonance was at the level of $0.03 - 0.04\%$ (limited by the statistical uncertainty of the sample). The favored transition for $\Upsilon(3S) \rightarrow h_b(1P)$ is via radiation of a π^0, and the branching fraction for that process is expected to be at the level of 0.1%, while the branching fraction for $h_b(1P) \rightarrow \gamma\eta_b(1S)$ was measured by the Belle Collaboration to be about 49%, (Mizuk, 2012) as mentioned in Section 18.4.4.1.

The product of these two branching fractions, marking the rate at which $h_b(1P)$ is expected to be produced from the $\Upsilon(3S)$ in the *BABAR* data sample, is therefore about 0.05%, comparable to the statistical uncertainty of this technique. This product of branching fractions is confirmed by the evidence from the *BABAR* Collaboration for $\Upsilon(3S) \rightarrow \pi^0 h_b(1P)$, $h_b(1P) \rightarrow \gamma\eta_b(1S)$, discussed in Section 18.4.4.3.

Another predicted leading process from the $\Upsilon(3S)$ that can produce the $h_b(1P)$ is $\Upsilon(3S) \rightarrow \pi^+\pi^- h_b(1P)$, but this has been found by the *BABAR* Collaboration to occur with a branching fraction $< 2.5 \times 10^{-4}$ at 90% confidence level (Lees, 2011l). In addition, the contribution of these processes to the photon spectrum overlaps with the much more significant $\chi_{b0}(1P)$ spectral line. Therefore, the non-observation of this photon spectral line in the data from this photon-conversion technique is consistent with independent evidence that the rate is below or comparable to the statistical sensitivity of this technique. In fact, in this study the contribution from these two sources was a fixed component of the fit, and found to be comparable to statistical uncertainties in the region where such a signal would be expected.

Table 18.4.7. Measured radiative transition rates, where the first uncertainty is statistical, the second is due to systematic effects, and the third (where present) is due to uncertainties on secondary branching fractions (Lees, 2011m). Numbers in parentheses are the 90% confidence level upper limits.

Transition	Branching Fraction in %
$\Upsilon(3S) \rightarrow \gamma\chi_{b0}(1P)$	$0.27 \pm 0.04 \pm 0.02$
$\Upsilon(3S) \rightarrow \gamma\chi_{b1}(1P)$	$0.05 \pm 0.03^{+0.02}_{-0.01} (< 0.10)$
$\Upsilon(3S) \rightarrow \gamma\chi_{b2}(1P)$	$1.06 \pm 0.03^{+0.07}_{-0.06}$
$\chi_{b0}(1P) \rightarrow \gamma\Upsilon(1S)$	$2.2 \pm 1.5^{+1.0}_{-0.7} \pm 0.2 (< 4.6)$
$\chi_{b1}(1P) \rightarrow \gamma\Upsilon(1S)$	$34.9 \pm 0.8 \pm 2.2 \pm 2.0$
$\chi_{b2}(1P) \rightarrow \gamma\Upsilon(1S)$	$19.5 \pm 0.7^{+1.3}_{1.5} \pm 1.0$
$\chi_{b0}(2P) \rightarrow \gamma\Upsilon(2S)$	$-4.7 \pm 2.8^{+0.7}_{-0.8} \pm 0.5 (< 2.8)$
$\chi_{b1}(2P) \rightarrow \gamma\Upsilon(2S)$	$18.9 \pm 1.1 \pm 1.2 \pm 1.8$
$\chi_{b2}(2P) \rightarrow \gamma\Upsilon(2S)$	$8.3 \pm 0.8 \pm 0.6 \pm 1.0$
$\chi_{b0}(2P) \rightarrow \gamma\Upsilon(1S)$	$0.7 \pm 0.4^{+0.2}_{-0.1} \pm 0.1 (< 1.2)$
$\chi_{b1}(2P) \rightarrow \gamma\Upsilon(1S)$	$9.9 \pm 0.3^{+0.5}_{0.4} \pm 0.9$
$\chi_{b2}(2P) \rightarrow \gamma\Upsilon(1S)$	$7.0 \pm 0.2 \pm 0.3 \pm 0.9$

Finally, the $\Upsilon(3S)$ data in the range $[600, 1100]$ MeV were expected to contain photons due to the transitions $\chi_{bJ}(2P) \rightarrow \gamma\Upsilon(1S)$ and $\Upsilon(3S) \rightarrow \gamma\eta_b(1S)$. The latter transition was seen, but only with a significance of 2.7σ and so no independent measurement of the $\eta_b(1S)$ mass was possible from this sample; more data is needed to fully utilize this technique for measuring that transition. However, the rates for the transitions $\chi_{bJ}(2P) \rightarrow \gamma\Upsilon(1S)$ were measured and are reported in Table 18.4.7.

The $\Upsilon(2S)$ data in the range $[300, 800]$ MeV were expected to contain photons due to the transitions $\chi_{bJ}(1P) \rightarrow \gamma\Upsilon(1S)$ and $\Upsilon(2S) \rightarrow \gamma\eta_b(1S)$. No evidence was seen for the latter transitions, and the rates of the transitions $\chi_{bJ}(1P) \rightarrow \gamma\Upsilon(1S)$ are reported in Table 18.4.7.

18.4.6.3 Searches for $\Upsilon(1S)$ and $\Upsilon(2S)$ radiative transitions to charmonium states

The Belle Collaboration searched for radiative transitions from $\Upsilon(2S)$ (Shen, 2010b) and $\Upsilon(1S)$ (Wang, 2011) to charmonium states using the following data samples : on-resonance samples of 5.7 fb^{-1} at the $\Upsilon(1S)$ (102 million $\Upsilon(1S)$ events) and a 24.7 fb^{-1} at the $\Upsilon(2S)$ (158 million $\Upsilon(2S)$ events), and continuum samples of 1.8 fb^{-1} at $\sqrt{s} = 9.43$ GeV and 1.7 fb^{-1} collected at $\sqrt{s} = 9.993$ GeV.

The search for the χ_{cJ} was conducted using the $\gamma J/\psi$ mode, where J/ψ was observed in both $\mu^+\mu^-$ and e^+e^- decay modes. The $\mu^+\mu^-$ mode shows a clear J/ψ signal, while the e^+e^- mode has some residual radiative Bhabha background. No clear χ_{cJ} signal is observed in both $\Upsilon(1S)$ and $\Upsilon(2S)$ data samples, as shown in Fig. 18.4.18.

The search for η_c was done using full hadronic reconstruction of the η_c in the modes: $K_S K^\pm\pi^\mp$, $\pi^+\pi^- K^+K^-$, $2(K^+K^-)$, $2(\pi^+\pi^-)$, and $3(\pi^+\pi^-)$. The combined mass
Figure 18.4.18. The $\gamma J/\psi$ invariant mass distributions in (top) the $\Upsilon(1S)$ (Shen, 2010b) and (bottom) $\Upsilon(2S)$ (Wang, 2011) data samples. No clear χ_{cJ} signal is observed. The solid curve is the best fit, the dashed curve is the background, and the shaded histogram is from the normalized J/ψ mass sidebands.

distributions of the hadronic final states are shown in Fig. 18.4.19 for the five η_c decay modes from $\Upsilon(1S)$ and $\Upsilon(2S)$ data, respectively. The large J/ψ signal is due to the ISR process $e^+e^- \to \gamma_{ISR}J/\psi$, while the accumulation of events within the η_c mass region is small.

18.4.6.4 Searches for $\Upsilon(1S)$ and $\Upsilon(2S)$ radiative transitions to charmonium-like states

In addition to many conventional charmonium states, a number of charmonium-like states (the so-called "XYZ particles") have been discovered with unusual properties. These may include exotic states, such as quark-gluon hybrids, meson molecules, and multi-quark states (Brambilla et al., 2011). Many of these new states are established in a single production mechanism or in a single decay mode only. To better understand them, it is necessary to search for such states in more production processes and/or decay modes. For charge-parity-even charmonium-like states, radiative decays of the narrow Υ states below the open bottom threshold can be examined. There are no calculations for radiative decays for "XYZ particles" due to the limited knowledge of their nature.

The Belle Collaboration searched for four of these XYZ states, the $X(3872)$, $X(3915)$, $Y(4140)$ and $X(4350)$, us-
Figure 18.4.19. The mass distributions for a sum of the five η_c decay modes (top) from $\Upsilon(1S)$ (Shen, 2010b) and (bottom) $\Upsilon(2S)$ (Wang, 2011) data, respectively. The solid curve is a sum of the corresponding functions obtained from a simultaneous fit to all the η_c decay modes, and the dashed curve is a sum of the background functions from the fit. The shaded histogram is a sum of the continuum events (not normalized in $\Upsilon(2S)$ data). The J/ψ signal is produced via ISR rather than from a radiative decay of an $\Upsilon(nS)$ resonance.

ing the $\Upsilon(1S)$(Shen, 2010b) and $\Upsilon(2S)$ (Wang, 2011) data samples described in the previous section.

The $X(3872)$ signal was searched for via $X(3872) \to \pi^+\pi^- J/\psi$ and $\pi^+\pi^-\pi^0 J/\psi$. Except for a few residual ISR produced $\psi(2S)$ signal events, only a small number of events appear in the $\pi^+\pi^- J/\psi$ invariant mass distributions for both $\Upsilon(1S)$ and $\Upsilon(2S)$ decays. Belle observed two events in the $\Upsilon(1S)$ data with masses of 3.67 GeV/c^2 and 4.23 GeV/c^2; only a few events were observed in the $\Upsilon(2S)$ data.

The search for $X(3915)$ was undertaken in the $\omega J/\psi$ mode. No events were observed within the $X(3915)$ mass region in $\Upsilon(1S)$ data. One event was observed with $m(\pi^+\pi^-\pi^0 J/\psi)$ at 3.923 GeV/c^2 and $m(\pi^+\pi^-\pi^0)$ at 0.790 GeV/c^2 from $\Upsilon(2S)$ data.

Finally, the $Y(4140)$ in both $\Upsilon(1S)$ and $\Upsilon(2S)$ data, and $X(4350)$ in $\Upsilon(2S)$ data only were searched for using the $\phi J/\psi$ mode. No candidates were observed in either in the $Y(4140)$ or $X(4350)$ mass regions.

Since there is no evidence for charmonium or charmonium-like states signals in the modes studied, Belle placed upper limits on the branching fractions of $\Upsilon(1S)$

Table 18.4.8. Summary of the limits on $\Upsilon(1S)$ and $\Upsilon(2S)$ radiative decays to charmonium and charmonium-like states R. Here $\mathcal{B}_R$ is the upper limit at the 90% C.L. on the decay branching fraction in the charmonium state case, and on the product branching fraction in the case of a charmonium-like state.

State (R)	$\mathcal{B}_R$ ($\Upsilon(1S)$)	$\mathcal{B}_R$ ($\Upsilon(2S)$)
χ_{c0}	6.5×10^{-4}	1.0×10^{-4}
χ_{c1}	2.3×10^{-5}	3.6×10^{-6}
χ_{c2}	7.6×10^{-6}	1.5×10^{-5}
η_c	5.7×10^{-5}	2.7×10^{-5}
$X(3872) \to \pi^+\pi^- J/\psi$	1.6×10^{-6}	0.8×10^{-6}
$X(3872) \to \pi^+\pi^-\pi^0 J/\psi$	2.8×10^{-6}	2.4×10^{-6}
$X(3915) \to \omega J/\psi$	3.0×10^{-6}	2.8×10^{-6}
$Y(4140) \to \phi J/\psi$	2.2×10^{-6}	1.2×10^{-6}
$X(4350) \to \phi J/\psi$	$\cdots$	1.3×10^{-6}

and $\Upsilon(2S)$ radiative decays. Table 18.4.8 lists final results for the upper limits on the branching fractions. The results obtained on the χ_{cJ} and η_c production rates are consistent with the theoretical predictions of Gao, Zhang, and Chao (2007). With much larger $\Upsilon(1S)$ and $\Upsilon(2S)$ data samples in the future at super flavor factories, we can obtain better results for charmonium final states which can tell us if experimental results support or disfavor theoretical predictions. If any one of charmonium-like states can be observed, it will do much help to understand its nature.

18.4.6.5 Search for $\chi_b(1P)$ exclusive decays to double charmonium

The cross sections of the double-charmonium production processes $e^+e^- \to J/\psi\eta_c$, $J/\psi\eta_c'$, $\psi(2S)\eta_c$, $\psi(2S)\eta_c'$, $J/\psi\chi_{c0}$, and $\psi(2S)\chi_{c0}$ measured at the Belle (Abe, 2002j, 2004g) and *BABAR* (Aubert, 2005n) experiments were approximately an order of magnitude larger than the leading order non-relativistic QCD (NRQCD) predictions (Braaten and Lee, 2003; Liu, He, and Chao, 2003, 2008). It was shown that the calculations are very sensitive to the choices of the values of some parameters (Bodwin, Lee, and Braaten, 2003; Bodwin, Lee, and Yu, 2008; Braaten and Lee, 2003; He, Fan, and Chao, 2007; Zhang, Gao, and Chao, 2006) and the agreement between theory and experiment can be achieved if one takes into account radiative and relativistic corrections.

Similar to the production in e^+e^- annihilation, double charmonium final states can also be produced in bottomonium decays, which supplied a new test of the dynamics of hard exclusive processes and the structure of the charmonia. While $\eta_b \to J/\psi J/\psi$ has been calculated (Sun, Hao, and Qiao, 2011), the P-wave spin-triplet bottomonium states χ_{bJ} (J=0, 1, 2) decays into double charmonium states were calculated using different theoretical models.

Under the NRQCD factorization approach, Zhang, Dong, and Feng (2011) calculated $\chi_{bJ} \to J/\psi J/\psi$ to a relativistic correction of the order v_c^2 and considered a small pure QED contribution. The branching fraction is predicted to be of order 10^{-5} for χ_{b0} or $\chi_{b2} \to J/\psi J/\psi$, and 10^{-11} for $\chi_{b1} \to J/\psi J/\psi$; Sang, Rashidin, Kim, and Lee (2011) considered the corrections to all orders in the charm-quark velocity v_c in the charmonium rest frame, and found decay partial widths that are about a factor of three larger than those determined by Zhang, Dong, and Feng (2011). In the light cone (LC) formalism, however, much larger production rates (with also large uncertainties) are obtained by Braguta, Likhoded, and Luchinsky (2009): $\mathcal{B}(\chi_{bJ} \to J/\psi J/\psi) = 9.6 \times 10^{-5}$ or 1.1×10^{-3}, $\mathcal{B}(\chi_{bJ} \to J/\psi\psi(2S)) = 1.6 \times 10^{-4}$ or 1.6×10^{-3}, and $\mathcal{B}(\chi_{bJ} \to \psi(2S)\psi(2S)) = 6.6 \times 10^{-5}$ or 5.9×10^{-4} for J=0 or 2, respectively. It is therefore very important to pin down the source of such significant discrepancies between the NRQCD factorization and LC formalisms.

In perturbative QCD theory, the branching fraction of $\mathcal{B}(\chi_{b0} \to J/\psi J/\psi) \approx 3 \times 10^{-5}$ and for χ_{b1} decays, it is even larger (Kartvelishvili and Likhoded, 1984). It has been argued (Braguta, Likhoded, and Luchinsky, 2005) that taking into account the relative motion of quarks in the amplitude of the decay of χ_b meson to c-quarks increases the branching fractions of the decays of χ_{b0} (0^{++}) and χ_{b2} (2^{++}) into a pair of J/ψ mesons by an order of magnitude.

Based on a 24.7 fb^{-1} $\Upsilon(2S)$ data sample collected by the Belle Collaboration, no significant signals are found for the $\chi_{bJ} \to J/\psi J/\psi$, $J/\psi\psi(2S)$, or $\psi(2S)\psi(2S)$ final states (Shen, Yuan, Iijima, 2012). The upper limits on the χ_{bJ} decay branching fractions are lower than the theoretical predictions using LC formalism, while are not in contradiction with other calculations(Zhang, Dong, and Feng, 2011) using NRQCD factorization approach.

18.4.6.6 Two-body Hadronic Transitions: π^0, η

In the charmonium system, single-meson transitions between states have been well-established; the transition $\psi' \to \eta J/\psi$ has a branching ratio of 3.3%, one tenth of the dominant $\pi^+\pi^-$ transition (Beringer et al., 2012). In contrast, the first such transition in the bottomonium system, $\chi_b(2P) \to \omega\Upsilon(1S)$, was observed by the CLEO Collaboration in 2002 (Severini et al., 2004).

Generally, the hadronic transitions between heavy quarkonia are described by the QCD multipole expansion model (QCDME) (Kuang, 2006). In this framework the $\pi\pi$ transitions are mediated by the emission of two gluons in the E1 state, while the η transitions proceed either via E1M2 or M1M1 terms. Such terms should be suppressed by a factor which is inversely proportional to the mass of the heavy quark. The suppression should be even larger when the η is replaced by π^0, and the transition violates isospin. In the case of charmonium, the suppression factor is about 1/25. In the proximity of thresholds, coupled channel effects can provide different mechanisms to evade the spin flip suppression.
Figure 18.4.20. The distribution of $M_{3\pi}$ vs $\Delta M_\eta = M_{3\pi ll} - M_{ll}$ for $\eta\Upsilon(1S)$ candidate events, demonstrating the observed signal (Aubert, 2008bc). Solid lines delimit the signal region, while dashed lines delimit the sideband regions used for the background estimate. Crosses represent the data from the $\Upsilon(1S) \to e^+e^-$ sample and dots the data from the $\Upsilon(1S) \to \mu^+\mu^-$ sample.

Figure 18.4.21. Signal of $\Upsilon(2S) \to \eta\Upsilon(1S)$ from the Belle Collaboration result (Tamponi, 2013).

The *BABAR* Collaboration observed the transition $\Upsilon(4S) \to \eta\Upsilon(1S)$ (Aubert, 2008bc) using $347.5\,\text{fb}^{-1}$ of data taken at the $\Upsilon(4S)$ resonance. The observed rate was 2.5 times larger than that of the $\Upsilon(4S) \to \pi^+\pi^-\Upsilon(1S)$ transition, which is the dominant hadronic transition in both charmonium and bottomonium. The *BABAR* Collaboration performed the search for the hadronic transitions $\pi^+\pi^-\Upsilon(1,2S)$ and $\eta\Upsilon(1S)$ using the $\eta \to \pi^+\pi^-\pi^0$ mode, where the Υ is decaying either to e^+e^- or to $\mu^+\mu^-$. Candidate events were selected requiring at least four charged tracks in acceptance; the lepton candidates are required to have center-of-mass momentum between 4.20 and $5.25\,\text{GeV}/c$, and the dilepton pair is required to have invariant mass within $\pm 200\,\text{MeV}$ $\left(^{+200}_{-350}\,\text{MeV}\right)$ of the nominal $\Upsilon(1S)$ ($\Upsilon(2S)$) mass. The dipion and dilepton candidates are constrained to have a common vertex.

The dominant background is due to $e^+e^-\gamma$ and $\mu^+\mu^-\gamma$, where a photon converts in material and creates an e^+e^- pair that is misidentified as a pion pair. This background is rejected by requiring the pion pair to have an opening angle above $18°$ in the laboratory frame; in addition, the invariant mass of the low momentum pair, calculated assuming the $e^\pm$ mass hypothesis, is required to satisfy $m_{e^+e^-} > 100\,\text{MeV}/c^2$.

The two photons used in π^0 reconstruction are required to have $E_\gamma > 50\,\text{MeV}$ and an invariant mass, $m_{\gamma\gamma}$, in the range $[110, 150]\,\text{MeV}/c^2$. The residual background, from $\Upsilon(mS) \to \pi\pi\Upsilon(nS)$ transitions, is reduced by requiring $\Delta M = M_{\pi\pi ll} - M_{ll}$ to be at least $20\,\text{MeV}/c^2$ away from

known transitions. The distribution of $M_{3\pi}$ vs $\Delta M_\eta = M_{3\pi ll} - M_{ll}$ for $\eta\Upsilon(1S)$ candidate events is shown in Fig. 18.4.20. Solid lines delimit the signal region, while dashed lines delimit the sideband regions used for the background estimate. The signal observed by *BABAR* has a significance of $11(6.2)\sigma$ in the $\mu\mu(ee)$ channel.

Shortly after the observation of the $\Upsilon(4S) \to \eta\Upsilon(1S)$ transition, the CLEO Collaboration reported the first observation of $\Upsilon(2S) \to \eta\Upsilon(1S)$, with a significance of $5.3\,\sigma$ (He et al., 2008). The observed branching ratio was about two times smaller than the theoretical prediction. Using their samples of $\Upsilon(2, 3S)$ decays, the *BABAR* (Lees, 2011n) and Belle Collaborations (Tamponi, 2013) have studied the η and π^0 transitions between narrow bottomonium states.

The dominant peaking backgrounds are due to the favored neutral and charged dipion and diphoton (via χ_b) transitions, and the continuum $e^+e^- \to e^+e^-(n\gamma)$, $\mu^+\mu^-(n\gamma)$ processes. The dominant transition $\Upsilon(2S) \to \pi^-\pi^+\Upsilon(1S)$, which is expected to yield about $\mathbf{O}(10^3)$ more events, can be used as normalization sample. By normalizing the rate of η and π^0 transitions to the rate of the $\pi^+\pi^-$ transition, the systematic error of the measurement is reduced by cancellation of common uncertainties.

Both experiments detect the η meson in the $\gamma\gamma$ and the $\pi^+\pi^-\pi^0$ final states. Due to the tighter requirements imposed by the Bhabha veto at trigger level, the *BABAR* Collaboration was only able to use the $\Upsilon \to \mu^+\mu^-$ final state, while the Belle Collaboration uses both leptonic final states.

Charged tracks with momenta in the collider center-of-mass frame are required to have be greater than $4\,\text{GeV}/c$; such tracks are selected as candidate leptons from $\Upsilon(1S)$ decay. Particle identification is applied to categorize events as having electrons or muons in the final state.

The momentum of all photons detected in the ECL in the proximity of each leptonic track is added to its momentum, to reduce the effect of final state radiation (FSR) and bremsstrahlung. In order to suppress the contribution from continuum QED processes, a single-constraint kine-

Table 18.4.9. Branching ratios (in units of 10^{-4}) and upper limits (at 90% C.L.) for η and π^0 transitions from *BABAR* (Aubert, 2008bc; Lees, 2011n) and Belle (Tamponi, 2013), compared to previous results from CLEO (He et al., 2008).

transition	*BABAR*	Belle	*CLEO*
$\Upsilon(2S) \to \eta\Upsilon(1S)$	$2.39 \pm 0.31 \pm 0.14$	$3.57 \pm 0.25 \pm 0.21$	$2.1_{0.6}^{0.7} \pm 0.3$
$\Upsilon(2S) \to \pi^0\Upsilon(1S)$	–	< 0.41	< 1.8
$\Upsilon(3S) \to \eta\Upsilon(1S)$	< 1.0	–	< 1.8
$\Upsilon(3S) \to \pi^0 h_b(1P)$	$7.4 \pm 2.2 \pm 1.4$	–	–
$\Upsilon(4S) \to \eta\Upsilon(1S)$	$1.96 \pm 0.06 \pm 0.09$	–	–

matic fit with a constraint on the $\Upsilon(1S)$ mass is then applied on the two lepton candidate momenta, corrected for nearby photons, as described above. The threshold on the confidence level of this fit has been optimized using the Monte Carlo simulation for each specific channel.

A requirement on the polar angle of the e^- track with respect to the beam direction, $\cos(\theta_{e^-}^*) < 0.5$, is imposed to further suppress singly or doubly radiative Bhabha events, which represent the dominant QED background. The Bhabha requirement is not included in the $\Upsilon(2S) \to \pi^0\Upsilon(1S)$ analysis, since the $\Upsilon(1S)$ mass constraint provides already a good suppression of the QED processes.

The $\pi^+\pi^-$ candidate for the $\eta \to \pi^+\pi^-\pi^0$ decay (and also for the $\Upsilon(2S) \to \pi^+\pi^-\Upsilon(1S)$ transition used by the Belle Collaboration) is selected requiring the two tracks to be oppositely charged, to originate from the primary interaction point, and to have a large opening angle in the e^+e^- CM frame (*e.g.* $\cos(\theta_{ch^+,ch^-}^*) < 0.6$ in the Belle Collaboraton result), in order to reject the e^+e^- pairs coming from photon conversions in the inner detector. In the search for the $\Upsilon(3S) \to \eta\Upsilon(1S)$ transition, an additional requirement on $\Delta M_{\pi\pi} = M_{\pi\pi ll} - M_{ll}$ is imposed, to avoid contamination from the $\Upsilon(2,3S) \to \pi^+\pi^-\Upsilon(1,2S)$ transitions.

A second kinematic fit is then performed after the η or π^0 selection, constraining all final state particles (*i.e.* the dilepton, the dipion and/or the best photon pair) to have an invariant mass equal to the $\Upsilon(2,3S)$ mass, to generate from the same vertex, and to have a total energy equal to the sum of the beam energies.

An unbinned maximum-likelihood fit to the measured distribution of one (Belle, Fig. 18.4.21) or two (*BABAR*) observables is then performed to extract the signal yields. Each observed distribution is fit to a sum of signal and background components, with functional forms determined from the simulations. The value of the branching fraction for each mode is then extracted. The results of all analyses are summarized in Table 18.4.9.

The branching ratio for the $\Upsilon(3S) \to \pi^0 h_b(1P)$ transition is obtained by combining the product of branching ratio measured by *BABAR* in the study of the reaction $\Upsilon(3S) \to \pi^0 h_b(1P); h_b \to \gamma\eta_b(1S)$, with $\mathcal{B}(h_b(1P) \to \eta_b(1S))$, measured by Belle. The evidence of an isospin violating transition at least one order of magnitude larger

than yet unobserved η transition from $\Upsilon(3S)$ is even more surprising than the enhanced $\eta\Upsilon(1S)$ rate from $\Upsilon(4S)$.

18.4.6.7 Exclusive $\Upsilon(1S)$ and $\Upsilon(2S)$ decays into light hadrons

A number of channels in ψ decays have been studied, most of which satisfy predictions about their properties to within experimental errors. One example of a property which does not conform to expectation arises from the comparison of ψ decays into vector-pseudoscalar (VP) and vector-tensor (VT) final states: $\rho\pi$, $K^*\bar{K}$, $\rho a_2(1320)$ and $\omega f_2(1270)$. The rates of decay to these final states deviate from expectations, such as those implies by the "12% rule" (Section 18.4.6.1). It is interesting, therefore, to see if similar patterns of deviation occur in the bottomonium system by studying similar final states of Υ decay.

Although 82% of the $\Upsilon(1S)$ and 59% of the $\Upsilon(2S)$ decays are expected to be light-hadron final states, little experimental information exists on exclusive decays of the Υ resonances below the $B\bar{B}$ threshold. This situation is very different in charmonium sector, where numerous channels have been measured and used to perform model tests.

The Belle Collaboration published first observations of exclusive, light-hadron final states of the $\Upsilon(1S)$ and $\Upsilon(2S)$ (Shen, 2012). A large number of final states were studied and the key results are summarized in Table 18.4.10.

The measurements are mostly consistent with the prediction from pQCD (Section 18.4.6.1), $Q_{21} = 0.77 \pm 0.07$. The one measured mode that demonstrates a deviation from the prediction is $\omega\pi^+\pi^-$, which is consistent with the prediction at the level of 2.6σ. For the final states measured so far, the predictions from pQCD appear to be reliable within the experimental uncertainties.

18.4.6.8 $\Upsilon(4S)$ decays to $B\bar{B}$

The $\Upsilon(4S)(10580)$ is a resonance state that has a mass slightly above the $B\bar{B}$ threshold. It decays mostly into $B^0\bar{B}^0$ and B^+B^- pairs which are not available to the lighter resonances due to the phase space.

Given the similar masses of B^+ and B^0, it is expected that the branching fractions $f_{00} \equiv \mathcal{B}(\Upsilon(4S) \to B^0\bar{B}^0)$

Table 18.4.10. Results from the Belle Collaboration (Shen, 2012) in the measurement of exclusive hadronic decays of the $\Upsilon(1S)$ and $\Upsilon(2S)$ mesons. Here, $\mathcal{B}$ is the measured branching fraction (in units of 10^{-6}), and where the signficance of the result is low $\mathcal{B}^{\mathrm{UP}}$ (the 90% confidence level upper limit on the branching fraction) is also reported. Q_{21} is the computed ratio of the $\Upsilon(2S)$ and $\Upsilon(1S)$ branching fractions. Where the significance is small, Q_{21}^{UP} (the upper limit on the value of Q_{21}) is also reported. The first error in $\mathcal{B}$ and Q_{21} is statistical, and the second systematic.

Channel	$\Upsilon(1S)$		$\Upsilon(2S)$			
	$\mathcal{B}$	$\mathcal{B}^{\mathrm{UP}}$	$\mathcal{B}$	$\mathcal{B}^{\mathrm{UP}}$	Q_{21}	Q_{21}^{UP}

and $f_{+-} \equiv \mathcal{B}(\Upsilon(4S) \to B^+ B^-)$ are around 0.5. However, predictions for the ratio $R^{+/0} \equiv f_{+-}/f_{00}$ range from 1.03 to 1.25 (Aubert, 2005r). This is due to the effect of the Coulomb force in the decays of $\Upsilon(4S)$ into $B^0 \bar{B}^0$ and $B^+ B^-$ pairs. The kinematic aspects of the $\Upsilon(4S)$ decays are treated as non-relativistic. The B meson velocity in the $\Upsilon(4S)$ rest frame is relatively small,

$$\beta = v/c = \sqrt{1 - \frac{4m_B^2}{m_{\Upsilon(4S)}^2}} \approx 0.065, \quad (18.4.17)$$

where m_B and $m_{\Upsilon(4S)}$ are the masses of the B meson and the $\Upsilon(4S)$ resonance, respectively.

Table 18.4.11 shows the experimental results on $R^{+/0}$. All measurements assumed the isospin invariance in $\Gamma(B^+ \to x^+) = \Gamma(B^0 \to x^0)$, where x^+ and x^0 are the charged and neutral final particles.

The only measurement that did not follow the above assumption is the measurement from the Belle experiment, Hastings, 2003. This measurement used dilepton events, but assumed that there is isospin invariance, $\Gamma(B^+ \to \ell^+ X) = \Gamma(B^0 \to \ell^+ X)$. Therefore, this result is treated slightly differently, described as follows:

- Using the corresponding lifetime ratio (Table 18.4.11), each measurement from CLEO and *BABAR* is converted into its original measurement of $R^{+/0} \times \tau(B^+)/\tau(B^0)$
- No statistical and systematic correlation between the measurements from CLEO and *BABAR* is assumed, and a simple weighted average of $R^{+/0} \times \tau(B^+)/\tau(B^0)$ is computed.
- This weighted average is converted into an average value of $R^{+/0}$ by dividing it by the latest average of the lifetime ratio, $\tau(B^+)/\tau(B^0) = 1.079 \pm 0.007$.

- The measurement of $R^{+/0}$ from the Belle experiment is adjusted using the current values of $\tau(B^+)/\tau(B^0) = 1.079 \pm 0.007$ and $\tau(B^0) = 1.519 \pm 0.007$ ps.
- The weighted-average value of $R^{+/0}$ from CLEO and *BABAR* is then averaged with the adjusted value of the $R^{+/0}$ from Belle, assuming there is 100% correlation of the systematic uncertainty due to the limited knowledge of the lifetime ratio of $\tau(B^+)/\tau(B^0)$.

Most measurements of the $R^{+/0}$ have been made assuming isospin symmetry in specific decay rates and resulting in an average value of $R^{+/0}$,

$$R^{+/0} = 1.056 \pm 0.028 \text{ (total)}. \quad (18.4.18)$$

This global average of $R^{+/0}$ is in good agreement with isospin invariance in the decay of $\Upsilon(4S) \to B\bar{B}$ pairs at the level of 2σ.

In 2005, the *BABAR* collaboration reported (Aubert, 2005r) the first measurement of the branching fraction of $\mathcal{B}(\Upsilon(4S) \to B^0 \bar{B}^0)$, f_{00}, using a novel technique: the partial reconstruction method (Section 17.5.1.4). This is a direct measurement of the f_{00} that does not depend on the isospin invariance nor requires the knowledge of the B lifetime ratio, $\tau(B^+)/\tau(B^0)$. The measurement is based on the comparison between the number of events of a single- and double-tag sample using the decay of $\bar{B}^0 \to D^{*+} \ell^- \bar{\nu}_\ell$, and yields

$$f_{00} = 0.487 \pm 0.010 \text{(stat)} \pm 0.008 \text{(syst)} \quad (18.4.19)$$

The two results in Equations 18.4.18 and 18.4.19 result from very different approaches and are completely independent. Combining the two results leads to $f_{+-} = 0.514 \pm 0.019$ and the sum of f_{00} and f_{+-} is equal to 1.001 ± 0.030 which is consistent with unity.

Table 18.4.11. Published measurements of $R^{+/0} = f_{+-}/f_{00}$ values in the decay of $\Upsilon(4S)$ resonance to $B\bar{B}$ pairs. The assumed lifetime ratio for each measurement is included.

Experiment	Mode B →	$R^{+/0}$ Result	$\tau(B^+)/\tau(B^0)$
CLEO (Alexander et al. (2001))	$J/\psi K^*$	$1.04 \pm 0.07 \pm 0.04$	1.066 ± 0.024
BABAR (Aubert, 2002c)	$(c\bar{c})K^*$	$1.10 \pm 0.06 \pm 0.05$	1.062 ± 0.029
CLEO (Athar et al. (2002))	$D^*\ell\nu$	$1.058 \pm 0.084 \pm 0.136$	1.074 ± 0.028
Belle (Hastings, 2003)	dilepton events	$1.01 \pm 0.03 \pm 0.09$	1.083 ± 0.017
BABAR (Aubert, 2004j)	$J/\psi K$	$1.006 \pm 0.036 \pm 0.031$	1.083 ± 0.017
BABAR (Aubert, 2005k)	$(c\bar{c})K^*$	$1.06 \pm 0.02 \pm 0.03$	1.086 ± 0.017
Average		1.056 ± 0.028 (total)	1.079 ± 0.007

Assuming $f_{00} + f_{+-} = 1$, the two results in Equations 18.4.18 and 18.4.19 lead to the most precise average values of f_{00} and f_{+-},

$$f_{00} = 0.487 \pm 0.006, \qquad (18.4.20)$$
$$f_{+-} = 0.513 \pm 0.006 \qquad (18.4.21)$$

and $R^{+/0}$,

$$R^{+/0} = 1.055 \pm 0.025 \qquad (18.4.22)$$

where the $R^{+/0}$ ratio differs from unity by 2.2σ.

18.4.7 Physics beyond the Standard Model

18.4.7.1 Light Higgs Searches

Motivation - low-mass, CP-odd Higgs boson

The existence of a low-mass Higgs boson ($m_{A^0} < m_{b\bar{b}}$) became one of the beyond-the-Standard Model search topics for the bottomonium data sample of the BABAR Collaboration. This was motivated by extensions of the Standard Model, such as the next-to-minimal supersymmetric Standard Model, or NMSSM, that was developed to solve problems in the MSSM (cf. Dermisek and Gunion, 2005). While the MSSM requires two Higgs field doublets in order to provide mass to all particles in the theory, the NMSSM adds one more Higgs singlet field for a total of seven physical Higgs bosons. One of these is a CP-odd state, and is the lightest of the seven Higgs bosons (henceforth denoted as A^0). The purpose of this additional Higgs field singlet is to solve the "naturalness" problem in the MSSM (*e.g.* the apparently fine-tuned value of the μ parameter). Depending on the couplings and mass of this A^0, it was possible that the branching fraction for $\Upsilon \rightarrow \gamma A^0$ could have been as high as 10^{-4} and thus easily accessible to the B Factory experiments (Dermisek, Gunion, and McElrath, 2007).

Experimental searches

The BABAR collaboration has searched for low-mass Higgs bosons produced in bottomonium decay using two decay modes: $A^0 \rightarrow \mu^+\mu^-$, $\tau^+\tau^-$ (Aubert, 2009ai,an). All of these searches assume that the parent Upsilon meson decays to the low-mass Higgs boson by radiating a photon,

$$\Upsilon \rightarrow \gamma A^0. \qquad (18.4.23)$$

Prior to the publication of the BABAR searches described in this section, the CLEO Collaboration published searches for the same final states (Love et al., 2008) using 21.5×10^6 $\Upsilon(1S)$ decays. They obtained 90% confidence level limits on the branching fraction for $A^0 \rightarrow \tau^+\tau^-$ decay covering the range $2m_\tau < m_{A^0} < 9.5$ GeV/c^2 (where m_τ is the tau lepton mass) that ranged between and $(1-48) \times 10^{-5}$. They obtained 90% confidence level limits on the branching fraction for $A^0 \rightarrow \mu^+\mu^-$ decay covering the range $m_{A^0} < 3.6$ GeV/c^2 that ranged between $(1-20) \times 10^{-6}$.

The BABAR searches use a data sample taken at a collider energy corresponding in the CM frame to the $\Upsilon(3S)$ mass. The sample contains $(121.8\pm1.2)\times10^6$ $\Upsilon(3S)$ mesons.

The BABAR searches proceed by selecting events containing a good photon candidate and two opposite electric charge tracks. The selection of these final states diverge after the defintion of the topology due to the differing kinematics of the two di-lepton final states.

$A^0 \rightarrow \mu^+\mu^-$

The $A^0 \rightarrow \mu^+\mu^-$ final state is selected by requiring that the photon have a CM energy $E_\gamma \geq 0.5$ GeV. Other photons can be present in an event only if their individual energies are below this threshold. The charged tracks are assigned a muon mass hypothesis and are henceforth refered to as "muon candidates" independent of whether additional particle identification is required. The muon candidates must original from a common point in space, and the vertex of the two charged tracks must have a

$\chi^2 < 20$ (for 1 degree of freedom) and be displaced by no more than 2 cm from the nominal e^+e^- interaction region in a plane transverse to the beams.

The dimuon system is combined with the highest-energy photon candidate to build an $\Upsilon(3S)$ candidate. A kinematic fit is performed to the three particles, constraining the total energy of the three particles to be within the beam-energy spread of the e^+e^- collision that should have produced the $\Upsilon(3S)$, and the constraint that the particles originate from the primary interaction region. The fit is required to satisfy $\chi^2 < 36$ (for 6 degrees of freedom), which corresponds to a probability of rejecting good kinematic fits that is less than 10^{-6}.

Particle identification is used in certain regions of photon energy in order to reject specific backgrounds. After the above kinematic selection, the primary background is determined from MC simulation to be $e^+e^- \to \mu^+\mu^-\gamma$. In a photon-energy region corresponding to $m_{A^0} < 1.05 \,\mathrm{GeV}/c^2$, contributions from $\phi \to K^+K^-$ (where $K^+ \to \mu^+\nu$) and $\rho \to \pi^+\pi^-$ are suppressed by requiring that both tracks be positively identified as muons using particle identification. In an m_{A^0} region corresponding to the location of the η_b mass, events are required to have no additional photons with $E_\gamma > 0.08$ GeV; this suppresses radiative transitions of the $\Upsilon(3S)$ to the $\Upsilon(2S)$ through a χ_b state.

The efficiency of the above selection of $A^0 \to \mu^+\mu^-$ is studied using a signal MC simulation and varies between 24–44%, depending on m_{A^0}. The signal yield is extracted from the data in the range $0.212 \le m_{A^0} \le 9.3 \,\mathrm{GeV}/c^2$ using a maximum-likelihood fit to the variable,

$$ m_R = \sqrt{m_{\mu\mu}^2 - 4m_\mu^2}. \qquad (18.4.24) $$

This equation represents twice the momentum of the muons in the rest frame of the parent particle. This is used instead of just $m_{\mu\mu}$ because it is a smooth function of $m_{\mu\mu}$ across the entire dimuon mass range, including close to the threshold for dimuon production ($m_{\mu\mu} \approx 2m_\mu$ corresponds to $m_R \approx 0$). The background distribution of $m_{\mu\mu}$ turns on sharply near threshold, whereas m_R has a more gradual rise and can be more easily empirically modeled with a simple analytic function. Two functions are developed for use in the maximum likelihood fit: a signal function (determined from signal MC simulation) and a background function (determined from data taken at $\sqrt{s} = M_{\Upsilon(4S)}$). The signal model is constructed from a sum of two Crystal Ball functions; the parameters of this model are determined from many independent simulations of an A^0 whose mass varies across the range of interest, and these parameters are cross-checked using a sample of J/ψ mesons obtained from initial-state radiation, $e^+e^- \to \gamma_{ISR}J/\psi$. The background model has alternative parameterizations in different regions of m_R; for $m_R < 0.23 \,\mathrm{GeV}/c^2$, a threshold (hyperbolic) function is used, while elsewhere the background is described by a first-order ($m_R < 9.3 \,\mathrm{GeV}/c^2$) or second-order ($m_R > 9.3 \,\mathrm{GeV}/c^2$) polynomial.

The fit for signal and background is performed in steps whose size varies by region. In addition to continuum back-
Figure 18.4.22. Upper limits on the product of branching fractions (at 90% C.L.) for $\Upsilon(nS) \to \gamma A^0$ and $A^0 \to \mu^+\mu^-$ for (a) $\Upsilon(3S)$ and (b) $\Upsilon(2S)$. The upper limit on the effective coupling, $f_Y^2 \mathcal{B}_{\mu\mu}$, is shown in (c). From (Aubert, 2009an).

ground, specific backgrounds that contribute peaks to the mass spectrum are accounted using the same model as for signal. The J/ψ and $\psi(2S)$ regions are excluded from the fit since those contributions overwhelm any possible signals in those regions.

The BABAR Collaboration reports no evidence for decay of a low-mass Higgs boson using these data and computes upper limits on the branching fraction for $\Upsilon(3S) \to \gamma A^0 \to \gamma(\mu^+\mu^-)$, shown in Fig. 18.4.22. These upper limits, including systematic uncertainties, range between $(0.25 - 5.2) \times 10^{-6}$ depending on the value of m_R (at the 90% confidence level). These results constrain the branching fraction for $\eta_b \to \mu^+\mu^-$ to be $< 0.8\%$ at the 90% confidence level.

$A^0 \to \tau^+\tau^-$

The search for $A^0 \to \tau^+\tau^-$ proceeds similarly to the dimuon search. Events must contain a photon satisfying $E_\gamma > 0.1$ GeV; any additional photons (up to nine are allowed) must each satisfy $E < 0.1$ GeV. The dominant background processes in this search are due to $e^+e^- \to \gamma\tau^+\tau^-$, $e^+e^- \to e^+e^-e^+e^-$, $e^+e^- \to e^+e^-\mu^+\mu^-$, and $e^+e^- \to q\bar{q}$. These are rejected by using eight discriminating variables: the total CM energy calculated from the two leptons and the most energetic photon; the squared missing mass obtained from the missing four-momentum; the aplanarity of the photon and A^0 candidate, which is the cosine of the angle between the photon and the plane of

the leptons; the largest cosine between the photon and one of the tracks; the cosine of the polar angle of the highest-momentum track; the transverse momentum of the event calculated in the CM frame; the cosine of the polar angle of the missing momentum vector; and the cosine of the opening angle between the tracks in the photon recoil frame. The selection on these variables is optimized simultaneously in order to achieve the best value of $S/\sqrt{B}$, where S is the number of expected signal and B is the number of expected background. The backgrounds vary depending on the photon energy, so this optimization is performed as a function of photon energy in five regions which slightly overlap in order to reduce discontinuities in performance between the regions.

The energy of the photon in the $\Upsilon(3S)$ rest frame is used to define a range of A^0 masses studied in this search, using the relationship

$$m_{A^0}^2 = m_{\Upsilon(3S)}^2 - 2m_{\Upsilon(3S)}E_\gamma \qquad (18.4.25)$$

where $m_{\Upsilon(3S)}$ is the nominal $\Upsilon(3S)$ mass. The range of photon energies studied corresponds to $m_{A^0} = [4.03, 10.10]\,\text{GeV}/c^2$, excluding the region $m_{A^0} = [9.52, 9.61]\,\text{GeV}/c^2$ due to an irreducible background from photons produced in the process $\Upsilon(3S) \to \gamma\chi_{bJ}(2P)$, $\chi_{bJ}(2P) \to \gamma\Upsilon(1S)$, where $J = 0, 1, 2$. The photon energy resolution varies over the range in this search, increasing from 8 MeV at $E_\gamma \approx 0.2\,\text{GeV}$ to 55 MeV at $E_\gamma \approx 4.5\,\text{GeV}$. The efficiency of event selection also varies with photon energy, ranging as follows: 10-14% for the $\tau\tau \to ee$ final state; 12-20% for $\tau\tau \to e\mu$; and 22-26% for $\tau\tau \to \mu\mu$ (neutrinos are not explicitly written in the final states).

The photon energy spectrum is modeled using the combination of a peaking function for signal and a predominantly smooth function for background. The data are first treated as purely background and fit with only the latter function. This allows the parameters of the background to be determined as initial values for the next stage of the fit to the data.

Backgrounds causing real peaks in the photon spectrum are expected from radiative decays from the $\Upsilon(3S)$ resonance to lower-mass bottomonium states, specifically $\Upsilon(3S) \to \gamma\chi_{bJ}(2P)$, $\chi_{bJ}(2P) \to \gamma\Upsilon(nS)$, and $\Upsilon(nS) \to \tau^+\tau^-$ (J = 0, 1, 2; n = 1, 2). Peaks arise in the photon spectrum when the photon from the $\chi_{bJ}(2P)$ decay is used as the photon radiated by the $\Upsilon(3S)$ when it decays to an A^0. Each of the peaks is described using a Crystal Ball function whose means are fixed by the photon energies expected from the PDG values of the bottomonia masses (Beringer et al., 2012) and whose widths are fixed from the MC predictions of the reconstructed widths of the photon peaks. The other parameters of the Crystal Ball functions are also fixed from the MC simulation of these decays.

The results of a fit of the background model to the photon energy spectrum in each final state are shown in Fig. 18.4.23. A complete fit of the data including the signal model is performed by scanning the photon energy in 307 steps and fitting for signal and background yields at each step. This procedure finds no significant yield of
Figure 18.4.23. (a), (c), (e): Photon energy distributions for the different $\tau\tau$-decay modes (Aubert, 2009ai). Filled circles show the data; dotted lines represent contributions from $\Upsilon(3S) \to \gamma\chi_{bJ}(2P)$, $\chi_{bJ}(2P) \to \gamma\Upsilon(2S)$; dotted-dashed lines show contributions from $\Upsilon(3S) \to \gamma\chi_{bJ}(2P)$, $\chi_{bJ}(2P) \to \gamma\Upsilon(1S)$; and solid lines show the total background function. For each $\tau\tau$-decay mode, the difference between the background function and the data divided by the uncertainty in the data is shown in (b), (d) and (f).

signal events anywhere in the spectrum. The branching fraction product $\mathcal{B}(\Upsilon(3S) \to \gamma A^0)\mathcal{B}(A^0 \to \tau^+\tau^-)$ is calculated, along with the upper limit at the 90% C.L., both as a function of Higgs mass, as shown in Fig. 18.4.24. The upper limits on the product branching fraction range between $(1.5 - 16) \times 10^{-5}$ at 90% C.L. for a mass range of $4.03 < m_{A^0} < 10.10\,\text{GeV}/c^2$, excluding $9.52 < m_{A^0} < 9.61$ GeV/c^2 to veto the $\chi_{bJ}(2P)$ with $\chi_{bJ}(2P) \to \gamma\Upsilon(1S)$.

Impact of the results

The low-mass Higgs boson models discussed earlier in this section predicted that the branching fraction for $\Upsilon(1S) \to \gamma A^0$ could range as high as $\sim 10^{-3}$ (the range of possible branching fractions is dependent on the specific NMSSM model used). The measurements from the *BABAR* collaboration put strong constraints on the upper range of this kind of decay down to the level of 10^{-6}, removing a few orders of magnitude of possible range from the top level of predicted branching fractions.
Figure 18.4.24. (a) Product branching fractions as a function of the Higgs mass (Aubert, 2009ai). For each point, both the statistical uncertainty (from the central value to the horizontal bar) and the total uncertainty (statistical and systematic added in quadrature) are shown (from the central value to the end of the error bar). In (b), the corresponding 90% C.L. upper limits on the product of the branching fractions versus the Higgs mass values are shown, with total uncertainty (solid line) and statistical uncertainty only (dashed line). The shaded vertical region represents the excluded mass range corresponding to the $\chi_{bJ}(2P) \to \gamma \Upsilon(1S)$ states.

18.4.7.2 Invisible Final States of the $\Upsilon(1S)$

Motivation - low-mass dark matter

The nature of dark matter is one of the great modern physics puzzles. Assuming dark matter is composed of at least one species of particle, the properties of this particle have not been measured (*e.g.* mass). If the mass of dark matter is small ($< m_{b\bar{b}}$), then there is the possibility of detecting it using rare processes involving undetectable (invisible) final states. One of these, $\Upsilon \to$ invisible, was motived by work by McElrath (2005), where it was suggested that a new interaction that couples Standard Model particles to dark matter particles could mediate the decay of the Υ. Based on the interaction cross-section required to achieve the "freeze-out" of dark matter annihilations in the early universe (a process that is required to explain the significant remnant of dark matter in today's universe), it was estimated that the branching fractions for $\Upsilon \to (\gamma+)$ invisible (the dominant decay mechanism depended on the spin of the dark matter constituent) could be as high as 0.41% — easily measured at the B-factories with even a modest sample of Υ mesons.

The *BABAR* and Belle collaborations have both searched for invisible final states of $\Upsilon(1S)$ decay (Tajima, 2007; Aubert, 2009b; del Amo Sanchez, 2011j). Both collaborations produced results in the search for purely invisible final states, $\Upsilon \to$ invisible while the *BABAR* collaboration also produced results for radiative invisible final states,

$\Upsilon \to \gamma +$ invisible. These searches are sensitive to different possible angular momentum configurations of unknown invisible final states.

Searches for $\Upsilon \to$ invisible

The *BABAR* and Belle searches for purely invisible final states proceed similarly. The Belle search appeared first and used a sample of 11×10^6 $\Upsilon(3S)$ mesons (Tajima, 2007), while the *BABAR* search appeared later and used a sample of 91.4×10^6 $\Upsilon(3S)$ mesons (Aubert, 2009b). Both searches used the transition

$$\Upsilon(3S) \to \pi^+ \pi^- \Upsilon(1S) \qquad (18.4.26)$$

to "tag" the presence of the $\Upsilon(1S)$ meson without reconstructing it by using the kinematics of the dipion system. Specifically, if the pions are both produced recoiling against the $\Upsilon(1S)$ state then from four-momentum conservation the mass of the system recoiling against the dipion is given by

$$M_{\text{recoil}}^2(\pi^+\pi^-) = s + M_{\pi^+\pi^-}^2 - 2\sqrt{s}E_{\pi^+\pi^-}^* \qquad (18.4.27)$$

where s is the square of the collider CM energy and $M_{\pi^+\pi^-}$ ($E_{\pi^+\pi^-}$) is the mass (energy) of the dipion system. For a real dipion transition $\Upsilon(3S) \to \pi^+\pi^-\Upsilon(1S)$, $M_{\text{recoil}}^2(\pi^+\pi^-) = M_{\Upsilon(1S)}^2$.

The major challenges in this search are the trigger efficiency for signal events and the large background from pions that come from non-transition decays and from real transition decays where the final-state products of the $\Upsilon(1S)$ are simply undetected due to detector effects. The trigger efficiency is a challenge due to the low transverse momentum possessed by the pions; the energy from the transition is shared between the two pions, typically leading to one low-momentum pion and one higher-momentum pion.

Both the Belle and *BABAR* trigger systems require that low-multiplicity events be triggered only when at least one of the tracks has a sufficient p_T to distinguish it from background, and that the opening-angle between the tracks in the plane transverse to the beams satisfy a minimum requirement. The Belle collaboration evaluated their trigger efficiency by studying the efficiency with which events are selected by a single-track trigger and then subsequently by different requirements on a second track in those events. The *BABAR* collaboration evaluated their trigger efficiency by explicitly reconstructing a control sample of events where $\Upsilon(3S) \to \pi^+\pi^-\Upsilon(1S)$ and the $\Upsilon(1S)$ then decays to a pair of leptons (either electrons or muons). The pions in this sample have identical kinematics to those in an equivalent $\Upsilon(1S) \to$ invisible decay, except that these events are triggered by the high-momentum leptons and not the lower-momentum pions. A selection similar to the one applied by the *BABAR* trigger was then used on the pions to evaluate the efficiency with which the dipion system is selected.

The backgrounds to this search come from the two sources mentioned above: events with pions that come from sources other than the $\Upsilon(3S) \to \Upsilon(1S)$ dipion transition (combinatorial) and events with pions that come from a real transition but where the $\Upsilon(1S)$ decay products are simply unreconstructed due to detector effects (peaking). The pions from combinatorial sources have no peak at $M_{\text{recoil}}(\pi^+\pi^-) = M_{\Upsilon(1S)}$ but dominate the data samples prior to any rejection after selection the pions. Both collaboration use combinations of kinematic information (Belle uses a Fisher discriminant while *BABAR* uses a Random Forest of Decision Trees - see Chapter 4 for a description of these tools) to reject this source of background. Any remaining background has a smooth distribution through the signal region around the $\Upsilon(1S)$ mass and is easily modeled using a polynomial function whose parameters are determined by fitting the data directly.

The peaking background from real dipion transitions is studied using Monte Carlo simulations and the control sample described above, where $\Upsilon(1S) \to \ell^+\ell^-$ is explicitly reconstructed using electron and muon final states. Both collaborations compare the rate at which both final-state leptons, or just one final-state lepton, are reconstructed as a function of polar angle in the detector. This allows them to correct the MC simulation of these backgrounds using data measurements of the detector acceptance for the $\Upsilon(1S)$ final-state products. In addition to this technique, the *BABAR* collaboration studied the non-leptonic $\Upsilon(1S)$ decay backgrounds by using a control sample where
Figure 18.4.25. The fits to the recoil mass spectra. (top) The Belle fit, where the solid curve shows the result of the fit to signal plus background distributions, the shaded area shows the total background contribution, the dashed line shows the combinatorial background contribution, and the dot-dashed line shows the expected signal for $\mathcal{B}(\Upsilon(1S) \to \text{invisible}) = 6 \times 10^{-3}$ (Tajima, 2007). (bottom) The *BABAR* fit to $M_{rec} \equiv M_{\text{recoil}}(\pi^+\pi^-)$, where the solid line shows the fit including both combinatorial and peaking contributions and the dash-dotted line indicates the contribution only from combinatorial background (Aubert, 2009b).

a photon of energy $E_\gamma > 0.250\,\text{GeV}$ is present in addition to the pions; this selection is orthogonal to the nominal signal selection. This sample is enriched in hadronic $\Upsilon(1S)$ decays and was used to correct the modeling of acceptance for such decays in the nominal selection.

The shape of the real transition background will be identical to that of the signal because in both cases a real $\Upsilon(1S)$ is recoiling against the dipion system. Thus the recoil mass shape of this background (and that of the signal) can be determined from the $\Upsilon(1S) \to \ell^+\ell^-$ control sample but the yield of the real transition backgrounds must be determined from the aforementioned studies and fixed in the final fit to the data. The Belle collaboration estimated their real transition background to be $133.2^{+19.7}_{-14.69}$ events, while the *BABAR* collaboration measured their peaking background to be 2444 ± 123 events, with the dominant contribution coming from $\Upsilon(1S) \to \ell^+\ell^-$ decays where the final-state leptons are undetected.

The fits to the recoil mass spectra from both experiments are shown in Fig. 18.4.25. Neither experiment observed a significant deviation from their expected yield of peaking events due to background sources. Both experiments set upper limits on the branching fraction for $\Upsilon(1S) \rightarrow$ invisible. Folding in the measured value for $\Upsilon(3S) \rightarrow \pi^+\pi^-\Upsilon(1S)$, the Belle collaboration determined that

$$\mathcal{B}(\Upsilon(1S) \rightarrow \text{invisible}) < 2.5 \times 10^{-3} \qquad (18.4.28)$$

at 90% C.L. and the *BABAR* collaboration determined that

$$\mathcal{B}(\Upsilon(1S) \rightarrow \text{invisible}) < 3.0 \times 10^{-4} \qquad (18.4.29)$$

at 90% C.L.

Impact of the results

The measurements described here for $\Upsilon(1S) \rightarrow$ invisible leave only about an order-of-magnitude of branching fraction space left before encountering the Standard Model predicted rate for $\Upsilon(1S) \rightarrow \nu\bar{\nu}$. This has closed much of the space for low-mass dark matter, with $m_\chi < m_{\Upsilon(1S)}/2$, to be produced in this way.

Search for $\Upsilon \rightarrow \gamma +$ invisible

The search for radiative invisible final states, $\Upsilon(1S) \rightarrow \gamma +$ invisible also proceeds from a dipion transition sample but uses a sample of 98.3×10^6 $\Upsilon(2S)$ mesons and the transition $\Upsilon(2S) \rightarrow \pi^+\pi^-\Upsilon(1S)$ to tag the presence of the $\Upsilon(1S)$ meson. Such a search has been performed by *BABAR* (del Amo Sanchez, 2011j). The presence of a photon in addition to the dipion system is then used the tag the decay of the $\Upsilon(1S)$ via $\Upsilon(1S) \rightarrow \gamma +$ invisible. The analysis assumes that the invisible system recoiling against the photon is a resonance (*e.g.* a low-mass Higgs), denoted A^0, that subsequently decays into a two-body invisible final state, $A^0 \rightarrow \chi\bar{\chi}$, where χ denotes an undetectable long-lived particle.

The signal events have a low multiplicity and are triggered in two ways: either by the presence of a pair of tracks each with $p_T > 0.25$ GeV/c or by the presence of a single photon with energy in the CM frame $E^* > 0.8$ GeV. Because of the trigger selection depends on the energy of the photon, the analysis is performed in regions corresponding to the mass of the recoiling resonance. The two regions are a high-mass region, $7.5 \leq m_{A^0} \leq 9.2$ GeV/c^2 (corresponding to $3.5 \leq m_\chi \leq 4.5$ GeV/c^2) and a low-mass region $m_{A^0} \leq 8.0$ GeV/c^2 ($m_\chi \leq 4$ GeV/c^2). The low-mass region relies entirely on the single-photon trigger, while the high-mass region relies entirely on the track trigger.

The reconstructed dipion system is required to contain two positively identified pion candidates (to reject electron and muon contamination) and have $p_T < 0.5$ GeV/c. Neither pion can have momentum $p > 1.0$ GeV/c. The photon must have a CM energy satisfying $E^* > 0.15$ GeV

and lie well within the central part of the electromagnetic calorimeter. Additional photons can be present as long as their individual energies are less than that of the signal photon and their total energy in the laboratory frame does not exceed 0.14 GeV. A multilayer perceptron neural network is then used to combine kinematic variables from the dipion system into a single discriminant that can reject background. The neural network is trained on data taken at a collider CM energy below the $\Upsilon(2S)$ resonance, and on signal MC simulation. In the low-mass region, this approach retains 87% of simulated signal events while rejecting 96% of events from non-$\Upsilon(2S)$ (continuum) events. In the high-mass region, this approach retains 73% of signal while rejecting 98% of continuum background.

In addition to backgrounds from sources other than the $\Upsilon(2S)$, there could be backgrounds from real $\Upsilon(1S)$ radiative decays where the final-state products are difficult to detect reliably. For instance, $\Upsilon(2S) \rightarrow \pi^+\pi^-\Upsilon(1S)$, where the $\Upsilon(1S)$ then decays to either $\Upsilon(1S) \rightarrow \gamma n\bar{n}$ or $\Upsilon(1S) \rightarrow \gamma K_L^0 K_L^0$, are allowed decays where the final-state hadrons are not efficiently reconstructed in the *BABAR* detector. To reject these backgrounds, events are rejected where there is activity in the *BABAR* instrumented flux return within a 20° window opposite the reconstructed signal photon. This requirement is only applied in the low-mass region for $m_{A^0} < 4$ GeV/c^2. In the high-mass region there is a potential contamination from the process $e^+e^- \rightarrow e^+e^-\gamma^*\gamma^*$ where $\gamma^*\gamma^* \rightarrow \eta'$ and $\eta' \rightarrow \gamma\pi^+\pi^-$ while the electron and positron escape detection at low-angles to the beams. This is largely rejected by requiring the opening angle between the photon and the dipion system be no more than 160°.

The signal is extracted from a maximum likelihood fit to two variables: the dipion recoil mass $M_{\text{recoil}}(\pi^+\pi^-)$ and the "missing mass", *i.e.* the mass of the system recoiling against the reconstructed dipion and photon,

$$M_{\text{recoil}}^2(\pi^+\pi^-\gamma) = (P_{e^+e^-} - P_{\pi^+\pi^-} - P_\gamma)^2. \qquad (18.4.30)$$

The fit is performed in steps of $M_{\text{recoil}}^2(\pi^+\pi^-\gamma)$. The models contain contributions from multiple sources, including signal (whose shape is determined from MC simulation), continuum background, radiative $\Upsilon(1S)$ decays, and background from real $\Upsilon(3S) \rightarrow \Upsilon(1S)$ transitions. Projections of the fits in each of the two dimensions are shown in Fig. 18.4.26. No significant yield of signal events is obtained from any of the scan points in the fits. The 90% C.L. upper limits on the product of branching fraction $\mathcal{B}(\Upsilon(1S) \rightarrow \gamma A^0) \times \mathcal{B}(A^0 \rightarrow \text{invisible})$ are shown in Fig. 18.4.27 and ranges $(1.9 - 4.5) \times 10^{-6}$ for the low-mass region and $(2.7 - 37) \times 10^{-6}$ in the high-mass region, assuming a scalar A^0.

The low-mass dark matter models cited earlier in this section predicted that the branching fraction for the radiative final state could be as high as $10^{-5} - 10^{-4}$. The experimental results discussed here cover well that upper range of the predicted branching fractions and exclude the largest possible rates predicted by these models.
Figure 18.4.26. Projection plots from the fit with $N_{\rm sig} = 0$ onto (a,c,e) recoil mass $M_{\rm recoil} \equiv M_{\rm recoil}(\pi^+\pi^-)$ and (b,d,f) missing mass-squared $M_X^2 \equiv M_{\rm recoil}^2(\pi^+\pi^-\gamma)$ (del Amo Sanchez, 2011j). (a,b): low-mass region with a veto on activity in the *BABAR* instrumented flux return (IFR); (c,d): low-mass region without IFR veto; (e,f): high-mass region. Overlaid is the fit with $N_{\rm sig} = 0$ (solid blue line), continuum background (black dashed line), radiative leptonic $\Upsilon(1S)$ decays (green dash-dotted line), and (c,d) radiative hadronic $\Upsilon(1S)$ decays or (e,f) η' background (magenta dotted line).
Figure 18.4.27. 90% C.L. upper limits for $\mathcal{B}(\Upsilon(1S) \to \gamma A^0) \times \mathcal{B}(A^0 \to \text{invisible})$ (del Amo Sanchez, 2011j).

18.4.7.3 Search for Lepton Flavor Violation

Motivation: new interactions

Lepton flavor is an accidentally conserved quantum number in the original formulation of the Standard Model; however, the observation of neutrino mixing implies that charged lepton flavor violation should occur, albeit at a scale that is suppressed by a factor of $(\Delta m_\nu^2/M_W^2)^2 \leq$

10^{-48}, as discussed by Feinberg (1958), Bilenky and Pontecorvo (1976), Strumia and Vissani (2006). An experimental observation of such violation at present experimental capabilities would be unambiguous evidence of physics beyond the Standard Model, as discussed by Ellis, Gomez, Leontaris, Lola, and Nanopoulos (2000), Ellis, Raidal, and Yanagida (2004), Pati and Salam (1974), Georgi and Glashow (1974). For instance, supersymmetry includes mechanisms by which such violation naturally occurs.

Experimental measurement

The *BABAR* Collaboration performed a search for lepton flavor violation using the decays $\Upsilon(nS) \to (e^\pm/\mu^\pm)\tau^\mp$, where $n = 2, 3$. The searches were performed using $(98.6 \pm 0.9) \times 10^6$ $\Upsilon(2S)$ decays and $(116.7 \pm 1.2) \times 10^6$ $\Upsilon(3S)$ decays (Lees, 2010c). In addition, data from other resonances and from runs taken away from Upsilon resonances were used to characterize and study the backgrounds.

The search uses the fact that the collider is producing the parent Upsilon resonance at rest in the CM frame; the electron or muon that results directly from the Upsilon decay (the "primary lepton") will have energy very close to the single-beam energy in the Upsilon rest frame, $E_B = \sqrt{s}/2$. The primary tau lepton will decay, and a second lepton, or a charged pion, consistent with tau decay is then searched for. If a second lepton is found, it is required to have a different flavor from the primary lepton. If a pion is found, one or two additional neutral pions must also be reconstructed in the same event. These measures are required in order to suppress Bhabha events or μ-pair backgrounds.

The main source of background in this search is from $e^+e^- \to \tau^+\tau^-$ events. The four individual search channels each have other sources of background, arising primarily from lepton and hadron misidentification. Bhabha events are further suppressed by requiring that the visible mass in each candidate event has less than 95% of the collider CM energy (indicating the presence of neutrinos, which are not present in Bhabha events). In addition, the missing momentum in each event must not point close to the beamline. Higher-order QED backgrounds, as from two-photon fusion, are suppressed by requiring that the transverse momentum component of the charge particles' vector sum is more than 20% of the quantity $\sqrt{s} - |\boldsymbol{p}_1| - |\boldsymbol{p}_2|$, where $\boldsymbol{p}_i$ is the three-momentum of charged particle i.

The primary lepton momentum is defined by the requirement that $x \equiv |\boldsymbol{p}_1|/E_B > 0.75$. For the hadronic tau decays, the momentum of the tau daughter charged particle is required to satisfy $|\boldsymbol{p}_2|/E_B < 0.8$, and the invariant masses of the track and neutral pion(s) system must be consistent with the mass of either the $\rho^\pm$ or the $a_1^\pm$. The μ-pair background in the $\mu\tau$ channel is suppressed by requiring that the opening angle between the charged tracks in the plane transverse to the beams is less than 172°.

After all selection criteria are applied, the selection efficiency determined from a signal MC simulation range

Table 18.4.12. Branching fractions and 90% CL ULs for lepton-flavor violating $\Upsilon(nS) \to \ell^\pm \tau^\mp$ decays (Lees, 2010c). The first error is statistical and the second is systematic.

	$\mathcal{B}$ (10^{-6})	UL (10^{-6})
$\mathcal{B}(\Upsilon(2S) \to e^+\tau^-)$	$0.6^{+1.5+0.5}_{-1.4-0.6}$	< 3.2
$\mathcal{B}(\Upsilon(2S) \to \mu^+\tau^-)$	$0.2^{+1.5+1.0}_{-1.3-1.2}$	< 3.3
$\mathcal{B}(\Upsilon(3S) \to e^+\tau^-)$	$1.8^{+1.7+0.8}_{-1.4-0.7}$	< 4.2
$\mathcal{B}(\Upsilon(3S) \to \mu^+\tau^-)$	$-0.8^{+1.5+1.4}_{-1.5-1.3}$	< 3.1

between $(4-6)\%$, depending on the signal mode, including the tau decay branching fractions.

The signal yield in the data is determined by an unbinned extended maximum likelihood fit to the distribution of x, defined earlier. Signal events are expected to peak at $x \approx 0.97$, while τ-pair background exhibits a smoothly falling shape that cuts off at the kinematic endpoint of $x = 0.97$ (the lepton kinematic endpoint for charged leptons produced in tau decay). Bhabha and μ-pair background exhibit a peak at $x = 1$, which is about $(2.5-3)\sigma_x$ above the signal, where $\sigma_x \approx 0.01$ is the detector resolution on x.

Probability density functions are obtained for each of these components. The signal and Bhabha/μ-pair *p.d.f.*s are obtained from MC simulation. Signal events are described using a Crystal Ball function, while the Bhabha/μ-pair backgrounds have a smooth component modeled using and ARGUS function and a peaking component modeled using a Gaussian. The τ-pair background is modeled using a polynomial convoluted with a detector resolution function. The fit procedure is validated by using $\Upsilon(4S)$ and off-resonance data that are separated into samples with comparable numbers of events to those expected at the $\Upsilon(3S)$ and $\Upsilon(2S)$. No significant signal yield is obtained in these control tests.

The results of the fits to the $\Upsilon(3S)$ and $\Upsilon(2S)$ data are given in Table 18.4.12. No significant signal yields are obtained. These results are then used to place constraints on physics beyond the Standard Model. For example, Domingo and Ellwanger (2011) use this measurement to put limits on the decay of a Higgs boson to a pair of low-mass *CP*-odd Higgs bosons, interpreting this result as a limit on the mixing of the η_b meson with such a *CP*-odd Higgs boson.

18.4.7.4 Test of Lepton Universality

Motivation - mass-dependent couplings

The Standard Model expresses no preference for the partial width $\Gamma_{\Upsilon(1S) \to \ell\ell}$ that depends on lepton flavor, up to corrections due to phase space (where $\ell = e, \mu, \tau$). This is referred to as "lepton universality" in the decay of the $\Upsilon(1S)$ meson. One can compute the ratio of partial widths to different final states and measure those ratios in data to see whether the Standard Model prediction is correct. For

instance, the ratio of the τ-to-μ partial widths is predicted to be $R_{\tau\mu}(\Upsilon(1S)) \approx 0.992$ in the Standard Model.

Experimental measurement

The *BABAR* Collaboration has searched for violation of lepton universality in Υ decay using the $\Upsilon(3S)$ and $\Upsilon(2S)$ data samples (del Amo Sanchez, 2010r). The analysis determines the ratio of branching fractions,

$$\frac{\mathcal{B}(\Upsilon(1S) \to \mu^+\mu^-)}{\mathcal{B}(\Upsilon(1S) \to \tau^+\tau^-)} \qquad (18.4.31)$$

whose value is definitively predicted in the Standard Model. For instance, work by Sanchis-Lozano (2004), Fullana and Sanchis-Lozano (2007), and Domingo, Ellwanger, Fullana, Hugonie, and Sanchis-Lozano (2009) calculate the Standard Model rate and then discuss the implications of beyond-the-Standard Model physics on altering this value. Deviation from the SM prediction would indicate the presence of an interaction that couples differently to the two lepton flavors, such as the presence of a low-mass *CP*-odd Higgs Boson like the one searched for in 18.4.7.1. The analysis uses the recoil method to tag the presence of the $\Upsilon(1S)$ in the final state and the presence of leptons to indicate the final-state decay of the $\Upsilon(1S)$.

The *BABAR* Collaboration has measured the above ratio as a test of lepton universality (del Amo Sanchez, 2010r). The measurement uses a sample of $(121.8 \pm 1.2) \times 10^6 \Upsilon(3S)$ mesons; 10% of the sample is used to tune the analysis and the remaining 90% is used to obtain the final results. A previous measurement of $R_{\tau\mu}(\Upsilon(1S))$ was performed by the CLEO Collaboration (Besson et al., 2007) and found $R_{\tau\mu}(\Upsilon(1S)) = 1.02 \pm 0.02 \, (stat.) \pm 0.05 \, (syst.)$.

The *BABAR* measurement uses the transition $\Upsilon(3S) \to \pi^+\pi^-\Upsilon(1S)$ to tag the existence of the $\Upsilon(1S)$ meson, followed by $\Upsilon(1S) \to \ell^+\ell^-$. Only τ decays to a single charged particle and neutrinos are considered. Event selection is optimized using MC simulations.

Events are required to contain exactly four charged tracks, each with transverse momentum satisfying $0.1 < p_T < 10.0 \, \text{GeV}/c$. The four tracks are geometrically constrained to come from the same spatial location, and the distance of closest approach of each track must lie within 10 cm of the interaction region along the beam axis and within 1.5 cm in the plane transverse to the beam axis. The ratio of the second-to-zeroth Fox-Wolfram moments for the events must be < 0.97 in order to reject events like radiative Bhabha scatters and $\mu^+\mu^-\gamma$, where the photon converts to a pair of tracks. In addition, the absolute value of the cosine of the polar angle of the event thrust axis must be less than 0.96.

As in previous measurements using this topology, the $\Upsilon(1S)$ candidate is formed from an opposite-charge lepton pair which are constrained to arise from a common spatial point. The $\Upsilon(1S) \to \mu^+\mu^-$ and $\Upsilon(1S) \to \tau^+\tau^-$ final states have different background contributions. Due to the presence of neutrinos in the tau final states, backgrounds from $e^+e^- \to \tau^+\tau^-$ and non-leptonic $\Upsilon(1S)$ decays are possible.
Figure 18.4.28. The recoil mass distribution for the dimuon (left) and di-tau (center) final states, and the dilepton mass for the dimuon final state (right) (del Amo Sanchez, 2010r).

The $\Upsilon(1S) \rightarrow \mu^+\mu^-$ final state (denoted D_μ) is required to contain same-flavor identified muons. The difference between the intial-state and final-state energies is required to be less than 0.5 GeV, to select events where the four tracks represent all of the final-state particles (*e.g.* no significant missing energy from neutrinos). The magnitude of the dipion momentum in the CM frame is required to satisfy < 0.875 GeV/c, and the cosine of the angle between the two lepton candidates is required to satisfy < -0.96.

For the $\Upsilon(1S) \rightarrow \tau^+\tau^-$ candidates (denoted D_τ), a tighter set of restrictions are required to reject backgrounds mentioned above. The difference between the intial-state and final-state energies is required to be greater than 5.0 GeV, to select events with significant missing energy due to neutrinos. The magnitude of the dipion momentum in the CM frame is required to satisfy < 0.825 GeV/c and each pion must have a CM momentum satisfying < 0.725 GeV/c. The measured difference in the energy of the $\Upsilon(3S)$ and $\Upsilon(1S)$ must satisfy $0.835 < \Delta E^* < 0.925$ GeV. A boosted decision tree (see Chapter 4 for a description of this tool) is used to further reject background, employing event-shape and kinematic variables. The performance of the classifier is assessed using data taken at a CM energy below the $\Upsilon(3S)$ mass.

In order to select events resulting from the dipion transition, a requirement is placed on the difference in the invariant mass of the $\Upsilon(3S)$ and $\Upsilon(1S)$ states; as determined from the final-state tracks, $\Delta M < 2.5$ GeV/c^2. In addition, the dipion mass is required to satisfy $0.28 < M_{\pi^+\pi^-} < 0.90$ GeV/c^2. For events with multiple track combinations satisfying these cuts, the combination with the ΔM closest to the nominal value is chosen.

An unbinned extended maximum likelihood fit is used to extract the signal yields. The fit employs two variables: for the $\Upsilon(1S) \rightarrow \mu^+\mu^-$ final state, the fit used the mass recoiling against the dipion system (Equation 18.4.3) and the invariant mass of the lepton pair. Monte Carlo simulations are used to verify these variables are uncorrelated, and the total likelihood is the product of the likelihoods in each dimension. For the $\Upsilon(1S) \rightarrow \tau^+\tau^-$ final state, only the dipion recoil mass is used.

The use of a ratio of branching fraction to the two possible final states allows for the cancellation of common systematic uncertainties. The two final-state samples are simultaneously fitted using the likelihood functions, and the result of the fit is $R_{\tau\mu} = 1.006 \pm 0.013$ (statistical uncertainty only). The projections of the fits to the data in the different variables are shown in Fig. 18.4.28.

Residual systematic uncertainties that do not cancel in the ratio are due to the trigger selection efficiency, event selection, and muon selection. The event selection efficiency systematic uncertainty is determined by comparing the shape of each variable in data and MC; the difference in efficiency due to shape differences is determined to be 1.2%. The muon identification systematic uncertainty is determined in situ by comparison the data and MC rates at which only one, or both, tracks are identified as muons. This uncertainty is determined to be 1.2%, and a correction factor of 1.023 on the efficiency is also determined. A correction to the di-tau final-state trigger efficiency is determined to be 1.020; the systematic uncertainty on the efficiency is determined to be 0.10%. For the di-muon mode, the systematic uncertainty on the trigger efficiency is determined to be 0.18%.

The *p.d.f.* shape uncertainty for the signal components is determined by varying the parameters; the model parameters were determined from the 10% of data used for developing the analysis. This uncertainty on the *p.d.f.* shapes is determined to be 0.22%. The recoil mass shape is assumed to be the same for the two final states; shape effects due to trigger efficiency are assumed to be neglectable, and this assumption incurs a systematic uncertainty of 0.6%.

Taking into account correction factors and systematic uncertainties, the final measured ratio of branching fractions is determined to be:

$$R_{\tau\mu} = 1.005 \pm 0.013 \, (stat.) \pm 0.022 \, (syst.). \quad (18.4.32)$$

No significant deviation from the Standard Model expectation of one is observed.

Chapter 19
Charm physics

In this chapter we proceed to the studies of open charm. It is fair to say that charm physics — more precisely the studies of hadrons containing a charm quark — underwent a revival of interest, both experimentally and theoretically, during the time of the B Factories. The main reasons for this are threefold; the first reason may be called *experimental*, the second *electroweak*, and the third *strong*. The experimental reason is the awareness of the community that B Factories are an abundant source of charm hadrons as well as B mesons. The cross-section for $e^+e^- \to \Upsilon(4S)$ production at $\sqrt{s} \approx 10.58$ GeV is around 1.1 nb, while that for the so-called continuum production of charm quark pairs, $e^+e^- \to \gamma^* \to c\bar{c}$, is around 1.3 nb. For an integrated luminosity of $1\,\mathrm{ab}^{-1}$ this corresponds to about 600×10^6 D^{*+} mesons produced together with another charmed hadron, available for study. The electroweak reason is due to the first experimental evidence for mixing phenomena in the system of neutral D mesons, which became available in 2007. At about that time it became obvious that — on using the world averages of the measured quantities including results from hadron colliders — the mixing parameters can and will be measured to sub-percent accuracy. Such measurements *per se* represent a possible way to search for processes beyond the SM. When it became clear that with the experimentally determined values of parameters it would be difficult to make specific statements about the presence of New Physics phenomena, experimental as well as theoretical efforts turned to studies of CP violation in the charm sector. This remains the focus of charm physics measurements today. Last but certainly not least there has been a third, strong-sector reason for the increased interest in charm physics. The discovery of the $X(3872)$ particle in 2003 (the observation of this particle has been confirmed and its properties studied by many experiments) with some of its properties similar to the conventional charmonia, but some in obvious disagreement with those, provides strong evidence that QCD has a rich spectrum of states beyond conventional mesons and baryons. Most of these so-called exotic states (although not all of them) bear a resemblance to hadrons composed of charm quarks. Surprises in the spectroscopy of charm hadrons continued also in the open charm sector with the discovery of $D_{s0}^*(2317)^+$ and $D_{s1}(2460)^+$ in 2003 and 2004, with their properties significantly different than expected from the naïve quark model.

The topic of conventional and exotic charmonium-like states is addressed in Chapter 18. This chapter focuses on the studies of open charm: mesons and baryons with a single charm quark. These states yield a number of interesting results which are, in many ways, complementary to results from B mesons. For any study of charm mesons their decay modes must be known. The latter are the subject of the first section in the chapter. The following section discusses the electroweak aspect of the charm physics with the results on mixing and CP violation parameters.

The strong-sector is in more details illuminated in the last two sections on the charm meson and charm baryon spectroscopy.

19.1 Charmed meson decays

Chunhui Chen, Patrick Roudeau, Anže Zupanc

19.1.1 Introduction

The first discovered weak decays of the charm hadrons were $D^0 \to K^-\pi^+$, $K^-\pi^+\pi^+\pi^-$ (Goldhaber et al., 1976) and $D^+ \to K^-\pi^+\pi^+$ (Peruzzi et al., 1976) observed by MARK III at the SPEAR e^+e^- collider operating at charm threshold. They allowed D mass measurements and established the Glashow-Iliopoulos-Maiani (GIM) mechanism (Glashow, Iliopoulos, and Maiani, 1970), which required existence of a charm quark to explain absence of flavor-changing neutral currents (FCNC) at tree level, resulting in large suppression of the strangeness-changing kaon decays like $K^0 \to \mu^+\mu^-$. Later on, the $D_s^+ \to \phi\pi^+$ decay was discovered by CLEO at CESR (Chen et al., 1983), and followed by the color-suppressed $D_s^+ \to \bar{K}^{*0}K^+$ observed by ARGUS at DORIS-II (Albrecht et al., 1986).

Since then, charm decay measurements have been thoroughly performed, and triggered off by searches for nonstandard weak interactions, as well as need for understanding of non-perturbative features in strong interactions. Both aspects are significantly different from the b-quark sector, making the measurements in general more difficult. Charm sector offers however an unique way to test the flavor physics of up-type quarks,[112] complementary to down-type quarks being investigated through measurements of strange and bottom decays.

Short distance contributions to flavor changing neutral current processes of the charm quark are highly GIM suppressed in the Standard Model, since the mass differences of the down-type quarks are small compared to the weak boson mass. A perturbative calculation of $c \to u$ FCNC processes yield a suppression factor $(m_b^2 - m_d^2)/m_W^2$, whereas FCNC in B and K decays are relatively strong due to the factor $(m_t^2 - m_u^2)/m_W^2$; thus the heavy top quark weakened the GIM suppression mechanism. However, due to the fact that in D decays no particular suppression happens due to CKM factors, there are in general large long distance contributions, making an analysis of the short-distance dynamics difficult. As an example, the short distance contribution to $D^0 - \bar{D}^0$ oscillation is very small, by far exceeded by long distance contributions that are hard to compute.

Consequently, long-distance dynamics, like final state interactions (FSI), play an important role, since they are in general much larger in charm meson decays than for $B_{(s)}$ decays. In many cases they exceed the short-distance

---

[112] Top quarks due to their short lifetime do not hadronize, thus many phenomena cannot be studied.

contributions even by a few order of magnitudes. Compared to B decays there is a smaller energy release in $D_{(s)}$ decays, resulting in production of slower daughter particles, which thus are more likely to influence each other before they leave interaction region. Any precision electroweak predictions require then theoretical improvement in calculating long-distance QCD effects to remove substantial hadronic uncertainties. Strategies for NP searches and interpretation of measurements highly depend on quantitative information on hadronic effects. Such effects are non-perturbative and their theoretical calculations are still challenging for any approach/method. As charm quark lies inbetween the light flavours ($m_{u,d,s} \leq \Lambda_{QCD}$) described by chiral perturbation theory (ChPT) and heavy quarks ($m_b \gg \Lambda_{QCD}$) treated by heavy-quark effective theory (HQET), charm decays can bring new insight into non-perturbative QCD. Since heavy-quark mass expansion does not work as well for charm decays, thus computation of hadronic effects is more difficult than for corresponding B decays. Despite of this, charm decays can still help to establish theoretical tools and allow their callibration for calculations inevitable for $B_{(s)}$ decays.

19.1.1.1 Quark diagrams for weak decays of charm mesons

Quark diagrams underlying hadronic, semileptonic and leptonic decays of charm mesons are shown in Fig. 19.1.1. Taking into account topology of these quark graphs, they are either simple tree-level diagrams (Fig. 19.1.1(a-d,g,h)) or penguin diagrams (Fig. 19.1.1(e,f)) representing higher-order, loop-level processes.

Tree-level hadronic decays (Fig. 19.1.1(a-c)) and semileptonic ones (Fig. 19.1.1(f)) proceed through $c \to W^+ s$ current and thus have amplitudes governed by the CKM matrix element $|V_{cs}| \simeq 0.97$. These decays are Cabibbo-favored (CF) processes, while the corresponding Cabibbo-suppressed (CS) decays proceed via $c \to W^+ d$ and involve $|V_{cd}| \simeq 0.22$. Unless W^+ materializes into either $l^+\nu_l$ leptons (Fig. 19.1.1(g,h)) or $u\bar{d}$ pair (Fig. 19.1.1(a,b,d)) inducing the CKM factor of $|V_{ud}|$, Cabibbo suppression may arise from the light-quark $u\bar{s}$ vertex involving $|V_{us}|$. Thus the CF modes at the tree level proceed through $c \to s\bar{d}u$, singly Cabibbo-suppressed (SCS) ones through either $c \to d\bar{d}u$ or $c \to s\bar{s}u$, while doubly Cabibbo-suppressed (DCS) modes via $c \to d\bar{s}u$.

Figures 19.1.1(a,b,e,g) represent spectator decays, in which a light constituent antiquark does not participate in the weak interaction, contrary to non-spectator decays shown in Fig. 19.1.1(c,d,f,h).

Decays of ground charmed mesons to final states involving leptons (Fig. 19.1.1(g,h)) are the simplest and the cleanest channels and, as such, enable tests of the SM predictions or the Lattice-QCD calculations in the charm sector.

Semileptonic $D_{(s)} \to Xl^+\nu_l$ decays (where $l = e$ or μ), comprise significant fractions of $D_{(s)}$ total widths (see Section 19.1.5); up to about for 6% D^0, 16% for D^+ and 6% for D_s^+ mesons. In the underlying CF decay diagram (Fig. 19.1.1(g)), a virtual W^+ boson decays to the $l^+\nu_l$
Figure 19.1.1. Quark diagrams for charm meson decays: hadronic (a-f), semileptonic (g), leptonic (h). Diagrams underlying hadronic decays: external W emission (a), internal W emission (b), W exchange (c), W annihilation (d), W-loop penguin (e) and W-loop penguin annihilation (f).

system, while the $s\bar{q}$ pair hadronizes into a strange meson independently of the leptonic current. This hadronization is described by related form factors; single one for spin-0 hadron and three form factors for vector meson. The form factors increase with momentum transfer $q^2 \equiv M^2(l^+\nu_l)$, as for maximal q^2 value the final state hadron is at rest in the initial D rest frame and an overlap of wave functions of initial and final states is largest. Measurements of shape of the form factor and its value at maximal q^2 allow one to test theoretical calculations performed with either HQET based models or with LQCD. Since semileptonic decays often serve as a reference for hadronic decays, it is important to check whether the D_s^+ semileptonic decays mirror

the D ones. Precision of D_s^+ decays like $D_s^+ \to \eta^{(')}l^+\nu_l$ and $D_s^+ \to \phi l^+\nu_l$ (with uncertainties of $\pm 6\%$-$\pm 20\%$), is still lower than for $CF\ D \to \bar{K}^{(*)}l^+\nu_l$ and $CS\ D \to \pi l^+\nu_l$ or $D \to \rho l^+\nu_l$ decays (with uncertainties of $\pm 2\%$-$\pm 3\%$).

Hadronic analogue of the semileptonic process is shown in Fig. 19.1.1(a) where an externally-emitted virtual W^+ materializes into quark pair forming the final-state hadron. The corresponding process with an internal W emission (Fig. 19.1.1(b)) has different quark pairings. Such a diagram represents a color-suppressed decay, as it requires a color matching between the quarks originating from different decay vertices. In the simplest approach based on analogy to semileptonic decays, presented hadronic decays are expressed as a product of two hadronic currents describing formation of mesons out of quark-antiquark pairs. In this approach, called naïve factorization, the hadronic currents for a two body decay are expressed by the decay constants of the respective meson and the form factors for the $D \to$ meson transition (see Section 19.1.1.3). Non-perturbative strong interactions, like soft-gluon effects and rescattering of the final-state particles, complicates the simple picture represented by the quark diagrams, and thus renders factorization invalid. Measurements performed so far suggest that naïve factorization for D decays does not work as well as for B decays, where a QCD based factorization has been formulated using a $1/m_b$ expansion. Overall it is fair to say that there is no satisfactory theoretical framework for the description of exclusive non-leptonic charm decays.

Leptonic $D_{(s)}^+ \to l^+\nu_l$ decays (see Section 19.1.6), proceed through W-annihilation diagram (Fig. 19.1.1(h)). Due to helicity suppression which results in the m_l^2 lepton-mass dependence of the decay width, rate for light charged leptons is small. Since $D_s^+ \to l^+\nu_l$ decays involve V_{cs}, with respect to V_{cd} underlying $D^+ \to l^+\nu_l$, leptonic D_s^+ decay rates are significantly larger than those for D^+. All the strong interaction effects, namely hadronic dynamics of the initial meson, are factorized into its decay constant $f_{D_{(s)}^+}$, which is related to an overlap of wave functions of the constituent quark and antiquark. Measurement of $D_{(s)}^+ \to l^+\nu_l$ allows ones to determine the product $f_{D_{(s)}^+}|V_{cd(cs)}|$, thus to extract $f_{D_{(s)}^+}$ one needs the $|V_{cd(cs)}|$ value from other than leptonic decays.

Decay constants are fundamental parameters, and can serve as a test how well we are able to model dynamics of, in general, non-perturbative effects of hadronic dynamics. By measuring $f_{D_{(s)}^+}$ one can verify the Lattice-QCD calculations used for calculation of B decay constants, which are difficult to measure as their leptonic decays are additionally suppressed by the tiny value of V_{ub}. Also, having both f_{D^+} and $f_{D_s^+}$ measured one can directly estimate $SU(3)$-flavor symmetry breaking and compare it with theory prediction. Such a test would help to estimate reliably effects of violation of the $SU(3)$-symmetry based $f_{B_s} = f_B$ relation, as f_{B_s} cannot be directly measured and must rely on f_B measurement.

The **W-annihilation** hadronic decays (Fig. 19.1.1(d)), although the helicity suppression is

here mitigated by strong interactions, are still strongly suppressed with respect to the tree-level spectator processes; similar applies to **W-exchange** processes (Fig. 19.1.1(c)). First signal for W-exchange decay was $D^0 \to \bar{K}^0\phi$ (Albrecht et al., 1985a) owing to the fact that helicity suppression does not apply to spin-0 meson decays with vector particle in final state. Though its large branching ratio of 10^{-2} suggests that some QCD effects, like rescattering, are involved in the decay dynamics.

The CKM elements parameterizing the mixing of the first two families into the third are all at least of order λ^2 in the Wolfenstein parameterization, and hence charm physics can be described to a good approximation by taking into account only the first two families. To this end, we have approximatively $V_{us}V_{cs}^* \approx -V_{ud}V_{cd}^*$ which has the interesting implication that the effective interaction for SCS $c \to u$ transitions takes the form

$$H_{\text{eff}} = \frac{G_F}{\sqrt{2}} V_{us} V_{cs}^* (\bar{c}u)_{\text{V-A}} [(\bar{s}s)_{\text{V-A}} - (\bar{d}d)_{\text{V-A}}] \quad (19.1.1)$$

which vanishes in the $SU(3)$ limit, *i.e.* once the strange and the down quark have the same mass. However, $SU(3)$ is severely broken and hence this suppression due to the $SU(3)$ flavor symmetry is not very effective.

19.1.1.2 Hadronic decays; application of symmetries

D mesons decay dominantly (84%) into hadronic final states and, as a charm-quark mass is quite sizable, number of hadronic $D_{(s)}$ decays is quite large. About 63% of the total width are two-body modes, as multibody processes are in fact quasi-two-body ones if intermediate resonances are considered as a single particle. Study of dynamics of multibody $D_{(s)}$ decays via either Dalitz plot or partial-wave analysis (PWA), can bring important information on light-flavor hadron spectroscopy (see Section 19.1.4).

All the two-body hadronic decays of charm mesons can be classified according to the six diagrams shown in Fig. 19.1.1(a-f). Measurements of two-body exclusive $D_{(s)}$ decays allow a quark-diagram analysis in which one determines magnitudes and signs of the amplitudes corresponding to the individual diagrams (Chau and Cheng, 1986) (Cheng and Chiang, 2010) (Bhattacharya and Rosner, 2010) (Bhattacharya and Rosner, 2009) (Bhattacharya, Gronau, and Rosner, 2012). Such decomposition allowed to understand important properties of charm mesons. As an example, external and internal diagrams in Fig. 19.1.1 (a,b) give rise to respectively the $D^0 \to K^-\pi^+$ and $D^0 \to \bar{K}^0\pi^0$ decays, while they both can lead to the $D^+ \to \bar{K}^0\pi^+$ final state. Destructive interference between CF external and internal amplitudes in D^+ decays, along with fewer CF D^+ channels, increases significantly the D^+ lifetime. Somewhat enhanced contribution from the exchange diagram (Fig. 19.1.1(c)) to the D^0 width could also reduce the D^0 lifetime. A pattern similar to the one for the $D \to \bar{K}\pi$ decays is also preferred by the data for the decays with vector meson in the final state, $D^+ \to \bar{K}^{*0}\pi^+$ and $D^+ \to \bar{K}^0\rho^+$. On the other hand,

$\tau(D^0) < \tau(D_s^+)$ lifetime difference can be explained with W-annihilation contribution to the D_s decay width, via for example $D_s^+ \to \rho\pi$, as all the spectator diagrams contribute similarly into D_s^+ and D^0 decays.

These analyses also show that the measured rates of the $D \to \bar{K}\pi$ decays, and many other channels with either two pseudoscalars or pseudoscalar and vector in final state, hardly can be fitted if the contributing quark amplitudes are real. This suggests that strong interactions modify the weak decay amplitudes, so that they carry phases induced by, for example, rescattering effects.

Using the fitted amplitudes one can make predictions for not yet measured decays based on their quark-diagram structure. Precision measurements of certain $D_{(s)}$ channels, especially those involving vector mesons, can help to determine better or/and ambiguously the suppressed amplitudes: exchange amplitudes ($D^0 \to \bar{K}^{*0}K^0$, $\bar{K}^0K^{*0}$, $D^0 \to \bar{K}^{*0}\eta^{(\prime)}$), annihilation amplitudes ($D_s^+ \to \eta^{(\prime)}\pi^+$, $D_s^+ \to \rho^+\pi^0$, $D_s^+ \to \omega\pi^+$) and penguin amplitudes ($D^0 \to \pi^0\pi^0$, $D^0 \to \bar{K}^0K^0$).

A powerful method of studying rescattering is an isospin analysis as isospin invariance holds to a very high accuracy. The isospin analysis requires an isospin decomposition of decay amplitudes for all possible charge states in isospin-related final states. For $D \to \bar{K}\pi$ decays, the decay amplitudes ($\mathcal{A}$) for $D^0 \to K^-\pi^+$, $D^0 \to \bar{K}^0\pi^0$ and $D^+ \to \bar{K}^0\pi^+$ are linear combinations of the partial-wave isospin amplitudes (A_I) with $I = 1/2$ and $I = 3/2$:

$$\mathcal{A}(D^0 \to K^-\pi^+) = \sqrt{1/3}A_{3/2} + \sqrt{2/3}A_{1/2}$$
$$\mathcal{A}(D^0 \to \bar{K}^0\pi^0) = \sqrt{2/3}A_{3/2} - \sqrt{1/3}A_{1/2}$$
$$\mathcal{A}(D^+ \to \bar{K}^0\pi^+) = \sqrt{3}A_{3/2}, \quad (19.1.2)$$

decomposition of the $D^0 \to \pi^+\pi^-$, $D^0 \to \pi^0\pi^0$ and $D^+ \to \pi^+\pi^0$ amplitudes into the $I = 0$ and $I = 2$ isospin amplitudes gives:

$$\mathcal{A}(D^0 \to \pi^+\pi^-) = \sqrt{1/3}A_2 + \sqrt{2/3}A_0$$
$$\mathcal{A}(D^0 \to \pi^0\pi^0) = \sqrt{2/3}A_2 - \sqrt{1/3}A_0$$
$$\mathcal{A}(D^+ \to \pi^+\pi^0) = \sqrt{3/2}A_2, \quad (19.1.3)$$

while the $D^0 \to \bar{K}K$ final states form the isospin amplitudes of $I = 0$ and $I = 1$ as:

$$\mathcal{A}(D^0 \to K^-K^+) = \sqrt{1/2}A_1 + \sqrt{1/2}A_0'$$
$$\mathcal{A}(D^0 \to \bar{K}^0K^0) = \sqrt{1/2}A_1 - \sqrt{1/2}A_0'$$
$$\mathcal{A}(D^+ \to \bar{K}^0K^+) = \sqrt{2}A_1. \quad (19.1.4)$$

The amplitudes $A_i^{(\prime)}$ are in general complex numbers; however, only their relative phase is observable. This allows us to introduces relative final-state phase between the isospin amplitudes in Eqs (19.1.2)–(19.1.4), defined as $\delta_{K\pi} = \arg(A_{3/2}/A_{1/2})$, $\delta_{\pi\pi} = \arg(A_2/A_0)$ and $\delta_{KK} = \arg(A_1/A_0)$.

Having measured partial widths for all three final states in each of Eqs (19.1.2)–(19.1.4), one can obtain magnitudes of isospin amplitudes and their relative phase. Old

CLEO analyses (Bishai et al., 1997) (Selen et al., 1993) showed that the isospin-amplitude relative phases for both, $D \to \overline{K}\pi$ and $D \to \pi\pi$ decays were almost 90°, implying large FSI. Adding the isospin amplitudes with no phase allowed estimation of the decay rates without rescattering: $\mathcal{B}(D^0 \to K^-\pi^+)_{\mathrm{no\ FSI}} \approx 1.3\ \mathcal{B}(D^0 \to K^-\pi^+)$, $\mathcal{B}(D^0 \to \pi^+\pi^-)_{\mathrm{no\ FSI}} \approx 1.6\ \mathcal{B}(D^0 \to \pi^+\pi^-)$. An isospin phase shift for $D \to \overline{K}K$ decays was however found to be consistent with zero. Thus elastic FSI explains neither enhanced $\mathcal{B}(D^0 \to K^-K^+)$, nor the decay rate of about 10^{-4} for $D^0 \to \overline{K}^0 K^0$ which, if one neglects W-exchange amplitude, should be in the SM forbidden. Therefore either inelastic FSI or large W-exchange contribution could explain the latter. Another issue emerging from the isospin analyses is related to a large $I = 2$ amplitude for $D \to \pi\pi$ decays, $|A_2|/|A_0| = 0.72 \pm 0.17$. This indicates that there is no $\Delta I = 1/2$ for the D decays into two pions, while it is well known that for $K \to \pi\pi$ decays A_2 is very small.

Each of the Equations 19.1.2-19.1.4 leads to a triangle relation among the decay amplitudes. Nonzero area for the formed triangle would be an evidence for either a difference in phases between the isospin amplitudes or contributions from quark-diagram amplitudes with different weak (CKM) phases. The latter would be a sign of isospin violation, possibly originating form a NP contribution.

Unlike the isospin symmetry, the $SU(3)$-flavor symmetry is heavily broken, and its long-standing indication in charm decays comes from the $D^0 \to K^-K^+$ and $D^0 \to \pi^+\pi^-$ widths, which, without $SU(3)$ violation and with phase-space related factor removed, are expected to be equal. The measured ratio is $\Gamma(D^0 \to K^-K^+)/\Gamma(D^0 \to \pi^+\pi^-) \simeq 3$, although a phase-space allowed in a numerator is smaller. An $SU(3)$-breaking effect in a dominant, external W-emission amplitude itself may arise from a difference in decay constants of pion and kaon, $f_K > f_\pi$. It implies a larger external amplitude for $D^0 \to K^-K^+$, but is insufficient to explain the measured ratio. Due to inelastic FSI the $\pi\pi$ mode can be converted into $\overline{K}K$ via for example scalar resonances coupling to both these final states. To confirm this scenario one needs quantitative estimation of inelastic rescattering.

Penguin diagram contributes to $D^0 \to K^-K^+$ and $D^0 \to \pi^+\pi^-$ with opposite relative signs, and for the KK mode is destructive with respect to the tree amplitude, reducing the expected width ratio and thus making the situation even worse. The penguin contribution is expected to be small, however, similarly to the exchange amplitude, the long-distance QCD effects can enhance it significantly and make the theoretical calculations very difficult. On the other hand, knowledge of a size of the penguin amplitude is of great importance for estimation of the CP violation expected in the charm sector within the SM (see Section 19.2). Measurement of a width for $D^0 \to \pi^0\pi^0$, containing the same penguin pollution as $D^0 \to K^-K^+$ and $\pi^+\pi^-$, will allow an estimation of the penguin contribution.

19.1.1.3 Methods for estimating matrix elements

Theoretical description of charm-changing decay, $D \to f$, exploits an (low-energy) effective Hamiltonian constructed with the help of an Operator Product Expansion (OPE) (framework) in terms of local operators O_i and the (couplings) Wilson coefficients c_i. Following the same line of argument as for B decays, one obtains an effective Hamiltonian of the form:

$$\langle f|\mathcal{H}_{eff}|D\rangle = \frac{G_F}{\sqrt{2}} V_{CKM} \langle f| \sum_i c_i(\mu)O_i(\mu)|D\rangle, \quad (19.1.5)$$

where G_F is Fermi constant and V_{CKM} is a factor related to the CKM matrix elements involved in the decay. The renormalization scale μ separates contributions from long-distance dynamics (with length scales above $1/\mu$) and short-distance interactions (with length scales below $1/\mu$). All degrees of freedom with masses above μ give rise to effectively point-like interactions and are integrated out into the coefficents c_i using perturbation theory. Degrees of freedom having mass scales below μ remain dynamical and are included in the operators O_i. Their hadronic matrix elements (hadronic expectation values), $\langle f| \sum_i c_i(\mu)O_i(\mu)|D\rangle$, involve non-perturbative dynamics. Typically $\mu \approx m_c$ is used as it assures that $\mu \gg \Lambda_{QCD}$ and thus c_i, which depends on the strong coupling constant, can be treated perturbatively. Also such a choice provides a resonable momentum cut-off for hadron wave functions used to calculate the hadronic matrix elements. These calculations, especially for nonleptonic transitions, are still challenging.

The effective Hamiltonian for the $\Delta C = 1$ weak decay is (Buchalla, Buras, and Lautenbacher, 1996):

$$\mathcal{H}_{eff}^{\Delta C=1} = \frac{G_F}{\sqrt{2}} \Big[\sum_{q=d,s} V_{uq}V_{cq}^* (c_1 O_1 + c_2 O_2)$$
$$-V_{ub}V_{cb}^* \sum_{i=3}^{6} c_i O_i + c_{8g}O_{8g} \Big] + h.c.,$$
$$(19.1.6)$$

where O_1 and O_2 are the tree-level operators expressed as the current products:

$$O_1 = (\bar{q}c)_{V-A}(\bar{u}q)_{V-A}, O_2 = (\bar{u}c)_{V-A}(\bar{q}q)_{V-A}. \quad (19.1.7)$$

Although the weak decays are mainly driven by the operator O_1, QCD effects also induce other operators such as O_2 and, in general, both terms contribute to the amplitudes in Fig 19.1.1(a-d). The remaining operators correspond to the penguin contributions in Fig 19.1.1(e-f):

$$O_{3,5} = (\bar{u}c)_{V-A} \sum_{q'=u,d,s} (\bar{q}'q')_{V\mp A},$$
$$O_{4,6} = \sum_{q'=u,d,s} (\bar{u}q')_{V-A} \sum_{q'=u,d,s} (\bar{q}'c)_{V\mp A},$$
$$O_{8g} = -\frac{g_s}{8\pi^2} m_c \bar{u}\sigma_{\mu\nu}(1+\gamma_5)G^{\mu\nu}c, \quad (19.1.8)$$

where g_s is the strong decay constant, $G^{\mu\nu}$ denotes the QCD field strength tensor, while the $(\bar{q}q)_{V\mp A}$ current structure in Eq. (19.1.7)-(19.1.8) corresponds to $(\bar{q}\gamma(1\mp\gamma_5)q)$. The Wilson coefficients evaluated at $\mu \approx m_c$ are $c_1 \simeq 1.21$, $c_2 = -0.41$, $c_3 = 0.02$, $c_4 = -0.04$, $c_5 = 0.01$, $c_6 = -0.05$ and $c_{8g} = -0.06$ (Buchalla, Buras, and Lautenbacher, 1996).

The remaining task, namely the calculation if the matrix elements of the effective operators, is difficult for charm decays, since charm is neither heavy enough for a reliable $1/m_c$ expansion, nor light enough to be described in terms of chiral perturbation theory. Motivated by the form of the effective Hamiltonian, a pragmatic approach has been suggested some decades ago (Bauer, Stech, and Wirbel, 1987) by introducing two parameters a_1 and a_2 according to

$$A(D \to f) \sim a_1 \langle f|(\bar{q}c)_H (\bar{u}q)_H|D\rangle + a_2 \langle f|(\bar{u}c)_H (\bar{q}q)_H|D\rangle,$$
(19.1.9)

where the subscripts H mean that the matrix element is calculated in naïve factorization:

$$\langle f_1 f_2|(\bar{q}c)_H (\bar{u}q)_H|D\rangle \simeq \langle f_1|(\bar{q}c)|0\rangle \langle f_2|(\bar{u}q)|D\rangle,$$
$$\langle f_1 f_2|(\bar{u}c)_H (\bar{q}q)_H|D\rangle \simeq \langle f_1|(\bar{u}c)|0\rangle \langle f_2|(\bar{q}q)|D\rangle.$$
(19.1.10)

The quantities a_1 and a_2 are scale-invariant, phenomenological parameters, which are assumed to be universal for all the decays. Comparing with the QCD calculation of the effective Hamiltonian, we write

$$a_1 = c_1 + \xi c_2, \ a_2 = c_2 + \xi c_1$$
(19.1.11)

where ξ parameterizes the long distance effects that are not correctly treated by naïve factorization.

The matrix elements appearing in the naïve factorization (19.1.10) correspond to the meson decay constants and form factors and can be taken from measurements of the (semi)leptonic $D_{(s)}$ decays. The $a_{1,2}$ can then be fitted from the experimental data and first such a analysis, the Bauer-Stech-Wirbel (BSW) analysis, was performed for the $D \to K\pi$ decays (Bauer, Stech, and Wirbel, 1987) and yielded $a_1 = 1.3 \pm 0.1$ and $a_2 = -0.5 \pm 0.1$. Once compared with the theoretical expectations, $a_1 = 1.25 - 0.48\xi$ and $a_2 = -0.48 + 1.25\xi$, suggested $\xi \simeq 0$.

The non-spectator, exchange and annihilation diagrams (Fig. 19.1.1(c-d)) are within the factorization described using a vacuum insertion:

$$\langle f_1 f_2|(\bar{q}c)_H (\bar{u}q)_H|D\rangle \simeq \langle f_1 f_2|(\bar{q}c)_H|0\rangle \langle 0|(\bar{u}q)_H|D\rangle,$$
(19.1.12)

and are in general a small correction with respect to the decays determined by the a_1 or/and a_2. An impact of the non-spectator diagrams on the two-body charm decays was also studied in the BSW analysis (Bauer, Stech, and Wirbel, 1987).

Naïve factorization as defined by BSW approach is very simply and allows us to parameterize most of the hadronic decays with just two parameters. However, this simple ansatz is not satisfactory for the improved measurements, and thus more sophisticated theoretical approaches need to be developed.

19.1.2 Branching ratio measurements

The large statistics accumulated at B Factories and clean environment of the e^+e^- experiment allowed precision measurements of absolute branching fraction of favored weak $D_{(s)}$ decays, previously obtained using sometimes only a few hundred signal events. Such measurements require a knowledge of a total number of produced $D_{(s)}$ mesons to normalize the $D_{(s)}$ signal reconstructed in the decay mode of interest. That can be achieved either via an exclusive reconstruction of $e^+e^- \to c\bar{c}$ events for measurement of directly produced $D_{(s)}$ (Belle technique), or through tagging selected B decays as a source of charmed mesons (BABAR technique). The measured decays serve as a reference for measurements of the branching fractions of the $D_{(s)}$ to any other final state, improve our knowledge of most of the decays of the $B_{(s)}$ mesons, and of fundamental parameters of the Standard Model.

The suppressed $D_{(s)}$ decays are measured with respect to the favored processes having a similar topology. Relative branching ratio measurements allow cancelation of numerous systematic uncertainties. Precision measurements of the suppressed charm decays give insight into decay dynamics and allow tests of the various symmetries assumed in the theoretical calculations.

19.1.2.1 Absolute Branching Fraction of $D^0 \to K^-\pi^+$

The $D^0 \to K^-\pi^+$ is a reference mode for many measurements of the D decays. CLEO-c (He et al., 2005) published its result on this branching fraction, the most precise at the time, which was widely used (Yao et al., 2006). BABAR using $210\,\mathrm{fb}^{-1}$ data, has produced even more precise measurement based on a different technique (Aubert, 2008p). The $D^0 \to K^-\pi^+$ decays are identified in a sample of D^0 mesons produced in $D^{*+} \to D^0\pi^+$ decays and obtained with partial reconstruction of $\bar{B}^0 \to D^{*+}(X)\ell^-\bar{\nu}_\ell$ (see also Section 7.3.2). Such B candidates are selected by retaining events containing a charged lepton ($\ell = e, \mu$) and a low momentum (soft) pion (π_s^+) which may arise from the decay $D^{*+} \to D^0\pi_s^+$. Momenta of the lepton and the soft pion must respectively satisfy the $1.4 < p_{\ell^-} < 2.3\,\mathrm{GeV}/c$ and $60 < p_{\pi_s^+} < 190\,\mathrm{MeV}/c$. The minimum p_{ℓ^-} and $p_{\pi_s^+}$ are optimized to minimize uncertainties due to charm production in B decays and tracking errors, respectively, while the maximum momenta are determined by the available phase space. The two tracks must be consistent with originating from a common vertex, constrained to the beam-spot in the plane transverse to the beam axis. Then they combine p_{ℓ^-}, $p_{\pi_s^+}$ and the probability from the vertex fit into a likelihood ratio variable, optimized to reject $B\bar{B}$ background. Using conservation of momentum and energy, the invariant mass squared of the undetected neutrino is calculated as:

$$\mathcal{M}_\nu^2 \equiv (E_\mathrm{beam} - E_{D^*} - E_\ell)^2 - (\boldsymbol{p}_{D^*} + \boldsymbol{p}_\ell)^2,$$
(19.1.13)

where E_beam is half the total center-of-mass (c.m.) energy and E_ℓ (E_{D^*}) and $\boldsymbol{p}_\ell$ ($\boldsymbol{p}_{D^*}$) are the energy and momentum

of the lepton (the D^* meson) in the c.m. system. Since the magnitude of the B meson momentum in the c.m. system $|\boldsymbol{p}_B| \ll |\boldsymbol{p}_\ell|, |\boldsymbol{p}_{D^*}|$, they set $\boldsymbol{p}_B = 0$ in the above equation. As a consequence of the limited phase space available in the D^{*+} decay, the soft pion is emitted nearly at rest in the D^{*+} rest frame. The D^{*+} four-momentum can therefore be computed by approximating its direction as that of the soft pion, and parameterizing its momentum as a linear function of the soft-pion momentum.

All events where D^{*+} and ℓ^- originate from the same B meson, producing a peak near zero in the $\mathcal{M}_\nu^2$ distribution, are considered as signal candidates. This sample of events is referred to as the *inclusive* sample. Sample of events with the same charge of π_s and lepton is also selected for background studies and is referred to as wrong-charge sample. Number of the inclusive signal events is obtained from a minimum χ^2 fit to the $\mathcal{M}_\nu^2$ distribution in the interval $-10 < \mathcal{M}_\nu^2 < 2.5 \, \text{GeV}^2/c^4$. Figure 19.1.2(a) shows the fit result in the $\mathcal{M}_\nu^2$ projection, with signal and background shapes obtained with the MC simulations, while the $\mathcal{M}_\nu^2$ distribution of the wrong-charge sample that contains background candidates only is shown in Fig. 19.1.2(b). The inclusive yield for $\mathcal{M}_\nu^2 > -2 \, \text{GeV}^2/c^4$ is $N^{\text{incl}} = (2171 \pm 3 \pm 18) \times 10^3$.
Figure 19.1.2. From (Aubert, 2008p). The $\mathcal{M}_\nu^2$ distribution of the inclusive sample, for right-charge (a) and wrong-charge (b) samples. The data are represented by solid points with uncertainty. The MC fit results are overlaid on the data, as explained in the figure.

To obtain the *exclusive* signal sample, $D^0 \to K^- \pi^+$ decays are reconstructed using all tracks in the event, aside from the ℓ^- and π_s^+, with momenta in the direction transverse to the beam axis exceeding $0.2 \, \text{GeV}/c$. They combine pairs of tracks with opposite charge and compute the invariant mass $m(K\pi)$ assigning the kaon mass to the track with charge opposite the π_s charge. D^0 candi-

dates from the mass range $1.82 < m(K\pi) < 1.91 \, \text{GeV}/c^2$ are combined with the π_s^+. Events having the mass difference, $\Delta M = m(K^- \pi^+ \pi_s^+) - m(K^- \pi^+)$, in the range of $142.4 < \Delta M < 149.9 \, \text{MeV}/c^2$ are selected as the signal candidates (see Fig. 19.1.3). The exclusive selection yields $N^{\text{excl}} = (33.8 \pm 0.3) \times 10^3$ signal events. The branching
Figure 19.1.3. From (Aubert, 2008p). Continuum subtracted ΔM distribution for data (points with error bars) and backgrounds overlaid as explained in the figure.

fraction is computed as:

$$\mathcal{B}(D^0 \to K^- \pi^+) = N^{\text{excl}}/(N^{\text{incl}} \zeta \varepsilon_{(K^- \pi^+)}), \quad (19.1.14)$$

where $\varepsilon_{(K^- \pi^+)} = (36.96 \pm 0.09)\%$ is the D^0 reconstruction efficiency from MC simulation, and $\zeta = 1.033 \pm 0.002$ is the selection bias introduced by the partial reconstruction. The measured result is:

$$\mathcal{B}(D^0 \to K^- \pi^+) = (4.007 \pm 0.037 \pm 0.072)\%, \quad (19.1.15)$$

where the first uncertainty is statistical and the second uncertainty is systematic. This result is comparable in precision with the so far the most precise measurement by Cleo-c (Dobbs et al., 2007b) and is consistent with it within one standard deviation.

19.1.2.2 Absolute Branching Fractions of D_s^+ decays

Belle has measured absolute branching fractions of $D_s^+ \to K^+ K^- \pi^+$, $D_s^+ \to \bar{K}^0 K^+$ and $D_s^+ \to \eta \pi^+$ (Zupanc, 2013b) being reference modes for the leptonic D_s^+ decays (see Section 19.1.6). The analysis is based on the $913 \, \text{fb}^{-1}$ and the studied D_s mesons are produced in the following reaction:

$$e^+ e^- \to c\bar{c} \to D_{tag} K X_{frag} D_s^{*-}, \; D_s^{*-} \to D_s^- \gamma, \quad (19.1.16)$$

where one of the charm quarks hadronizes into the D_s, while the other into *tagging* charm hadron D_{tag}, which is reconstructed as $D^{(*)+}$, $D^{(*)0}$ or Λ_c^+. The ground charmed hadrons, D^+, D^0 and Λ_c^+, are reconstructed in 18 hadronic decay modes in total, with up to one π^0 in the final state to keep low background level. In order to reject background from $e^+e^- \to B\bar{B}$ events and combinatorial background the e^+e^- center-of-mass D_{tag} momentum is required to be greater than $2.3\,\text{GeV}/c^2$ (or $2.5\,\text{GeV}/c^2$ for less clean D_{tag} modes). To further clean up the reconstructed sample of the ground D_{tag} hadrons several variables being either topological (the D_{tag} decay vertex quality, distance between production and decay vertices, angle between D_{tag} momentum vector and production-to-decay vector), related to the dynamics (D_{tag} decay angle) or quality of the decay products (charged hadron identification, π^0 quality) are combined into a single neural network output variable (`NBout`), being a probability that a given D_{tag} candidate is a correctly reconstructed signal. The `NBout` selection is optimized using NeuroBayes neural network (see Section B) trained on a small data sample; the optimization procedure maximizes the signal significance measured from the D_{tag} invariant-mass distribution. Within the selected D_{tag} sample, D^+ and D^0 mesons originating from $D^{*+} \to D^0\pi^+$, $D^+\pi^0$ and $D^{*0} \to D^0\pi^0$, $D^0\gamma$ decays are identified using the invariant-mass difference $\Delta M(D^*) \equiv M(D\pi/\gamma) - M(D)$.

An additional K in Eq. (19.1.16), detected as either K^+ or K_S^0, assures strangeness conservation in the event,[113] while X_{frag} is a fragmentation system denoting additional particles that can be created in the hadronization. The X_{frag} is formed from the remaining charged pions (up to three) and up to one π^0 candidate. The $D_{tag}KX_{frag}$ combinations are required to have a common vertex, total electric charge of ± 1 (giving inclusively reconstructed $D_s^{*\mp}$) and *right sign* of their charm and strangeness quantum numbers relative to their total charge (charm in the D_{tag} and strangeness of the primary K, if specified, are required to be opposite to the charge of the D_s^*).

The method uses only D_s^+ mesons produced through parent D_s^{*+}, so one requires a photon consistent with $D_s^{*+} \to D_s^+\gamma$. This provides a powerful constraint on the D_s^+ signal and improves a resolution of the missing mass used to identify D_s^+ signal and defined as:

$$M_{miss}(D_{tag}KX_{frag}\gamma) \equiv \sqrt{p_{miss}^2(D_{tag}KX_{frag}\gamma)},$$
$$(19.1.17)$$

where p_{miss} is the missing four-momentum in the event

$$p_{miss}(D_{tag}KX_{frag}\gamma) = p_{e^+} + p_{e^-} - p_{D_{tag}} - p_K - p_{X_{frag}} - p_\gamma$$
$$(19.1.18)$$

For correctly reconstructed events described by Eq. (19.1.16), the $M_{miss}(D_{tag}KX_{frag}\gamma)$ peaks at the nominal D_s mass, while the corresponding $M_{miss}(D_{tag}KX_{frag})$ at the nominal D_s^* mass. To improve the D_s signal resolution, the D_s^* candidates within the $2.0 <$

$M_{miss}(D_{tag}KX_{frag}) < 2.25\,\text{GeV}/c^2$ region are selected and refitted with a D_s^* mass constraint.

To obtain a fully *inclusive* D_s^+ sample used for normalization in the branching fraction calculation, there are no requirements on the D_s^+ decay products. The inclusive D_s^+ signal yield is obtained from the fit to the $M_{miss}(D_{tag}KX_{frag}\gamma)$ spectrum for each X_{frag} mode separately. Figs 19.1.4 show the fitted spectra for X_{frag} modes giving the largest yields, X_{frag} = nothing, $\pi^\pm$, and $\pi^+\pi^-$. Signal component is modeled with histogram from the MC simulations and is convolved with a Gaussian resolution (of about $2\,\text{MeV}/c^2$) measured from real data using fully reconstructed $D_s \to \phi\pi$ decays. Background contributions are: mis-reconstructed signal (K or X_{frag} pion originating from D_s decays), reflections from $D^{*0} \to D^0\gamma$ or $D_{(s)}^* \to D_{(s)} \to D^0\pi^0$ (being sources of the signal photon), wrong γ (wrongly reconstructed in the calorimeter) and γ coming from π^0 decays not originating from $D_{(s)}^*$. Their shapes are histograms obtained from the generic MC, while normalizations are mostly kept free in the fit. Total inclusive D_s^+ yield is measured to be $(94.4 \pm 1.3 \pm 1.4) \times 10^3$.

To obtain *exclusive* D_s^+ sample within the inclusive sample, all the tracks of $D_s^+ \to K^+K^-\pi^+$ decays are fully reconstructed using the events with exactly three such charged tracks remaining. The exclusively reconstructed $D_s^+ \to K^+K^-\pi^+$ events are identified as a peak at D_s^+ nominal mass in the $M(K^+K^-\pi^+\gamma)$ mass distribution (Fig. 19.1.5). To increase reconstruction efficiency for $D_s^+ \to \bar{K}^0K^+$ and $D_s^+ \to \eta\pi^+$, only the charged kaon and pion, respectively, are explicitly reconstructed. The $D_s^+ \to \bar{K}^0K^+$ signal is identified in the missing mass squared distribution $M_{miss}^2(D_{tag}KX_{frag}\gamma K)$ (Fig. 19.1.6) and expected at mass squared of K^0 nominal mass, while the $D_s^+ \to \eta\pi^+$ in the $M_{miss}^2(D_{tag}KX_{frag}\gamma\pi)$ (Fig. 19.1.7) at η nominal mass squared. All these spectra are fitted with signals parameterized using MC simulations with data-based resolution taken into account. In the background part, in addition to a smooth combinatorial background, there are also peaking reflections, modeled in the fits with MC simulations and included in the fits (see Figs 19.1.5-19.1.7 for details). In the $D_s^+ \to \eta\pi^+$ case contribution from $D_s^+ \to \tau^+\nu_\tau \to \pi^+\bar{\nu}_\tau\nu_\tau$ is suppressed by requiring that extra neutral energy in the electromagnetic calorimeter (not associated to the particles used in the inclusive or exclusive D_s^+ reconstruction) to be larger than $1\,\text{GeV}$, as significant energy deposit is expected from the η decay products while none from the tauonic decays.

The absolute $\mathcal{B}$ of D_s^+ to given f final state reconstructed in the exclusive sample is:

$$\mathcal{B}(D_s \to f) = \frac{N^{excl}(D_s^+ \to f)}{N^{incl}(D_s^+) \cdot f_{bias} \cdot \varepsilon(D_s^+ \to f|incl\ D_s^+)},$$
$$(19.1.19)$$

where $N^{incl}(D_s)$ is a number of inclusively reconstructed D_s mesons, $N^{excl}(D_s \to f)$ is the number of exclusively reconstructed $D_s \to f$ decays, while $\varepsilon(D_s \to f|incl\ D_s)$ is the efficiency of exclusive $D_s \to f$ reconstruction given inclusively reconstructed D_s and is determined from MC simulations of the events containing the signal decays. The

---

[113] In the case of *tagging* Λ_c^+ an antiproton is also required to balance the baryon number in the event.
Figure 19.1.4. From (Zupanc, 2013b). Inclusive D_s in $M_{miss}(D_{tag}KX_{frag}\gamma)$ for three out of seven possible X_{frag} modes. The solid blue (red) line shows the contribution of signal and background (background only) candidates. The cumulative contributions of candidates originating from different background sources as described in the text are shown with different gray dashed lines. Dashed vertical lines indicate the signal region considered in further analysis.
Figure 19.1.5. From (Zupanc, 2013b). $M(K^+K^-\pi^+\gamma)$ mass distribution of exclusively reconstructed $D_s^+ \to K^+K^-\pi^+$ decays within the inclusive D_s sample, with the fit result superimposed and including fitted signal contribution (solid green line), reflection from $D_s^* \to D_s\pi^0 \to K^+K^-\pi^+\gamma\gamma$ with one of the photons missing (full dark gray histogram) and combinatorial background (dashed red line).
Figure 19.1.6. From (Zupanc, 2013b). $M_{miss}^2(D_{tag}KX_{frag}\gamma K)$ distribution of partially reconstructed $D_s^+ \to \bar{K}^0K^+$ decays within the inclusive D_s sample. The fit result is superimposed and includes fitted signal contribution (solid green line), reflections from charged kaon originating from $D_s^+ \to \eta K^+$ and $D_s^+ \to \pi^0 K^+$ (full grey histograms) and other true D_s decays (for example $D_s^+ \to \eta\pi^+$ with pion being misidentified as kaon) (full blue histogram), and combinatorial background (dashed red line).

efficiency of inclusive D_s reconstruction depends on the D_s-decay mode and drops with increasing multiplicity of the f final state. It is accounted for by introducing a factor f_{bias} which is a ratio of efficiency of inclusive D_s reconstruction for $D_s \to f$ and for D_s decaying generically *i.e.* to all known decay modes. This number is further corrected to account for a different multiplicities of final state particles in D_s decays in MC and real data. Fitted exclusive yields of the hadronic D_s decays and measured absolute branching fractions are summarized in Table 19.1.1. Precision of these measurements is approximately equal to the precission of the curent world average values.

All the measured decays are Cabibbo-favored processes. However, since the flavor of neutral kaon in $D_s^+ \to \bar{K}^0K^+$ is not determined, the doubly Cabibbo suppressed decays, $D_s^+ \to K^0K^+$, also contribute to the signal in Fig. 19.1.6. Its expected contribution is at the level of 10^{-4}, thus, much below the statistical uncertainty of the measured $\mathcal{B}$. The $D_s^+ \to K^+K^-\pi^+$ decays entirely pro-

Table 19.1.1. Absolute $\mathcal{B}$ of D_s^+ from (Zupanc, 2013b)

Decay mode	*Exclusive* yield	$\mathcal{B}$ [%]
$D_s^+ \to K^+K^-\pi^+$	4094 ± 123	$5.06 \pm 0.15 \pm 0.21$
$D_s^+ \to \bar{K}^0K^+$	2018 ± 75	$2.95 \pm 0.11 \pm 0.09$
$D_s^+ \to \eta\pi^+$	788 ± 59	$1.82 \pm 0.14 \pm 0.07$

ceed through resonances contributing to either the KK or $K\pi$ systems (see Section 19.1.4.9), which correspond respectively to color-allowed and color-suppressed contributions. A corresponding decay model is assumed in the $D_s^+ \to K^+K^-\pi^+$ MC simulations used for estimation the efficiency for Eq. (19.1.19).
Figure 19.1.7. From (Zupanc, 2013b). $M_{miss}^2(D_{tag}KX_{frag}\gamma\pi)$ distribution of partially reconstructed $D_s^+ \to \eta\pi^+$ decays within the inclusive D_s sample. The fit result is superimposed and includes fitted signal contribution (solid green line), reflections from charged pion originating from $D_s^+ \to K^0\pi^+$ (full grey histograms) and other true D_s decays ($D_s^+ \to \rho K^+ \to \pi^+\pi^- K^+$ and $D_s^+ \to \bar{K}^0 K^+$ due to K-π mis-reconstruction) (full blue histogram), and combinatorial background (dashed red line).

19.1.2.3 The D_s^{*+} and D^{*0} Branching Ratios

The decay of any excited $c\bar{s}$ meson into $D_s^+\pi^0$ violates isospin conservation,[114] thus guaranteeing a small partial width. The amount of suppression is a matter of large theoretical uncertainty according to most models of charm-meson radiative decay (Goity and Roberts, 2001). One such a model (Cho and Wise, 1994) suggests that the decay $D_s^{*+} \to D_s^+\pi^0$ may proceed via π^0-η mixing. Even including such considerations, the radiative decay $D_s^{*+} \to D_s^+\gamma$ is still expected to dominate. An existence of isospin-violating decay modes, such as $D_s^{*+} \to D_s^+\pi^0$, is particularly relevant given the observations of the new narrow D_{sJ}^+ states decaying dominantly into $D_s^{(*)+}\pi^0$ (see Section 19.3). In particular, in contrast to the D_s^{*+} meson, there is no experimental evidence for the electromagnetic decay of the $D_{sJ}(2317)^+$. Besides the $D_s^+\pi^0$ and $D_s^+\gamma$ final states, no other decay modes of the D_s^{*+} have been observed and none are expected to occur at a significant level.

The decay $D^{*0} \to D^0\pi^0$, in contrast to $D_s^{*+} \to D_s^+\pi^0$, does not violate isospin conservation.[115] As for the D_s^{*+}, the $D^0\pi^0$ and $D^0\gamma$ decay modes are expected to saturate the D^{*0} decay width.

The *BABAR* analysis of the $D_{(s)}^*$ decays is based on $90.4\,\text{fb}^{-1}$ (Aubert, 2005s). D_s mesons are reconstructed via the decay sequence $D_s^+ \to \phi\pi^+$, $\phi \to K^+K^-$, and the scaled momentum must satisfy $x_p(D_s^+) > 0.6$. The D_s^+ signal sample is of $(73.5 \pm 0.3) \times 10^3$ events. In a search for the $D_s^{*+} \to D_s^+\pi^0$, the D_s^+ and π^0 are combined and a fit is applied to the distribution of the mass difference $\Delta m(D_s^+\pi^0) = m(K^+K^-\pi^+\pi^0) - m(K^+K^-\pi^+)$. The re-

---

[114] The $D_s^{(*)}$ has $I = 0$, while in the final state there is $I = 1$ due to the pion.

[115] The $D^{(*)0}$ has $I = 1/2$, so the final state pion ($I = 1$) can be combined with the D^0 to a total of $I = 1/2$.
Figure 19.1.8. From (Aubert, 2005s). The D_s^{*+} signals in: (a) $\Delta m(D_s^+\pi^0)$ and (b) $\Delta m(D_s^+\gamma)$. The dots represent data points, the solid curve shows the fitted function, the dashed curve indicates the fitted background.

sult of this fit is shown in Fig. 19.1.8(a), and the obtained signal yield is 560 ± 40. To obtain the $D_s^{*+} \to D_s^+\gamma$ signal event yield, a fit is applied to the distribution of the mass difference $\Delta m(D_s^+\gamma) = m(K^+K^-\pi^+\gamma) - m(K^+K^-\pi^+)$, as shown in Fig. 19.1.8(b). The fit function is a sum of a third-order polynomial to model the background plus a Crystal Ball function for the signal.

After correcting for efficiency, the measured branching ratio is:

$$\frac{\Gamma(D_s^{*+} \to D_s^+\pi^0)}{\Gamma(D_s^{*+} \to D_s^+\gamma)} = 0.062 \pm 0.005 \pm 0.006, \quad (19.1.20)$$

and is consistent with the previous measurement (Gronberg et al., 1995), but has higher precision.

The ratio $\Gamma(D^{*0} \to D^0\pi^0)/\Gamma(D^{*0} \to D^0\gamma)$, where $D^0 \to K^-\pi^+$, is measured using the same selection criteria for the π^0 and photon candidates as in the D_s^{*+} reconstruction. The $D^0 \to K^-\pi^+$ signal sample consists of $(996.0 \pm 1.5) \times 10^3$ events. These D^0 candidates combined with the π^0 candidates result in the mass difference $\Delta m(D^0\pi^0) = m(K^-\pi^+\pi^0) - m(K^-\pi^+)$ shown in Fig. 19.1.9(a). A fit, using a double Gaussian for the signal, yields $(69.0 \pm 0.5) \times 10^3$ signal events. The D^0 candidates combined with photons produce the distribution of the mass difference $\Delta m(D^0\gamma) = m(K^-\pi^+\gamma) - m(K^-\pi^+)$ shown in Fig. 19.1.9(b). In this case, a peak corresponding to the $D^{*0} \to D^0\gamma$ signal is close to a large reflection from $D^{*0} \to D^0\pi^0$ with one photon from π^0 decay missing (such a reflection appears also in D_s^{*+} decay, but with a lower rate and less distinctive shape). The $D^{*0} \to D^0\gamma$ signal is modeled by the Crystal Ball function and the fitted signal yield is $(67.9 \pm 0.7) \times 10^3$ events. The resulting branching ratio, corrected for efficiency, is:

$$\frac{\Gamma(D^{*0} \to D^0\pi^0)}{\Gamma(D^{*0} \to D^0\gamma)} = 1.74 \pm 0.02 \pm 0.13. \quad (19.1.21)$$

19.1.3 Cabibbo-suppressed decays

Cabibbo-suppressed (*CS*) charm decays offer a good laboratory for studying weak interactions. Branching ratio
Figure 19.1.9. From (Aubert, 2005s). The D^{*0} signals in: (a) $\Delta m(D^0\pi^0)$ and (b) $\Delta m(D^0\gamma)$. The dots represent data points, the solid curve shows the fitted function, the dashed curve indicates the fitted background.

Figure 19.1.10. From (Aubert, 2006v). $M(\pi^+\pi^0)$ and $M(K^+\pi^0)$ with the likelihood fit results. The dashed lines show the projected backgrounds in the D^+ signal region.

measurements provide insight into charm decay dynamics and sources of $SU(3)$ flavor symmetry breaking, as well as allow to investigate beyond SM effects affecting decay rates. The CS charm decays are very sensitive probes of the CP violation and $D^0 - \bar{D}^0$ mixing, as described in Section 19.2. Understanding the size of the $SU(3)$-violating effects in $D_{(s)}$ decays can help to disantangle New Physics effects from ones having origins in long-distance QCD effects.

While Cabibbo-favored (CF) modes at the tree level proceed through $c \to s\bar{d}u$, the singly Cabibbo-suppressed (SCS) decays are mediated by $c \to d\bar{d}u$ or $c \to s\bar{s}u$, and the underlying process for doubly Cabibbo-suppressed (DCS) modes is $c \to d\bar{s}u$. The SCS decay rates are naïvely expected to be suppressed relative to CF decay rate by $\tan^2\theta_C$, where $\tan\theta_C = \frac{|V_{cd}|}{|V_{cs}|} \approx 0.23$ and θ_C is the Cabibbo angle. Correspondingly, the ratio of DCS and CF decay rates is expected to be of $\tan^4\theta_C$. The $SU(3)$ symmetry can be however broken by strong final-state interactions, interference between different contributing amplitudes and leading to the same final states. In particular, the two-body SCS decays of D^0 meson have anomalous rates. The $D^0 \to \pi^-\pi^+$ branching fraction is observed to be suppressed relative to the $D^0 \to K^-K^+$ by a factor of almost three (Yao et al., 2006), even though the phase space for the former is larger. On the other hand, three-body decay rates have larger uncertainties but do not exhibit such a suppression. Number of analyses of the CS charm decays were previously performed mainly by MARK III, Argus, CLEO and FOCUS.

19.1.3.1 The $D^+ \to \pi^+\pi^0$ and $D^+ \to K^+\pi^0$ Branching Fractions

BABAR has measured branching fractions of the SCS $D^+ \to \pi^+\pi^0$ and the DCS $D^+ \to K^+\pi^0$ decays with respect to the well-measured $D^+ \to K^-\pi^+\pi^+$ decay mode, with a data sample of $124.3\,\text{fb}^{-1}$ (Aubert, 2006v). In order to reduce a large combinatorial background in the D^+ signal modes, only D^+ mesons that originate from $D^{*+} \to D^+\pi^0$ decays are considered. D^+ candidates for the signal modes are obtained by combining a
charged track, identified either as a pion or kaon, with a reconstructed π^0 candidate and requiring $x_p(D^*) > 0.6$. The scaled momentum of the D^{*+}, $x_p(D^*)$, is defined as $x_p(D^*) \equiv p^*(D^{*+})/p^*_{max}(D^{*+})$, where $p^*(D^{*+})$ is the momentum of the D^* in the e^+e^- c.m. frame and $p^*_{max}(D^{*+}) \equiv \sqrt{s/4 - m^2_{D^*}}$ is the maximal D^* c.m. momentum allowed, with s being the square of the energy of the initial e^+e^- system. The energy of the π^0 in the laboratory frame (lab) is required to be greater than $0.2\,\text{GeV}$. Requirements on the D^+ helicity angle θ_h, $-0.9 < \cos\theta_h < 0.8$ for the $D^+ \to \pi^+\pi^0$ and $-0.9 < \cos\theta_h < 0.7$ for the $D^+ \to K^+\pi^0$, are motivated by uniformly distributed $\cos\theta_C$ expected for signal events and peaking at ± 1 for background. The θ_h is defined as the angle between the direction of the D^+ charged daughter and the direction of the D^{*+} meson evaluated in the D^+ rest frame. Figure 19.1.10 shows the measured invariant-mass spectra, $M(\pi^+\pi^0)$ and $M(K^+\pi^0)$, with the fit results superimposed. The signal yields for $D^+ \to \pi^+\pi^0$ and $D^+ \to K^+\pi^0$ are respectively 1229 ± 98 and 189 ± 35, while for the $D^+ \to K^-\pi^+\pi^+$ reference mode is 101380 ± 415. The branching ratio of the signal and reference modes is obtained as a ratio of the measured yields (N) corrected for the reconstruction efficiencies (ε):

$$\frac{\mathcal{B}(D \to \text{signal})}{\mathcal{B}(D \to \text{reference})} = \frac{N(\text{signal})}{N(\text{reference})} \times \frac{\varepsilon(\text{reference})}{\varepsilon(\text{signal})}. \tag{19.1.22}$$

The measured branching ratios:

$$\frac{\mathcal{B}(D^+ \to \pi^+\pi^0)}{\mathcal{B}(D^+ \to K^-\pi^+\pi^+)} = (1.33 \pm 0.11 \pm 0.09) \times 10^{-2},$$

$$\frac{\mathcal{B}(D^+ \to K^+\pi^0)}{\mathcal{B}(D^+ \to K^-\pi^+\pi^+)} = (2.68 \pm 0.50 \pm 0.26) \times 10^{-3}, \tag{19.1.23}$$

combined with the world-average value of $\mathcal{B}(D^+ \to K^-\pi^+\pi^+) = (9.4 \pm 0.3)\%$ yield in the following branching fractions for the CS decays:

$$\mathcal{B}(D^+ \to \pi^+\pi^0) = (1.25 \pm 0.10 \pm 0.09 \pm 0.04) \times 10^{-3},$$
$$\mathcal{B}(D^+ \to K^+\pi^0) = (2.52 \pm 0.47 \pm 0.25 \pm 0.08) \times 10^{-4}, \tag{19.1.24}$$

where the last error is due to the uncertainty in the reference mode branching fraction. This represents the first observation of the DCS $D^+ \to K^+\pi^0$ decays and an improved measurement of the SCS $D^+ \to \pi^+\pi^0$ branching fraction.

19.1.3.2 The $D^+ \to K_S^0 K^+$ and $D_s^+ \to K_S^0\pi^+$ Branching Fractions

Both $D^+ \to \bar{K}^0 K^+$ and $D_s^+ \to \bar{K}^0\pi^+$ are DCS decays involving the color-favored tree, penguin and annihilation diagrams, while the related CF modes are $D^+ \to \bar{K}^0\pi^+$ and $D_s^+ \to \bar{K}^0 K^+$.

Belle has measured branching fractions of the corresponding $D_{(s)}^+$ decays including K_S^0 in the final states, namely $D^+ \to K_S^0 K^+$ and $D_s^+ \to K_S^0\pi^+$ with respect to the $D^+ \to K_S^0\pi^+$ and $D_s^+ \to K_S^0 K^+$ decays, using $605\,\mathrm{fb}^{-1}$ data collected at the $\Upsilon(4S)$ resonance (Won, 2009). An additional $60\,\mathrm{fb}^{-1}$ of the off-resonance data collected below the $\Upsilon(4S)$ have been used for the optimization procedures. They select the $K_S^0 \to \pi^+\pi^-$ candidates having daughter-pion tracks separated from the interaction point (IP) in the plane perpendicular to the beam axis and $\pi^+\pi^-$ vertex displaced from the IP, whereas the direction of the K_S^0 momentum must agree with the direction of the decay vertex point from the IP. Selection criteria on the related distances and angle are optimized, separately for high-momentum (above 1.5 GeV/c) and the remaining K_S^0 candidates, to maximize a significance of the K_S^0 signal identified in the $M(\pi^+\pi^-)$ invariant-mass spectrum. The reconstructed $D_{(s)}^+ \to K_S^0 h^+$ candidates, where $h^+ = K^+$, π^+, are required to have a good quality decay vertex and the c.m. momentum greater than 2.6 GeV/c to remove the $D_{(s)}^+$ produced in B meson decays. Removing the $K_S^0 h^+$ pairs with an invariant mass close to the nominal $D_{(s)}^+$ mass but having in the laboratory frame (*lab*) highly asymmetrical momenta, has significantly improved significance of the CS $D_{(s)}^+$ signals.

The $M(K_S^0 K^+)$ and $M(K_S^0\pi^+)$ invariant mass distributions after the final selections, shown in Fig 19.1.11, exhibit clear signals for both CF and DCS decays in the both decay channels. All the signals are parameterized using double Gaussians with a common mean value. In the maximum-likelihood fits performed to the mass spectra, all the signal parameters are kept free, except for the broad Gaussian fraction and width for the $D_s^+ \to K_S^0\pi^+$; those are fixed to the values obtained for the $D^+ \to K_S^0\pi^+$ mode. In addition to the smooth combinatorial background, there is a peaking background due to particle misidentification. It appears in the $D_s^+ \to K_S^0 K^+$ mass region, when π^+ from $D^+ \to K_S^0\pi^+$ decays is misidentified as K^+. Similarly, when K^+ is misidentified as π^+ in $D_s^+ \to K_S^0 K^+$ decays, a peaking structure appears under the $D^+ \to K_S^0\pi^+$. The shapes and yields of these peaking backgrounds are obtained from the MC simulations in which hadron momentum scale and resolution are tuned with the data.
Figure 19.1.11. From (Won, 2009). $M(K_S^0 K^+)$ (top) and $M(K_S^0\pi^+)$ (bottom) for the selected candidates. Points with error bars show the data, the histograms represent the fit results. Signals for $D_{(s)}^+ \to K_S^0 K^+$ (top) and $D_{(s)}^+ \to K_S^0\pi^+$ (bottom), peaking backgrounds originating from misidentified $D^+ \to K_S^0\pi^+$ (top) and $D_s^+ \to K_S^0 K^+$ (bottom) decays, and random combinatorial backgrounds are also shown. The inset in the bottom plot is enlarged view of the D_s^+ region.

Based on the fitted signal yields and reconstruction efficiencies (of about $12 - 15\%$) obtained with the tuned MC, the measured branching ratios are:

$$\frac{\mathcal{B}(D^+ \to K_S^0 K^+)}{\mathcal{B}(D^+ \to K_S^0\pi^+)} = (18.99 \pm 0.11 \pm 0.22)\%$$

$$\frac{\mathcal{B}(D_s^+ \to K_S^0\pi^+)}{\mathcal{B}(D_s^+ \to K_S^0 K^+)} = (8.03 \pm 0.24 \pm 0.19)\%.$$

$$(19.1.25)$$

These are the most precise measurements to date and agree with the present WA values of respectively $(20.6 \pm 1.4)\%$ and $(8.4 \pm 0.9)\%$.

The ratio for D^+ is larger than naïve expectation of $\tan^2\theta_C$ due to destructive interference between color-favored and color-suppressed tree diagrams contributing to the CF $D^+ \to \bar{K}^0\pi^+$ decay. Increase of the ratio mesured for D_s^+ over the $\tan^2\theta_C$ can be due to the color suppression in the tree amplitude in the $D_s^+ \to \bar{K}^0 K^+$. Using the WA values for CF modes, the branching fractions for CS decays are:

$$\mathcal{B}(D^+ \rightarrow K_S^0 K^+) = (2.75 \pm 0.08) \times 10^{-3}$$
$$\mathcal{B}(D_s^+ \rightarrow K_S^0 \pi^+) = (1.20 \pm 0.09) \times 10^{-3},$$

(19.1.26)

with statistical and systematic uncertainties summed in quadrature. However, experimentaly measured are $D_{(s)}$ decays including K_S^0 and converting them to the $\mathcal{B}$ involving K^0 or $\bar{K}^0$ is not straightforward, as the corresponding DCS and CF modes can interfere with the unknown interference phase.

19.1.3.3 $D^+ \rightarrow K^+ \eta^{(')}$ and $D^+ \rightarrow \pi^+ \eta^{(')}$

D^+ decays into two-body final states with $\eta^{(')}$ are all the CS decays with poorly studied $SU(3)$ flavor symmetry structure. Such DCS decays, $D^+ \rightarrow K^+ \eta^{(')}$, have not been observed before, while their SCS counterparts, $D^+ \rightarrow \pi^+ \eta^{(')}$, are quite well measured by CLEO.

Belle analysis of the $D^+ \rightarrow h^+ \eta^{(')}$ decays (Won, 2011), with $h^+ = K^+$, π^+, is based on the data sample of 791 fb^{-1} and exploits the decays $\eta \rightarrow \pi^+ \pi^- \pi^0$ and $\eta' \rightarrow \eta \pi^+ \pi^-$ with $\eta \rightarrow \gamma\gamma$. This allows reconstruction of the D^+ decay vertex formed using only charged tracks. The π^0 and $\eta^{(')}$ candidates are selected based on the invariant masses of their decay products. For the final selection the authors optimize criteria to maximize significance of the $D^+ \rightarrow K^+ \eta^{(')}$ signal studied with the MC simulations. The following variables are considered in the optimization: the D^+ c.m. momentum, the $\eta^{(')}$ *lab* momentum, as well as variables related to the decay topology: an angle between momentum vector of the reconstructed D^+ and the vector joining its production and decay vertices, and χ^2 of the hypothesis that the candidate tracks forming the D^+ are isolated from the primary vertex, defined as a point of intersection of the D^+ momentum vector with the IP. Such an isolation is expected due to the finite D^+ lifetime. The optimized selection cuts are also applied to the normalization modes, $D^+ \rightarrow \pi^+ \eta^{(')}$.

The measured $M(\pi^+ \eta^{(')})$ and $M(K^+ \eta^{(')})$ distributions are shown in Fig. 19.1.12. The signal function is modelled with a sum of Gaussian and bifurcated Gaussian. In the fits for the DCS decays, widths of both Gaussians and bifurcated Gaussian fraction are fixed to the values obtained for the SCS decays and scaled according to the difference obtained with the MC simulations. Observed background is purely combinatorial and smooth, no peaking background has been detected. The signal yields of the DCS modes amount to 166 ± 23 for the $D^+ \rightarrow K^+ \eta$ and 188 ± 19 for the $D^+ \rightarrow K^+ \eta'$, while reconstruction efficiencies are at the level of 1.5%. The measured branching ratios are:

$$\frac{\mathcal{B}(D^+ \rightarrow K^+ \eta)}{\mathcal{B}(D^+ \rightarrow \pi^+ \eta)} = (3.06 \pm 0.43 \pm 0.14) \times 10^{-2}$$
$$\frac{\mathcal{B}(D^+ \rightarrow K^+ \eta')}{\mathcal{B}(D^+ \rightarrow \pi^+ \eta')} = (3.77 \pm 0.39 \pm 0.10) \times 10^{-2}.$$

(19.1.27)

The $D^+ \rightarrow K^+ \eta^{(')}$ decays are observed for the first time and have completed a class of the DCS D^+ decays to pairs of light pseudoscalar mesons. The measured ratios are within errors in agreement with $SU(3)$ based expectations. Using the measurements of the $\mathcal{B}(D^+ \rightarrow \pi^+ \eta^{(')})$ from (Mendez et al., 2010), the absolute branching fractions for the DCS modes are $\mathcal{B}(D^+ \rightarrow K^+ \eta) = (1.08 \pm 0.17 \pm 0.08) \times 10^{-4}$ and $\mathcal{B}(D^+ \rightarrow K^+ \eta') = (1.76 \pm 0.22 \pm 0.12) \times 10^{-4}$.

Using relations from (Chiang and Rosner, 2002), the measured $\mathcal{B}(D^+ \rightarrow K^+ \eta^{(')})$ toghether with the WA value $\mathcal{B}(D^+ \rightarrow K^+ \pi^0) = (1.72 \pm 0.20) \times 10^{-4}$ (Chiang and Rosner, 2002) are used to calculate a relative phase difference between the contributing tree and annihilation amplitudes, δ_{TA}, to be $(72 \pm 9)°$ or $(288 \pm 9)°$. It is an important information for final-state interactions in D decays. Similar measurement for penguin amplitudes is impossible, as they contribute to DCS decays involving K^0, while these are overwhelmed by CF decays involving $\bar{K}^0$ in the detected K_S^0.

19.1.3.4 Branching Ratios of the Decays $D^0 \rightarrow \pi^- \pi^+ \pi^0$ and $D^0 \rightarrow K^- K^+ \pi^0$

The *BABAR* experiment has measuread the rates of three-body CS decays $D^0 \rightarrow \pi^- \pi^+ \pi^0$ and $D^0 \rightarrow K^- K^+ \pi^0$ relative to the CF decay $D^0 \rightarrow K^- \pi^+ \pi^0$, using 232 fb^{-1} (Aubert, 2006ak). To reduce combinatorial backgrounds, the D^0 candidates are reconstructed in decays $D^{*+} \rightarrow D^0 \pi_s^+$. The number of D^0 signal events in each decay mode is obtained by fitting the observed D^0 candidate mass distributions (Fig. 19.1.13) to the sum of signal and background components, where the latter has combinatorial contributions and reflection contributions from real three-body D^0 decays where a kaon (pion) is misidentifed as a pion (kaon). The reconstruction efficiency for each event is calculated as a function of its position in the D^0 Dalitz plot. The resulting branching ratios,

$$\frac{\mathcal{B}(D^0 \rightarrow \pi^- \pi^+ \pi^0)}{\mathcal{B}(D^0 \rightarrow K^- \pi^+ \pi^0)} = (10.59 \pm 0.06 \pm 0.13) \times 10^{-2}$$
$$\frac{\mathcal{B}(D^0 \rightarrow K^- K^+ \pi^0)}{\mathcal{B}(D^0 \rightarrow K^- \pi^+ \pi^0)} = (2.37 \pm 0.03 \pm 0.04) \times 10^{-2},$$

(19.1.28)

combined with $\mathcal{B}(D^0 \rightarrow K^- \pi^+ \pi^0) = (14.1 \pm 0.5) \times 10^{-2}$ (Yao et al., 2006), give:

$$\mathcal{B}(D^0 \rightarrow \pi^- \pi^+ \pi^0) = (1.493 \pm 0.008 \pm 0.018 \pm 0.053) \times 10^{-2},$$
$$\mathcal{B}(D^0 \rightarrow K^- K^+ \pi^0) = (0.334 \pm 0.004 \pm 0.006 \pm 0.012) \times 10^{-2}.$$

(19.1.29)

The measured branching ratios contain the phase space factor which enters decay rate as[116] $\Gamma = \int d\Phi |\mathcal{M}|^2 =$

---

[116] Branching fraction and decay width for given process $D \rightarrow f$ are related through $\mathcal{B}(D \rightarrow f) = \Gamma(D \rightarrow f) \times \tau_D$, where $\tau_D \equiv 1/\Gamma_{total}$ is D lifetime
Figure 19.1.12. From (Won, 2011). Invariant mass ditributions for the $\pi^+\eta$, $\pi^+\eta'$, $K^+\eta$ and $K^+\eta'$ final states. Points with error bars and histograms correspond respectively to the data and fit result.
Figure 19.1.13. From (Aubert, 2006ak). Fitted mass for the $\pi^-\pi^+\pi^0$, and $K^-K^+\pi^0$ data samples. Dots are data points, the solid curves are the fit. The dot-dashed lines show the level of combinatorial background, the shaded region represents the total background.

$\Phi \times \langle|\mathcal{M}|^2\rangle$, where Φ is the phase space of a particular final state, $\mathcal{M}$ is the decay matrix element, and $\langle|\mathcal{M}|^2\rangle$ is average $|\mathcal{M}|^2$ value over the Dalitz plot and the three-body phase space. The relative Φ for the studied decays is $\pi^-\pi^+\pi^0 : K^-\pi^+\pi^0 : K^+K^-\pi^+ = 5.0 : 3.2 : 1.7$, which gives:

$$\frac{\langle|\mathcal{M}|^2\rangle(D^0 \to \pi^-\pi^+\pi^0)}{\langle|\mathcal{M}|^2\rangle(D^0 \to K^-\pi^+\pi^0)} = (6.68 \pm 0.04 \pm 0.08) \times 10^{-2}$$

(19.1.30)

$$\frac{\langle|\mathcal{M}|^2\rangle(D^0 \to K^-K^+\pi^0)}{\langle|\mathcal{M}|^2\rangle(D^0 \to K^-\pi^+\pi^0)} = (4.53 \pm 0.06 \pm 0.08) \times 10^{-2}$$

(19.1.31)

$$\frac{\langle|\mathcal{M}|^2\rangle(D^0 \to K^-K^+\pi^0)}{\langle|\mathcal{M}|^2\rangle(D^0 \to \pi^-\pi^+\pi^0)} = (6.78 \pm 0.14 \pm 0.21) \times 10^{-1}.$$

(19.1.32)

The deviations from the naïve picture, in which the ratios 19.1.30 and 19.1.31 are of the order $\tan^2\theta_C$, while 19.1.32 is of order unity, are less than 35% for these three-body final states. In contrast, the corresponding ratios may be calculated for the two-body decays $D^0 \to \pi^-\pi^+$, $D^0 \to K^-\pi^+$, and $D^0 \to K^-K^+$. Using the WA values for these two-body branching ratios (Yao et al., 2006), the ratios corresponding to Eqs (19.1.30)–(19.1.32), are, respectively, 0.034 ± 0.001, 0.111 ± 0.002, and 3.53 ± 0.12. Thus the naïve Cabibbo-suppression model works well for three-body final states, but not so good for two-body decays.

19.1.3.5 Doubly-Cabibbo Suppressed $D_s^+ \to K^+K^+\pi^-$ and $D^+ \to K^+\pi^+\pi^-$ Decays

The expected branching ratio for the DCS $D_s^+ \to K^+K^+\pi^-$ with respect to its CF counterpart $D_s^+ \to K^+K^-\pi^+$ is about $\frac{1}{2}\tan^4\theta_C$. A factor modifying the $SU(3)$ based expectation arises from the phase space suppresion for the $D_s^+ \to K^+K^+\pi^-$ due to the two identical kaons in the final state. For a similar reason, the ratio of decays rates for corresponding DCS and CF D^+ decays, $D^+ \to K^+\pi^+\pi^-$ and $D^+ \to K^-\pi^+\pi^+$, should be about $2\tan^4\theta_C$. Thus within $SU(3)$ symmetry one expects

$$\frac{\mathcal{B}(D_s^+ \to K^+K^+\pi^-)}{\mathcal{B}(D_s^+ \to K^+K^-\pi^+)} \frac{\mathcal{B}(D^+ \to K^+\pi^+\pi^-)}{\mathcal{B}(D^+ \to K^-\pi^+\pi^+)} = \tan^8\theta_C,$$

(19.1.33)

as the phase-space related factors cancel out (Lipkin, 2003). In order to test this prediction, Belle has searched for the DCS $D_s^+ \to K^+K^+\pi^-$ decays and studied the other decays entering Eq. (19.1.33) with 605 fb^{-1} data (Ko, 2009). All the $D_{(s)}^+$ candidates are required to have the scaled momentum x_p greater than 0.5 and a good quality decay vertex. In addition, track isolation and consistency of the $D_{(s)}^+$ momentum vector with its production-to-decay vector (see Section 19.1.3.3) are required, with related variables optimized for the CF decays using a small part of the data further discarded from the measurement.
Figure 19.1.14. From (Ko, 2009). Invariant mass ditributions for the $K^+\pi^+\pi^-$ and $K^-\pi^+\pi^+$ final states. Points with error bars correspond to the data, histogram is fit result and include signal, random (combinatorial) background and peaking background from $D_s^+ \to K^+K^-\pi^+$.

Figure 19.1.15. From (Ko, 2009). Invariant mass ditributions for the $K^+K^+\pi^-$ and $K^+K^-\pi^+$ final states. Points with error bars correspond to the data, histogram is fit result and includes signal, random (combinatorial) background and peaking background from $D^+ \to K^-\pi^+\pi^+$ and $D^{*+} \to D^0\pi^+$ with $D^0 \to K^+K^-$.

The measured $M(K^+\pi^+\pi^-)$ and $M(K^-\pi^+\pi^+)$, shown in Fig. 19.1.14, exibit the D^+ signals, while $M(K^+K^+\pi^-)$ and $M(K^+K^-\pi^+)$ in Fig. 19.1.15 the D_s^+ signals. The signals are parameterized with double Gaussians, with the parameters for the DCS modes fixed to the values fitted for the CF decays. There are peaking backgrounds detected coming from the K-π misidentification: $D_s^+ \to K^+K^-\pi^+$ reflecting in $D^+ \to K^+\pi^+\pi^-$ and $D^+ \to K^-\pi^+\pi^+$, and $D^+ \to K^-\pi^+\pi^+$ contributing to $D_s^+ \to K^+K^-\pi^+$. Shapes of the reflections are determined from the real data by assigning a nominal kaon (pion) mass to pion (kaon) track, and their yields are kept free in the fits. The measured branching ratios are:

$$\frac{\mathcal{B}(D^+ \to K^+\pi^+\pi^-)}{\mathcal{B}(D^+ \to K^-\pi^+\pi^+)} = (0.569 \pm 0.018 \pm 0.014) \times 10^{-2}$$

$$\frac{\mathcal{B}(D_s^+ \to K^+K^+\pi^-)}{\mathcal{B}(D_s^+ \to K^+K^-\pi^+)} = (0.229 \pm 0.028 \pm 0.012) \times 10^{-2}.$$

$$(19.1.34)$$

Reconstruction efficiencies used for these $\mathcal{B}$ calculations are based on the MC simulations which include intermediate resonances contributing to the $D^+ \to K^-\pi^+\pi^+$, $D^+ \to K^+\pi^+\pi^-$ and $D_s^+ \to K^+K^-\pi^+$ decays (Amsler et al., 2008; Anjos et al., 1993). As the Dalitz-plot model for the $D_s^+ \to K^+K^+\pi^-$ is not known, it is generated according to the phase space model, while the largest relative differences obtained with various decay models assumed are included in the sytematic uncertainty.

The double branching ratio in Eq. (19.1.33) is measured to be $(1.57 \pm 0.21)\tan^8\theta_C$, with the error being the total uncertainty. Its slight deviation from the expected value can be the effect of different resonant intermediate state, which are not taken into account in the prediction (Lipkin, 2003). Using the world average values for the CF branching fractions (Amsler et al., 2008), the absolute $\mathcal{B}$ for the DCS decays are:

$$\mathcal{B}(D^+ \to K^+\pi^+\pi^-) = (5.2 \pm 0.2 \pm 0.1) \times 10^{-4},$$
$$\mathcal{B}(D_s^+ \to K^+K^+\pi^-) = (1.3 \pm 0.2 \pm 0.1) \times 10^{-4}.$$

$$(19.1.35)$$

The former is an improvement of the existing measurement, the latter comprises the first significant measurement.

19.1.3.6 Wrong-Sign Decays $D^0 \to K\pi$, $D^0 \to K\pi\pi^0$, $D^0 \to K\pi\pi$

Some DCS D^0 decays are measured for the sake of the $D^0 - \bar{D}^0$ mixing phenomenon appearing in so called *wrong-sign* (WS) decays (see Section 19.2), like $D^0 \to K^+\pi^-$, $D^0 \to K^+\pi^-\pi^0$ or $D^0 \to K^+\pi^-\pi^+\pi^-$, named after a charge of the final state kaon being opposite to the one produced in counterpart CF processes: $D^0 \to K^-\pi^+$, $D^0 \to K^-\pi^+\pi^0$ or $D^0 \to K^-\pi^+\pi^-\pi^-$, and being called *right-sign* (RS) decays. The WS process proceeds either through direct DCS decay (for example $D^0 \to K^+\pi^-$) or through $D^0 - \bar{D}^0$ mixing followed by RS CF decays (*i.e.* $D^0 - \bar{D}^0 \to K^+\pi^-$). These two decays can be distinguished by the D^0 decay-time distribution (Eq. 19.2.22),

Table 19.1.2. R_{WS} measurements from (Tian, 2005; Zhang, 2006) $[10^{-3}]$.

Decay mode	Branching Ratio
$\frac{D^0 \to K^+\pi^-}{D^0 \to K^-\pi^+}$	$3.77 \pm 0.08 \pm 0.05$
$\frac{D^0 \to K^+\pi^-\pi^0}{D^0 \to K^-\pi^+\pi^0}$	$2.29 \pm 0.15^{+0.13}_{-0.09}$
$\frac{D^0 \to K^+\pi^-\pi^+\pi^-}{D^0 \to K^-\pi^+\pi^+\pi^-}$	$3.20 \pm 0.18^{+0.18}_{-0.13}$

and the R_D entering this formula is the ratio of the DCS and CF decays.

In the Belle studies of the $D^0 \to K^+\pi^-$ (Zhang, 2006) and of the $D^0 \to K^+\pi^-\pi^0$ and $D^0 \to K^+\pi^-\pi^+\pi^-$ (Tian, 2005) the D^0 mesons originating from $D^{*+} \to D^0\pi^+$ decays are studied, and both RS and WS signals are obtained from the two-dimensional fit to invariant mass of the D^0 decay products, $M(D^0)$, and an energy release in D^{*+} decays, $Q \equiv M(D^{*+}) - M(D^0) - m_\pi$. Measured ratios of the WS to the RS signals are summarized in Table 19.1.2. Efficiencies for both multi-body D^0 decays take into account that they are dominated by various intermediate resonances, that can be different for the RS and WS decays. The event yields are corrected for acceptance in multi-dimensional space comprised of the invariant mass squared for various $K\pi$ and $\pi\pi$ subsystems. Given that the mixing is small, $R_{WS} \approx R_D$. Fit to distribution of the WS $D^0 \to K^+\pi^-$ proper decay time yields $R_D = (3.64 \pm 0.17) \times 10^{-3}$, in agreement with the R_{WS}. Thus the R_{WS} gives a good estimate of the branching ratio of the DCS to CF rates. In terms of consistency with the $SU(3)$ symmetry based prediction, all the results in Table 19.1.2 are consistent with the expected $\tan^4 \theta_C$.

19.1.3.7 Summary of the CS decays

The measured ratios of CS to CF branching ratios are summarized in Table 19.1.3, while branching fractions of CS decays, extracted from measurements relative to reference modes are listed in Table 19.1.4.

19.1.4 Dalitz analysis of three-body charmed meson decays

19.1.4.1 Introduction

Dalitz plot analyses of three-body charm decays can provide new information on the resonances that contribute to observed three-body final states. In addition, since the intermediate quasi-two-body modes are dominated by light quark meson resonances, new information on light meson spectroscopy can be obtained. Comparison between the production of resonances in decays of differently flavored charmed mesons $D^0(c\bar{u})$, $D^+(c\bar{d})$ and $D_s^+(c\bar{s})$ can yield new information on their possible quark composition. Another benefit of studying charm decays is that, in some cases, partial wave analyses are able to isolate the

Table 19.1.3. Branching ratios measured by Belle and *BABAR*.

Ratio	type	$\mathcal{B}\ [10^{-2}]$

Table 19.1.4. Branching fractions of CS decays, extracted from measurements relative to reference modes. Errors are respectively statistical, systematic and due to the uncertainty in the reference mode branching fraction. If single error is quoted it includes all these contributions.

Decay mode	Branching Fraction
$D^+ \to \pi^+\pi^0$	$(1.25 \pm 0.10 \pm 0.09 \pm 0.04) \times 10^{-3}$
$D^+ \to K^+\pi^0$	$(2.52 \pm 0.47 \pm 0.25 \pm 0.08) \times 10^{-4}$
$D^+ \to K_S^0 K^+$	$(2.75 \pm 0.08) \times 10^{-3}$
$D_s^+ \to K_S^0 \pi^+$	$(1.20 \pm 0.09) \times 10^{-3}$
$D^+ \to K^+\eta$	$(1.08 \pm 0.17 \pm 0.08) \times 10^{-4}$
$D^+ \to K^+\eta'$	$(1.76 \pm 0.22 \pm 0.12) \times 10^{-4}$
$D^+ \to K^+\pi^+\pi^-$	$(5.2 \pm 0.2 \pm 0.1) \times 10^{-4}$
$D_s^+ \to K^+K^+\pi^-$	$(1.3 \pm 0.2 \pm 0.1) \times 10^{-4}$
$D^0 \to \pi^-\pi^+\pi^0$	$(1.493 \pm 0.008 \pm 0.018 \pm 0.053) \times 10^{-2}$
$D^0 \to K^-K^+\pi^0$	$(0.334 \pm 0.004 \pm 0.006 \pm 0.012) \times 10^{-2}$

scalar contribution almost background free. A dedicated description of the Dalitz analysis methods can be found in Chapter 13. Table 19.1.5 gives a list of various three-body charm Dalitz analyses performed by the B Factories together with references and corresponding sections with a detailed description.

19.1.4.2 Dalitz Plot Analysis of $D^0 \to \overline{K}^0 K^+ K^-$

The paper from *BABAR* (Aubert, 2005f) focuses on the study of the three-body D^0 meson decay

$$D^0 \to \overline{K}^0 K^+ K^-,$$

where the $\overline{K}^0$ is detected via the decay $K_S^0 \to \pi^+\pi^-$. The D^0 is tagged with a D^*. In a first analysis *BABAR* made use

Table 19.1.5. Dalitz analyses of three-body charm decays performed by the B Factories.

Decay	Reference	Section with description
$D^0 \to \overline{K}^0 K^+ K^-$	(Aubert, 2005f, 2008l)	19.1.4.2
$D^0 \to K_S^0 \pi^+ \pi^-$	(Aubert, 2008l; Zhang, 2006)	19.1.4.4
$D^0 \to K^+ \pi^- \pi^0$	(Aubert, 2009u)	19.1.4.5

19.1.4.3 Partial Wave Analysis of $D^0 \to \overline{K}^0 K^+ K^-$.

It is assumed that near threshold the production of the $K^+ K^-$ system can be described in terms of the diagram shown in Fig. 19.1.17. The helicity angle, θ_K, is then defined as the angle between the K^+ for D^0 (or K^- for $\overline{D}^0$) in the $K^+ K^-$ rest frame and the $K^+ K^-$ direction in the D^0 (or $\overline{K}^0$) rest frame. The $K^+ K^-$ mass distribution has been modified by weighting each D^0 candidate by the spherical harmonic $Y_L^0(\cos \theta_K)$, $L = 0 - 4$, divided by its (Dalitz-plot-dependent) fitted efficiency. The resulting distributions $\langle Y_L^0 \rangle$ are shown in Fig. 19.1.18 and are proportional to the $K^+ K^-$ mass-dependent harmonic moments. It is found that all the $\langle Y_L^0 \rangle$ moments are small or consistent with zero, except for $\langle Y_0^0 \rangle$, $\langle Y_1^0 \rangle$ and $\langle Y_2^0 \rangle$.
Figure 19.1.17. The kinematics describing the production of the $K^+ K^-$ system in the threshold region of the decay $D^0 \to \overline{K}^0 K^+ K^-$.

of $91.5\,\text{fb}^{-1}$ collecting N=13536 ± 116 events with a 97.3% purity. An additional analysis, with increased statistics ($\approx$ 69000 candidates) has been performed in with the aim of measuring ϕ_3. We first describe the lower statistics analysis and in particular the partial wave analysis of the $K^+ K^-$ threshold region.

The Dalitz plot for these $D^0 \to \overline{K}^0 K^+ K^-$ candidates is shown in Fig. 19.1.16.

In the $K^+ K^-$ threshold region, a strong $\phi(1020)$ signal is observed, together with a rather broad structure. A large asymmetry with respect to the $\overline{K}^0 K^+$ axis can also be seen in the vicinity of the $\phi(1020)$ signal, which is the result of interference between S- and P-wave amplitude contributions to the $K^+ K^-$ system. The $f_0(980)$ and $a_0(980)$ S-wave resonances are, in fact, just below the $K^+ K^-$ threshold, and might be expected to contribute in the vicinity of $\phi(1020)$. An accumulation of events due to a charged $a_0(980)^+$ can be observed on the lower right edge of the Dalitz plot. This contribution, however, does not overlap with the $\phi(1020)$ region and this allows the $K^+ K^-$ scalar and vector components to be separated using a partial wave analysis in the low mass $K^+ K^-$ region.

In order to interpret these distributions a simple partial wave analysis has been performed, involving only S- and P-wave amplitudes. This results in the following set of equations (Chung, 1997):

$$\sqrt{4\pi} \langle Y_0^0 \rangle = S^2 + P^2$$

$$\sqrt{4\pi} \langle Y_1^0 \rangle = 2 \mid S \mid\mid P \mid \cos \phi_{SP}$$

$$\sqrt{4\pi} \langle Y_2^0 \rangle = \frac{2}{\sqrt{5}} P^2, \qquad (19.1.36)$$

where S and P are proportional to the size of the S- and P-wave contributions and ϕ_{SP} is their relative phase. Under these assumptions, the $\langle Y_2^0 \rangle$ moment is proportional to P^2 so that it is natural that the $\phi(1020)$ appears free of background, as is observed.
Figure 19.1.18. From (Aubert, 2005f). The unnormalized spherical harmonic moments $\langle Y_L^0 \rangle$ as functions of K^+K^- invariant mass. The histograms represent the result of the full Dalitz plot analysis.

Figure 19.1.19. From (Aubert, 2005f). Results from the K^+K^- Partial Wave Analysis corrected for phase space. (a) P-wave strength, (b) S-wave strength. (c) $m(\overline{K}^0K^+)$ distribution, (d) $\cos\phi_{SP}$ in the $\phi(1020)$ region. (e) ϕ_{SP} in the threshold region after having subtracted the fitted $\phi(1020)$ phase motion shown in (d).

A strong $S-P$ interference is evidenced by the rapid motion of the $\langle Y_1^0 \rangle$ moment in Fig. 19.1.18 in the $\phi(1020)$ mass region.

Figure 19.1.20. (Aubert, 2005f). Comparison between the phase-space-corrected K^+K^- and $\overline{K}^0K^+$ normalised to the same area in the mass region between 0.992 and 1.05 GeV/c^2.

The above system of equations 19.1.36 can be solved directly for S^2, P^2 and $\cos\phi_{SP}$. However, since these amplitudes are defined in a D^0 decay, it is necessary to correct for phase space. The corrected spectra are shown in Fig. 19.1.19.

The distributions have been fitted using the following model:

- The P-wave is entirely due to the $\phi(1020)$ meson (Fig.19.1.19(a)).
- The scalar contribution in the K^+K^- mass projection is entirely due to the $a_0(980)^0$ (Fig. 19.1.19(b)).
- The $\overline{K}^0K^+$ mass distribution is entirely due to $a_0(980)^+$ (Fig. 19.1.19(c)).
- The angle ϕ_{SP} (Fig. 19.1.19(d)) is obtained fitting the S, P waves and $\cos\phi_{SP}$ with $c_{a_0}BW_{a_0} + c_\phi BW_\phi e^{i\alpha}$. Here BW_{a_0} and BW_ϕ are the Breit-Wigner functions (BW) describing the $a_0(980)$ and $\phi(1020)$ resonances.

The $a_0(980)$ scalar resonance has a mass very close to the $K\overline{K}$ threshold and decays mostly to $\eta\pi$. It has been described by a coupled channel Breit-Wigner shape of the form:

$$BW_{ch}(a_0)(m) = \frac{g_{K\overline{K}}}{m_0^2 - m^2 - i(\rho_{\eta\pi}g_{\eta\pi}^2 + \rho_{K\overline{K}}g_{K\overline{K}}^2)}$$

(19.1.37)

where $\rho(m) = 2q/m$ while $g_{\eta\pi}$ and $g_{K\overline{K}}$ describe the $a_0(980)$ couplings to the $\eta\pi$ and $K\overline{K}$ systems respectively. Fixing m_0 and $g_{\eta\pi}$ to the Crystal Barrel measurements (Abele et al., 1998) it is possible to measure:

$$g_{K\overline{K}} = (464 \pm 29)\,\text{MeV})^{1/2}.$$

(19.1.38)

Figure 19.1.19(e) shows the residual $a_0(980)$ phase, obtained by first computing ϕ_{SP} in the range $(0,\pi)$ and then

Table 19.1.6. From (Aubert, 2008l). Complex amplitudes $a_r e^{i\phi_r}$ and fit fractions, obtained from the fit of the $D^0 \to K_S^0 K^+ K^-$ Dalitz plot distribution. The mass and width of the $\phi(1020)$, and the $g_{K\bar{K}}$ coupling constant are simultaneously determined in the fit, yielding $M_{\phi(1020)} = 1.01943 \pm 0.00002$ GeV/c^2, $\Gamma_{\phi(1020)} = 4.59319 \pm 0.00004$ MeV/c^2, and $g_{K\bar{K}} = 0.550 \pm 0.010$ GeV/c^2. Errors for amplitudes are statistical only. Uncertainties (largely dominated by systematic contributions) are not estimated for the fit fractions.

Component	a_r	ϕ_r (deg)	Fraction (%)
$K_S^0 a_0(980)^0$	1	0	55.8
$K_S^0 \phi(1020)$	0.227 ± 0.005	-56.2 ± 1.0	44.9
$K_S^0 f_0(1370)$	0.04 ± 0.06	-2 ± 80	0.1
$K_S^0 f_2(1270)$	0.261 ± 0.020	-9 ± 6	0.3
$K_S^0 a_0(1450)^0$	0.65 ± 0.09	-95 ± 10	12.6
$K^- a_0(980)^+$	0.562 ± 0.015	179 ± 3	16.0
$K^- a_0(1450)^+$	0.84 ± 0.04	97 ± 4	21.8
$K^+ a_0(980)^-$	0.118 ± 0.015	138 ± 7	0.7
Figure 19.1.21. From (Aubert, 2008l). $D^0 \to K_S^0 K^+ K^-$ Dalitz plot projections from $D^{*+} \to D^0 \pi^+$ events on (d) m_-^2, (e) m_+^2, and (f) m_0^2. The curves are the reference model fit projections.

subtracting the known phase motion due to the $\phi(1020)$ resonance.

In this fit the possible presence of an $f_0(980)$ contribution has not been considered. This assumption can be tested by comparing the K^+K^- and $\overline{K}^0K^+$ phase space corrected mass distributions. Since the $f_0(980)$ has isospin 0, it cannot decay to $\overline{K}^0K^+$. Therefore an excess in the K^+K^- mass spectrum with respect to $\overline{K}^0K^+$ would indicate the presence of an $f_0(980)$ contribution.

Figure 19.1.20 compares the K^+K^- and $\overline{K}^0K^+$ mass distributions, normalised to the same area between 0.992 and 1.05 GeV/c^2 and corrected for phase space. It is possible to observe that the two distributions show a good agreement, supporting the argument that the $f_0(980)$ contribution is small.

We now refer to the higher statistics Dalitz plot analysis from *BABAR* (Aubert, 2008l). The description of the $D^0 \to K_S^0 K^+ K^-$ decay amplitude consists of five distinct resonances leading to 8 two-body decays: $K_S^0 a_0(980)^0$, $K_S^0 \phi(1020)$, $K^- a_0(980)^+$, $K_S^0 f_0(1370)$, $K^+ a_0(980)^-$, $K_S^0 f_2(1270)^0$, $K_S^0 a_0(1450)^0$, and $K^- a_0(1450)^+$. This isobar model is essentially identical to that used in the previous analysis, but for the addition of the $a_0(1450)$ scalar, whose contribution is strongly supported by the much

larger data sample, as well as of a D-wave contribution parameterized with the $f_2(1270)$ tensor. Attempts to improve the model quality by adding other contributions (including the non-resonant term) did not give better results.

Table 19.1.6 summarizes the values obtained for all free parameters of the $D^0 \to K_S^0 K^+ K^-$ Dalitz model, the complex amplitudes $a_r e^{i\phi_r}$, the mass and width of the $\phi(1020)$ and the coupling constant $g_{K\bar{K}}$, together with the fit fractions. The value of $g_{K\bar{K}}$ is consistent with the previous result, and differs significantly from the measurement reported in (Abele et al., 1998). All amplitudes are measured with respect to $D^0 \to K_S^0 a_0(980)^0$, which gives the largest contribution. The sum of fit fractions is 152.3%, and the reduced χ^2 is 1.09 (with statistical errors only) for 6856 degrees of freedom, estimated from a binning of the Dalitz plot into square regions of size 0.045 GeV^2/c^4. Figure 19.1.21(d,e,f) shows the fit projections overlaid with the data distributions. The Dalitz plot distributions are well reproduced, with some small discrepancies at the peaks of the m_-^2 and m_+^2 projections.

19.1.4.4 $D^0 \to K_S^0 \pi^+ \pi^-$ Dalitz model

This analysis from *BABAR* is related to the measurement of ϕ_3 (Section 17.8) and makes use of 487 000 $D^0 \to K_S^0 \pi^+ \pi^-$ events tagged with a D^{*+} with 97.7% purity (Aubert, 2008l). The *P*- and *D*-waves of the $D^0 \to K_S^0 \pi^+ \pi^-$ decay amplitude are described using a total of 6 resonances leading to 8 two-body decay amplitudes: the Cabibbo allowed (CA) $K^*(892)^-$, $K^*(1680)^-$, $K_2^*(1430)^-$, the doubly-Cabibbo suppressed (DCS) $K^*(892)^+$, $K_2^*(1430)^+$, and the *CP* eigenstates $\rho(770)^0$, $\omega(782)$, and $f_2(1270)$. Since the $K\pi$ *P*-wave is largely dominated by the $K^*(892)^\mp$, the mass and width of this resonance are simultaneously determined from the fit to the tagged D^0 sample, $M_{K^*(892)^\mp} = 893.61 \pm 0.08$ MeV/c^2 and $\Gamma_{K^*(892)^\mp} = 46.34 \pm 0.16$ MeV/c^2 (errors are statistical only). The mass and width values of the $K^*(1680)^-$ are taken from (Aston et al., 1988), where the interference between the $K\pi$ *S*- and *P*-waves is properly accounted for.

They adopt the same parameterizations for K, ρ, and P as in Yao et al. (2006), Anisovich and Sarantsev (2003), and Link et al. (2004a). The K matrix is written as

$$K_{uv}(s) = \left(\sum_\alpha \frac{g_u^\alpha g_v^\alpha}{m_\alpha^2 - s} + f_{uv}^{\text{scatt}} \frac{1 - s_0^{\text{scatt}}}{s - s_0^{\text{scatt}}} \right) f_{A0}(s),$$

$$(19.1.39)$$

where g_u^α is the coupling constant of the K-matrix pole m_α to the uth channel. The parameters f_{uv}^{scatt} and s_0^{scatt} describe the slowly-varying part of the K-matrix. The factor

$$f_{A0}(s) = \frac{1 - s_{A0}}{s - s_{A0}} \left(s - s_A \frac{m_\pi^2}{2} \right), \quad (19.1.40)$$

suppresses the false kinematical singularity at $s = 0$ in the physical region near the $\pi\pi$ threshold (the Adler zero (Adler, 1965)). The parameter values used in this analysis are listed in Section 13, and are obtained from a global analysis of the available $\pi\pi$ scattering data from threshold up to 1900 MeV/c^2 (Anisovich and Sarantsev, 2003). The parameters f_{uv}^{scatt}, for $u \neq 1$, are all set to zero since they are not related to the $\pi\pi$ scattering process. Similarly, for the P vector we have

$$P_v(s) = \sum_\alpha \frac{\beta_\alpha g_v^\alpha}{m_\alpha^2 - s} + f_{1v}^{\text{prod}} \frac{1 - s_0^{\text{prod}}}{s - s_0^{\text{prod}}}.$$

$$(19.1.41)$$

Note that the P-vector has the same poles as the K-matrix, otherwise the F_1 vector would vanish (diverge) at the K-matrix (P-vector) poles. The parameters β_α, f_{1v}^{prod} and s_0^{prod} of the initial P-vector are obtained from the fit to the tagged $D^0 \to K_S^0 \pi^+ \pi^-$ data sample.

For the $K\pi$ *S*-wave contribution to Eq. (19.1.39) they use a parameterization extracted from scattering data (Aston et al., 1988) which consists of a $K_0^*(1430)^-$

or $K_0^*(1430)^+$ BW (for CA or DCS contribution, respectively) together with an effective range non-resonant component with a phase shift,

$$\mathcal{A}_{K\pi \ L=0}(\mathbf{m}) = F \sin \delta_F e^{i\delta_F} + R \sin \delta_R e^{i\delta_R} e^{i2\delta_F} ,$$

$$(19.1.42)$$

with

$$\delta_R = \phi_R + \tan^{-1} \left[\frac{M\Gamma(m_{K\pi}^2)}{M^2 - m_{K\pi}^2} \right] ,$$

$$\delta_F = \phi_F + \cot^{-1} \left[\frac{1}{aq} + \frac{rq}{2} \right]. \quad (19.1.43)$$

The parameters a and r play the role of a scattering length and effective interaction length, respectively, F (ϕ_F) and R (ϕ_R) are the amplitudes (phases) for the non-resonant and resonant terms, and q is the momentum of the spectator particle in the $K\pi$ system rest frame. Note that the phases δ_F and δ_R depend on $m_{K\pi}^2$. M and $\Gamma(m_{K\pi}^2)$ are the mass and running width of the resonant term. This parameterization corresponds to a K-matrix approach describing a rapid phase shift coming from the resonant term and a slow rising phase shift governed by the non-resonant term, with relative strengths R and F. The parameters M, Γ, F, ϕ_F, R, ϕ_R, a and r are determined from the fit to the tagged D^0 sample, along with the other parameters of the model. Other recent experimental efforts to improve the description of the $K\pi$ *S*-wave using K-matrix and model independent parameterizations from high-statistics samples of $D^+ \to K^- \pi^+ \pi^+$ decays are described in Aitala et al. (2006), Link et al. (2007), and Bonvicini et al. (2008).

Table 19.1.7 summarizes the values obtained for all free parameters of the $D^0 \to K_S^0 \pi^+ \pi^-$ Dalitz model: CA, DCS, and *CP* eigenstates complex amplitudes $a_r e^{i\phi_r}$, $\pi^+ \pi^-$ *S*-wave P-vector parameters, and $K\pi$ *S*-wave parameters, along with the fit fractions. The non-resonant term of Eq. (19.1.42) has not been included since the $\pi\pi$ and $K\pi$ *S*-wave parameterizations naturally account for their respective non-resonant contributions. The fifth P-vector channel and pole have also been excluded since the $\eta\eta'$ threshold and the pole mass m_5 are both far beyond our $\pi\pi$ kinematic range, and thus there is little sensitivity to the associated parameters, f_{15}^{prod} and β_5, respectively. The amplitudes are measured with respect to $D^0 \to K_S^0 \rho(770)^0$ which gives the second largest contribution.

The $K\pi$ and $\pi\pi$ *P*-waves dominate the decay, but significant contributions from the corresponding *S*-waves are also observed (above 6 and 4 standard deviations, respectively). They obtain a sum of fit fractions of $(103.6 \pm 5.2)\%$, and the goodness-of-fit is estimated through a two-dimensional χ^2 test performed binning the Dalitz plot into square regions of size 0.015 GeV^2/c^4, yielding a reduced χ^2 of 1.11 (including statistical errors only) for 19274 degrees of freedom. The variation of the contribution to the χ^2 as a function of the Dalitz plot position is approximately uniform. Figure 19.1.22(a,b,c) shows the Dalitz fit projections overlaid with the data distributions. The Dalitz plot distributions are well reproduced, with some

Table 19.1.7. From (Aubert, 2008l). CA, DCS, and *CP* eigenstates complex amplitudes $a_r e^{i\phi_r}$, $\pi\pi$ *S*-wave *P*-vector parameters, $K\pi$ *S*-wave parameters, and fit fractions, as obtained from the fit of the $D^0 \to K_S^0 \pi^+ \pi^-$ Dalitz plot distribution from $D^{*+} \to D^0 \pi^+$. P-vector parameters $f_{1v}^{'\mathrm{prod}}$, for $v \neq 1$, are defined as $f_{1v}^{'\mathrm{prod}}/f_{11}^{\mathrm{prod}}$. Errors for amplitudes are statistical only, while for fit fractions include statistical and systematic uncertainties, largely dominated by the latter. Upper limits on fit fractions are quoted at 95% confidence level.

Figure 19.1.22. From (Aubert, 2008l). $D^0 \to K_S^0 \pi^+ \pi^-$ Dalitz plot projections from $D^{*+} \to D^0 \pi^+$ events on (a) m_-^2, (b) m_+^2, and (c) m_0^2. The curves are the reference model fit projections.
Figure 19.1.23. From (Zhang, 2006). Dalitz plot distribution of $D^0 \to K_S^0 \pi^+ \pi^-$) and the projections for data (points with error bars) and the fit result (curve). Here, $m_\pm^2$ corresponds to $m^2(K_S^0 \pi^\pm)$ for D^0 decays and to $m^2(K_S^0 \pi^\mp)$ for $\bar{D}^0$ decays.

small discrepancies in low and high mass regions of the m_0^2 projection, and in the $\rho(770)^0 - \omega(782)$ interference region.

As a cross-check, they alternatively parameterize the $\pi\pi$ and $K\pi$ S-waves using the isobar approximation with the following BW amplitudes (plus the non-resonant contribution): the CA $K_0^*(1430)^-$, the DCS $K_0^*(1430)^+$, and the CP eigenstates $f_0(980)$, $f_0(1370)$, σ and an ad hoc σ'. Masses and widths of the σ and σ' scalars are obtained from the fit, $M_\sigma = 528 \pm 5$, $\Gamma_\sigma = 512 \pm 9$, $M_{\sigma'} = 1033 \pm 4$, and $\Gamma_{\sigma'} = 99 \pm 6$, given in MeV/$c^2$. Mass and width values for the $K_0^*(1430)^\mp$, $f_0(980)$, and $f_0(1370)$ are taken from (Aitala et al., 2001b, 2002). They obtain a sum of fit fractions of 122.5%, and a reduced χ^2 of 1.20 (with statistical errors only) for 19274 degrees of freedom, which strongly disfavors the isobar approach in comparison to the K-matrix formalism.

Belle study of the $D^0 \to K_S^0 \pi^+ \pi^-$ decays, based on 540 fb^{-1} of the data, has been performed for the $D^0 - \bar{D}^0$ mixing measurement (Zhang, 2006). The reconstructed signal yield of D^0 mesons, tagged with $D^{*+} \to D^0 \pi^+$ decays, is of $(534.4 \pm 0.8) \times 10^3$ events and the signal purity amounts to about 95%. The Dalitz distribution for the $D^0 \to K_S^0 \pi^+ \pi^-$ candidates is modeled assuming an isobar model in which the total $D^0 \to K_S^0 \pi^+ \pi^-$ amplitude is a sum of 18 quasi-two-body amplitudes, described with relativistic Breit-Wigner functions, and a constant nonresonant term. The amplitudes and their relative phases, obtained from an unbinned maximum likelihood fit performed to the Dalitz distribution, are summarized in Ta-

Table 19.1.8. From (Zhang, 2006). Fit results for Dalitz plot parameters for $D^0 \to K_S^0 \pi^+ \pi^-$. The errors are statistical only.

Resonance	Amplitude	Phase (°)	Fraction

ble 19.1.8. The main features of the Dalitz plot are well reproduced as can be seen from the Dalitz plot and its
Figure 19.1.24. From (Aubert, 2009u). Dalitz plots for the (a) RS $D^0 \to K^- \pi^+ \pi^0$ and (b) WS $D^0 \to K^+ \pi^- \pi^0$ samples. (c, d) $m^2_{K^+\pi^-}$ and $m^2_{K^+\pi^0}$ projections with superimposed fit results (line). The light histogram represents the mistag background, while the dark histogram shows the combinatoric background;

projections shown, along with projections of the fit result, in Fig. 19.1.23. The goodness-of-fit of the Dalitz plot is estimated to be $\chi^2/ndf = 2.1$ for $3653 - 40$ degrees of freedom (ndf). The K-matrix formalism was used in addition to the above mentioned isobar model in estimation of systematic uncertainties for the $D^0 - \bar{D}^0$ mixing measurement.

19.1.4.5 Dalitz Plot Analysis of three-body (wrong-sign) $D^0 \to K^+ \pi^- \pi^0$ decays.

This analysis from *BABAR* (Aubert, 2009u) has been performed on a data sample of 384 fb^{-1}. The Dalitz analysis is performed on the wrong-sign (WS) dataset only consisting of $D^{*+} \to D^0(\to K^+ \pi^- \pi^0)\pi^+$ events. The right sign (RS) sample ($D^{*+} \to D^0(\to K^- \pi^+ \pi^0)\pi^+$) is composed of $658,986$ events with a purity of 99%, the WS by 3009 events with a purity of 50%. The efficiency of the signal region selection is 54.6%. In the Dalitz plot analysis, the fit fraction of the non-resonant contribution to the K-π S-wave is absorbed into the $K^{*+}_0(1430)$ and $K^{*0}_0(1430)$ fit fractions. Projections of the fit results are shown in Fig. 19.1.24(b-d), amplitudes, phases, and fractions are given in Table 19.1.9.

19.1.4.6 Dalitz Plot Analysis of $D^0 \to K^- K^+ \pi^0$ decay.

Using 385 fb^{-1} of e^+e^- collisions, *BABAR* has performed a Dalitz analysis of the singly Cabibbo-suppressed decay $D^0 \to K^- K^+ \pi^0$ (Aubert, 2007d). Fig. 19.1.25 shows the

Table 19.1.9. From (Aubert, 2009u). Fit results for the WS $D^0 \to K^+ \pi^- \pi^0$ data sample. The total fit fraction is 102% and the $\chi^2/ndof$ is 188/215.

$D^0 \to K^- K^+ \pi^0$ Dalitz plot and mass projections, together with results from the Dalitz plot analysis. The LASS $K\pi$ S-wave amplitude gives the best agreement with data and they use it in the nominal fits. The $K\pi$ S-wave modeled by the combination of $\kappa(800)$ (with parameters taken from Aitala et al., 2002), a nonresonant term and $K_0^*(1430)$ has a smaller fit probability (χ^2 probability < 5%). The best fit with this model (χ^2 probability 13%) yields a charged κ of mass (870 ± 30) MeV/c^2, and width (150 ± 20) MeV/c^2, significantly different from those reported in Aitala et al. (2002) for the neutral state. This does not support the hypothesis that production of a charged, scalar κ is being observed. The E-791 amplitude Aitala et al. (2006) describes the data well, except near threshold (χ^2 probability 23%).
Figure 19.1.25. From (Aubert, 2007d). Dalitz plot for $D^0 \to K^- K^+ \pi^0$ data (a), and the corresponding squared invariant mass projections (b–d). The three-body invariant mass of the D^0 candidate is constrained to the nominal value. In plots (b–d), the dots (with error bars, black) are data points and the solid lines (blue) correspond to the best isobar fit models.

Table 19.1.10. From (Aubert, 2007d). The results obtained from the $D^0 \to K^-K^+\pi^0$ Dalitz plot fit. The amplitude coefficients, a_r and ϕ_r, are computed relatively to those of the $K^*(892)^+$. The $a_0(980)$ contribution, when it is included in place of the $f_0(980)$, is given in square brackets. The $K\pi$ S-wave states are inicated as $K^\pm\pi^0(S)$. The LASS amplitude is used to describe the $K\pi$ S-wave states in both the isobar models (I and II).

Two different isobar models describe the data well. Both yield almost identical behavior in invariant mass (Fig. 19.1.25b–19.1.25d). The results of the best fits (Model I: $\chi^2/\nu = 702.08/714$, probability 61.9%; Model II: $\chi^2/\nu = 718.89/717$, probability 47.3%) are summarized in Table 19.1.10. They find that the $K\pi$ S-wave is not in phase with the P-wave at threshold as it was in the LASS scattering data. Both fitting models include significant contributions from $K^*(892)$, and each indicates that $D^0 \to K^{*+}K^-$ dominates over $D^0 \to K^{*-}K^+$. This suggests that, in tree-level diagrams, the form factor for D^0 coupling to K^{*-} is suppressed compared to the corresponding K^- coupling. While the measured fit fraction for $D^0 \to K^{*+}K^-$ agrees well with a phenomenological prediction (Buccella, Lusignoli, Miele, Pugliese, and Santorelli, 1995) based on a large $SU(3)$ symmetry breaking, the corresponding results for $D^0 \to K^{*-}K^+$ and the color-suppressed $D^0 \to \phi\pi^0$ decays differ significantly from the predicted values.

In a limited mass range, from threshold up to 1.02 GeV/c^2, they also measure the scalar amplitude using a model-independent partial-wave analysis. Agreement with similar measurements from $D^0 \to K^-K^+\bar{K}^0$ decay (Aubert, 2005f), and with the isobar models considered here, is excellent.

19.1.4.7 $D^0 \to \pi^+\pi^-\pi^0$

This analysis from *BABAR* makes use of $N_S = 44780 \pm 250$ signal and $N_B = 830 \pm 70$ background events (Aubert, 2007w). Table 19.1.11 summarizes the results of the Dalitz plot analysis. The Dalitz plot distribution of the data is shown in Fig. 19.1.26(a-c). The distribution is marked by three destructively interfering $\rho\pi$ amplitudes, suggesting an $I = 0$-dominated final state (Zemach, 1964).

19.1.4.8 $D_s^+ \to \pi^+\pi^-\pi^+$

BABAR has performed a Dalitz plot analysis of $D_s^+ \to \pi^+\pi^-\pi^+$ (Aubert, 2009i) and $D_s^+ \to K^+K^-\pi^+$ (del Amo Sanchez, 2011b) using 380 fb^{-1}. The selection of the two channels is similar and it will be described only once.

The three tracks are fitted to a common vertex, and the χ^2 fit probability (labeled P_1) must be greater than 0.1 %. A separate kinematic fit which makes use of the D_s^+ mass constraint, to be used in the Dalitz plot analysis, is also performed. To help discriminate signal from background, an additional fit which uses the constraint that the three tracks originate from the e^+e^- luminous region (beam spot) is performed. The χ^2 probability of this fit is labeled as P_2, and it is expected to be large for background and small for D_s^+ signal events, since in general the latter will have a measurable flight distance.

The combinatorial background is reduced by requiring the D_s^+ to originate from the decay

$$D_s^{*+} \to D_s^+\gamma \qquad (19.1.44)$$

using the mass difference $\Delta m = m(\pi^+\pi^-\pi^+\gamma) - m(\pi^+\pi^-\pi^+)$. Each D_s^+ candidate is characterized by three variables: the center-of-mass momentum p^*, the difference in probability $P_1 - P_2$, and the signed decay distance d_{xy} between the D_s^+ decay vertex and the beam spot projected in the plane normal to the beam collision axis. The distributions for these variables for background are inferred from the $D_s^+ \to \pi^+\pi^-\pi^+$ invariant mass sidebands. Since these variables are (to a good approximation) independent of the decay mode, the distributions for the three-pion invariant mass signal, are inferred from the $D_s^+ \to K^+K^-\pi^+$ decay. These normalized distributions are then combined in a likelihood ratio test. The cut on the likelihood ratio has been chosen in order to obtain the largest statistics with background small enough to perform a Dalitz plot analysis.

The distributions of these variables for the $D_s^+ \to K^+K^-\pi^+$ decay for signal and background are shown in Fig. 19.1.27.

The resulting D_s^+ signal region contains 13179 events with a purity of 80%. The resulting Dalitz plot, symmetrized along the two axes, is shown in Fig. 19.1.28. We observe a clear $f_0(980)$ signal, evidenced by the two narrow crossing bands. We also observe a broad accumulation of events in the 1.9 GeV^2/c^4 region. The efficiency is found to be almost uniform as a function of the $\pi^+\pi^-$ invariant mass with an average value of ≈ 1.6 %.

In the Dalitz plot analysis spin-1 and spin-2 resonances are described by relativistic Breit-Wigner function. For
Figure 19.1.26. From (Aubert, 2007w). (a,b) Projections of the $D^{*+} \to D^0(\to \pi^+\pi^-\pi^0)\pi^+$ data events and *p.d.f.* onto the Dalitz plot variables $s_+ = m^2(\pi^+\pi^0)$ and $s_- = m^2(\pi^-\pi^0)$. (c) The 2-dimensional (s_+, s_-) distribution of the $D^{*+} \to D^0\pi^+$ data.

Table 19.1.11. From (Aubert, 2007w). Result of the fit to the $D^0 \to \pi^+\pi^-\pi^0$ sample, showing the amplitudes ratios $R_r \equiv a_r/a_{\rho^+(770)}$, phase differences $\Delta\phi_r \equiv \phi_r - \phi_{\rho^+(770)}$, and fit fractions $f_r \equiv \int |a_r A_r(s_+, s_-)|^2 ds_- ds_+$ (see 13.4.4). The first (second) errors are statistical (systematic). The mass (width) of the σ meson is taken as 400 (600) MeV/c^2.

the $\pi^+\pi^-$ S-wave amplitude, a different approach is used because:

- Scalar resonances have large uncertainties. In addition, the existence of some states needs confirmation.
- Modelling the S-wave as a superposition of Breit-Wigner functions is unphysical since it leads to a violation of unitarity when broad resonances overlap.

To overcome these problems, the Model-Independent Partial Wave Analysis introduced by the Fermilab E791 Collaboration (Aitala et al., 2006) has been used. Instead of including the S-wave amplitude as a superposition of relativistic Breit-Wigner functions, the $\pi^+\pi^-$ mass spectrum is divided into 29 slices and the S-wave is parameterized by an interpolation between the 30 endpoints in the complex plane:

$$A_{S-\text{wave}}(m_{\pi\pi}) = \text{Interp}(c_k(m_{\pi\pi})e^{i\phi_k(m_{\pi\pi})})_{k=1,30} \quad (19.1.45)$$

The amplitude and phase of each endpoint are free parameters. The width of each slice is tuned to get approximately the same number of $\pi^+\pi^-$ combinations ($\simeq 13179 \times 2/29$). Interpolation is implemented by a Relaxed Cubic Spline. The phase is not constrained in a specific range in order to allow the spline to be a continuous function.

The background shape is obtained by fitting the D_s^+ sidebands. In this fit, resonances are assumed to be incoherent, *i.e.* are represented by Breit-Wigner intensity terms only. A good representation of the background includes contributions from K_S^0, $\rho^0(770)$ and three ad-hoc scalar resonances with free parameters.

The resulting S-wave $\pi^+\pi^-$ amplitude and phase is shown in Fig. 19.1.29(a),(b). The results from the Dalitz analysis are summarized in Table 19.1.12.

The Dalitz-plot projections together with the fit results are shown in Fig. 19.1.30. The labels $m^2(\pi^+\pi^-)_{\text{low}}$ and $m^2(\pi^+\pi^-)_{\text{high}}$ refer to the lower and higher values of the two $\pi^+\pi^-$ mass combinations.

Total	$97.2\pm3.7\pm3.8$		
χ^2/NDF	$\frac{437}{422-64} = 1.2$		
Figure 19.1.30. From (Aubert, 2009i). Dalitz plot projections (points with error bars) and fit results (solid histogram) from $D_s^+ \to \pi^+\pi^-\pi^+$ Dalitz plot analysis. (a) $m^2(\pi^+\pi^-)_{\text{low}}$, (b) $m^2(\pi^+\pi^-)_{\text{high}}$, (c) total $m^2(\pi^+\pi^-)$, (d) $m^2(\pi^+\pi^+)$. The hatched histograms show the background distribution.

The fit χ^2 is computed by dividing the Dalitz plot into 30×30 cells with 422 cells having entries.

19.1.4.9 Dalitz plot analysis of $D_s^+ \to K^+ K^- \pi^+$

The Dalitz analysis of $D_s^+ \to K^+ K^- \pi^+$ is described in (del Amo Sanchez, 2011b). The selection of the channel is similar to that of the $D_s^+ \to \pi^+ \pi^- \pi^+$ channel (see Section 19.1.4.8). The resulting $K^+ K^- \pi^+$ mass distribution contains 96307 ± 369 events with 95% purity. The $D_s^+ \to K^+ K^- \pi^+$ Dalitz plot is shown in Fig. 19.1.31.

Figure 19.1.32. From (del Amo Sanchez, 2011b). $K^+ K^-$ mass spectrum from $D_s^+ \to K^+ K^- \pi^+$ in the threshold region weighted by (a) Y_0^0, (b) Y_1^0, and (c) Y_2^0, corrected for efficiency and phase space, and background-subtracted.

Figure 19.1.31. From (del Amo Sanchez, 2011b). $D_s^+ \to K^+ K^- \pi^+$ Dalitz plot.

Partial Wave Analysis of the $K^+ K^-$ threshold region for $D_s^+ \to K^+ K^- \pi^+$.

In the $K^+ K^-$ threshold region both $a_0(980)$ and $f_0(980)$ can be present, and both resonances have very similar parameters which suffer from large uncertainties. In this section a model-independent information on the $K^+ K^-$ S-wave is obtained by a performing a partial wave analysis in the $K^+ K^-$ threshold region. The procedure is similar to that reported in the analysis of the $D^0 \to \overline{K}^0 K^+ K^-$ decay (Section 19.1.4.2).

Figure 19.1.32 shows the $K^+ K^-$ mass spectrum up to $1.5 \, \text{GeV}/c^2$ weighted by the spherical harmonics moments. These distributions are corrected for efficiency and phase space, and background is subtracted using the D_s^+ sidebands.

The results from the Partial Wave Analysis are shown in Fig. 19.1.33. We observe a threshold enhancement in the S-wave (Fig. 19.1.33(a)), and the expected $\phi(1020)$ Breit-Wigner (BW) in the P-wave (Fig. 19.1.33(b)). We also observe the expected $\mathcal{S}$-$\mathcal{P}$ relative phase motion in the $\phi(1020)$ region (Fig. 19.1.33(c)). In Fig. 19.1.33(c), the $\mathcal{S}$-$\mathcal{P}$ phase difference is plotted twice because of the sign ambiguity associated with the value of $\phi_{\mathcal{S}\mathcal{P}}$ extracted

Figure 19.1.33. From (del Amo Sanchez, 2011b). Squared (a) S- and (b) P-wave amplitudes; (c) the phase difference ϕ_{SP}; (d) ϕ_S obtained as explained in the text. The curves result from the fit described in the text.
Figure 19.1.34. From (del Amo Sanchez, 2011b). (a) Comparison between $K\overline{K}$ S-wave intensities from different charmed meson Dalitz plot analyses. (b) Comparison of the $K\overline{K}$ S-wave intensity from $D_s^+ \to K^+K^-\pi^+$ with the $\pi^+\pi^-$ S-wave intensity from $D_s^+ \to \pi^+\pi^-\pi^+$.

from $\cos(\phi_{\mathcal{SP}})$. The lines represent the result from the fit performed using S-P interfering amplitudes.

The mass-dependent $f_0(980)$ phase is extracted by adding the mass-dependent $\phi(1020)$ Breit-Wigner phase to the $\phi_{\mathcal{SP}}$ distributions of Fig. 19.1.33(c). The phase ambiguity of Fig. 19.1.33(c) is resolved by choosing as the physical solution the one which decreases rapidly in the $\phi(1020)$ peak region, since this reflects the rapid forward Breit-Wigner-phase motion associated with a narrow resonance. The result is shown in Fig. 19.1.33(d), where we see that the S-wave phase is roughly constant, as would be expected for the tail of a resonance.

In Fig. 19.1.34(a) the S-wave profile from this analysis is compared with the S-wave intensity values extracted for Dalitz plot analyses of $D^0 \to \overline{K}^0 K^+K^-$ (Aubert, 2005f) and $D^0 \to K^+K^-\pi^0$ (Aubert, 2007d). The four distributions are normalized in the region from threshold up to 1.05 GeV/c^2 and show a substantial agreement. As the $a_0(980)$ and $f_0(980)$ mesons couple mainly to the $u\overline{u}/d\overline{d}$ and $s\overline{s}$ systems respectively, the former is favored in $D^0 \to \overline{K}^0 K^+K^-$ and the latter in $D_s^+ \to K^+K^-\pi^+$. Both resonances can contribute in $D^0 \to K^+K^-\pi^0$. We conclude that the S-wave projections in the $K\overline{K}$ system for both resonances are consistent in shape. It has been suggested that this feature supports the hypothesis that the $a_0(980)$ and $f_0(980)$ are 4-quark states (Maiani, Polosa, and Riquer, 2007). Figure 19.1.34(b)) also compares the S-wave profile from this analysis with the $\pi^+\pi^-$ S-wave profile extracted from *BABAR* data in a Dalitz plot analysis of $D_s^+ \to \pi^+\pi^-\pi^+$ Aubert (2009i). The observed agreement supports the argument that only the $f_0(980)$ is present in this limited mass region.

Dalitz plot analysis of $D_s^+ \to K^+K^-\pi^+$

In the full Dalitz plot analysis, the $\overline{K}^*(892)^0$ amplitude is chosen as reference. The decay fractions, amplitudes, and relative phase values are summarized in Table 19.1.13 where the first error is statistical, and the second is systematic. We observe that the decay is dominated by the
Figure 19.1.35. From (del Amo Sanchez, 2011b). $D_s^+ \to K^+K^-\pi^+$: Dalitz plot projections. The data are represented by points with error bars, the fit results by the histograms. The upper right plot shows zoom of the $m^2(K^+K^-)$ in the ϕ mass region.

$\overline{K}^*(892)^0 K^+$ and $\phi(1020)\pi^+$ amplitudes and that the fit quality is substantially improved by leaving the $\overline{K}^*(892)^0$ parameters free in the fit. The fitted parameters are:

$$m_{\overline{K}^*(892)^0} = (895.6 \pm 0.2_{\text{stat}} \pm 0.3_{\text{sys}}) \,\text{MeV}/c^2$$
$$\Gamma_{\overline{K}^*(892)^0} = (45.1 \pm 0.4_{\text{stat}} \pm 0.4_{\text{sys}}) \,\text{MeV} \quad (19.1.46)$$

We notice that the width is about 5 MeV lower than that in Amsler et al. (2008). However this measurement is consistent with results from other Dalitz plot analyses (Mitchell et al., 2009a) and measurements with semileptonic $D^+ \to \overline{K}^*(892)^0 e^+\nu_e$ decays (see Section 19.1.5.6).

The $f_0(1370)$ contribution is also left free in the fit, and we obtain the following parameter values:

$$m_{f_0(1370)} = (1.22 \pm 0.01_{\text{stat}} \pm 0.04_{\text{sys}}) \,\text{GeV}/c^2$$
$$\Gamma_{f_0(1370)} = (0.21 \pm 0.01_{\text{stat}} \pm 0.03_{\text{sys}}) \,\text{GeV} \quad (19.1.47)$$

These values are within the broad range of values measured by other experiments (Amsler et al., 2008).

The nonresonant contribution is consistent with zero.

The results of the best fit are superimposed on the Dalitz plot projections in Fig. 19.1.35. The normalized fit residuals shown under each distribution (Fig. 19.1.35) are defined as $(N_{\text{data}} - N_{\text{fit}})/\sqrt{N_{\text{data}}}$.

Table 19.1.13. From (del Amo Sanchez, 2011b). Results from the $D_s^+ \to K^+ K^- \pi^+$ Dalitz plot analysis. The table gives fit fractions, amplitudes and phases from the best fit. Quoted uncertainties are statistical and systematic, respectively.

Decay Mode	Decay fraction (%)	Amplitude	Phase (radians)
$\bar{K}^*(892)^0 K^+$	$47.9 \pm 0.5 \pm 0.5$	1.(Fixed)	0.(Fixed)
$\phi(1020)\,\pi^+$	$41.4 \pm 0.8 \pm 0.5$	$1.15 \pm 0.01 \pm 0.26$	$2.89 \pm 0.02 \pm 0.04$
$f_0(980)\,\pi^+$	$16.4 \pm 0.7 \pm 2.0$	$2.67 \pm 0.05 \pm 0.20$	$1.56 \pm 0.02 \pm 0.09$
$\bar{K}_0^*(1430)^0 K^+$	$2.4 \pm 0.3 \pm 1.0$	$1.14 \pm 0.06 \pm 0.36$	$2.55 \pm 0.05 \pm 0.22$

P-wave/S-wave ratio in the $\phi(1020)$ region

The decay mode $D_s^+ \to \phi(1020)\pi^+$ is used often as the normalizing mode for D_s^+ decay branching fractions, typically by selecting a $K^+ K^-$ invariant mass region around the $\phi(1020)$ peak. The observation of a significant S-wave contribution in the threshold region means that this contribution must be taken into account in such a procedure.

BABAR has estimated the P-wave/S-wave ratio in an almost model-independent way. Integrating the distributions of $\sqrt{4\pi}pq'\langle Y_0^0 \rangle$ and $\sqrt{5\pi}pq'\langle Y_2^0 \rangle$ (Fig. 19.1.32), where p is the K^+ momentum in the $K^+ K^-$ rest frame, and q' is the momentum of the bachelor π^+ in the D_s^+ rest frame, in a region around the $\phi(1020)$ peak yields $\int(|\mathcal{S}|^2 + |\mathcal{P}|^2)pq'\mathrm{d}m_{K^+K^-}$ and $\int|\mathcal{P}|^2pq'\mathrm{d}m_{K^+K^-}$ respectively.

The S-P interference contribution integrates to zero, and the P-wave and S-wave fractions are defined as

$$f_{P-\text{wave}} = \frac{\int |P|^2 pq'\mathrm{d}m_{K^+K^-}}{\int(|S|^2 + |P|^2)pq'\mathrm{d}m_{K^+K^-}} \quad (19.1.48)$$

$$f_{S-\text{wave}} = \frac{\int |S|^2 pq'\mathrm{d}m_{K^+K^-}}{\int(|S|^2 + |P|^2)pq'\mathrm{d}m_{K^+K^-}}$$
$$= 1 - f_{P-\text{wave}}. \quad (19.1.49)$$

The experimental mass resolution is estimated to be $\simeq 0.5$ MeV/c^2 at the ϕ mass peak. Table 19.1.14 gives the resulting S-wave and P-wave fractions computed for three $K^+ K^-$ mass regions. The last column of Table 19.1.14 shows the measurements of the relative overall rate (N/N_{tot}) defined as the number of events in the

$K^+ K^-$ mass interval over the number of events in the entire Dalitz plot after efficiency correction and background subtraction.

19.1.5 Semileptonic charm decays

19.1.5.1 Introduction

Exclusive semileptonic decays of B and D mesons are a favored means of determining the weak interaction couplings of quarks within the Standard Model because of their relative abundance; in addition, the hadronic uncertainties in their theoretical description are by far better under control than in hadronic decays. Our knowledge of the form factors parameterizing the hadronic current is limiting the precision on extractions of the couplings $|V_{cb}|$ and $|V_{ub}|$. Form factors from B and D meson semileptonic decays have been calculated using lattice QCD techniques whilst heavy quark symmetry relates the two form factors. Measurements of $D \to K/\pi\ell^+\nu_\ell$ are required to confront the theoretical predictions.[117]

Charm meson semileptonic decays with two pseudo scalar mesons (P_1, P_2) emitted in the final state allow also to study the strong interaction of the two pseudoscalar mesons in systems with well defined values of isospin and angular momentum, without parasitic effects from the presence of a third hadron as in Dalitz plot analyses. In particular S-wave systems can be isolated and properties of P-wave resonances can be accurately measured. Large statistics are analyzed, exceeding previous analyses by two orders of magnitude, in particular for the D_s^+ meson.

19.1.5.2 $D \to K/\pi\ell^+\nu_\ell$ decays

To measure D meson semileptonic decays with a pseudo scalar particle emitted in the final state ($D_{\ell 3}$ decays), Belle and BABAR have used completely different techniques. In Belle, events with all particles reconstructed are selected. This allows to isolate signal events over a low background

Table 19.1.14. From (del Amo Sanchez, 2011b). S-wave and P-wave fractions computed in three $K^+ K^-$ mass ranges around the $\phi(1020)$ peak. Errors are statistical only.

$m_{K^+K^-}$ (MeV/c^2)	$f_{S-\text{wave}}$ (%)	$f_{P-\text{wave}}$ (%)	$\frac{N}{N_{\text{tot}}}$ (%)

---

[117] Inclusion of charge-conjugate states is implied throughout this section.

level and a high resolution in $q^2 = (p_\ell + p_{\overline{\nu}_\ell})^2$, at the price of a low efficiency. In *BABAR*, a more inclusive approach allows to have larger statistics at the price of a higher background level and poorer q^2 resolution. In this case, additional measurements allow to control distributions from background events.

19.1.5.3 Belle measurement

To achieve good resolution in the neutrino momentum and q^2, the $\overline{D}^0$ is tagged by fully reconstructing the remainder of the event (Widhalm, 2006). Events of the type $e^+e^- \rightarrow D_{\text{tag}}^{(*)} D_{\text{sig}}^{*-} X$ with $D_{\text{sig}}^{*-} \rightarrow \overline{D}_{\text{sig}}^0 \pi_s^-$ are seeked, where X may include additional $\pi^\pm$, π^0, or $K^\pm$ mesons. Each candidate is assembled from a fully reconstructed "tag-side" charm meson $(D_{\text{tag}}^{(*)})$ which can be $D^{*+} \rightarrow D^0\pi^+$, $D^+\pi^0$ or $D^{*0} \rightarrow D^0\pi^0$, $D^0\gamma$ with $D^{+/0} \rightarrow K^-(\text{n}\pi)^{++/+}$, n = 1, 2, 3. To the $(D_{\text{tag}}^{(*)})$ is added a charged pion, that is kinematically consistent with the π_s^- from D_{sig}^{*-} decay, and the candidate X is formed from combinations of unassigned π and K^+K^- pairs, conserving total event electric charge. The 4-momentum of D_{sig}^{*-} is found by energy-momentum conservation, assuming a $D_{\text{tag}}^{(*)} D_{\text{sig}}^{*-} X$ event. The candidate $\overline{D}_{\text{sig}}^0$ 4-momentum is calculated from that of the D_{sig}^{*-} and π_s^-. The corresponding $\overline{D}_{\text{sig}}^0$ invariant mass distribution, obtained after analyzing an integrated luminosity of 282 fb^{-1}, contains $56461 \pm 309 \pm 830$ signal over 39789 ± 830 background events, the latter beeing estimated using wrong sign combinations in data and few corrections from the simulation. Within this sample of $\overline{D}_{\text{sig}}^0$ tags, the semileptonic decay $\overline{D}_{\text{sig}}^0 \rightarrow K^+/\pi^+\ell^-\overline{\nu}_\ell$ is reconstructed with K^+/π^+ and ℓ^- candidates from among the remaining tracks. The neutrino 4-momentum is reconstructed by energy-momentum conservation, its invariant mass squared, m_ν^2, is required to satisfy $|m_\nu^2| < 0.05\,\text{GeV}^2/c^4$. About 1300 and 150 semileptonic decays are isolated for each lepton flavor (e and μ) in Cabibbo-allowed and Cabibbo-suppressed decays respectively. These numbers have to be corrected for remaining background contributions from other semileptonic and hadronic decays where a hadron is mis-identified as a lepton. Corrections amount typically to 2% and 20% respectively in Cabibbo-allowed and Cabibbo-suppressed decays. The accuracy on branching fraction measurements is limited by systematic uncertainties for Cabibbo-allowed decays whereas systematic and statistical uncertainties are similar in Cabibbo-suppressed events. The main contribution to systematic uncertainties comes from the evaluation of fake $\overline{D}_{\text{sig}}^0$ tags. The resolution in $q^2 = (p_\ell+p_{\overline{\nu}_\ell})^2$ is found to be $0.0145\pm0.0007_{\text{stat}}\,\text{GeV}^2/c^2$ in MC signal events. This is much smaller than statistically reasonable bin widths, which have been chosen as 0.067 (0.3) GeV^2/c^2 for kaon (pion) modes, and hence no unfolding is necessary.

Measured hadronic form factors obtained by Belle are given in Figure 19.1.36 where they are compared with several theoretical expectations.
Figure 19.1.36. From (Widhalm, 2006). Form factors for (a) $D^0 \rightarrow K^-\ell^+\nu_\ell$, in q^2 bins of $0.067\,\text{GeV}^2/c^2$ and (b) $D^0 \rightarrow \pi^-\ell^+\nu_\ell$, in q^2 bins of $0.3\,\text{GeV}^2/c^2$. Overlaid are the predictions of the simple pole model using the physical pole mass (dashed) (Amoros, Noguera, and Portoles, 2003) and a quenched (light grey) (Abada et al., 2003) and unquenched (dark grey) LQCD calculation (Aubin et al., 2005). The shaded band reflects the theoretical uncertainty.

19.1.5.4 *BABAR* measurement

$D^0 \rightarrow K^-e^+\nu_e(\gamma)$ decays are reconstructed in $e^+e^- \rightarrow c\overline{c}$ events from the continuum where the D^0 originates from $D^{*+} \rightarrow D^0\pi^+$ (Aubert, 2007ab). The analyzed integrated luminosity is 75 fb^{-1} and semileptonic decays with a muon are not selected. In each event, the direction of the thrust axis is used to define two hemispheres. In each hemisphere, pairs of oppositely charged leptons and kaons are searched. Since the ν_e momentum is unmeasured, a kinematic fit is performed, constraining the invariant mass of the candidate $K^-e^+\nu_e$ system to the D^0 mass. In this fit, the D^0 momentum and the neutrino energy are estimated from the other particles measured in the event. Each D^0 candidate is retained if the χ^2 probability of the kinematic fit exceeds 10^{-3} and it is combined with a charged pion, with the same charge as the lepton, and situated in the same hemisphere. The mass difference $\delta(m) = m(D^0\pi^+) - m(D^0)$ is evaluated and signal events accumulate at low values of this variable. Only events with $\delta(m) < 0.16\,\text{GeV}/c^2$ are used in the analysis. Background events are rejected by applying cuts on Fisher discriminant variables against $B\overline{B}$, other $c\overline{c}$, and light quark events.

To improve the accuracy of the reconstructed D^0 momentum, the nominal D^{*+} mass is added as a constraint in the previous fit and only events with a χ^2 probability higher than 1% are kept. There are 85260 selected D^0 candidates containing an estimated number of 11280
Figure 19.1.37. From (Aubert, 2007ab). Comparison of the measured variation of $f_+^K(q^2)/f_+^K(0)$ obtained in BABAR and in the FOCUS experiment (Link et al., 2005). The band corresponds to an estimate from LQCD (Aubin et al., 2005).

background events. The 4-momentum squared of the leptonic system is obtained using the fitted D^0 and kaon 4-momenta: $q_r^2 = (p_{D^0} - p_K)^2$. The resolution on the reconstructed q^2 obtained from the simulation is found to be around $0.16\,\text{GeV}/c^2$. To obtain the true q^2 distribution, the measured one is corrected for selection efficiency, detector resolution and radiative effects. This is done using an unfolding algorithm based on MC simulation of these effects. Other data samples are used to validate the MC simulation. Events with $D^{*+} \rightarrow D^0\pi^+$, $D^0 \rightarrow K^-\pi^+$ allows to control the charm quark hadronization mechanism and the reconstruction accuracy of the D^0 4-momentum from other particles in the event. A sample of $D^{*+} \rightarrow D^0\pi^+$, $D^0 \rightarrow K^-\pi^+\pi^0$ decays is used also to verify the reconstruction accuracy on q_r^2 and to define corrections. To reduce systematic uncertainties on the semileptonic decay branching fraction determination, this quantity is measured relative to the $D^{*+} \rightarrow D^0\pi^+$, $D^0 \rightarrow K^-\pi^+$ decay channel which is isolated in data and in the simulation using, as much as possible, similar selection criteria. This has also the advantage that future improvements in the $\mathcal{B}(D^0 \rightarrow K^-\pi^+)$ determination can be incorporated (this was indeed the case since results have been published). The uncertainty on the branching fraction measurement is dominated by systematic uncertainties which have different origins (reconstruction algorithm, electron identification, background subtraction, control of the discriminant Fisher variable distribution and, counting of D^{*+} events in the normalization channel) of similar importance.

Figure 19.1.37 gives the measured variation versus q^2 of the ratio $f_+^K(q^2)/f_+^K(0)$ obtained in BABAR.

19.1.5.5 Comparison with theory and with other experiments

In $D^0 \rightarrow K^-/\pi^- e^+\nu_e$ decays, neglecting the electron mass, the differential decay rate depends on only one form factor, $f_+^{K/\pi}(q^2)$:

$$\frac{d\Gamma}{dq^2} = \frac{G_F^2}{24\pi^3}|V_{cq}|^2 \left|\boldsymbol{p}_P(q^2)\right|^3 \left|f_+^P(q^2)\right|^2, \qquad (19.1.50)$$

where G_F is the Fermi constant, $|V_{cq}|$ with $q = s$ or d, respectively for $P = K$ or π, is the absolute value of the corresponding CKM element, and $\boldsymbol{p}_P(q^2)$ is the pseudoscalar (P) three-momentum in the D^0 rest frame.

The unitarity of the first line of the CKM matrix is verified with high accuracy using beta decays of nuclei, $K_{\ell3}$, and $K_{\ell2}$ decays (Antonelli et al., 2010b):

$$|V_{ud}| = 0.97425(22), \;\; |V_{us}| = 0.2253(9), \qquad (19.1.51)$$

giving:

$$|V_{ud}|^2 + |V_{us}|^2 - 1 = -0.0001(8). \qquad (19.1.52)$$

Note the the contribution from $|V_{ub}|^2$ is completely negligible. The unitarity condition for the first column reads:

$$|V_{ud}|^2 + |V_{cd}|^2 + |V_{td}|^2 = 1. \qquad (19.1.53)$$

There could be large effects from new physics in the present value of $|V_{td}|$ but they will have essentially no contribution in the unitarity constraint as $|V_{td}| \sim |V_{ub}|$. So, independently of effects from new physics in $B^0\bar{B}^0$ oscillations, one can use $|V_{cd}| = |V_{us}| = 0.2253(9)$. Using this, together with the unitarity condition of the second line of the CKM matrix, one gets:

$$|V_{cs}| = |V_{ud}| - \frac{|V_{cb}|^2}{2} = 0.97343 \pm 0.00023, \qquad (19.1.54)$$

using the value $|V_{cb}| = (40.6 \pm 1.3) \times 10^{-3}$ (Nakamura et al., 2010). $D_{\ell3}$ decays depend on the product $|V_{cq}|\left|f_+^P(q^2)\right|$ and, as the CKM elements $|V_{cq}|$ are precisely determined, charm semileptonic decays allow to measure the absolute values of the corresponding hadronic form factors and their variation versus q^2.

The most general expressions of the form factor $f_+^P(q^2)$ are analytic functions satisfying the dispersion relation:

$$f_+^P(q^2) = \frac{Res(f_+^P)_{q^2=m_{D_q^*}^2}}{m_{D_q^*}^2 - q^2} + \frac{1}{\pi}\int_{t_+}^{\infty} dt \frac{\text{Im}f_+^P(t)}{t - q^2 - i\epsilon}. \qquad (19.1.55)$$

The singularities in the complex $t \equiv q^2$ plane originate from the interaction of the charm and light s or d quarks (for $P = K$ and π, respectively) forming charmed hadron vector states. They represent a pole, situated at the $D_q^* = D_s^{*+}$ or D^{*+} mass squared and a cut, along the positive real axis, starting at threshold ($t_+ = (m_D + m_P)^2$) for D^0P production.

This cut t-plane can be mapped onto the open unit disk with center at $t = t_0$ using the variable:

$$z(t, t_0) = \frac{\sqrt{t_+ - t} - \sqrt{t_+ - t_0}}{\sqrt{t_+ - t} + \sqrt{t_+ - t_0}}. \qquad (19.1.56)$$

In this variable, the physical region for the semileptonic decay ($0 < t < t_- = q^2_{\max} = (m_D - m_P)^2$) corresponds to a real segment extending between $\pm z_{\max} = \pm 0.051$ for $D \to K$ and ± 0.17 for $D \to \pi$. This value of $z_{\max}$ is obtained for $t_0 = t_+ \left(1 - \sqrt{1 - t_-/t_+}\right)$, where $t_+ = (m_D + m_P)^2$. The z expansion of f^P_+ is thus expected to converge quickly. The most general parameterization (Hill, 2006), consistent with constraints from QCD,

$$f_+(t) = \frac{1}{P(t)\Phi(t, t_0)} \sum_{k=0}^{\infty} a_k(t_0) \, z^k(t, t_0), \qquad (19.1.57)$$

is based on earlier considerations by (Boyd and Savage, 1997) and other references quoted therein. For $D^0 \to K^- e^+ \nu_e$, the function $P(t) = z(t, m^2_{D^*_s})$ has a zero at the D^*_s pole mass and $|P| = 1$ along the unit circle. For $D^0 \to \pi^- e^+ \nu_e$, as the D^{*+} mass is higher than $(m_{D^0} + m_{\pi^+})$, $P(t) = 1$. The expression for Φ can be found in (Boyd and Savage, 1997).

The choice of P and Φ is such that:

$$\sum_{k=0}^{\infty} a_k^2(t_0) \leq 1. \qquad (19.1.58)$$

Having measured the first coefficients of this expansion, Eq. (19.1.58) can constrain the others. This constraint is used in B meson semileptonic decays and found to be quite effective. For charm, this approach is not really justified because the charm quark mass is rather light rendering the perturbative QCD determination of the function Φ questionable and because the z physical range is quite limited. Numerically it appears that the first measured coefficients are quite small and no useful constraint can be placed on higher order coefficients (a_k with $k \geq 3$).

It seems preferable to consider phenomenological models to describe the q^2 variation of $f^P_+(q^2)$ because they have a simple physical interpretation. In the simple pole model,

$$f_+(q^2)_{\text{simple pole}} = \frac{f_+(0)}{1 - \frac{q^2}{m^2_{\text{pole}}}}. \qquad (19.1.59)$$

The pole mass value $m_{\text{pole}} = m_{D^*_s}$ (m_{D^*}) respectively for $D^0 \to K^- (\pi^-) \ell^+ \nu_\ell$. When fitting data, m_{pole} is taken as a free parameter and its value can be compared with these expectations.

The q^2 dependence of the form factor is nonperturbative and the only first-principles approaches are lattice QCD calculations. Nevertheless, a vector-dominance assumption would lead to a single pole form with the pole located at $q^2 = m^2_{D^*_s}$ for the $D \to K$ vector form factor. However, this does not take into account contributions from other states, and so also double-pole

Table 19.1.15. Values of fitted parameters for different models of the hadronic form factor q^2 dependence in $D \to K \ell^+ \nu_\ell$ decays. The different labels given in the first column correspond to the following references: Belle (Widhalm, 2006), *BABAR* (Aubert, 2007ab), and CLEO-c (Besson et al., 2009). The simple pole and ISGW2 models, with nominal values of the parameters, are excluded.

Source	Simple pole	BK	ISGW2
	m_{pole} (GeV/c^2)	α_{BK}	α_I (GeV^{-2})
Belle(2006)	1.82(4)(3)	0.52(8)(6)	0.51(3)(3)
BABAR(2007)	1.884(12)(15)	0.38(2)(3)	0.226(5)(6)
CLEOc(2009)	1.93(2)(1)	0.30(3)(1)	0.211(5)(3)
Expectation	2.112	~ 0.5	0.104

structures have been suggested. The Isgur Scora Grinstein Wise (ISGW2) quark model (Isgur, Scora, Grinstein, and Wise, 1989; Scora and Isgur, 1995) belongs to this category:

$$f_+(q^2)_{\text{ISGW2}} = \frac{f_+(q^2_{\max})}{(1 + \alpha_I (q^2_{\max} - q^2))^2}, \quad \alpha_I = \frac{1}{12} r^2. \qquad (19.1.60)$$

This expression is normalized at $q^2 = q^2_{\max} = (m_{D^0} - m_P)^2$. For $D \to K$, the predicted values of the parameters are $f_+(q^2_{\max}) = 1.23$ and $r = 1.12$ GeV^{-1}.

The modified pole model of (Becirevic and Kaidalov, 2000) (BK model) has also two poles. The first pole is at the vector meson mass and the second accounts for higher mass vector states:

$$f_+(q^2)_{\text{BK}} = \frac{f_+(0)}{\left(1 - \frac{q^2}{m^2_{D^*_s}}\right)\left(1 - \alpha_{\text{BK}} \frac{q^2}{m^2_{D^*_s}}\right)}. \qquad (19.1.61)$$

The authors predict $\alpha_{\text{BK}} \sim 0.5$.

All proposed ansatze fit well the measured distributions. However, apart for the BK model (which doesn't have precisely determined expectations), predicted values of the parameters differ markedly from the measurements as indicated in Table 19.1.15. Effects from hadronic singularities, in addition to the pole at the $D^*_{s(d)}$ mass, are thus measurable. The simple pole and ISGW2 models, with nominal values of the parameters, are excluded.

QCD based form-factor calculations can also be performed in the framework of QCD sum rules. In particular, light-cone QCD sum rules are well suited for the calculation of form factors especially for heavy-to-light transitions. The input into these sum rules is the light-cone distribution of the quarks in the pion or kaon; a more detailed description of this can be found in Section 17.1 where this is applied to the $B \to \pi$ form factor. A recent discussion of the form factors for semileptonic charm decays can be found in (Khodjamirian, Klein, Mannel, and Offen, 2009). It turns out that the QCD sum rule calculation yields a form factor which is compatible with lattice

determinations as well as with the BK parameterization; it can be used to perform an independent and competitive extraction of V_{cs} and V_{cd} from semileptonic charm decays.

To compare absolute determinations of the form factors, obtained by several experiments and from LQCD, results are evaluated at $q^2 = 0$ in Table 19.1.16. Measurements at B factories are five times more accurate than previous determinations. Corresponding results from CLEO-c were published later with similar accuracy and central values. The measurement accuracy on $f_+^{K/\pi}(0)$ combined results reaches 1 and 3% respectively. They are in agreement with LQCD recent expectations (Na, Davies, Follana, Lepage, and Shigemitsu, 2010; Na et al., 2011). In spite of spectacular progress from lattice QCD, present computations are still a factor three (two) less accurate than actual measurements for $D \to K$ ($D \to \pi$). In future, detailed comparisons of the measured and expected variations of the hadronic form factors versus q^2 are expected. Combining experimental and theoretical uncertainties, one can say also that, at present, the values of $|V_{cs}|$ and $|V_{cd}|$ obtained from the measurements of D_{l3} decays and using the values of the corresponding hadronic form factors from lattice QCD, agree with expectations from unitarity with a relative uncertainty of 2.7% and 5% respectively.

19.1.5.6 The $D^+ \to K^- \pi^+ e^+ \nu_e$ decay

Detailed study of the $D^+ \to K^- \pi^+ e^+ \nu_e$ decay channel (del Amo Sanchez, 2011a) is of interest for three main reasons:

- it allows measurements of the different $K\pi$ resonant and non-resonant amplitudes that contribute to this decay. In this respect, BABAR has measured the S-wave contribution and searched for radially excited P-wave and for D-wave components.
- high statistics allows accurate measurements of the properties of the $\overline{K}^*(892)^0$ meson, the main contribution to the decay. Both resonance parameters and hadronic transition form factors are precisely measured. The latter can be compared with hadronic model expectations and lattice QCD computations.
- variation of the $K\pi$ S-wave phase versus the $K\pi$ mass can be determined, and compared with other experimental determinations.

The approach used to reconstruct D^+ mesons decaying into $K^- \pi^+ e^+ \nu_e$ is similar to that already explained in Section 19.1.5.2. Charged and neutral particles are boosted to the center-of-mass system and the event thrust axis is determined. A plane perpendicular to this axis is used to define two hemispheres.

A candidate D^+ is represented by a positron, a charged kaon, and a charged pion present in the same hemisphere. A vertex is formed using these three tracks, and events with the corresponding χ^2 probability larger than 10^{-7} are kept. The value of this probability is used with other

Table 19.1.16. Summary of hadronic form factor measurements at $q^2 = 0$. Measurements from CLEOc(2009) supercede those from CLEOc(2008). Results at B factories have an accuracy similar to CLEOc and results are compatible. All published results have been corrected for normalization branching fractions, lifetimes, and assumed values for CKM matrix elements if needed, using values quoted in (Nakamura et al., 2010). The different labels quoted in the first column correspond to the following references : E691 (Anjos et al., 1989), CLEO (Crawford et al., 1991), CLEOII (Bean et al., 1993), E687(1995) (Frabetti et al., 1995), E687(1996) (Frabetti et al., 1996a), BES II (Ablikim et al., 2004a), CLEO III (Huang et al., 2005), Belle (Widhalm, 2006), BABAR (Aubert, 2007ab), CLEO-c (2008) (Dobbs et al., 2008), CLEO-c (2009) (Besson et al., 2009), and HPQCD (Na, Davies, Follana, Lepage, and Shigemitsu, 2010; Na et al., 2011). Combining measurements from Belle , BABAR and CLEO-c, and assuming that uncertainties are uncorrelated, the corresponding averaged values are obtained. LQCD results obtained by the HPQCD collaboration are given in the last line. They agree with the measurements.

informations combined in two Fisher discriminant variables to reject, respectively, $\Upsilon(4S)$ decays and continuum background events.

To estimate the neutrino momentum, the $(K^- \pi^+ e^+ \nu_e)$ system is constrained to the D^+ mass. In this fit, estimates of the D^+ direction and of the neutrino energy are included from measurements obtained from all tracks registered in the event. The D^+ direction estimate is taken as the direction of the vector opposite to the momentum sum of all reconstructed particles but the kaon, the pion, and the positron. The neutrino energy is evaluated by subtracting from the hemisphere energy the energy of reconstructed particles contained in that hemisphere.

Analyzing an integrated luminosity of 347 fb^{-1}, about 244×10^3 signal events are selected with a ratio Signal / Background= 2.3.

As there are four particles in the final state, the differential decay rate has five degrees of freedom that can be

expressed in the following variables (Cabibbo and Maksymowicz, 1965; Pais and Treiman, 1968):

- m^2, the mass squared of the $K\pi$ system;
- q^2, the mass squared of the $e^+\nu_e$ system;
- $\cos(\theta_K)$, where θ_K is the angle between the K three-momentum in the $K\pi$ rest frame and the line of flight of the $K\pi$ in the D rest frame;
- $\cos(\theta_e)$, where θ_e is the angle between the charged lepton three-momentum in the $e\nu_e$ rest frame and the line of flight of the $e\nu_e$ in the D rest frame;
- χ, the angle between the normals to the planes defined in the D rest frame by the $K\pi$ pair and the $e\nu_e$ pair. χ is defined between $-\pi$ and $+\pi$.

For the differential decay partial width, we use the formalism given in (Lee, Lu, and Wise, 1992). Apart for the S-wave for which there is one hadronic form factor, each higher spin component has three form factors associated. Using the conclusions of the $D^0 \to K^- e^+ \nu_e$ analysis, where we find that all usual ansatze give a good parameterization of data, and noting that the q^2 range is even more limited, we use the simple pole model to describe the q^2 dependence of these form factors. As an example, for the $\overline{K}^*(892)^0$ meson, we use:

$$V(q^2) = \frac{V(0)}{1 - \frac{q^2}{m_V^2}},$$

$$A_1(q^2) = \frac{A_1(0)}{1 - \frac{q^2}{m_A^2}}, \qquad (19.1.62)$$

$$A_2(q^2) = \frac{A_2(0)}{1 - \frac{q^2}{m_A^2}}.$$

Hadronic resonances are parameterized using relativistic Breit-Wigner distributions with mass dependent widths and a Blatt-Weisskopf damping factor. For the S-wave component we fit the amplitude and measure the phase in several mass intervals.

A binned distribution of data events is analyzed. The expected number of events in each bin depends on signal and background estimates and the former is a function of the values of the fitted parameters. We perform a minimization of a negative log-likelihood distribution. This distribution has two parts. One corresponds to the comparison between measured and expected number of events in bins which span the five dimensional space of the differential decay rate. The other part is used to measure the fraction of background events and corresponds to the distribution of the values of one of the Fisher discriminant variables. There are 2800 bins in total.

19.1.5.7 Measured components

The $K^-\pi^+$ final state is dominated by the $\overline{K}^*(892)^0$ meson (94.1%) and the S-wave component (5.8%). There is marginal evidence for the first radial excitation of the P-wave (0.3%) and a stringent limit is placed on a

Table 19.1.17. Comparison between *BABAR* (del Amo Sanchez, 2011a) measurements and present world averages (Nakamura et al., 2010). Values for $\mathcal{B}(D^+ \to \overline{K}^*(1410)^0/\overline{K}_2^*(1430)^0 e^+\nu_e)$ are corrected for their respective branching fractions into $K^-\pi^+$.

Branching fraction	*BABAR*	PDG 2010
$\mathcal{B}(D^+ \to K^-\pi^+ e^+\nu_e)(\%)$	4.00(3)(4)(9)	4.1 ± 0.6
$\mathcal{B}(D^+ \to K^-\pi^+ e^+\nu_e)_{\overline{K}^*(892)^0}(\%)$	3.77(4)(5)(9)	3.68 ± 0.21
$\mathcal{B}(D^+ \to K^-\pi^+ e^+\nu_e)_{S-wave}(\%)$	0.232(7)(7)(5)	0.21 ± 0.06
$\mathcal{B}(D^+ \to \overline{K}^*(1410)^0 e^+\nu_e)(\%)$	< 0.6 at 90% C.L.	
$\mathcal{B}(D^+ \to \overline{K}_2^*(1430)^0 e^+\nu_e)(\%)$	< 0.05 at 90% C.L.	

D-wave contribution. The small $\overline{K}^*(1410)^0$ contribution agrees with the naïve expectation based on corresponding measurements in τ decays and its phase relative to the $\overline{K}^*(892)^0$ is compatible with zero. Branching fractions for these components are obtained by reference to the $D^+ \to K^-\pi^+\pi^+$ channel which is measured using a similar analysis, and are reported in Table 19.1.17.

The S-wave contribution is dominated by events with a mass below the $\overline{K}_0^*(1430)$ resonance pole and, for the first time, the S-wave phase is measured at several values of the $K^-\pi^+$ mass. The $K\pi$ hadronic system can have two isospin components ($I = 1/2, 3/2$) however, in charm semileptonic decays, the $c \to s$ transition corresponds to $\Delta I = 0$ and only the $I = 1/2$ component is produced. The $K\pi$ scattering S-wave, with isospin $I = 1/2$, remains elastic up to the $K\eta$ threshold, but since the coupling to this channel is weak, it is considered in practice to be elastic up to the $K\eta'$ threshold. In this elastic regime, the Watson theorem (Watson, 1954) implies that, phases measured in $K\pi$ elastic scattering and in a decay channel in which the $K\pi$ system has no strong interaction with other hadrons are equal modulo π radians for the same values of isospin and angular momentum. The ambiguity is solved by determining the sign of the S-wave amplitude from data. This theorem does not provide any constraint on the corresponding amplitude moduli. In particular, it is not legitimate (though nonetheless frequently done) to assume that the S-wave amplitude in a decay is proportional to the elastic amplitude. In Figure 19.1.38 the $K^-\pi^+$ S-wave phase with $I = 1/2$ measured in the elastic channel (Aston et al., 1988; Estabrooks et al., 1978) and in D^+ semileptonic decays, are compared. We measure that the two amplitudes differ by a negative sign and that phases are compatible within uncertainties, in agreement with the Watson theorem. Similar analyses of the $D^+ \to K^-\pi^+\pi^+$ Dalitz plot (Aitala et al., 2006; Bonvicini et al., 2008; Link et al., 2007, 2009) measure a significant difference between the variation of the $K\pi$ S-wave and of the elastic phases versus the $K\pi$ mass. This difference has thus to be attributed to final state interactions with the third hadron.
Figure 19.1.38. From (del Amo Sanchez, 2011a). Points (red crosses) give the S-wave phase variation assuming a signal containing S-wave, $\overline{K}^*(892)^0$ and $\overline{K}^*(1410)^0$ components. The S-wave phase is assumed to be constant within each considered mass interval. Error bars include systematic uncertainties. The full line corresponds to the fitted parameterized S-wave phase variation expected from elastic scattering experiments. The phase variation measured in $K\pi$ scattering by (Estabrooks et al., 1978) (triangles) and LASS (Aston et al., 1988) (squares), after correcting for the $I = 3/2$ isospin component, are given.

19.1.5.8 Detailed measurements of the $\overline{K}^*(892)^0$

Using a model for signal which includes S-wave, $\overline{K}^*(892)^0$ and $\overline{K}^*(1410)^0$ contributions, and the simple pole ansatz for the q^2 variation of hadronic form factors, parameters of the $\overline{K}^*(892)^0$ component are obtained from a fit to the five-dimensional decay distribution. These parameters, listed in Table 19.1.18, define the $\overline{K}^*(892)^0$ lineshape and the relative contributions of the different form factors: $r_2 = A_2(0)/A_1(0)$ and $r_V = V(0)/A_1(0)$. The analysis is not sensitive to the q^2 dependence of the vector form factor ($V(q^2)$) but we measure, for the first time the effective pole mass of the axial vector form factors ($A_{1,2}(q^2)$) and find a value compatible with expectations $m_{\text{pole}} \sim m_{D_{s1}}$.

The branching fraction of $D^+ \to \overline{K}^*(892)^0 e^+\nu_e$ is determined by normalizing the signal yield of $D^+ \to K^-\pi^+e^+\nu_e$ to the reconstructed yield of $D^+ \to K^-\pi^+\pi^+$ (with the branching fraction as measured in (Dobbs et al., 2007a)), after subtracting the S-wave and $\overline{K}^*(1410)^0$ contributions, and after correcting for the efficiency difference. The decay rate depends only on the value of $A_1(0)$. In the zero-width approximation for the $\overline{K}^*(892)^0$ resonance the measured decay rate corresponds to:

$$A_1(0) = 0.6200 \pm 0.0056 \pm 0.0065 \pm 0.0071. \quad (19.1.63)$$

The last uncertainty includes the uncertainty of $Br(D^+ \to K^-\pi^+\pi^+)$ as well as the systematic uncertainty due to external parameters used in the extraction of $A_1(0)$ (values of $|V_{cs}|$ and τ_D^+).

Table 19.1.18. Measured properties (del Amo Sanchez, 2011a) of the $D^+ \to \overline{K}^*(892)^0 e^+\nu_e$ decay channel and of the $\overline{K}^*(892)^0$ resonance are compared with corresponding world averages (Nakamura et al., 2010). r_{BW} is the Blatt-Weisskopf damping parameter. m_A is the pole mass of the axial vector form factors.

Measured quantity	BABAR	PDG 2010
$m_{K^*(892)^0}\,(\text{MeV}/c^2)$	$895.4 \pm 0.2 \pm 0.2$	895.94 ± 0.22
$\Gamma^0_{K^*(892)^0}\,(\text{MeV}/c^2)$	$46.5 \pm 0.3 \pm 0.2$	48.7 ± 0.8
$r_{BW}\,(\text{GeV}/c)^{-1}$	$2.1 \pm 0.5 \pm 0.5$	2.72 ± 0.55
r_V	$1.463 \pm 0.017 \pm 0.031$	1.62 ± 0.08
r_2	$0.801 \pm 0.020 \pm 0.020$	0.83 ± 0.05
$m_A\,(\text{GeV}/c^2)$	$2.63 \pm 0.10 \pm 0.13$	no result

In the present analysis, the measured distribution in five dimensions is not unfolded and the experimental resolution expected from the simulation is controlled using data. Because angular distributions are completely determined by the kinematics for each helicity component, measurements are giving the decay rate variation versus the remaining two variables, q^2 and m^2. The q^2 dependence of hadronic form factors is smooth and can be parameterized in a simple way as explained in Section 19.1.5.2. For the mass measurement, the experimental resolution is high. It results that the distribution, for which statistical and systematic error matrices on the fitted parameters are provided, can be compared with different theoretical expressions when they will be available.

19.1.5.9 Measured and expected values of the hadronic form factors

The normalization and specific q^2 behavior of the hadronic form factors are obtained in some specific limits for which intermediate scales are identified. When a heavy hadron decays semileptonically into another heavy hadron a new symmetry emerges which gives constraints on the behaviour of the form factors. This symmetry is exact in the limit of infinite quark mass values, which can be formulated as an effective field theory, the Heavy Quark Effective Theory (HQET) (Isgur and Wise, 1989; Shifman and Voloshin, 1988). For finite values of quark masses, and depending on the form factors, corrections start at order $1/m_Q$ or $1/m_Q^2$. These properties are used to determine the value of V_{cb} from measurements of $\overline{B} \to D^*\ell\overline{\nu}_\ell$ as corrections are expected to be at order $1/m_Q^2$ for $q^2 \sim q_{max}^2$. For charm, the value of the charm-quark mass is of the order of $2-3$ times Λ_{QCD} and the strange quark cannot be described as a heavy quark. Considerations based on HQET are thus expected not to hold for charm semileptonic decays; still they may serve as a starting point, and hence we consider it of interest to review the constraints on form factors, implied by HQET, and to indicate how they are violated in charm to eventually get insights for B decays. For infinite

Table 19.1.19. Comparison between measured and expected values of the form factors in $D^+ \to \overline{K}^*(892)^0 e^+ \nu_e$ decays, evaluated at $q^2 = 0$. Only measurements from BABAR (del Amo Sanchez, 2011a) and FOCUS (Link et al., 2002) which are corrected for the S-wave contribution are listed. Results from PDG 2010 (Nakamura et al., 2010) include those from FOCUS and all previous measurements. Expected values are coming from the HMχT model (Fajfer and Kamenik, 2005) and LQCD (Gill, 2002) computations.

	FOCUS 2002	BABAR	PDG 2010	HMχT	LQCD
r_V	1.504(57)(39)	1.493(14)(21)	1.62(8)	1.6	1.23(10)
r_2	0.875(49)(64)	0.775(11)(11)	0.83(5)	0.50	0.94(12)
$A_1(0)$		0.6200(56)(65)(71)		0.62	0.65(3)
$A_2(0)$		0.480(8)(10)		0.31	0.61(7)
$V(0)$		0.926(12)(19)		0.99	0.80(5)

quark masses one has the following equalities (Neubert, 1994b):

$$f_+(q^2) = V(q^2) = A_2(q^2) = \frac{A_1(q^2)}{1 - \frac{q^2}{(m_H + m_V)^2}} = R^{-1}\xi(q^2)$$
(19.1.64)

The Isgur-Wise function $\xi(q^2)$ satisfies $\xi(q^2_{max}) = 1$. The parameter $R = 2\sqrt{m_H\, m_{P(V)}}/(m_H + m_{P(V)})$ is equal to $\sim 0.9(0.8)$ for $B(D)$ semileptonic favored decays. M_H is the heavy hadron mass whereas $m_{P(V)}$ are the pseudo scalar and vector meson masses. In this limit, the ratio of form factors are equal for $q^2 = q^2_{max}$: $r_V(q^2_{max}) = r_2(q^2_{max}) = R^{-2}$. For other values of q^2 they read:

$$r_{V(2)}(q^2) = \frac{1}{1 - \frac{q^2}{(m_H + m_V)^2}} R_{1(2)}(q^2)$$
(19.1.65)

with $R_{1(2)}(q^2_{max}) = 1$. Corrections to these expressions correspond to expansions in $1/m$, where m can take the values of the masses of the two quarks involved in the weak transition, and in the strong coupling constant, from perturbative QCD. It is an unambiguous prediction of HQET that $R_1(q^2) > 1$ as both the QCD and $1/m$ corrections are positive. For $R_2(q^2)$, QCD corrections are small and $1/m$ corrections seem to decrease the value of the ratio. HQET relates the form factors in semileptonic decays to pseudoscalar and vector particles as expressed in Equation (19.1.64). According to (Amundson and Rosner, 1993), QCD corrections alone cannot explain the ratio $\mathcal{B}(D \to \overline{K}^* e^+ \nu_e)/\mathcal{B}(D \to K^- e^+ \nu_e) = 0.62 \pm 0.02$ as they have rather similar effects on all form factors.

In previous considerations it is assumed that the charm and also the strange quark behave as a heavy quark in $c \to s\ell^+\nu_\ell$ decays. It is also possible to relate form factors in B and D semileptonic decays to light hadrons (Isgur and Wise, 1990a).

Results on absolute values and on ratios of hadronic form factors evaluated at $q^2 = 0$ are compared in Table 19.1.19. In this table, BABAR measurements are quoted for fixed values of the pole masses $m_V = 2.1$ GeV/c^2 and

$m_V = 2.5$ GeV/c^2, and only experimental results corrected for the S-wave contribution are kept.

The HMχT model proposed by (Fajfer and Kamenik, 2005, 2006) generalizes the approach of Becirevic and Kaidalov and satisfies the scaling laws of obtained in the infinite mass limit as well as the known scaling at large energy of the outgoing kaon. Values from lattice QCD (Abada et al., 2003; Gill, 2002) are obtained using the quenched approximation. The relative accuracy of experimental measurements is typically 2% whereas it is around 10% for lattice QCD. Theoretical expectations agree with the general picture ($A_2(0) \leq A_1(0) < V(0)$) but significant differences are observed.

19.1.5.10 The $D_s^+ \to K^+ K^- e^+ \nu_e$ decay

Using 214 fb^{-1} of data collected at the $\Upsilon(4S)$ resonance, BABAR measure the $D_s^+ \to K^+ K^- e^+ \nu_e$ channel decay characteristics, for events produced in the continuum (Aubert, 2008be), in a similar manner as described above for $D^+ \to K^- \pi^+ e^+ \nu_e$ (Section 19.1.5.6).

The $K^+ K^-$ mass distribution is displayed in Figure 19.1.39(a). It contains about 25×10^3 signal events whereas
Figure 19.1.39. From (Aubert, 2008be). a) $K^+ K^-$ invariant mass distribution from $D_s^+ \to K^+ K^- e^+ \nu_e$ data and simulated events. MC events have been normalized to the data luminosity according to the different cross sections. The arrows indicate the selected $K^+ K^-$ mass interval. In b), each event is weighted by the measured value of $\cos \theta_K$. Negative entries are produced by the $c\bar{c}$ background asymmetry in $\cos \theta_K$.

Table 19.1.20. Comparison between measured and expected values of the form factors in $D_s^+ \rightarrow \phi e^+ \nu_e$ decays, evaluated at $q^2 = 0$. The different labels listed in the first column correspond to the following references: E653 (Kodama et al., 1993), E687 (Frabetti et al., 1994b), CLEO II (Avery et al., 1994a), E791 (Aitala et al., 1999a), FOCUS (Link et al., 2004b), BABAR (Aubert, 2008be), HMχT (Fajfer and Kamenik, 2005), UKQCD (Gill, 2002), and HPQCD (Donald, Davies, and Koponen, 2011). Results for $K^* e^+ \nu_e$ correspond to the BABAR measurement (del Amo Sanchez, 2011a).

	$A_1(0)$	r_V	r_2

UKQCD(2001)	$0.63(2)$	$1.35(7)$	$0.98(8)$
HPQCD(2011)	$0.603(20)$	$1.52(12)$	$0.62(12)$

previous experiments and CLEO-c have collected few hundred events only. The analysis focuses on the $\phi e^+ \nu_e$ final state in the $K^+ K^-$ mass range between 1.01 and 1.03 GeV/c^2 for which accurate hadronic form factors normalization and q^2 dependence are measured. These results are given in Table 19.1.20 where they are compared with previous measurements and those obtained for $D^+ \rightarrow \overline{K}^*(892)^0 e^+ \nu_e$.

The accuracy of experimental measurements compared to previous ones is improved by a factor five. The form factors are defined in an analogous way as for the $D^+ \rightarrow \overline{K}^*(892)^0 e^+ \nu_e$ decays in Section 19.1.5.6. Also the angular variables are analogous, with a difference that θ_K is the angle between the K^+ meson direction in the $K^+ K^-$ rest frame and the $K^+ K^-$ direction in the D_s^+ rest frame. The comparison between the values of the form factors measured in the two channels $D^+ \rightarrow \overline{K}^*(892)^0 e^+ \nu_e$ and $D_s^+ \rightarrow \phi e^+ \nu_e$ shows that they are compatible within uncertainties, apart for the parameter $V(0)$. This indicates that $SU(3)$ violations are small. Recent unquenched LQCD computations (Donald, Davies, and Koponen, 2011) are in better agreement with data than previous unquenched results (Gill, 2002).

The ϕ resonance is dominant in this $K^+ K^-$ mass region although a small S-wave component is measured, for the first time, through its interference with the ϕ (see Figure 19.1.39(b)). After integration over the θ_e and χ angular variables, the differential decay rate is proportional to:

$$|F_1|^2 + \sin^2 \theta_K \left(|F_2|^2 + |F_3|^2 \right). \qquad (19.1.66)$$

The form factors F_i are function of q^2, m^2 and, θ_K. Considering contributions from $S-$ and $P-$wave of the $K^+ K^-$ system, only the form factor F_1 depends on θ_K:

$$F_1 = F_{10} + \cos \theta_K F_{11}. \qquad (19.1.67)$$

Form factors F_{10} and F_{11} correspond respectively to $S-$ and P-wave contributions. Using this last expression, the first term in Eq. (19.1.66) generates an interference between the two wave components. The value of the parameter which quantifies this interference, $r_0 = (15.1 \pm 2.6 \pm 1.0)$ GeV^{-1}, is obtained with more than 5σ significance.[118] This is the only experimental result on the contribution from the S-wave component, precisely in the $K^+ K^-$ mass region of the ϕ meson. D_s^+ decays can be used in $B_s^0 \rightarrow J/\psi \phi$ analyses determining the CP violating phase β_s. They can provide for an evaluation of the S-wave contribution in the ϕ resonance region, as proposed in (Stone and Zhang, 2009). Using measurements from CLEO-c of $D_s^+ \rightarrow f_0 e^+ \nu_e$, $f_0 \rightarrow \pi^+ \pi^-$, they conclude that there could be, in the ϕ mass region, about 10% contribution from the f_0 in the $K^+ K^-$ final state. Such a large S-wave component can add uncertainties in the measurement of β_s. The direct measurement done in BABAR contradicts these expectations because they obtain, within a range of ± 10 MeV/c^2 centered on the nominal ϕ meson mass, a relative contribution of the S-wave equal to $(0.22^{+0.12}_{-0.08} \pm 0.03)$%. The S-wave decay rate in $B_s^0 \rightarrow J/\psi K^+ K^-$ channel, within the same $K^+ K^-$ mass interval is thus expected to be below 1%, in agreement with the limit of 6% at 95%C.L. obtained by CDF (Aaltonen et al., 2012c). The recent measurement by LHCb $((4.2 \pm 1.5 \pm 1.8)\%$ (Aaij et al., 2012h)) is less than 2σ away form this limit.

19.1.6 D_s^+ leptonic decays

19.1.6.1 Introduction

The cleanest transitions where a partial decay width can show the manifestation of NP are $D_{(s)}^+ \rightarrow \ell^+ \nu_\ell$ ($\ell = \mu, \tau$). The decay partial widths depend on a single hadronic parameter, namely the decay constants $f_{D_{(s)}}$:

$$\Gamma(D_{(s)}^+ \rightarrow \ell^+ \nu_\ell) \qquad (19.1.68)$$

$$= \frac{G_F^2}{8\pi} f_{D_{(s)}}^2 m_\ell^2 m_{D_{(s)}} \left(1 - \frac{m_\ell^2}{m_{D_{(s)}}^2} \right)^2 |V_{cd(s)}|^2,$$

where G_F is the Fermi coupling constant, m_ℓ and $m_{D_{(s)}}$ are the masses of the charged lepton and of the D meson, respectively. $V_{cd(s)}$ is the corresponding CKM matrix element. As these decay channels are suppressed by helicity conservation, corresponding decay rates are proportional to the square of the lepton mass. Decays into electrons are not observable whereas decays into τ leptons are favored in spite of the reduced phase-space.

---

[118] The precise definition of the r_0 parameter arises from the parameterization of F_{10} assuming f_0 production: $F_{10} = r_0[p_{KK} m_{D_s}/(1 - \frac{q^2}{m_A^2})][m_{f_0} g_\pi/(m_{f_0}^2 - m^2 - i m_{f_0} \Gamma_{f_0})]$, where p_{KK} is the momentum of the $K^+ K^-$ system in the D_s^+ rest frame.

D^+ leptonic decays are Cabibbo suppressed and difficult to measure at B factories meanwhile D_s^+ leptonic decays are measured in the muon and tau channels.

19.1.6.2 *BABAR* and Belle measurements

The approach pioneered by Belle (Widhalm, 2006) for semileptonic decays of D^0 mesons is used by the two B-factory experiments to measure absolute leptonic decay branching fractions of D_s mesons. As an example, in the *BABAR* analysis, the D_s meson production is tagged by considering events from the reaction $e^+e^- \to c\bar{c} \to H_c K X D_s^- \gamma$; H_c is D^0, D^+, D^* or Λ_c exclusively reconstructed, K a K^+ or K_S^0 and X a system of at most three pions, including at most one π^0 with a total electric charge appropriate to ensure the neutrality of the overall final state. The number of produced D_s mesons is obtained by considering the distribution in the recoil mass $M_{\mathrm{recoil}}(H_c K X \gamma)$ which has a peak at the D_s mass for signal events. The hadron H_c is reconstructed using 15 modes. In addition to the size of the mass window, several other properties of the H_c candidate are used. The center-of-mass (CM) momentum of the H_c must be at least 2.35 GeV/c in order to remove B meson backgrounds. Particle identification requirements are used on the tracks, a cut is applied on the probability of the H_c vertex fit, and a minimum lab energy of π^0 photons is requested. Only $H_c K X \gamma$ candidates with a total charge, a charm, and a strange quark content consistent with recoiling from a D_s^-, are selected from which the signal yield is extracted. A kinematic fit to each $H_c K X$ candidate is performed and the H_c mass is constrained to its nominal value. The 4-momentum of the signal D_s^{*-} is extracted as the missing 4-momentum in the event. It is required that the D_s^{*-} candidate mass be within 2.5σ of the signal peak. A similar kinematic fit is performed with the signal γ included and with the mass recoiling against the $H_c K X$ constrained to the nominal D_s^{*-} mass in order to determine the D_s^- 4-momentum. It is required that the D_s^- momentum exceeds 3 GeV/c and that its mass be greater than 1.82 GeV/c^2. Having reconstructed the inclusive D_s^- sample one proceeds to the selection of $D_s^- \to \mu^- \bar{\nu}_\mu$ events within that sample. The $H_c K X \gamma$ mass range between 1.934 and 2.012 GeV/c^2 is used and it is required that there be exactly one more charged particle in the remainder of the event, and that it be identified as a μ^-. In addition it is required that the extra neutral energy in the event, E_{extra}, be less than 1 GeV. E_{extra} is defined as the total energy of clusters in the electromagnetic calorimeter with individual energy greater than 30 MeV and not overlapping with the $H_c K X \gamma$ candidate. Since the only missing particle in the event should be the neutrino, the distribution of E_{extra} is expected to peak at zero for signal events. To extract the signal yield, the distribution of the mass squared of the system recoiling against the $H_c K X \gamma \mu^-$ combination, $M_{\mathrm{recoil}}^2(H_c K X \gamma \mu^-)$ is used. The method is slightly modified in the updated measurement by Belle (Zupanc, 2013b), as described in Section 19.1.2.2. The result is shown in Fig. 19.1.40. To

$\mathcal{B}(D_s^+ \to \tau^+ \nu_\tau)[10^{-2}]$	$5.70 \pm 0.21^{+0.31}_{-0.30}$	$5.00 \pm 0.35 \pm 0.49$

associated with $D_s^- \to \mu^- \bar{\nu}_\mu$ decays are removed by requiring $m_r^2 > 0.5\,\text{GeV}^2/c^4$. The E_{extra} distribution is used to extract the yield of signal events as illustrated in Figure 19.1.41 for the BABAR (del Amo Sanchez, 2010g) and Belle (Zupanc, 2013b) analysis.

These analyses have a 100 times lower tagging efficiency than CLEO-c data collected at threshold. Yet this small efficiency is compensated by the much higher registered integrated luminosity. Measured statistics for the D_s^{*-} tag and the signals are given in Table 19.1.21. From the obtained $D_s \to \ell\nu_\ell$ signal yields the branching fractions for individual modes are calculated and are given in Table 19.1.22.

19.1.6.3 Measured and Expected f_{D_s} Values

Using Eq. (19.1.69), measured branching fractions of D_s leptonic decays are used to extract the value of the decay constant $f_{D_s}^{expt.,SM}$. Results obtained by the different experiments are compared in Table 19.1.23. While measurements at CLEO-c are statistically limited, systematic uncertainties related to the background control dominate the methods developed at B factories which have a total combined accuracy similar to CLEO-c. Having two results with different systematics and similar uncertainty is important to have confidence in the final result as it was already illustrated for the measurement of $f_K^+(0)$ in charm semileptonic decays. The averaged value of all measurements is $f_{D_s} = (257.5 \pm 4.6)\,\text{MeV}$.

New physics can change Eq. (19.1.69) and the value of $f_{D_s}^{expt.,SM}$ extracted previously from data, in the Standard Model framework, may differ from QCD expectations. Several LQCD collaborations using an unquenched

formulation of QCD have computed the value of $f_{D_s}^{QCD}$ (see Table 19.1.24). These are in agreement with the measured values within the uncertainties.

Among new physics models which can change the leptonic charm meson decay rate, there are the Two Higgs Doublet Model (2HDM) and the Minimal Supersymmetric Model. (MSSM) In these models it is expected that the leptonic decay partial width, given in Equation (19.1.69) is modified according to expressions given in (Akeroyd and Mahmoudi, 2009) where references to previous studies can be found. For the D^+, the correction is negligible, whereas for the D_s^+ the relative variation on f_{D_s} is expected to be equal to:

$$k_s = \frac{\delta(f_{D_s})}{f_{D_s}} = -\frac{m_s}{m_c}\left(\frac{m_{D_s}\tan\beta}{m_H}\right)^2 \qquad (19.1.69)$$

for $\tan\beta > \sqrt{m_c/m_s} \simeq 3$. In this expression m_s and m_c are respectively the strange and the charm quark mass, m_H is the charged Higgs boson mass and $\tan\beta$ is the ratio between the vacuum expectations of the two Higgs doublets.

Because k_s is negative, it is expected that $f_{D_s}^{expt.,SM} < f_{D_s}^{QCD}$ in these models. First measurements from CLEO-c ($f_{D_s}^{expt.,SM} = 274(11)\,\text{MeV}$) (Ecklund et al., 2008) and evaluations from the HPQCD collaboration ($f_{D_s}^{QCD} = 241(3)\,\text{MeV}$) (Follana, Davies, Lepage, and Shigemitsu, 2008) were in the opposite direction. These circumstances provide rather stringent limits on the parameters (m_H and $\tan\beta$) of the previous models. At present, measured and expected values of f_{D_s} are more accurate and agree within 1.5 standard deviation. Derived limits on model parameters are thus less impressive. To have evidence (3σ) for

new physics from these models, the following condition must be satisfied:

$$\frac{m_H}{\tan\beta} < m_{D_s} \sqrt{\frac{m_s}{m_c}\frac{1}{3\sigma}}. \qquad (19.1.70)$$

The parameter σ is the total relative uncertainty on f_{D_s} coming from theory and measurements. At present $\sigma \sim 3\%$ and evidence for new physics can be obtained if $\frac{m_H}{\tan\beta} < 2.1\,\mathrm{GeV}/c^2$. In future, when precision of $\sim 1\%$ can be reached, this condition becomes: $\frac{m_H}{\tan\beta} < 3.6\,\mathrm{GeV}/c^2$. Unless the charged Higgs boson mass is rather low or the value of $\tan\beta$ quite large, no new physics contributions are expected and measurements of leptonic charm decays therefore provide stringent tests of lattice QCD calculations.

It should be noted also that relative uncertainties coming from external parameters as the τ mass, the D_s^+ mass, the value of $|V_{cs}|$, and the D_s^+ lifetime have a total contribution of 0.7%. The largest contribution is from the D_s^+ lifetime which needs therefore to be more accurately measured.

19.1.7 Rare or forbidden charmed meson decays

19.1.7.1 Measurement of the Branching Fractions of the Radiative Charm Decays $D^0 \to \bar{K}^{*0}\gamma$ and $D^0 \to \phi\gamma$

In the b-quark sector, radiative decay processes have provided a rich field to study the Standard Model of particle physics. These decays are dominated by short-range electroweak processes, whereas long-range contributions are suppressed. The situation is reversed in the charm sector, where radiative decays are expected to be dominated largely by non-perturbative processes, examples of which are shown schematically in Fig. 19.1.42. Long-range contributions to radiative charm decays are expected to increase the branching fractions for these modes to values of the order of 10^{-5}, whereas short-range interactions are predicted to yield rates at the 10^{-8} level. Given the expected dominance of long-range processes, radiative charm decays provide a laboratory in which these QCD-based calculations can be tested.

Numerous theoretical models have been developed to describe these radiative charm decays. The two most comprehensive studies (Burdman, Golowich, Hewett, and Pakvasa, 1995; Fajfer, Prelovsek, and Singer, 1999) predict very similar amplitudes for the dominant diagrams shown in Fig. 19.1.42.

The first observation of flavor changing radiative decay of charm mesons, $D^0 \to \phi\gamma$, was accomplished by Belle using $78\,\mathrm{fb}^{-1}$ (Abe, 2004c). To reduce the combinatorial background the measurement is performed using $D^{*+} \to D^0\pi^+$ decays, and the ϕ meson is reconstructed in decays to K^+K^-. The photons are required to have an energy in excess of $450\,\mathrm{MeV}/c^2$ (and not yielding a π^0 mass with any additional photon in the event - the π^0 veto). Furthermore, the $|\cos\theta_{hel}| < 0.4$ requirement, where θ_{hel} is the angle between the D^0 and the K^+ mesons
Figure 19.1.42. Feynman diagrams for the long-range electromagnetic contributions to $D^0 \to V\gamma$, $V = \bar{K}^{*0}, \phi$. Figures (a) and (b) show sample vector dominance processes, while (c) and (d) are examples of pole diagrams, where the circles signify the weak transition and P represents a pseudoscalar meson.

in the ϕ meson rest frame, strongly suppresses contribution of $D^0 \to \pi^0\gamma/\eta\gamma$ decays to the $\phi\gamma$ final state (for the former, due to angular momentum conservation, the distribution in $\cos\theta_{hel}$ is proportional to $\cos^2\theta_{hel}$ while in the latter it is proportional to $1 - \cos^2\theta_{hel}$). The yield of $D^0 \to \phi\gamma$ decays, as extracted from the $\phi\gamma$ invariant mass distribution, is $27.6 \pm^{7.4}_{6.5} \pm^{0.5}_{1.0}$ with a significance of 5.4 standard deviations. The branching fraction is determined using $D^0 \to K^+K^-$ for normalization and is found to be $\mathcal{B}(D^0 \to \phi\gamma) = (2.60 \pm^{0.70}_{0.61} \pm^{0.15}_{0.17}) \times 10^{-5}$. The largest contribution to the systematic uncertainty is due to the uncertainty of the $\mathcal{B}(D^0 \to K^+K^-)$ ($\pm 3.40\%$) and the choice of the fitting model and background estimation ($+2.46\%$ -3.99%).

BABAR has performed a measurement of the branching fractions for the Cabibbo-favored radiative decay, $D^0 \to \bar{K}^{*0}\gamma$, and the Cabibbo-suppressed radiative decay, $D^0 \to \phi\gamma$ (Aubert, 2008t).

The analysis is based on $387.1\,\mathrm{fb}^{-1}$ of data. They reconstruct radiative $D^0 \to V\gamma$, $V = \bar{K}^{*0}, \phi$ decays using the charged decay modes of the vector meson, $\bar{K}^{*0} \to K^-\pi^+$ ($\phi \to K^-K^+$). They form $\bar{K}^{*0}$ (ϕ) candidates from pairs of oppositely charged tracks identified as $K^-\pi^+$ (K^-K^+) and accept any $K^-\pi^+$ (K^-K^+) candidates with invariant mass in the range 0.848 to $0.951\,\mathrm{GeV}/c^2$ (1.01 to $1.03\,\mathrm{GeV}/c^2$). The significant background from $\pi^0 \to \gamma\gamma$ decays is suppressed by rejecting a photon candidate which, when paired with another photon in the event, results in an invariant mass consistent with the π^0 mass, $(0.115 < M(\gamma\gamma) < 0.150)\,\mathrm{GeV}/c^2$. Background from random $D^0 \to V\gamma$ candidates is reduced by requiring that the D^0 candidate be a product of the decay $D^{*+} \to D^0\pi_s^+$. The mass difference, $\Delta M = M(V\gamma\pi_s^+) - M(V\gamma)$ is required to be in the range $(0.1435 < \Delta M < 0.1475)\,\mathrm{GeV}/c^2$. Combinatoric background from $B\bar{B}$ events is reduced to a negligible level by requiring that the CM momentum of the D^{*+} candidate be greater than $2.62\,\mathrm{GeV}/c$.

The dominant background in the sample of $D^0 \to \bar{K}^{*0}\gamma$ candidates results from $D^0 \to K^-\pi^+\pi^0$ decays, where one of the photons from the π^0 decay is paired with the kaon and pion from the D^0 decay to closely mimic the signal mode. As described above, the π^0 veto suppresses such
(a) The $\phi\gamma$ invariant mass distribution.
(b) The $\bar{K}^{*0}\gamma$ invariant mass distribution.

Figure 19.1.43. From (Aubert, 2008t). Invariant mass distributions for data (points) and simulated events (histograms). The curves show the fit results and the individual signal and background contributions. BG refers to the combinatoric background.

events but, given the large branching fraction of this mode, $\mathcal{B}(D^0 \to K^-\pi^+\pi^0) = (13.5 \pm 0.6)\%$ (Beringer et al., 2012), a significant number of such candidates survives. It is possible to separate this background from signal on a statistical basis because of differences in the $K^-\pi^+\gamma$ invariant mass distribution. An additional background arises from $D^0 \to \bar{K}^{*0}\eta$ events where the η decays to two photons. This contribution peaks well below the nominal D^0 mass. The impact of both $D^0 \to \bar{K}^{*0}\pi^0$ and $D^0 \to \bar{K}^{*0}\eta$ is further reduced by using the $\bar{K}^{*0}$ helicity angle θ_H. The helicity angle is defined as the angle between the momentum of the $\bar{K}^{*0}$ meson parent particle (D^0) and the momentum of the $\bar{K}^{*0}$ daughter kaon as measured in the $\bar{K}^{*0}$ rest frame. Based on a Monte Carlo study an asymmetric selection of $-0.30 < \cos\theta_H < 0.65$ is chosen to maximize the signal significance. Similarly, but to a lesser extent, the signal of the Cabibbo-suppressed radiative decay $D^0 \to \phi\gamma$ is obscured by backgrounds from $D^0 \to \phi\pi^0$ and $D^0 \to \phi\eta$ decays. The $D^0 \to \bar{K}^{*0}\gamma$ yield is extracted using an unbinned extended maximum likelihood method (E-MLM) 11 to fit the $M(\bar{K}^{*0}\gamma)$ invariant mass spectrum.

The yield of $D^0 \to \phi\gamma$ events is extracted using an E-MLM to fit the two dimensional distribution of invariant mass, $M(\phi\gamma)$, and helicity, $\cos\theta_H$.

A Crystal Ball line shape (see Chapter 7) is used to model the invariant mass distributions for $D^0 \to \bar{K}^{*0}\gamma$ ($D^0 \to \phi\gamma$) signal events, and background reflections from $D^0 \to K^-\pi^+\pi^0$ ($D^0 \to \phi\pi^0$) decays. The fit results from data and expected signal and background contributions from MC are shown in Fig. 19.1.43. The resulting branching fractions relative to the well-studied decay $D^0 \to K^-\pi^+$ are $\mathcal{B}(D^0 \to \bar{K}^{*0}\gamma)/\mathcal{B}(D^0 \to K^-\pi^+) = (8.43 \pm 0.51 \pm 0.70) \times 10^{-3}$ and $\mathcal{B}(D^0 \to \phi\gamma)/\mathcal{B}(D^0 \to K^-\pi^+) = (7.15 \pm 0.78 \pm 0.69) \times 10^{-4}$.

This is the first measurement of $\mathcal{B}(D^0 \to \bar{K}^{*0}\gamma)$. In the context of the vector meson dominance (VMD) model the largest contribution to radiative D^0 decays is expected to come from a virtual ρ^0 coupling directly to a single photon, leading to the prediction that the branching ratios $\mathcal{B}(D^0 \to \phi\gamma)/\mathcal{B}(D^0 \to \bar{K}^{*0}\gamma)$ and $\mathcal{B}(D^0 \to \phi\rho^0)/\mathcal{B}(D^0 \to \bar{K}^{*0}\rho^0)$ should be equal (Burdman, Golowich, Hewett, and Pakvasa, 1995). Comparing these measurements of the radiative D^0 decays with the current world averages they find a good agreement with the prediction. Assuming all contributions are from VMD type processes and under the assumption that the ρ^0 meson is transversely polarized, as has been confirmed experimentally for $D^0 \to \bar{K}^{*0}\rho^0$, one expects $\mathcal{B}(D^0 \to V\gamma) \approx \alpha_{EM}\mathcal{B}(D^0 \to V\rho^0)$ where $\alpha_{EM} = 1/137$ is the fine structure constant (Burdman, Golowich, Hewett, and Pakvasa, 1995). However they find, for this branching fraction, about a factor of three larger than the VMD prediction. This indicates that enhancements from processes other than VMD are observed, which might be explained by incomplete cancellation between pole diagrams.

19.1.8 $D^0 \to \ell^+\ell^-$

In the Standard Model, the flavor-changing neutral current (FCNC) decays $D^0 \to e^+e^-$ and $D^0 \to \mu^+\mu^-$ are highly suppressed by the Glashow-Iliopoulos-Maiani (GIM) mechanism (Glashow, Iliopoulos, and Maiani, 1970) (Chapter 16). Their decay branching fractions have been estimated to be less than 10^{-13} even with long-distance processes included. This prediction is orders of magnitude beyond the reach of current experiments. Furthermore, the lepton-flavor-violating (LFV) decay $D^0 \to e^\pm\mu^\mp$ is forbidden in the SM in the limit of vanishing neutrino masses. These decays are in principle allowed due to a non-zero neutrino mass, but branching fractions are expected to be even much smaller than those of $D^0 \to \ell^+\ell^-$.

Some extensions to the Standard Model can enhance the FCNC processes by many orders of magnitude. For example, R-parity violating supersymmetry can increase the branching fractions of $D^0 \to e^+e^-$ and $D^0 \to \mu^+\mu^-$ to as high as 10^{-10} and 10^{-6}, respectively (Burdman, Golowich, Hewett, and Pakvasa, 2002). The same model also predicts the $D^0 \to e^\pm\mu^\mp$ branching fraction to be of the order of 10^{-6}. The upper bounds on the predicted branching fractions of $D^0 \to \mu^+\mu^-$ and $D^0 \to e^\pm\mu^\mp$ are close to the

current experimental sensitivities. As a result, searching for the FCNC and LFV decays in the charm sector is a potential way to test the SM and explore new physics. Similar arguments hold for rare K and B decays, but the charm decay is unique since it is sensitive to new physics coupling to the up-quark sector (similar as the D^0 mixing, see Section 19.2).

Both *BABAR* and Belle performed a search for the decay of $D^0 \to e^+e^-$, $D^0 \to \mu^+\mu^-$, and $D^0 \to e^\pm\mu^\mp$. A first analysis by *BABAR* was based on $122 \, \text{fb}^{-1}$ of data (Aubert, 2004z). Recently, a new anaysis has been performed using $468 \, \text{fb}^{-1}$ of data (Lees, 2012v). The measurement by Belle uses $660 \, \text{fb}^{-1}$ of data (Petric, 2010).

The $D^0 \to \ell^+\ell^-$ ($\ell = e, \mu$) branching ratio is determined by

$$\mathcal{B}(D^0 \to \ell^+\ell^-) = S(N_{\text{obs}} - N_{\text{bg}}), \qquad (19.1.71)$$

where N_{obs} is the number of $D^0 \to \ell^+\ell^-$ candidates observed, N_{bg} is the expected background and S is the sensitivity factor, defined as:

$$S \equiv \mathcal{B}(D^0 \to \pi^+\pi^-) \frac{1}{N_{\pi\pi}} \frac{\epsilon_{\pi\pi}}{\epsilon_{\ell\ell}}. \qquad (19.1.72)$$

Here $\mathcal{B}(D^0 \to \pi^+\pi^-)$ is the $D^0 \to \pi^+\pi^-$ branching fraction, $N_{\pi\pi}$ is the number of reconstructed $D^0 \to \pi^+\pi^-$ decays, $\epsilon_{\ell\ell}$ and $\epsilon_{\pi\pi}$ are the efficiencies for the corresponding decay mode. They choose $D^0 \to \pi^+\pi^-$ as the normalization mode because it is kinematically similar to $D^0 \to \ell^+\ell^-$ and therefore many common systematic uncertainties cancel in the calculation of the efficiency ratio $\epsilon_{\pi\pi}/\epsilon_{\ell\ell}$.

A pair of oppositely charged tracks is selected to form a $D^0 \to \ell^+\ell^-$ or $D^0 \to \pi^+\pi^-$ candidate with particle identification applied 5. In *BABAR*, the average electron and muon efficiencies are about 95 % and 60 %, and their hadron misidentification probabilities are measured from τ decay control samples to be around 0.2 % and 2.0 %. The corresponding single pion identification efficiency is around 90 %. At Belle, the average muon and electron identification efficiencies are around 90 % with less than 1.5 % and 0.3 % pion misidentification, respectively, whereas the pion identification efficiency is around 83 %. In the analysis, only D^0 mesons originating from the fragmentation of charm quark in the continuum $e^+e^- \to c\bar{c}$ are considered. The inclusion of D^0 mesons from B meson decays offers no advantage because of their higher combinatorial background. As a result, Belle (*BABAR*) requires the momentum of each D^0 (D^{*+}) candidate in the center-of-mass frame of the collision to be larger than $2.5 \, \text{GeV}/c$ ($2.4 \, \text{GeV}/c$). In order to further reduce the background, the D^0 candidate is required to originate from a $D^{*+} \to D^0\pi^+$ decay.

Candidate D^0 mesons are selected using two kinematic observables: the invariant mass of the D^0 decay product, $m_{\ell\ell}$, and the energy released in the D^{*+} decay, $\delta m = m_{D^{*+}} - m_{\ell\ell} - m_\pi$, where $m_{D^{*+}}$ is the invariant mass of the $D^0\pi^+$ combination and m_π is the π^+ mass. Additional experimental observables are exploited in order to increase

the search sensitivities. The *BABAR* analysis makes use a linear combination (Fisher discriminant 9) of the following five variables to reduce the combinatorial $B\bar{B}$ background:

- The measured D^0 flight length divided by its uncertainty.
- The value of $\cos\theta_{\text{hel}}$, where θ_{hel} is defined as the angle between the momentum of the positively-charged D^0 daughter and the boost direction from the lab frame to the D^0 rest frame, all in the D^0 rest frame.
- The missing transverse momentum with respect to the beam axis.
- The ratio of the 2nd and 0th Fox-Wolfram moments.
- The D^0 momentum in the CM frame.

The Belle analysis uses the maximum allowed missing energy E_{miss} in the event. MC study shows that the semileptonic B decay, which represent one of the dominant backgrounds, typically have large E_{miss} due to undetected neutrino.

In order to avoid biases, a blind analysis techniques (see Section 14) has been adopted. All events inside the D^0 signal region are blinded until the final event selection criteria are established. The estimate of the number of combinatorial background in the signal window is done using the observed event distribution in the control region. In the *BABAR* analysis they use a sideband region above the signal region in the D^0 mass ([1.90, 2.05] GeV) in a wide Δm window ([0.141, 0.149] GeV) while the Belle measurement makes use of the region defined by $\Delta m > 1 \, \text{MeV}/c^2$. The peaking background in the signal region due to misidentification of $D^0 \to \pi^+\pi^-$ decay is calculated by using the lepton misidentification rates measured from a control data sample. Finally, they determine the optimal selection criteria by maximizing the value $\epsilon_{\ell\ell}/N_{\text{sens}}$, where N_{sens} is the averaged 90 % confidence level upper limit on the number of observed signal events that would be obtained by an ensemble of experiments with the expected background and no real signal (Feldman and Cousins, 1998).

The number of $D^0 \to \pi^+\pi^-$ candidates in the data, $N_{\pi\pi}$, is extracted by fitting their invariant mass distribution with a binned maximum likelihood fit. The signal

Table 19.1.25. From Lees (2012v) and Petric (2010). Summary of the number of expected background events (N_{bg}), the sensitivity factor (S), number of observed events (N_{obs}), and the branching fraction upper limits at the 90 % C.L. for each decay mode. The errors quoted include statistical and systematic uncertainties.

UL	1.7×10^{-7}	$[0.6, 8.1] \times 10^{-7}$	3.3×10^{-7}
	Belle		
N_{bg}	1.7 ± 0.2	3.1 ± 0.1	2.6 ± 0.2
N_{obs}	0	2	3
$S \, [10^{-9}]$	$64.7(1 \pm 6.4\%)$	$48.4(1 \pm 5.3\%)$	$54.8(1 \pm 4.8\%)$
UL	7.9×10^{-8}	1.4×10^{-7}	2.6×10^{-7}

efficiencies of $D^0 \to \ell^+\ell^-$ and $D^0 \to \pi^+\pi^-$ are evaluated using a Monte Carlo simulation.

The branching fraction upper limits (UL) have been calculated including all uncertainties using an extended version (Conrad, Botner, Hallgren, and Perez de los Heros, 2003) of the Feldman-Cousins method (Feldman and Cousins, 1998). Systematic uncertainties are found to have a negligible effect on the limits. The results are listed in Table 19.1.25.

19.1.8.1 Search for the decay $D^0 \to \gamma\gamma$ and Measurement of the branching fraction for $D^0 \to \pi^0\pi^0$

In the Standard Model flavor-changing neutral currents (FCNC) are forbidden at tree level (Glashow, Iliopoulos, and Maiani, 1970). These decays are allowed at higher order (Hurth, 2003) and have been measured in the K and B meson systems. In the charm sector, however, the small mass difference between down-type quarks of the first two families translates to a large suppression at the loop level from the GIM mechanism. To date, measurements of radiative decays of charm mesons are consistent with results of theoretical calculations that include both short-distance and long-distance contributions and predict decay rates several orders of magnitude below the sensitivity of current experiments. While these rates are small, it has been predicted that new physics (NP) processes can lead to significant enhancements (Prelovsek and Wyler, 2001).

BABAR has searched for the rare decay of the D^0 meson to two photons, $D^0 \to \gamma\gamma$, and measured the branching fraction for a D^0 meson decaying to two neutral pions, $\mathcal{B}(D^0 \to \pi^0\pi^0)$ (Lees, 2012u). The data sample analyzed corresponds to an integrated luminosity of 470.5 fb^{-1}. The $D^0 \to K_S^0\pi^0$ decay is chosen for this purpose due to its large branching fraction of $(1.22 \pm 0.05)\%$ (Beringer et al., 2012) and partial cancellation of systematic uncertainties.

The invariant $\gamma\gamma$ mass distribution obtained from the $D^0 \to \gamma\gamma$ analysis is shown in Fig. 19.1.44 together with projections of the likelihood fit and the individual signal and background contributions. The signal yield is -6 ± 15, consistent with no $D^0 \to \gamma\gamma$ events. This result is converted to a branching fraction for $D^0 \to \gamma\gamma$ relative to the $D^0 \to K_S^0\pi^0$ reference mode using

$$\mathcal{B}(D^0 \to \gamma\gamma) = \frac{\frac{1}{\varepsilon_{\gamma\gamma}}N(D^0 \to \gamma\gamma)}{\frac{1}{\varepsilon_{D^0 \to K_S^0\pi^0}}N(D^0 \to K_S^0\pi^0)}$$
$$\times \mathcal{B}(D^0 \to K_S^0\pi^0), \quad (19.1.73)$$

where N and ε are the yield and efficiency of the respective modes and $\mathcal{B}(D^0 \to K_S^0\pi^0)$ is the known $D^0 \to K_S^0\pi^0$ branching fraction. In this analysis the $D^0 \to K_S^0\pi^0$ signal yield is 126599 ± 568 events. They find $\mathcal{B}(D^0 \to \gamma\gamma) = (-0.49 \pm 1.23 \pm 0.02) \times 10^{-6}$ where the errors are the statistical uncertainty and the uncertainty in the reference mode branching fraction, respectively. Therefore they place an upper limit on the branching fraction for the decay of a D^0 meson to two photons, $\mathcal{B}(D^0 \to \gamma\gamma) < 2.2 \times 10^{-6}$, at 90% confidence level.
Figure 19.1.44. From (Lees, 2012u). The $\gamma\gamma$ mass distribution for $D^0 \to \gamma\gamma$ candidates in data (data points). The curves show the result of an unbinned maximum likelihood fit to the measured mass distribution. The solid (blue) line shows the result of the fit, indicating a slightly negative signal yield (consistent with no signal). The long-dashed (red) curve corresponds to combinatoric background component, and the small-dash pink curve corresponds to the combinatoric background plus $D^0 \to \pi^0\pi^0$ background shape. The χ^2 value is determined from binned data and is provided as a goodness-of-fit measure. The pull distribution shows differences between the data and the solid blue curve with values and errors normalized to the Poisson error.

The invariant mass distribution for events in the $D^0 \to \pi^0\pi^0$ analysis is shown in Fig. 19.1.45. The signal yield for $D^0 \to \pi^0\pi^0$ is 26010 ± 304 events. For $D^0 \to K_S^0\pi^0$ the signal yield is 103859 ± 392 events. Adjusting Eq. (19.1.73) for the $D^0 \to \pi^0\pi^0$ case this yield can be converted to a branching fraction and obtain $B(D^0 \to \pi^0\pi^0) = (8.4 \pm 0.1 \pm 0.3) \times 10^{-4}$. The first error denotes the statistical uncertainty and the second error reflects the uncertainties in the reference mode branching fraction.
Figure 19.1.45. From (Lees, 2012u). The $\pi^0\pi^0$ mass distribution for $D^0 \to \pi^0\pi^0$ candidates in data (data points). The curves show the result of the unbinned maximum likelihood fit to the measured mass distribution. The solid (blue) line shows the result of the fit. The long-dashed (red) curve corresponds to the combinatoric background component. The χ^2 value is determined from binned data and is provided as a goodness-of-fit measure. The pull distribution shows differences between the data and the solid blue curve with values and errors normalized to the Poisson error.

Table 19.1.26. From (Lees, 2012u). Summary of predictions and measured values or limits for branching fractions for $D^0 \to \gamma\gamma$ and $D^0 \to \pi^0\pi^0$.

Theoretical predictions		
Mode	Value	Reference
$D^0 \to \gamma\gamma$ (SM,VMD)	$\approx (3.5 \, {}^{+4.0}_{-2.6}) \times 10^{-8}$	(Burdman, Golowich, Hewett, and Pakvasa, 2002)
$D^0 \to \gamma\gamma$ (SM,HQχPT)	$(1.0 \pm 0.5) \times 10^{-8}$	(Fajfer, Singer, and Zupan, 2001)
$D^0 \to \gamma\gamma$ (MSSM)	6×10^{-6}	(Prelovsek and Wyler, 2001)
Experimental results		
Mode	Value	Reference
$D^0 \to \gamma\gamma$ (2002)	$< 2.9 \times 10^{-5}$	(Coan et al., 2003)
$D^0 \to \gamma\gamma$ (2012)	$< 2.2 \times 10^{-6}$	(Lees, 2012u)
$D^0 \to \pi^0\pi^0$ (2006)	$(7.9 \pm 0.8) \times 10^{-4}$	(Rubin et al., 2006)
$D^0 \to \pi^0\pi^0$ (2010)	$(8.1 \pm 0.5) \times 10^{-4}$	(Mendez et al., 2010)
$D^0 \to \pi^0\pi^0$ (2012)	$(8.4 \pm 0.1) \times 10^{-4}$	(Lees, 2012u)

A summary of the relevant branching fractions is shown in Table 19.1.26.

19.1.9 Search for rare or forbidden semileptonic charm decays

BABAR has performed a search for charm semileptonic decays that are either forbidden or heavily suppressed in the Standard Model (Lees, 2011k). The decays are of the form $X_c^+ \to h^\pm \ell^\mp \ell^{(\prime)+}$, where X_c^+ is a charm hadron (D^+, D_s^+, or Λ_c^+), and $\ell^{(\prime)\pm}$ is an electron or muon. For D^+ and D_s^+ modes, $h^\pm$ can be a pion or kaon, while for Λ_c^+ modes it is a proton. Decay modes with oppositely charged leptons of the same lepton flavor are examples of flavor-changing neutral current (FCNC) processes, which are expected to be very rare because they cannot occur at tree level in the SM. Decay modes with two oppositely charged leptons of different flavor correspond to lepton-flavor violating (LFV) decays and are essentially forbidden in the SM because they can occur only through lepton mixing. Decay modes with two leptons of the same charge are lepton-number violating (LNV) decays and are forbidden in the SM. Hence, decays of the form $X_c^+ \to h^\pm \ell^\mp \ell^{(\prime)+}$ provide sensitive tools to investigate physics beyond the SM. The most stringent existing upper limits on the branching fractions for $X_c^+ \to h^\pm \ell^\mp \ell^{(\prime)+}$ decays range from 1 to 700×10^{-6} and do not exist for most of the Λ_c^+ decays.

Charm hadron candidates are formed from one track identified as either a pion, kaon, or proton (h) and two tracks, each of which is identified as an electron or a muon ($\ell\ell^{(\prime)}$). The total charge of the three tracks is required to be ± 1. For three-track combinations with a pion or kaon track, the $h\ell\ell^{(\prime)}$ invariant mass is required to lie between 1.7 and 2.1 GeV/c^2; for combinations with a proton, the invariant mass is required to lie between 2.2 and 2.4 GeV/c^2.

The combinatorial background at low p^* is very large and they therefore select charm hadron candidates with p^* greater than 2.5 GeV/c. The main backgrounds remaining after this selection are QED events and semileptonic B and charm decays, particularly events with two semileptonic decays.

The QED events are mainly radiative Bhabha, initial-state radiation, and two-photon events, which are all rich in electrons. These events are easily identified by their low multiplicity and/or highly jet-like topology. They strongly suppress this background by requiring at least five tracks in the event and that the hadron candidate be inconsistent with the electron hypothesis. The background from semileptonic B and charm decays is also suppressed by requiring the two leptons to be consistent with a common origin.

For low e^+e^- invariant mass there is a significant background contribution from photon conversions and π^0 decays to $e^+e^-\gamma$. These are both removed by requiring $m(e^+e^-) > 200$ MeV/c^2.

For the $D_{(s)}^+ \to \pi^+\ell^+\ell^-$ decay modes, they exclude events with $0.95 < m(e^+e^-) < 1.05$ GeV/c^2 and $0.99 < m(\mu^+\mu^-) < 1.05$ GeV/c^2 to reject decays through the ϕ resonance.

After the initial event selection, significant combinatorial background contributions remain from semileptonic B decays and other sources. The final candidate selection is performed by forming a likelihood ratio $R_{\mathcal{L}}$ and requiring the ratio to be greater than a minimum value $R_{\mathcal{L}}^{\min}$ 4.

The following three discriminating variables are used in the likelihood ratio: charm hadron candidate p^*, total reconstructed energy in the event and flight length significance.

Extended, unbinned, maximum-likelihood fits are applied to the invariant-mass distributions for the $h^\pm \ell^\mp \ell^{(\prime)+}$ candidates. The measured signal yields are converted into branching ratios by normalizing them to the yields of known charm decays. For the D^+ and D_s^+ mesons, they use decays to $\pi^+\phi$ as normalization modes. For the Λ_c^+, they use $\Lambda_c^+ \to pK^-\pi^+$ as the normalization mode. The upper limits are set using a Bayesian approach with a flat prior for the event yield in the physical region. The upper limit on the signal yield is defined as the number of signal events for which the integral of the likelihood from zero events to that number of events is 90% of the integral from zero to infinity. The systematic uncertainties are included in the likelihood as additional nuisance parameters. Examples of $h\ell\ell^{(\prime)}$ invariant-mass distributions for signal candidates are in Figs 19.1.46 and 19.1.47. The signal yields
Figure 19.1.46. From (Lees, 2011k). Invariant-mass distributions for $\Lambda_c^+ \to p\ell^+\ell^{(\prime)-}$ candidates. The solid lines are the results of the fits. The background component for the dimuon mode in which muon candidates arise from hadrons misidentified is shown as a dashed curve.

Table 19.1.27. From (Lees, 2011k). Signal yields for the fits to the 35 $X_c^+ \to h^\pm\ell^\mp\ell^{(\prime)+}$ event samples. The first error is the statistical uncertainty and the second is the systematic uncertainty. The third column lists the estimated signal efficiency. The fourth column gives for each signal mode the 90% C.L. upper limit (UL) on the ratio of the branching fraction of the signal mode to that of the normalization mode (BR). The last column shows the 90% C.L. upper limit on the branching fraction for each signal mode (BF). The upper limits include all systematic uncertainties.

Decay mode	Yield (events)	Eff. (%)	BR UL 90% C.L. (10^{-4})	BF UL 90% C.L. (10^{-6})
$D^+ \to \pi^+ e^+ e^-$	$-3.9 \pm 1.6 \pm 1.7$	1.56	3.9	1.1
$D^+ \to \pi^+ \mu^+ \mu^-$	$-0.2 \pm 2.8 \pm 0.9$	0.46	24	6.5

Figure 19.1.47. From (Lees, 2011k). Invariant-mass distributions for $D^+ \to K^- \ell^+ \ell^{(')+}$ (top) and $D_s^+ \to K^- \ell^+ \ell^{(')+}$ (bottom) candidates. The solid lines are the results of the fits. The background components for the dimuon modes and $D_{(s)}^+ \to K^- \mu^+ e^+$ in which candidates arise from misidentified hadrons are shown as dashed curves.

obtained from the unbinned likelihood fits are listed in Table 19.1.27 with statistical and systematic uncertainties. Only systematic uncertainties associated with the signal and background *p.d.f.*s are included in the systematic uncertainty for the yields. The curves representing the fits are overlaid in the figures. The most significant signal is seen in the distribution for $\Lambda_c^+ \to p\mu^+\mu^-$; the signal yield has a statistical-only significance of 2.6σ as determined from the change in log-likelihood with respect to zero assumed signal events. With 35 different measurements, a 2.6σ deviation is expected with about 25% probability.

19.1.10 Summary of charmed meson decays

Charm decays open the road to investigate the flavor physics of up-type quarks, which is complementary to the weak interactions of the (bottom and strange) down type quarks. Since the B decays are dominated by the $b \to c$ transitions, and the $e^+e^- \to c\bar{c}$ cross section is comparatively high, the B factories also generated plenty of charm which allowed detailed measurements with highly competitive precision.

FCNC processes of up-type quarks are predicted to be heavily GIM suppressed, which motivated measurements and searches of rare and even forbidden decays of charm at the B factories. Although for many FCNC processes it is difficult to make a precise theoretical prediction, the B factories added a lot of new information on these decays, constraining significantly the limits on physics beyond the SM.

Aside from the weak interactions also many studies of QCD related issues have been performed. The charm quark is neither heavy enough to be cleanly treated within

the heavy quark expansion, nor is it light enough to be sensibly included into chiral Lagrangians, and thus it nicely covers the intermediate region between the two limits. For this reason there has been a lot of effort to measure multibody decays, where a lot of information on QCD has been extracted from *e.g.* Dalitz analyses.

19.2.1 Introduction

19.2.1.1 Brief overview

The mixing phenomenon in B, D and K neutral meson system is an example of the flavor changing neutral current (FCNC) process. Within the SM, FCNC's are absent at the tree level (first order). However, mixing can occur through box diagrams (second order), as shown in Fig. 19.2.1.
Figure 19.2.1. Box diagram leading to $D^0 - \overline{D}^0$ mixing.

The strong suppression of FCNC's is a consequence of the GIM mechanism (Glashow, Iliopoulos, and Maiani, 1970) (see Chapter 16). In the past, measurements of mixing provided a basis for important discoveries. The discoveries of $K^0 - \overline{K}^0$ and $B_d^0 - \overline{B}_d^0$ mixing, for example, enabled predictions of the masses of the charm and top quarks, respectively, before the quarks were first observed at Brookhaven and SLAC (Aubert et al., 1974; Augustin et al., 1974), and at Fermilab (Abachi et al., 1995b; Abe et al., 1995). The probability for any of the above mentioned neutral mesons to transform into its anti-particle in the course of its lifetime is described by the mixing parameters x and y. The mixing parameters are defined as

$$\Gamma = \frac{\Gamma_1 + \Gamma_2}{2}$$
$$x = \frac{m_1 - m_2}{\Gamma}$$
$$y = \frac{\Gamma_1 - \Gamma_2}{2\Gamma} \, , \qquad (19.2.1)$$

where $\Gamma_{1,2}$ are the widths of the two mass eigenstates. The time integrated probability for a neutral meson initially

produced as P^0 to decay at a later time as $\overline{P}^0$ is given by $(x^2 + y^2)/2(x^2 + 1)$. By inspection of approximate values for x and y in Table 19.2.1 it is clear that this probability is by far the smallest for the system of neutral D mesons.

Table 19.2.1. Discoveries of neutral mesons and their mixing Approximate values of the mixing parameters are listed as well.

Meson	Discovery year and place	Mixing parameter
K^0	1950 Caltech	
Mixing	1956 Columbia	$x \approx 1, \;\; y \approx 1$
B_d^0	1983 CESR	
Mixing	1987 DESY	$x \approx 0.8, \;\; y \sim 0$
B_s^0	1992 LEP	
Mixing	2006 Fermilab	$x \approx 26, \;\; y \sim 0.05$
D^0	1976 SLAC	
Mixing	2007 KEK, SLAC	$x \sim 0.01, \;\; y \sim 0.01$

The reason for the small rate of mixing of D^0 mesons lies in the fact that they are the only flavored neutral mesons composed of up-type quarks. The GIM mechanism, as explained below, is even more efficient for the case of up-type quark FCNC's. For the same reason measurements of mixing in the D^0 system yield complementary constraints on possible contributions from new physics (NP) processes beyond the SM to those arising from the measurements of FCNC's of down-type quarks (B or K mesons). In 2007 the B Factories established evidence for mixing in the neutral charm mesons system, and those results were published back-to-back in Phys. Rev. Lett. as (Aubert, 2007j) and (Staric, 2007). These results are discussed in Sections 19.2.2 and 19.2.3, respectively.

19.2.1.2 Mixing

A general description of oscillations of pseudoscalar neutral mesons is given in Section 10.1. In the following we emphasize some of the specifics of the D^0 system. The mixing parameters are defined in Eq. (19.2.1).

In the absence of CP violation ($q = p = 1/\sqrt{2}$ in Eq. 10.1.2), $D_{1(2)}$ is the CP-even (odd) state if one adopts the phase convention $CP|D^0\rangle = |\overline{D}^0\rangle$ and $CP|\overline{D}^0\rangle = |D^0\rangle$.[119]

The amplitude for the process of Fig. 19.2.1, $\langle \overline{D}^0 | H^{\Delta C = 2} | D^0 \rangle$, can be schematically written as

$$\sum_{i,j=d,s,b} V_{ui}^* V_{ci} V_{cj} V_{uj}^* \mathcal{F}(m_W^2, m_i^2, m_j^2), \qquad (19.2.2)$$

---

[119] For the mixing parameter x (y) one subtracts the mass (width) of the CP-odd state (or in case of CP violation of the state which has a larger CP-odd component) from that of the CP-even state (or in case of CP violation of the state which has a larger CP-even component).

where the kinematic function $\mathcal{F}$ arises from the integration over the momenta of particles exchanged in the loop. The formulation above nicely reflects the GIM mechanism: if masses of all (down-type) quarks exchanged in the loop were equal, *i.e.* $m_i = m_j$, the function $\mathcal{F}$ would be a factor common to all terms in the sum which would make the amplitude zero due to the unitarity of the CKM matrix.

Based on dimensional arguments (Nachtmann, 1990) the form of $\mathcal{F}$ is

$$\mathcal{F}(m_W^2, m_i^2, m_j^2) \propto f_0 m_W^2 \qquad (19.2.3)$$
$$+ f_1 m_i^2 + f_2 m_j^2 + f_3 m_i m_j + \mathcal{O}(m_W^{-2}) \; .$$

Due to the unitarity of the CKM matrix, only the $m_i m_j$ terms survives in the sum (19.2.2), and hence

$$\langle \overline{D}^0 | H^{\Delta C=2} | D^0 \rangle \propto \sum_{i,j=d,s,b} V_{ui}^* V_{ci} V_{cj} V_{uj}^* m_i m_j \; . \quad (19.2.4)$$

Furthermore, due to the small magnitude of the V_{ub} coupling, the b quark contribution is negligible. The amplitude is proportional to $V_{us}^* V_{cs} V_{cd} V_{ud}^*$, and vanishes in the limit $m_d \sim m_s$. The D^0 mixing thus arises only as a consequence of the $SU(3)_{\text{flavor}}$ symmetry breaking resulting from the small differences between the masses of down-type quarks.

The short distance contribution calculated from the box diagrams (like the one in Fig. 19.2.1) is proportional to the local $\Delta C = 2$ operator $\overline{u} \gamma_\mu (1-\gamma^5) c \overline{u} \gamma^\mu (1-\gamma^5) c$ and reads (Bigi and Uraltsev, 2001b; Burdman and Shipsey, 2003; Georgi, 1992)

$$\langle \overline{D}^0 | H^{\Delta C=2} | D^0 \rangle = \frac{G_F^2 m_c^2}{4\pi^2} V_{cs}^* V_{cd}^* V_{ud} V_{us} \frac{(m_s^2 - m_d^2)^2}{m_c^4} \times$$
$$\langle \overline{D}^0 | \overline{u} \gamma_\mu (1-\gamma^5) c \overline{u} \gamma^\mu (1-\gamma^5) c | D^0 \rangle \; . \quad (19.2.5)$$

Equation (19.2.5) shows that this amplitude is doubly-Cabibbo suppressed. Furthermore, the factor $(m_s^2 - m_d^2)^2 / m_c^4$ shows explicitly that D^0 mixing vanishes in the limit of exact $SU(3)_{\text{flavor}}$ symmetry limit, when $m_s = m_d$.

It has been discussed (Bigi and Uraltsev, 2001b; Georgi, 1992) that the contribution shown in Eq. (19.2.5) is the first term of systematic expansion in $1/m_c$. The peculiar feature of this leading term is the strong suppression by the factor $(m_s^2 - m_d^2)^2 / m_c^4$, which is not present any more in the subleading terms of the expansion. In fact, already the first subleading terms exhibits only a factor m_s^2/m_c^2. This indicates that the leading term cannot properly describe D^0 mixing, and that large long-distance contributions are present.

Taking into account the long-distance contributions by adding the second order terms from $H^{\Delta C=1}$ involving intermediate hadronic states $|n\rangle$ one obtains

$$(M - \frac{i}{2}\Gamma)_{ij} = m_D \delta_{ij} + \qquad (19.2.6)$$
$$\frac{1}{2m_D} \langle \overline{D}^0 | H^{\Delta C=2} | D^0 \rangle +$$

$$\frac{1}{2m_D} \sum_n \frac{\langle \overline{D}^0 | H^{\Delta C=1} | n \rangle \langle n | H^{\Delta C=1} | D^0 \rangle}{m_D - E_n + i\epsilon} \; .$$

Neglecting, for the moment, the last term in the equation above and evaluating M_{ij}, Γ_{ij} from the box diagram ($\langle \overline{D}^0 | H^{\Delta C=2} | D^0 \rangle$), and taking into account the relations for the eigenvalues of the effective Hamiltonian Eq. (10.1.15), it is possible to estimate the expected magnitude of the mixing parameter, $|x| \sim \mathcal{O}(10^{-5})$. Mixing with this rate would be unobservable with the present experimental facilities.

However, the last term in Eq. (19.2.6) also contributes, and represents the long distance contribution to the effective Hamiltonian. The contribution arises from on- and off-shell intermediate states $|n\rangle$ accessible to both D^0 and $\overline{D}^0$ (see for example Fig. 19.2.2). Due to the non-perturbative
Figure 19.2.2. $K^+ K^-$ as an example of an intermediate state accessible to both D^0 and $\overline{D}^0$, contributing to $D^0 - \overline{D}^0$ mixing. Black circles represent quark processes for $D^0 \to K^+ K^-$ and its charge conjugate, similar to the process shown in Fig. 19.2.4.

quantum chromodynamic nature of these effects, their contribution is much more difficult to evaluate than the short distance contribution illustrated in Fig. 19.2.1. In general, two methods have been exploited to estimate the magnitude of the mixing parameters that consider these long distance contributions: the exclusive approach (Donoghue, Golowich, Holstein, and Trampetic, 1986; Falk, Grossman, Ligeti, Nir, and Petrov, 2004), considering various possible exclusive intermediate states, and the Operator Product Expansion (OPE) method (Bigi and Uraltsev, 2001b; Georgi, 1992).

The former method is conceptually straightforward. If we consider only the possible two-body pseudoscalar intermediate states, $K^- \pi^+$, $K^- K^+$, $\pi^- \pi^+$ and $K^+ \pi^-$, their contributions are summarized in Table 19.2.2.

The second and third columns of the table show the CKM elements for various states entering the expressions $|\langle \overline{D}^0 | H^{\Delta C=1} | n \rangle|^2$ and $\langle \overline{D}^0 | H^{\Delta C=1} | n \rangle \langle n | H^{\Delta C=1} | D^0 \rangle$, according to the Wolfenstein parameterization (see Chapter 16). The minus signs in the third column are a consequence of a relative sign between the V_{us} and V_{cd} elements of the CKM matrix. Naïvely one expects the contribution to the mixing, when summed over the considered states, to vanish, *i.e.*

$$\sum_n \langle \overline{D}^0 | H^{\Delta C=1} | n \rangle \langle n | H^{\Delta C=1} | D^0 \rangle = 0. \quad (19.2.7)$$

Table 19.2.2. Pairs of pseudoscalar mesons accessible to D^0 and $\overline{D}^0$. The CKM suppression factors entering two expressions in Eq. (19.2.6) are listed in the second and the third column. Due to the $SU(3)_{\text{flavor}}$ symmetry breaking the ratios of branching fractions ($\mathcal{B}$) differ from the naïve CKM expectation (fourth column). From these one can estimate the contributions important for the mixing amplitude, listed in the fifth column.

State	$\lvert\langle\overline{D}^0\rvert H^{\Delta C=1}\lvert n\rangle\rvert^2 \propto$	$\langle\overline{D}^0\rvert H^{\Delta C=1}\lvert n\rangle\langle n\rvert H^{\Delta C=1}\lvert D^0\rangle \propto$	Measured $\mathcal{B}/\mathcal{B}_0$	Contribution to mixing
$K^+\pi^-$	1	$-\lambda^2$	r_1	$-\sqrt{r_1 r_4}\,\lambda^2$
K^-K^+	λ^2	λ^2	$r_2\lambda^2$	$r_2\lambda^2$
$\pi^-\pi^+$	λ^2	λ^2	$r_3\lambda^2$	$r_3\lambda^2$
$K^-\pi^+$	λ^4	$-\lambda^2$	$r_4\lambda^4$	$-\sqrt{r_1 r_4}\,\lambda^2$
		$\Sigma = 0$		$\Sigma = \lambda^2\left(r_2 + r_3 - 2\sqrt{r_1 r_4}\right)$

However, $SU(3)_{\text{flavor}}$ symmetry breaking causes differences beyond those in the CKM factors contributing to the various states. These can be estimated from the measured branching fractions as given schematically in the fourth column of the table. If one denotes the expected $\mathcal{B}$ for a final state i by $\lambda^n\mathcal{B}_0^i$, the measured $\mathcal{B}$ is $r_i\lambda^n\mathcal{B}_0^i$. The factors $r_i \neq 1$ point to $SU(3)$ symmetry breaking. The contributions to the mixing amplitude as evaluated using the measured branching fractions is given in the last column. The sum over all the states yields $\lambda^2(r_2 + r_3 - 2\sqrt{r_1 r_4})$ which is in general different from zero. In order to precisely calculate the mixing parameters, one would need to take into account other possible intermediate states for some of which the branching fractions are not well known. Nevertheless it is possible to estimate the magnitude of the mixing parameters to be $|x| \lesssim \mathcal{O}(10^{-3})$ and $|y| \lesssim \mathcal{O}(10^{-2})$ (Falk, Grossman, Ligeti, Nir, and Petrov, 2004). These are in rough agreement with the expectation of the OPE method, $|x|, |y| \lesssim \mathcal{O}(10^{-3})$ (Bigi and Uraltsev, 2001b).

In summary, theoretical expectations based on the SM are that the mixing rate in the D^0 system is small, arising mainly from long distance contributions that are difficult to estimate. Despite this difficulty, the measurement of mixing in this system over a wide range of decay modes and with sufficient precision can provide important constraints on possible NP parameters. Importantly and uniquely, such constraints will be complementary to those from down-type FCNC processes.

On the experimental side, observations of D^0 mixing come predominantly from measurements of the time evolution of neutral D meson decays to final states f that are accessible to both D^0 and $\overline{D}^0$. In such cases, as illustrated in Fig. 19.2.3, direct decay and decay preceded by mixing interfere. Mixing can, in principle, also be observed in semi-leptonic decays of D^0 mesons where the leptons have the wrong sign. The only way, in the SM, for such decays to occur is through D^0-$\overline{D}^0$ mixing, with a tiny rate $\propto (x^2 + y^2)/2 \sim 5 \times 10^{-5}$.

At the B Factories, $c\bar{c}$ pairs are produced in the electroweak annihilation of electrons and positrons. In the fragmentation of primary quarks various species of charmed hadrons together with lighter hadrons are produced. In general, pairs of D^0 and $\overline{D}^0$ mesons are not
Figure 19.2.3. Illustration of interference between direct D meson decays and decays through mixing into the final state f, accessible to either D^0 or $\overline{D}^0$.

in a quantum correlated state.[120] The time evolution of the mass eigenstates $D_{1,2}$ (*i.e.* of the eigenstates of the effective Hamiltonian, see Section 10.1) follows a simple exponential form

$$|D_{1,2}(t)\rangle = e^{-i(m_{1,2} - i\Gamma_{1,2}/2)t}|D_{1,2}(t=0)\rangle \ , \quad (19.2.8)$$

and the form of the experimentally accessible flavor states is

$$|D^0(t)\rangle = \frac{1}{2p}\left[|D_1(t)\rangle + |D_2(t)\rangle\right]$$
$$|\overline{D}^0(t)\rangle = \frac{1}{2q}\left[|D_1(t)\rangle - |D_2(t)\rangle\right] \ . \quad (19.2.9)$$

Writing out the time evolution of the mass eigenstates we arrive at

$$|D^0(t)\rangle = \left[|D^0\rangle\cosh\left(\frac{ix+y}{2}\Gamma t\right) - \right. \quad (19.2.10)$$
$$\left. -\frac{q}{p}|\overline{D}^0\rangle\sinh\left(\frac{ix+y}{2}\Gamma t\right)\right]e^{(-im-\Gamma/2)t}$$

$$|\overline{D}^0(t)\rangle = \left[|\overline{D}^0\rangle\cosh\left(\frac{ix+y}{2}\Gamma t\right) - \right.$$
$$\left. -\frac{p}{q}|D^0\rangle\sinh\left(\frac{ix+y}{2}\Gamma t\right)\right]e^{(-im-\Gamma/2)t} \ .$$

---

[120] This is different from $D^0\overline{D}^0$ production at the charm threshold. There, the pair of D mesons from the decay of a $\psi(3770)$ is in a quantum correlated state similar to a pair of B mesons produced in the decay of an $\Upsilon(4S)$.

In the above equations we use the notation $|D^0\rangle$ and $|\overline{D}^0\rangle$ for the two flavor eigenstates.[121] The time evolutions can be simplified. Since $|x|$, $|y| \ll 1$, the time dependent decay rate of an initially produced D^0 meson to a final state f can be written as

$$\frac{d\Gamma(D^0 \to f)}{dt} \propto \left| A_f - \frac{q}{p}\frac{ix+y}{2}\overline{A}_f \Gamma t \right|^2 e^{-\Gamma t} \quad . \quad (19.2.11)$$

A_f and $\overline{A}_f$ denote the instantaneous decay amplitudes $\langle f|D^0\rangle$ and $\langle f|\overline{D}^0\rangle$, respectively. Analogously, for an initially produced $\overline{D}^0$ one finds

$$\frac{d\Gamma(\overline{D}^0 \to f)}{dt} \propto \left| \overline{A}_f - \frac{p}{q}\frac{ix+y}{2}A_f \Gamma t \right|^2 e^{-\Gamma t} \quad . \quad (19.2.12)$$

Further simplification arises if we ignore CP violation in mixing and mixing-induced CP violation (see further discussion in Section 19.2.1.3), *i.e.* assume that $p = q = 1/\sqrt{2}$:

$$\frac{d\Gamma(D^0 \to f)}{dt} \propto \left[|A_f|^2 - |\overline{A}_f||A_f|(x\sin\delta_f + y\cos\delta_f)(\Gamma t) \right.$$
$$\left. + |\overline{A}_f|^2 \frac{x^2+y^2}{4}(\Gamma t)^2 \right] e^{-\Gamma t} \, ,$$
$$\frac{d\Gamma(\overline{D}^0 \to f)}{dt} \propto \left[|\overline{A}_f|^2 + |A_f||\overline{A}_f|(x\sin\delta_f - y\cos\delta_f)(\Gamma t) \right.$$
$$\left. + |A_f|^2 \frac{x^2+y^2}{4}(\Gamma t)^2 \right] e^{-\Gamma t},$$
$$(19.2.13)$$

where δ_f is $\arg(A_f/\overline{A}_f)$. In Eqs (19.2.13), the first terms represent direct decay and the third terms describe decay preceded by mixing. The middle terms, linear in t, encode the interference between the two processes. They are also linear in the small parameters x and y, and it is those terms that make the time dependent decay rates sensitive to the values of the mixing parameters.

The specific dependence on these quantities differs for various final states f. When the amplitude for direct decay is Cabibbo-favored (CF), the first term dominates and the decays are, effectively, exponential and mixing can be neglected. When, however, the direct decay amplitude is doubly Cabibbo-suppressed (DCS), all three terms are of the same order of magnitude and such final states offer the maximum sensitivity to the mixing parameters.

19.2.1.3 *CP* violation

For most *BABAR* and Belle measurements of $D^0 - \overline{D}^0$ meson mixing, results on the mixing parameters are extracted first assuming that CP violation can be neglected, using Eq. (19.2.13). In some measurements a second fit to the data distributions is performed examining the possibility

---

[121] The experimental identification of these states is possible through decays into flavor specific final states, for example $\langle D^0|K^-\ell^+\nu_\ell\rangle \neq 0$ while $\langle \overline{D}^0|K^-\ell^+\nu_\ell\rangle = 0$.

for differences between D^0 and $\overline{D}^0$, and CP asymmetries are measured.

The decay rates in Eqs (19.2.11) and (19.2.12) depend also on the CP violating parameter q/p (cf. Chapter 10). In general, CP violation in the SM for processes involving charmed hadrons is expected to be tiny. This is conveniently seen in the parameterization of the CKM matrix given in Eq. (16.4.4). CP violation arises from the phase in the CKM matrix, and the elements of the matrix related to the first two generations of quarks, which appear in the charmed hadron processes, are almost real. Hence the magnitude of the CP violating effect is expected to be small. As an example, consider the Cabibbo suppressed decay $D^0 \to \pi^+\pi^-$, shown in Fig. 19.2.4. The relevant CKM phase entering the ratio of amplitudes for this decay and its charge conjugate is

$$\arg\frac{\langle \pi^+\pi^-|D^0\rangle}{\langle \pi^+\pi^-|\overline{D}^0\rangle} = 2 \, \arg(V_{cd}^* V_{ud}) \quad . \quad (19.2.14)$$

To see the expected magnitude of the CP violation due to this weak phase one needs to consider the parameterization of the CKM matrix at least up to the order λ^5. The usually adopted Wolfenstein parameterization to order λ^3 is given in Eq. (16.4.4) in Section 16. The parameterization including the order of λ^5 reads (see for example review "CP violation in meson decays" in Beringer et al. (2012))

$$\begin{pmatrix} 1-\lambda^2/2-\lambda^4/8 & \lambda & A\lambda^3(\rho-i\eta) \\ -\lambda+A^2\lambda^5[1-2(\rho+i\eta)]/2 & 1-\lambda^2/2-\lambda^4(1+4A^2)/8 & A\lambda^2 \\ A\lambda^3[1-(1-\lambda^2/2)(\rho+i\eta)] & -A\lambda^2+A\lambda^4[1-2(\rho+i\eta)]/2 & 1-A^2\lambda^4/2 \end{pmatrix}$$
$$+ \mathcal{O}(\lambda^6). \quad (19.2.15)$$

Evaluating Equation (19.2.14) yields

$$2 \, \arg(V_{cd}^* V_{ud}) \approx 2A^2\lambda^4\eta = 1.2 \times 10^{-3} \quad , \quad (19.2.16)$$

where in the last line we use values of parameters from Charles et al. (2005). CP violation effects in the charm sector are thus of the order of 10^{-3}. Recently some authors have argued that the CP asymmetries in Cabibbo-suppressed decays can be larger by some factor (Brod, Kagan, and Zupan, 2011).
Figure 19.2.4. $D^0 \to \pi^+\pi^-$ decay with the corresponding CKM elements.

In measurements of various observables sensitive to CP violation, the parameterization

$$\left|\frac{q}{p}\right|^2 \equiv 1 + A_M \qquad (19.2.17)$$

is often used. Three types of CP violating effects can be distinguished, as in any other neutral mesons system (see Section 16.6). First, CP violation in mixing occurs if $A_M \neq 0$ (alternatively, $|q/p| \neq 1$). CP violation in decay is present if $|A_f/\overline{A}_{\overline{f}}| \neq 1$. This effect is sometimes parameterized in terms of

$$\left|\frac{A_f}{\overline{A}_{\overline{f}}}\right|^2 \equiv 1 + A_D^f \quad . \qquad (19.2.18)$$

It should be noted that while the parameter A_M is universal for all D^0 decays, the parameter A_D^f depends on the final state f. This type of CP violation can only occur in decays to which at least two processes with different weak and strong phases contribute (see Eq. (16.6.5) in Chapter 16). For D mesons this is only possible in Cabibbo suppressed decays, where both tree (*e.g.* see Fig. 19.2.4) and penguin (Fig. 19.2.5) diagrams are possible. Finally,
Figure 19.2.5. Penguin diagram contributing to Cabibbo suppressed decays of D mesons.

there is a possibility of mixing-induced CP violation. This is characterized by

$$\text{Im}\left[\frac{q}{p}\frac{\overline{A}_f}{A_f}\right] \equiv \text{Im}[\lambda_f] \neq 0 \quad . \qquad (19.2.19)$$

Using previous parameterizations (and keeping only linear terms in small quantities A_M and A_D^f), λ_f is sometimes expressed as

$$\lambda_f = \sqrt{R_D^f}(1 + A_M/2)(1 - A_D^f/2)e^{-i(\delta_f - \phi)} \quad . \quad (19.2.20)$$

In the above expression, the parameter R_D^f is not related to CP violation, but to the possible Cabibbo suppression, $R_D^f = |A_{\overline{f}}/A_f|^2 = |\overline{A}_f/\overline{A}_{\overline{f}}|^2$. The phase δ_f includes a possible strong phase as well as the weak phase difference between the two amplitudes. For decays to CP eigenstates (such as K^+K^-) $R_D^f = 1$ and the strong phase difference is zero. If we neglect the weak phase differences of the

order of 10^{-3} then the only source of this type of CP violation in decays to CP eigenstates is $\phi \equiv \arg(q/p) \neq 0$ which can arise due to some unknown NP processes.

In the following sections we neglect CP violation in the neutral D meson system and address this important phenomenon separately in Sections 19.2.6 and 19.2.7.

19.2.1.4 D^0 Mixing in New Physics Models

Values of the mixing parameters for the D^0 meson system can differ significantly from SM estimates in several NP models. In Golowich, Hewett, Pakvasa, and Petrov (2007) the authors examined a large number of such models and calculated the contributions of new particles and processes to the mixing parameters x and y. Due to the large uncertainties in SM calculations, the values are obtained for specific NP contributions alone.[122] In this approach the parameters of a large majority of the models considered are additionally constrained by the measured values of the D^0 mixing parameters. An example of the sensitivity of the value of x to the mass and CKM elements of a possible fourth generation b' quark is shown in Fig. 19.2.6.[123]

Not only x but also y can be sensitive to some of the NP models considered. As pointed out in Eq. (19.2.5), the mixing parameters in the SM vanish in the exact $SU(3)_{\text{flavor}}$ limit. Moreover, the contribution to the mixing parameters enters only as a second order effect in the $SU(3)_{\text{flavor}}$ breaking. Hence the NP contributions to y could be significant for the models in which the contributions do not vanish in the $SU(3)_{\text{flavor}}$ symmetry limit (Golowich, Pakvasa, and Petrov, 2007). An example is the R-parity violating SUSY model, where the slepton mediated interaction is not suppressed in the $SU(3)_{\text{flavor}}$ symmetry limit and could lead to values as high as $|y| \approx 3.7\%$ for $M_{\tilde{\ell}} = 100$ GeV/c^2. Section 25.2 is a more general discussion on how one can constrain benchmark NP models using constraints from the B Factories.

19.2.1.5 General experimental remarks

Two experimental ingredients are necessary to exploit the decay time distributions of Eqs (19.2.11) and (19.2.12) for

---

[122] The neglection of the SM contribution leads to less restrictive limits in most cases. If there is also the SM contribution to the magnitudes of the mixing parameters, then the contribution from NP is smaller and hence the constraint gets more severe.

[123] Note that severe lower limits on the b' mass arise also from direct searches at the LHC. For example, the CMS collaboration finds $m(b') > 611$ GeV at 95% C.L., assuming $\mathcal{B}(b' \to Wt) = 100\%$ and hence $|V_{ub'}V_{cb'}| = 0$ (Chatrchyan et al., 2012c). The ATLAS collaboration provides lower mass limits as a function of $\mathcal{B}(b' \to Wt)$ (Gauthier, 2013); for values of the latter between 0.8 and 1.0 the limit is $m(b') > 700$ GeV at 95% C.L. This is complementary to the limit arising from $D^0 - \overline{D}^0$ mixing, which provides an upper limit on the b' mass for a given value of $|V_{ub'}V_{cb'}|$.

Figure 19.2.7. Illustration of D meson decay length determination with some typical dimensions.
Figure 19.2.6. Contours of x in the fourth generation b' quark mass and CKM elements ($|V_{ub'}V_{cb'}|$) plane (see text for explanation). Contours are shown for $x = [15.0, 11.7, 8.0, 5.0, 3.0] \times 10^{-3}$ (from right to left). From (Golowich, Hewett, Pakvasa, and Petrov, 2007).

measuring the mixing parameters. The first one is the determination of the initial neutral D meson flavor ("flavor tagging"), that is used to determine whether a D^0 or a $\overline{D}^0$ was produced at $t = 0$. The second ingredient is the determination of the decay time of a the neutral D meson, based on the measurement of its decay length between the production and decay point.

The initial flavor tagging is based on the decay chain $D^{*+} \to D^0\pi^+ \to f\pi^+$, and its charge conjugate $D^{*-} \to \overline{D}^0\pi^- \to \overline{f}\pi^-$. The charge of the pion produced in the decay of a D^* determines the flavor of the neutral daughter D meson. It should be noted that the average laboratory momentum of such pions is low, around $400\,\text{MeV}/c$, and hence they are usually denoted as "slow pions", π_s. The use of D's from D^*'s also reduces the amount of background in the event samples selected. The difference between the invariant masses of the D^{*+} and the D^0 meson, $\Delta m = m(f\pi^+) - m(f)$, is a powerful selection variable that restricts the amount of combinatorial background considerably. The effectiveness is further enhanced by the excellent experimental resolution in Δm arising from the cancellation of experimental uncertainty in the determination of the momenta of particles comprising the D^0. In some measurements an equivalent variable $Q = \Delta m - m_\pi$ is used instead of Δm.[124]

The determination of the D meson decay length is illustrated in Fig. 19.2.7 with typical dimensions indicated. The accuracy depends critically on the silicon detectors of the experiments, described in Chapter 2. The decay point is obtained from fitting the D meson decay products to a single vertex. The D^0 production point is obtained by intersecting the D^0 flight direction, determined by its momentum vector and decay vertex, with the e^+e^- interaction region. The charged ("slow") pion from the D^* decay can be fitted to a common space point together with
the D momentum and spatial constraints from the interaction region. This improves the momentum accuracy of the slow pion and, thereby, the experimental resolution in Δm. The average D^0 decay length at the B Factories is about 200 μm. The precision by which the interaction region is known is given in Chapter 6. The resulting resolution on the decay length is approximately 100 μm, depending on the final state considered. The proper decay time is obtained from the decay length l, momentum p and nominal mass of the D mesons m_D as $m_D l \cdot \boldsymbol{p}/p^2$.

In the measurement of the D^0 decay times, it is assumed that the D^0's are produced at the primary e^+e^- production vertex. For D^0's from B meson decays, this assumptions results in a biased measurement due to the finite decay time of the B mesons and the corresponding D^0 decay time distribution cannot be described by Eq. (19.2.13). This complication (and the related systematic uncertainties that would result from it) is avoided by requiring the CM momentum of the tagging D^* mesons to exceed the kinematic limit for $B \to D^*X$ decays.[125] The typical minimal value required for the D^* momentum is $2.5\,\text{GeV}/c$.

To measure the mixing parameters from the decay time distributions one needs an accurate description of the resolution, to be convolved with the expected distributions of Eqs (19.2.11) and (19.2.12). The simplest way of describing the resolution is to use a Gaussian function with an appropriate width, but this rarely turns out to be accurate enough. In general, the resolution function is more complicated since the resolution in an individual D meson decay time measurement depends on the specific kinematics of the decay. In most cases the resolution function can be successfully parameterized with two or three Gaussian functions of different widths. In an unbinned fit to the decay time distribution the width of the resolution function can be implemented on an event-by-event basis by multiplying the estimated accuracy of the decay time as obtained from the vertex fits by a factor which is either a free parameter in the fit or determined from some control sample of decays, if one exists. For a two Gaussian reso-

---

[124] Sometimes in the literature the same variable is denoted as q, not to be confused with q from Eq. (19.2.9), for example.

[125] The largest momentum of a D^*, in a two body $B \to D^*\pi$ decay in the CM system, where the B meson is approximately at rest, is about $2.3\,\text{GeV}/c$.

lution parameterization, the likelihood value for the i-th signal event is written as

$$\mathcal{L}_i(x,y) = \int_0^\infty dt' \frac{d\Gamma}{dt'}(t';x,y) \left[f e^{(t_i-t')^2/2S_1\sigma_i^2} + \right.$$

$$\left. (1-f)e^{(t_i-t')^2/2S_2\sigma_i^2} \right]. \quad (19.2.21)$$

in which σ_i is the uncertainty reported by the vertex reconstruction code for this event, and where $S_{1,2}$ are the scale factors mentioned above.

In constructing the resolution function special care should be devoted to possible biases in decay length measurements. These can occur due to a combination of the kinematic properties of decays (mainly arising from dependence on the opening angle of the final state tracks in the laboratory frame) and small residual misalignments of individual detector modules.[126] Such effects could result in a biased measurement of the mixing parameters. These effects can be included in the resolution function through various more sophisticated parameterizations, for example by allowing the mean value of the Gaussian function to deviate from zero. In some cases a further dependence of the mean value on the kinematic properties of the decay is required: for example, the bias can depend on the opening angle of the two tracks in the case of $D^0 \to K^\pm\pi^\mp$ decays; the opening angle is in turn strongly correlated with the invariant mass and hence the bias can vary as the invariant mass changes across the width of the signal peak, as shown in the example below in Fig. 19.2.18. In multi-body decays the bias and hence the mean value of the resolution function can also vary depending on the position of the decay in the Dalitz plane.

The parameterization of the resolution function must be studied to understand what effect such biases have on the determination of the mixing parameters. For this, a number of special simulated samples of events are produced with non-zero values for x and y and then subjected to the same selection, reconstruction and fitting procedures as the data to check for possible bias in these mixing parameters. Another test is to fit the Cabibbo-favored decays (*e.g.* $D^0 \to K^-\pi^+$) where the effects of mixing are negligible to obtain the average decay lifetime. The resulting values are compared to the current world average of (410.1 ± 1.5) fs (Beringer et al., 2012) to check for possible biases arising from the parameterization of the resolution function.

19.2.2 Hadronic wrong-sign decays

The earliest attempts to find evidence for $D^0 - \bar{D}^0$ mixing at the B Factories have used limited samples of "wrong sign" (WS) hadronic decays. The term WS decays is used for decays to flavor specific final states which are either DCS or can proceed through the mixing process. Both

---
[126] For example, misalignment between the silicon vertex device and the central tracking chamber.

BABAR and Belle have carefully studied the time dependence of the $D^0 \to K^+\pi^-$ + c.c. decays. These studies initially set limits on the mixing parameters and ultimately provided evidence for charm mixing at the 3.9σ level, as well as setting limits on CP violation (Zhang, 2006; Aubert, 2007j). These decays, expected to be particularly sensitive to mixing (Bigi and Uraltsev, 2001b; Blaylock, Seiden, and Nir, 1995), were first used to search for this phenomenon by the E791 collaboration (Aitala et al., 1998). This search resulted in the upper limit for the ratio of decays with and without mixing of $r_{mix} < 0.85\%$ at 90% C.L. The CLEO experiment provided limits on the mixing parameters using the same decay mode (see below for the definitions of x'^2 and y'), $x'^2 < 0.082\%$ and $-5.5\% < y' < 1.0\%$ at 95% C.L. (Godang et al., 2000).

Another type of WS decays that played important role in $D^0 - \bar{D}^0$ mixing measurements is the $D^0 \to K^+\pi^-\pi^+\pi^-$ ($K3\pi$) decay mode. It has been used to search for charm mixing since the earliest days of charm physics. In 1977, the SLAC/LBL magnetic detector at SPEAR was used to search for "same-sign" $K3\pi$ events where the kaon in the D^0 decay had the same charge as the kaon in the recoil products opposite the D^0 (Goldhaber et al., 1977). The result was that less than 18% (at 90% C.L.) of the observed D^0 decays exhibited the same-sign signature, which was consistent with the amount of charged particle mis-identification expected from their time-of-flight system. Other searches for wrong-sign decays also saw no signal but did set limits on the wrong-sign rate. In 1995, E791 (Aitala et al., 1998) reported a wrong-sign measurement of $D^0 \to K3\pi$ showing that the mixing rate is less than 0.85% at 90% C.L. This result was soon followed by evidence for the wrong-sign $K3\pi$ decay from CLEO with a relative rate with respect to the RS decays of $R_{WS}^{K3\pi} = [0.41^{+0.12}_{-0.11} \pm 0.04 \pm 0.10]\%$, where the first error is statistical, the second is systematic, and the third is due to phase space (Dytman et al., 2001). The result is consistent with the WS decays arising solely from DCS decays.

19.2.2.1 Method

The time-dependence of mixing in the decays of neutral mesons has been discussed in detail in Section 10.1 and, for charm mesons, in Section 19.2.1. The term WS decays is related to Eq. (19.2.13). If we select $f = K^-\pi^+$ the D^0 decays are CF and the second and third term in the expression for $d\Gamma(D^0 \to K^-\pi^+)/dt$ are negligible. On the other hand, the $\bar{D}^0$ decays are DCS. Hence the contribution of direct decay (first term of $d\Gamma(\bar{D}^0 \to K^-\pi^+)/dt$) is not much larger than the decay preceded by mixing ($\bar{D}^0 \to D^0 \to K^-\pi^+$, last term) and the interference between the two (second term). Hence the decays of an initially produced $\bar{D}^0$ to $K^-\pi^+$ (and analogously of an initially produced D^0 to $K^+\pi^-$), which are either DCS or can proceed through the mixing process, are called WS decays (as opposed to right sign (RS) decays, $\bar{D}^0 \to K^+\pi^-$ and $D^0 \to K^-\pi^+$). Experimentally, the WS and RS decays are selected based on the correlation between the

charge of the slow pion from the tagging $D^{*\pm}$ decay and the charge of the kaon from the D meson decay.

Evaluating the expressions in Eqs (19.2.13), we get the time dependence of the $D^0 \to K\pi$ WS decays for small values of the mixing parameters x and y, as defined in Eq. (19.2.1), and assuming that CP is conserved:

$$\frac{\Gamma_{\text{ws}}}{e^{-\Gamma t}} \propto R_D + \sqrt{R_D}\,y'\,\Gamma t + \frac{x'^2 + y'^2}{4}(\Gamma t)^2, \quad (19.2.22)$$

where we used a short hand notation $R_D = R_D^{K\pi}$. The parameters x' and y' are the parameters x and y rotated by a strong phase difference $\delta_{K\pi}$ between the CF and DCS decays:

$$x' = x\cos\delta_{K\pi} + y\sin\delta_{K\pi}$$
$$y' = y\cos\delta_{K\pi} - x\sin\delta_{K\pi}\,; \quad (19.2.23)$$

$\delta_{K\pi}$ is defined through $\overline{A}_{K^-\pi^+}/A_{K^-\pi^+} = -\sqrt{R_D^{K\pi}}e^{-i\delta_{K\pi}}$, c.f. Eq. (19.2.20). In the following, often the shorter notation δ for $\delta_{K\pi}$ is also used. Equation (19.2.22) reveals an exponential decay modulated by terms linear and quadratic in t. The differing time development of the three terms — constant, linear, and quadratic — can be used to separate the contributions from DCS decays and decays with mixing. In this approximation, the time-integrated rate, R_{WS}, is then

$$R_{\text{WS}} = R_D + y'\sqrt{R_D} + \frac{x^2 + y^2}{2}. \quad (19.2.24)$$

The mixing rate R_M is defined as $R_M = (x^2 + y^2)/2 = (x'^2 + y'^2)/2$. A mixing-only search (not allowing for CP violation) combines D^0 and $\overline{D}^0$ decays together. To include possible effects from CP violation, both *BABAR* and Belle apply Eq. (19.2.22) to D^0 and $\overline{D}^0$ decays separately, as discussed further in Section 19.2.7.

19.2.2.2 Measurements of $D^0 \to K^+\pi^-$ decays

Belle and *BABAR* used 400 fb^{-1} and 384 fb^{-1}, respectively, in their 2006 and 2007 studies of $K\pi$ WS mixing (Zhang, 2006; Aubert, 2007j). Both experiments used the decay chain $D^{*+} \to \pi_s^+ D^0$, $D^0 \to K^\pm\pi^\mp$, using the large statistics, RS decay $D^0 \to K^-\pi^+$ + c.c. to determine most of the parameters in the $p.d.f.$s used to describe the decay structure in four independent variables: the D^0 candidate mass $m_{K\pi}$, the mass difference Δm (or q), the reconstructed decay time t, and the event-by-event decay time error, σ_t. Both, *BABAR* and Belle perform a "blind" analysis (see Chapter 14), where the analysis procedure is finalized before examining the mixing results.

In both measurements particle identification criteria on charged kaon and pion candidates are imposed, as well as requirements on the quality of selected tracks and/or momentum of slow pions. Belle requires the momentum of the D^0 candidate in the center-of-mass frame to be > 2.7 GeV/c, which reduces the number of candidates

originating in combinatoric background and $B\overline{B}$ events. *BABAR* uses a requirement of 2.5 GeV/c for the same purpose.

Both experiments reconstruct the D^* decay chain by performing a vertex fit of the K and π candidate tracks, and extrapolating the flight direction of the resulting D^0 candidate back to the interaction region; the resulting intersection is taken as the D^* decay vertex (see Fig. 19.2.3). The π_s candidate is constrained to originate from the D^* vertex. Requirements on the χ^2 of all vertex fits are imposed. The resulting decay time t along with its associated uncertainty σ_t is calculated from the fitted vertex positions and their uncertainties, and from the reconstructed D^0 momentum. A typical value of σ_t is (130–160) fs.

Some events have multiple D^* candidates (about 5%).[127] At Belle, the events in which at least two D^* candidates with the opposite charge are found are rejected, which reduces the random π_s background (see below) by about 30% and the signal by 1%. In the case of same-sign D^* candidates, the one with the best vertex fit χ^2 was retained. At *BABAR*, if the D^* candidate shared daughter tracks with other D^* candidates, only the one with the largest $P(\chi^2)$ was used.

There are several background components required in order to correctly describe the two-dimensional RS and WS $(m_{K\pi}, \Delta m)$ or $(m_{K\pi}, q)$ distributions in addition to the signal components. *BABAR* defines three background types: "random π_s" background, where an unassociated π_s candidate is paired with a good D^0 candidate; "misreconstructed D^0" background, where a π_s candidate is paired with a D^0 that was reconstructed incorrectly, either with an incorrect particle hypothesis for one of the daughter tracks, or a multi-body decay reconstructed as a two-body decay; and combinatoric background. In RS events, misreconstructed D^0 candidates are primarily from semileptonic decays; in WS events, from "swapped D^0" candidates which are RS $D^0 \to K\pi$ decays with the K and π particle identifications interchanged.

Belle defines four background types: random π_s (rnd) as above; those with a correct π_s but with a misreconstructed D^0 decaying to (≥ 3)-body final states (d3b); charged D^+ and D_s^+ decays (ds3); and combinatoric background (cmb).

Both Belle and *BABAR* determine the shape of the background $p.d.f.$s from MC simulation and only their amplitudes are allowed to vary in the fits. Signal events peak in both $m_{K\pi}$ and Δm (or q). Random π_s events peak in $m_{K\pi}$ but not Δm (or q). Misreconstructed D^0 decays peak in Δm (or q) but not $m_{K\pi}$. Combinatoric events do not peak in either $m_{K\pi}$ or Δm (or q).

From the fits to the $(m_{K\pi}, \Delta m)$ or $(m_{K\pi}, q)$ distributions Belle finds $1,073,993 \pm 1108$ RS signal events and 4024 ± 88 WS signal events. Fig. 19.2.8 shows $m_{K\pi}$ and q distributions from the Belle analysis for RS and WS data. *BABAR* fits the RS and WS $(m_{K\pi}, \Delta m)$ plane simultaneously using shared parameters that describe the signal and

---

[127] The largest fraction of multiple D^* candidates results from combinations of a single D^0 candidate paired with multiple π_s candidates.

random π_s background. They find $1,141,500 \pm 1200$ RS signal events and 4030 ± 90 WS signal from the fits. Projections of the WS fit to data are shown in Fig. 19.2.9.
Figure 19.2.8. $m_{K\pi}$ and q distributions (Zhang, 2006): (a) RS $m_{K\pi}$ for 0 MeV $< q < 20$ MeV; (b) RS q for 1.81 GeV/$c^2 < m_{K\pi} < 1.91$ GeV/c^2; (c) WS $m_{K\pi}$ for 5.3 MeV $< q < 6.5$ MeV; and (d) WS q for 1.845 MeV/$c^2 < m_{K\pi} < 1.885$ MeV/c^2. Points with error bars represent the data and the histograms different components of the fit.
Figure 19.2.9. $m_{K\pi}$ and Δm distributions (Aubert, 2007j): (a) $m_{K\pi}$ for WS candidates in a signal-enhanced region (0.1445 GeV/$c^2 < \Delta m < 0.1465$ GeV/c^2); (b) Δm for WS candidates in a signal-enhanced region (0.1843 GeV/$c^2 < m_{K\pi} < 1.883$ GeV/c^2). Projections of the fitted signal and background *p.d.f.*s are shown.

The DCS decay parameter $R_{\rm D}$ and the mixing parameters x'^2 and y' are determined using unbinned, maximum-likelihood fits to the WS proper decay-time distribution. The fit is done in several stages in order to fix some of the parameters entering the final fit. The RS distribution is fitted first providing the parameters of the resolution

functions to be used in the fit to the WS decay-time distribution.
Figure 19.2.10. Belle (top, from Zhang, 2006) and *BABAR* (bottom, from Aubert, 2007j) WS decay-time distributions overlaid with projections of fits assuming no *CP* violation. Belle: Data distribution (points with error bars) for WS events in the signal enhanced region $|m_{K\pi} - m_{D^0}| < 22$ MeV/c^2 and $|q - 5.9$ MeV$| < 1.5$ MeV. *BABAR*: (a) Data distribution and fit projections for combined D^0 and $\overline{D}^0$ candidates in the signal enhanced region 1.843 GeV/$c^2 < m_{K\pi} < 1.883$ GeV/c^2 and 0.1445 GeV/$c^2 < \Delta m < 0.1465$ GeV/c^2. The fit result allowing (not allowing) mixing is shown as a solid (dashed) line. (b) Points indicate the difference between the data and the no-mixing fit. The solid curve shows the difference between fits with and without mixing.

The Belle decay-time fit uses a likelihood which is a function of the DCS and mixing parameters $R_{\rm D}$, x'^2, and y'. For event i, it is given by

$$\frac{dP_i}{dt'} =$$
$$\left[f_{\rm sig}^i P_{\rm sig}(t'; R_{\rm D}, x'^2, y') + f_{\rm rnd}^i P_{\rm rnd}(t') \right] \otimes R_{\rm sig}(t_i - t')$$
Figure 19.2.11. Belle (Zhang, 2006) and *BABAR* (Aubert, 2007j) confidence-level contours from the mixing fits. Belle (top): (x'^2, y') 95% confidence-level regions showing the best fit result (point) assuming *CP* conservation. The statistical-only (statistical plus systematic) contour for no *CP* violation is shown as a dotted (dashed) line. The solid line is the statistical plus systematic contour for the *CP*-allowed case. *BABAR* (bottom): Confidence-level contours and fit result (point) for $1 - \text{C.L.} = 0.317(1\sigma)$, $4.55 \times 10^{-2}(2\sigma)$, $2.70 \times 10^{-3}(3\sigma)$, $6.33 \times 10^{-5}(4\sigma)$, and $5.73 \times 10^{-7}(5\sigma)$. The no-mixing point is shown as a "+" sign.

$$+f_{\text{d3b}}^i P_{\text{d3b}}(t') \otimes R_{\text{d3b}}(t_i - t')$$
$$+f_{\text{ds3}}^i P_{\text{ds3}}(t') \otimes R_{\text{ds3}}(t_i - t')$$
$$+f_{\text{cmb}}^i \delta(t') \otimes R_{\text{cmb}}(t_i - t'). \qquad (19.2.25)$$

The f^i fractions are functions of $m_{K\pi}$, q, and σ_t, and are determined on an event-by-event basis. P_j is the expected decay-time distribution for event category j; it is given, for example, by Eq. (19.2.22) for $j = \text{sig}$. R_j is the resolution function for the corresponding events and $\otimes$ denotes the convolution. Signal and random π_s background events have the same resolution function since the slow pion is not used in the vertex fit. *BABAR* models the WS decay-
Figure 19.2.12. *BABAR* (Aubert, 2007j) WS branching fractions R_{WS} for disjoint regions of measured proper time from fits to the $(m_{K\pi}, \Delta m)$ plane (points with error bars). The dashed line shows the expected values of R_{WS} for each slice in proper time assuming the nominal mixing fit results. The χ^2 with respect to the mixing fit expectation is 1.5; assuming the no-mixing hypotheses (a constant R_{WS} for all time slices), the χ^2 is 24.

time behavior as given by Eq. (19.2.22) convolved with the signal resolution function as determined in the RS decay-time fit. The background distribution is modeled in a similar way as in the Belle case. The WS decay time distributions overlaid with the fit projections for both Belle and *BABAR* are shown in Fig. 19.2.10.

Both Belle and *BABAR* present results from fits under three different assumptions: (1) that no mixing or *CP* violation is present; (2) that mixing may be present, but that there is no *CP* violation; and (3) that mixing and *CP* violation may be present. The first two sets of results are shown in Table 19.2.3, while the last is discussed in Section 19.2.7. A large correlation between x'^2 and y' is seen in both experiments: -0.909 (Belle), -0.95 (*BABAR*).

BABAR finds the maximum-likelihood point to be in the non-physical region $x'^2 < 0$. Two-dimensional confidence-level contours (see Fig. 19.2.11) in x'^2 and y' are calculated based on the change in negative log-likelihood values with respect to the no-mixing point for *BABAR* and using the Feldman-Cousins likelihood ratio ordering (Feldman and Cousins, 1998) for Belle.

Systematic uncertainties are included in the contour evaluation as discussed below.

BABAR finds that the fit allowing mixing provides a substantially better result than the one without mixing, as seen in Fig. 19.2.11. The likelihood maximum is at an unphysical value $(x'^2 = -2.2 \times 10^{-4}, y' = 9.7 \times 10^{-3})$. The difference in the χ^2 between the most likely point in the physically allowed region and the no-mixing point $(x'^2 = 0, y' = 0)$ corresponds to a significance for mixing of 3.9σ $(1 - \text{C.L.} = 10^{-4})$ and provides evidence for mixing.[128]

---

[128] Here evidence is regarded as a result with a significance of more than three standard deviations. For the explanation about the significance see Chapter 11.

As a cross-check of the results, *BABAR* performs the no-mixing fit in slices in reconstructed decay time with approximately equal numbers of events. The resulting values of R_D increase with increasing decay time as seen in Fig. 19.2.12. The rate of increase is consistent with the measured mixing parameters and inconsistent with the no-mixing hypothesis.

Table 19.2.3. $D^0 - \overline{D}^0$ mixing results using $D^0 \to K\pi$ WS decays. When two uncertainties are given, the first is statistical and the second systematic. Results with a single uncertainty have both statistical and systematic components combined.

Parameter	Fit Results ($\times 10^{-3}$)	
	BABAR	Belle
	(Aubert, 2007j)	(Zhang, 2006)
	Assuming no mixing or *CP* violation	
R_D	$3.53 \pm 0.08 \pm 0.04$	$3.77 \pm 0.08 \pm 0.05$
	Assuming mixing but no *CP* violation	
R_D	$3.03 \pm 0.16 \pm 0.10$	3.64 ± 0.17
x'^2	$-0.22 \pm 0.30 \pm 0.21$	$0.18^{+0.21}_{-0.23}$
y'	$9.7 \pm 4.4 \pm 3.1$	$0.6^{+4.0}_{-3.9}$
Significance	3.9	2.0

Some of the sources of systematic uncertainties investigated are event yields, background modeling, and decay-time *p.d.f.* models. Belle also investigated the effects of changing selection criteria such as particle-identification criteria, vertex fit χ^2 requirement, and D^* momentum selection, which cause the signal-to-background rates to change.

The effect of each individual systematic variation was calculated from the change in $-2\Delta \ln \mathcal{L}$ evaluated in the (x'^2, y') plane between the nominal fit point and the new fit point of the variation under test. This value was scaled by a factor of 2.3, $\chi^{2'} \equiv -2\Delta \ln \mathcal{L}/2.3$, to yield the 68% confidence level for a single variable. The largest Belle systematic is from the D^* momentum requirement with $\chi^{2'} = 0.083$. When shifts from all systematic checks are added in quadrature, the overall scale factor is $\sqrt{1 + \sum \chi_i^{2'}} = 1.12$ which is used to scale the 95% C.L. contours as shown in Fig. 19.2.11. As a cross-check, Belle finds the results for the two SVD subsamples to be within 0.6σ of each other.

BABAR estimated systematic uncertainties and included them in the evaluation of contours in a manner similar to that of Belle, finding the largest contribution to $\sqrt{1 + \sum \chi_i^{2'}} = 1.3$ to be 0.06 from the modeling of the long decay-time component of background D decays in the signal region. A non-zero mean value of 3.6 fs for the decay-time was found and is attributed to detector misalignments; this contributes 0.05 to the systematic uncertainty.

BABAR validated the fitting procedure on MC data using both the full detector simulation and on ensembles of large parameterized (simulated MC) samples. The fit was found to be unbiased in all cases. A fit allowing for mixing

in the RS sample was performed and no significant mixing was observed, as expected. The staged fitting procedure was cross-checked by performing a single simultaneous fit in which all parameters were allowed to vary; results were consistent with the nominal fitting procedure.

19.2.2.3 Measurements of the $D^0 \to K^+\pi^-\pi^+\pi^-$

The advantages of the $K3\pi$ mode relative to $K\pi$ are its larger branching fraction (about 8.1% compared to 3.9% for $K\pi$) (Nakamura et al., 2010) and the improvement obtained in decay vertex resolution with four charged tracks instead of two (0.15–0.16 ps compared to 0.17–0.18 ps for $K\pi$ and KK).[129] On the other hand, the strong phase difference of the decay varies over its four-body phase space, making a simple interpretation of an average mixing rate measured over all of the phase space problematic. Possible approaches to this problem include limiting the measurement to specific regions of interest in phase space or performing a four-body, time-dependent fit to the decay using amplitude models. As with mixing studies using the $K\pi$ decay, *CP* violation can also be searched for by analyzing the difference between D^0 and $\overline{D}^0$ decays.

BABAR has reported preliminary results from a time-dependent analysis of the four-body decay $D^0 \to K^+\pi^-\pi^+\pi^-$ using a 230 fb^{-1} data sample (Aubert, 2006ap). The analysis is very similar to time-dependent analyses of $D^0 \to K\pi$. "Tagged" events (where the decay chain $D^{*+} \to \pi_s D^0$ is reconstructed) are used to determine the production flavor of the D^0 candidate via the charge of the slow pion π_s. The variables of interest are the reconstructed D^0 candidate mass $m_{K\pi\pi\pi}$, the mass difference Δm between the reconstructed D^{*+} and the D^0 candidate, and the decay time t and its uncertainty σ_t.

The D^{*+} and D^0 candidate masses and vertices are obtained from a vertex fit to the decay chain using a beam spot constraint. The fit to the entire chain is required to have large enough probability calculated from the fit χ^2, $P(\chi^2) > 0.01$. The D^0 proper decay time t is obtained from the vertex fit along with its uncertainty σ_t. A requirement is imposed on the decay time uncertainty of $\sigma_t < 0.5$ ps. Unbinned extended maximum-likelihood fits are performed to both right-sign and wrong-sign candidates. Two-dimensional distributions in $(m_{K\pi\pi\pi}, \Delta m)$ are fitted to a combination of *p.d.f.*s that describe the signal shapes and background contributions. The large amount of right-sign signal is used to determine the signal shape parameters for the wrong-sign signal. Approximately 3.5×10^5 right-sign signal candidates are found are found in each, D^0 and $\overline{D}^0$ sample, and about 1100 wrong-sign signal candidates for each. Backgrounds include "bad slow pion" events, where a properly-reconstructed D^0 has been paired with an unassociated pion; this background

---

[129] The improvement w.r.t. two body decays is less than a factor of $1/\sqrt{2}$ because of the lower momentum of the 4 tracks and thus increased multiple scattering.

source peaks in $m_{K\pi\pi}$ but not in Δm. Another background comes from D^0's where the kaon and one of the pions are interchanged, but the D^{*+} is otherwise correctly reconstructed. This source peaks in Δm only. The remaining background component is combinatoric, which has no peaking behavior.

Fits to the decay time distributions are performed. Analogously to Eq. (19.2.22) the wrong-sign time-dependence is fitted to

$$\frac{\Gamma_{\mathrm{WS}}(t)}{\Gamma_{\mathrm{RS}}(t)} = \widetilde{R}_D + \alpha \widetilde{y}' \sqrt{\widetilde{R}_D}(\Gamma t) + \frac{(x^2+y^2)}{4}(\Gamma t^2). \quad (19.2.26)$$

Quantities that are integrated over all or part of phase space are indicated by a tilde. α is a factor describing the suppression due to the strong phase variation over the phase space. Both a CP-conserving fit which considers D^0 and $\overline{D}^0$ candidates together and a fit that is potentially sensitive to CP violation which treats them separately are performed. A description of the latter is given in Section 19.2.7.

Systematics are evaluated by changing various parts of the analysis, including the σ_t selection, the *p.d.f.* parameterization of the decay time resolution function, background *p.d.f.* shapes, and the measured D^0 lifetime value. In the latter, the fitted lifetime value is fixed in the fit to the PDG value. Combined systematics are smaller than the statistical errors on the measured quantities by about a factor of five.

Assuming CP conservation, the *BABAR* preliminary analysis (Aubert, 2006ap) yields a measurement of R_M and the interference term $\alpha \widetilde{y}'$ of

$$R_M = [0.019^{+0.016}_{-0.015}(\mathrm{stat}) \pm 0.002(\mathrm{syst})]\%$$
$$\alpha \widetilde{y}' = -0.006 \pm 0.005(\mathrm{stat}) \pm 0.001(\mathrm{syst}) \quad (19.2.27)$$

which are consistent with the no-mixing hypothesis at the 4.3% confidence level. Results of the fit allowing for CP violation are given in Section 19.2.7.

Two-dimensional coverage probabilities of 68.3% and 95.0% ($\Delta \log \mathcal{L} = 1.15, 3.0$, respectively) are shown in Fig. 19.2.13 for the doubly Cabibbo-suppressed rate $\widetilde{R}_D$ vs. the mixing rate R_M, and for the interference term $\alpha \widetilde{y}'/\sqrt{x^2+y^2}$ vs. R_M.

19.2.2.4 Summary on hadronic wrong-sign decays

The measurements of decay time distributions in $D^0 \to K^+\pi^-$ decays played an important role in the initial searches and finally in the experimental discovery of the mixing phenomena in the neutral D meson system. It should be noted that neither of the B Factory experiments have performed measurements using their full data set, this remains a task for the future. The uncertainties of determinations of x'^2 and y' on measurements made with larger data sets will be, most probably, dominated
Figure 19.2.13. Likelihood contours for the CP conserving fit for $\widetilde{R}_D$ (top, from (Aubert, 2006ap)) and for the interference term (bottom, *BABAR* internal, from the (Aubert, 2006ap) analysis) vs. the mixing rate R_M. Solid line: $\Delta \ln \mathcal{L} = 1.15$; dotted line: $\Delta \ln \mathcal{L} = 3.0$.

by experimental systematic uncertainties. The same measurements provide important insights into a possible CP violation in the $D^0 - \overline{D}^0$ system as discussed further in Section 19.2.7.

It should be noted that an analysis of wrong-sign decays $D^0 \to K^+\pi^-\pi^0$ has also been made by the *BABAR* collaboration and is described in the section on decay time dependent Dalitz analyses, Section 19.2.4.1.

19.2.3 Decays to *CP* eigenstates

19.2.3.1 Method

If *CP* is conserved, $q = p \equiv \frac{1}{\sqrt{2}}$, and the mass eigenstates $|D_{1,2}\rangle = \frac{1}{\sqrt{2}}(|D^0\rangle \pm |\overline{D}^0\rangle)$ are *CP*-even and *CP*-odd; they decay with the lifetimes $\tau_1 = 1/\Gamma_1$ and $\tau_2 = 1/\Gamma_2$, respectively, into *CP*-even and *CP*-odd final states, obeying a simple exponential law, see Eq. (19.2.8). On the other hand the time evolution of decays to flavor specific final states is approximately exponential only for the Cabibbo-favored decays, like $D^0 \to K^-\pi^+$. In this case Eqs (19.2.13) simplify due to the fact that $|\overline{A}_f/A_f| \ll 1$ (and $|A_{\overline{f}}/A_{\overline{f}}| \ll 1$). Because of typically strong Cabibbo suppression one can neglect the Γt and $(\Gamma t)^2$ terms in Eqs (19.2.13).[130] Hence the decay time distribution is approximately exponential with a lifetime of $\tau_{\mathrm{FS}} = 1/\Gamma$, where τ_{FS} denotes the lifetime for decays into flavor specific final state.

The quantity which represents the relative lifetime difference between decays to *CP* and flavor specific final states is obtained experimentally as:

$$y_{CP} = \eta_{CP}\left(\frac{\tau_{\mathrm{FS}}}{\tau_{CP}} - 1\right), \qquad (19.2.28)$$

where $\eta_{CP} = +1\,(-1)$ for *CP*-even (*CP*-odd) final state, and τ_{CP} is the lifetime of decays to a *CP* final state. In the limit of *CP* conservation τ_{CP} equals the lifetime of the corresponding mass eigenstate, τ_1 if $\eta_{CP} = +1$ or τ_2 if $\eta_{CP} = -1$, and hence y_{CP} equals the mixing parameter y. If *CP* is violated y_{CP} obtains a contribution from x:

$$y_{CP} = y\cos\phi - \frac{1}{2}\left(A_M - A_D^f\right)x\sin\phi, \qquad (19.2.29)$$

with A_M and A_D^f defined in Eqs (19.2.17) and (19.2.18) and $\phi = \arg(q/p)$. We assume here that *CP* violation is small, *i.e.* $A_M, A_D^f \ll 1$, so that the time evolution is still well described by an exponential law.

To derive equation (19.2.29) one starts with Eqs (19.2.11) and (19.2.12); after squaring the modulus we obtain:

$$\frac{d\Gamma_{D^0 \to f}}{dt} \propto \left(1 - \mathrm{Re}\left[\lambda_f(ix+y)\right]\Gamma t\right)e^{-\Gamma t} \qquad (19.2.30)$$

and

$$\frac{d\Gamma_{\overline{D}^0 \to f}}{dt} \propto \left(1 - \mathrm{Re}\left[\lambda_f^{-1}(ix+y)\right]\Gamma t\right)e^{-\Gamma t}, \qquad (19.2.31)$$

where

$$\lambda_f = \frac{q}{p}\frac{\overline{A}_f}{A_f} \approx \eta_{CP}\left(1 + \frac{1}{2}\left[A_M - A_D^f\right]\right)e^{i\phi}. \qquad (19.2.32)$$

---

[130] For example, in $D^0 \to K^-\pi^+$ decays $|\overline{A}_{K^-\pi^+}/A_{K^-\pi^+}| = (5.75 \pm 0.07) \times 10^{-2}$ (Amhis et al., 2012). The decay time distribution $[d\Gamma(D^0 \to K^-\pi^+) + d\Gamma(\overline{D}^0 \to K^+\pi^-)]/dt \propto [1 - |\overline{A}_{K^-\pi^+}/A_{K^-\pi^+}|\,y\cos\delta_{K\pi}\,\Gamma t]e^{-\Gamma t}$, where $|\overline{A}_{K^-\pi^+}/A_{K^-\pi^+}|\,y\cos\delta_{K\pi} = 2.3 \times 10^{-5}$ (Amhis et al., 2012).

Then, Eqs (19.2.30) and (19.2.31) are added together, since in this particular measurement no distinction is made between two possible initial D^0 flavors (for measurements of *CP* violation in such decays, where one tags the flavor of the initial D^0, see Section 19.2.7). We obtain:

$$\frac{d\Gamma}{dt} \propto \left(1 - \eta_{CP}\left[y\cos\phi - \frac{1}{2}\left(A_M - A_D^f\right)x\sin\phi\right]\Gamma t\right)e^{-\Gamma t}. \qquad (19.2.33)$$

The expression in front of $e^{-\Gamma t}$ can be regarded as a linear expansion of another exponential function, since $x, y \ll 1$. Denoting the expression in the square brackets by y_{CP} one obtains

$$\frac{d\Gamma}{dt} \propto e^{-\eta_{CP}y_{CP}\Gamma t}e^{-\Gamma t} = e^{-(1+\eta_{CP}y_{CP})\Gamma t}. \qquad (19.2.34)$$

Comparison of the decay time for decays into *CP* eigenstates from the above equation, $\tau_{CP} = 1/[\Gamma(1+\eta_{CP}y_{CP})]$, to the average decay time for decays to flavor specific final states $\tau_{\mathrm{FS}} = 1/\Gamma$ yields Eq. (19.2.28).

The measured proper decay time distribution can be written as:

$$\frac{dN}{dt} = \frac{N}{\tau}\int_0^\infty R(t-t')e^{-t'/\tau}dt' + B(t), \qquad (19.2.35)$$

where R is a resolution function and $B(t)$ is a background distribution.

The most suitable decays to measure y_{CP} are the *CP*-even decays $D^0 \to K^+K^-$ and $D^0 \to \pi^+\pi^-$, because of their relatively large branching fractions and since the flavor specific decay $D^0 \to K^-\pi^+$ is kinematically similar. The latter is important in reducing the systematic uncertainty due to resolution function parameterization. Both *BABAR* and Belle have found that up to an overall scale factor in the width, the resolution function has the same shape for all three modes, including its offset t_0.

Among the *CP*-odd decays, $D^0 \to K_s^0\omega$ with $\omega \to \pi^+\pi^-\pi^0$ and $D^0 \to K_s^0\phi$ with $\phi \to K^+K^-$ have the largest branching fractions. Both resonances are also narrow. The drawbacks of these decays are smaller reconstruction efficiency due to K_s^0 and π^0 reconstruction, a contribution of other resonances which interfere with the ω or ϕ, and large differences in the kinematics compared to $D^0 \to K^-\pi^+$. Up to now only the measurement of $D^0 \to K_s^0\phi$ has been reported (see Section 19.2.3.3).

19.2.3.2 Results for the $D^0 \to KK/\pi\pi$

During the search for *CP* violation in charm decays, the observable y_{CP} has been measured by a number of experiments. In 2000 the interest of the scientific community was triggered by the result of the FOCUS collaboration, which observed a high value of the parameter, albeit with a rather large statistical uncertainty (Link et al., 2000). The excitement subsided in 2002 following the measurements from CLEO (Csorna et al., 2002) and Belle (Abe, 2002a) providing more precise values consistent with zero. The latter measurement was performed on an untagged

sample of D meson decays, the method is explained in more detail below. The year 2007 marks the start of the era of sub-percent accuracy measurements of y_{CP} using the large B Factories data samples resulting in a number of statistically significant results.

The Belle collaboration measured y_{CP} (Staric, 2007) using tagged samples. The $D^{*+} \to D^0 \pi_s^+$ decays are reconstructed with a slow pion π_s, and $D^0 \to K^+ K^-$, $K^- \pi^+$, and $\pi^+ \pi^-$.

The proper decay time of the D^0 candidate is calculated as described in Section 19.2.1.5. Selection based on the the $D^{(*)}$ momentum in the CM system as described there is also applied. The decay time uncertainty σ_t is evaluated event-by-event from the covariance matrices of the production and decay vertices, as explained in Section 6. Candidate D^0 mesons are selected using the invariant mass of the D^0 decay products, M, and the energy released in the D^{*+} decay, q.

According to Monte Carlo simulated distributions of t, M, and q, background events fall into four categories: (1) combinatorial, with zero apparent lifetime; (2) true D^0 mesons combined with random slow pions (this has the same apparent lifetime as the signal) (3) D^0 decays to three or more particles, and (4) other charm hadron decays. The apparent lifetime of the latter two categories is 10–30% larger than τ_{D^0}.

The sample of events for the lifetime measurements is selected using $|\Delta M|/\sigma_M$, where $\Delta M \equiv M - m_{D^0}$; $|\Delta q| \equiv q - (m_{D^{*+}} - m_{D^0} - m_\pi)c^2$; and σ_t. The invariant mass resolution σ_M varies from 5.5–6.8 MeV/c^2, depending on the decay channel. Selection criteria are chosen to minimize the expected statistical error on y_{CP}, using the MC: Belle requires $|\Delta M|/\sigma_M < 2.3$, $|\Delta q| < 0.80$ MeV, and $\sigma_t < 370$ fs. Using 540 fb^{-1} of data, they find 111×10^3 $K^+ K^-$, 1.22×10^6 $K^- \pi^+$, and 49×10^3 $\pi^+ \pi^-$ signal events, with purities of 98%, 99%, and 92% respectively.

The mixing parameter y_{CP} is determined from the binned maximum likelihood fit performed simultaneously to decay time distributions of all three decay modes. The resolution function of a single event is determined from the estimated accuracy of proper decay time σ_t as obtained from the covariance matrices of the vertex fits. Ideally, it is described by a normalized Gaussian distribution with a zero mean and with width equal to σ_t. However, such a description is not sufficient because of multiple scattering of final state particles in the detector material, which causes the tails of the distribution to increase. To parameterize the tails, one or two additional Gaussian terms are needed, which share a common mean t_0 and have widths proportional to σ_t. The common mean can be offset from zero due to detector misalignment. The parameterization for a single event thus reads:

$$R(t) = \sum_{k=1}^{n_g} w_k G(t; t_0, \sigma_k), \qquad (19.2.36)$$

where $G(t; t_0, \sigma_k) = \frac{1}{\sqrt{2\pi}\sigma_k} e^{-(t-t_0)^2/2\sigma_k^2}$ are the normalized Gaussian distributions, $\sigma_k = s_k \sigma_t$ are the widths, w_k are their fractions and n_g is the number of Gaus-
Figure 19.2.14. Normalized distribution of errors σ_t on the decay time t showing the construction of the resolution function using the fraction f_i in the bin with $\sigma_t = \sigma_i$. Belle internal, from the Staric (2012a) analysis.

sian terms (usually $n_g = 3$). This parameterization has the following free parameters: t_0, s_k, $k = 1, ..., n_g$ and w_k, $k = 1, ..., n_g - 1$. Parameters s_k and w_k are highly correlated, causing the fit to sometimes have problems converging. In order to ensure stable fitting the fractions w_k can be fixed, using MC simulation, from a fit to the distribution of pulls, *i.e.* the normalized residuals $(t - t_{\text{gen}})/\sigma_t$, where t_{gen} is the generated proper decay time of an event.

The form Eq. (19.2.36) is suitable for use in an unbinned maximum likelihood fit (see Chapter 11). The equivalent parameterization can be derived for a binned maximum likelihood fit. In this case we first construct the normalized distribution of σ_t by binning the events in a histogram. Such a distribution is shown in Fig. 19.2.14: a bin i corresponds to a fraction f_i of events with a time resolution $\sigma_t = \sigma_i$. The resolution function for the binned fit is thus:

$$R(t) = \sum_{i=1}^{n} f_i \sum_{k=1}^{n_g} w_k G(t; t_0, \sigma_{ki}), \qquad (19.2.37)$$

where $\sigma_{ki} = s_k \sigma_i$ and the first sum runs over bins i of the σ_t distribution. Note, that Eq. (19.2.37) has the same free parameters as Eq. (19.2.36).

The resolution function shape including the offset t_0 is found to be the same for all three considered decay modes. To account for small differences in the widths of resolution functions among various decay modes, two parameters S_{KK} and $S_{\pi\pi}$ are introduced to scale the overall width of the KK and $\pi\pi$ resolution functions relative to the width of the $K\pi$ resolution function. All other parameters can be shared among the different modes and can be determined by a simultaneous fit to all modes together.

The background term in Eq. (19.2.35) is parameterized assuming two lifetime components: an exponential and a δ function, each convolved with corresponding resolution functions as parameterized by Eq. (19.2.37). Separate $B(t)$

Figure 19.2.16. From (Aubert, 2009v). *BABAR* results of the simultaneous fit to decay time distributions of untagged samples: $D^0 \to K^- \pi^+$ (left) and $D^0 \to K^+ K^-$ (right).
Figure 19.2.15. From (Staric, 2007). Belle results of the simultaneous fit to decay time distributions of (a) $D^0 \to K^+ K^-$, (b) $D^0 \to K^- \pi^+$ and (c) $D^0 \to \pi^+ \pi^-$ decays. The cross-hatched area represents background contributions, the shape of which was fitted using M sideband events. (d) Ratio of decay time distributions between $D^0 \to K^+ K^-, \pi^+ \pi^-$ and $D^0 \to K^- \pi^+$ decays. The solid line is a fit to the data points and the dashed line represents the no-mixing hypothesis.

parameters for each final state are determined by fits to the t distributions of events in M sidebands. The MC is used to select the sideband region that best reproduces the timing distribution of background events in the signal region.

The results of a simultaneous fit are shown in Fig. 19.2.15. The fitted lifetime of $D^0 \to K^- \pi^+$, $\tau = (408.7 \pm 0.6(\text{stat}))$ fs, is consistent with the world average of (410.1 ± 1.5) fs. The value of y_{CP} is determined to be $y_{CP} = (1.31 \pm 0.32(\text{stat}) \pm 0.25(\text{syst}))\%$.

This result and the *BABAR* result in the $D^0 \to K^+ \pi^-$ decays, described in Section 19.2.2 represent the first experimental evidence for $D^0 - \bar{D}^0$ mixing.

Belle performed an updated measurement of $D^0 \to KK/\pi\pi$ decay modes using the full available data sample (Staric, 2012a). Using a larger data sample a small bias on the measured lifetime depending on the D meson polar angle in the CM system, θ^*, is observed. It is a consequence of small residual misalignments between the Belle tracking detectors. To reduce the systematic uncertainty due to such effects the measurement is performed in bins of $\cos\theta^*$ and the final value of y_{CP} is obtained as a weighted average of the values in individual bins. The final result is

$$y_{CP} = (1.11 \pm 0.22(\text{stat}) \pm 0.11(\text{syst}))\%, \qquad (19.2.38)$$

the significance of which is above five standard deviations considering the statistical uncertainty alone, and 4.5 σ including systematic uncertainties.
The *BABAR* analysis of the tagged samples (Aubert, 2008n) is similar to the Belle analysis. *BABAR* has used 384 fb^{-1} of data and an unbinned maximum likelihood fit performed simultaneously to the $K^+ K^-$, $K^- \pi^+$ and $\pi^+ \pi^-$ decay modes. The main difference with respect to the Belle analysis is the form of the resolution function used, Eq. (19.2.36). The result obtained is

$$y_{CP} = (1.24 \pm 0.39(\text{stat}) \pm 0.13(\text{syst}))\%, \qquad (19.2.39)$$

which is also evidence for $D^0 - \bar{D}^0$ mixing.

BABAR has also performed an additional method: here y_{CP} is measured using the untagged samples of $D^0 \to K^+ K^-$ and $D^0 \to K^- \pi^+$ (Aubert, 2009v). The event selection is similar to the tagged analysis except that the D^{*+} is not reconstructed. The background is much higher compared to the tagged analysis, as can be seen by comparing Fig. 19.2.15 and Fig. 19.2.16 for the corresponding decay modes. However, the signal yields compared to the tagged analysis are about five times higher. *BABAR* uses the same fitting procedure as in the tagged analysis; the fit is shown in Fig. 19.2.16. The result on 384 fb^{-1} of data is consistent with previous measurements, but with smaller statistical and higher systematic errors: $y_{CP} = (1.12 \pm 0.26(\text{stat}) \pm 0.22(\text{syst}))\%$. The significance of the result is 3.3 σ.

The above result is superseded by a similar analysis using 468 fb^{-1} (Lees, 2013d) which uses both untagged (for the y_{CP} measurement) and tagged (for A_Γ; see Section 19.2.7) D^0 decays:

$$y_{CP} = (0.72 \pm 0.18(\text{stat}) \pm 0.12(\text{syst}))\%. \qquad (19.2.40)$$

19.2.3.3 Results for the $D^0 \to K_S^0 \phi$

A large fraction of $D^0 \to K_S^0 K^+ K^-$ decays proceed via intermediate CP-odd $K_S^0 \phi$ and CP-even $K_S^0 a_0$ resonant states. Measurement of the apparent lifetimes $\tau_{K_S^0 \phi}$ and $\tau_{K_S^0 a_0}$ of candidates populating the ϕ and a_0 regions in the Dalitz plot, respectively, allows for the extraction of
Figure 19.2.17. From (Zupanc, 2009). Projections of time integrated Dalitz distribution (solid black line) to s_0 and contributions of CP-even and CP-odd amplitudes, $|\mathcal{A}_1|^2$ (dotted blue line) and $|\mathcal{A}_2|^2$ (dashed red line), respectively.

the mixing parameter y_{CP} as

$$y_{CP} \equiv \frac{\Gamma_{CP-\text{even}} - \Gamma_{CP-\text{odd}}}{\Gamma_{CP-\text{even}} + \Gamma_{CP-\text{odd}}}$$
$$= \frac{\tau_{K_S^0 \phi} - \tau_{K_S^0 a_0}}{\tau_{K_S^0 \phi} + \tau_{K_S^0 a_0}}. \qquad (19.2.41)$$

The above equation follows directly from the definition of Eq. (19.2.28), noting that $\tau_{CP=\pm1} = \tau/(1 \pm y_{CP})$.

However, as shown in Fig. 19.2.17, it is impossible to identify the CP value of the final state of an individual $D^0 \rightarrow K_S^0 K^+ K^-$ decay, since the a_0 contribution also populates the region $s_0 \equiv M_{K^+K^-}^2$ below the ϕ peak and vice versa. In order to extract the y_{CP} parameter correctly the CP content of each region needs to be estimated.

The time-dependent decay amplitudes of three-body decays of D^0 and $\overline{D}^0$ mesons to self-conjugated final states are described in detail in Section 19.2.4 and are given by

$$\frac{d\Gamma(D^0)}{ds_0 ds_+ dt} = e^{-t/\tau} \Bigg[|\mathcal{A}_1(s_0, s_+)|^2\, e^{(1+y)} \qquad (19.2.42)$$

$$+ |\mathcal{A}_2(s_0, s_+)|^2\, e^{(1-y)}$$

$$+ 2\mathrm{Re}\left[\mathcal{A}_1(s_0, s_+)\mathcal{A}_2^*(s_0, s_+)\right] \cos\left(\frac{xt}{\tau}\right)$$

$$+ 2\mathrm{Im}\left[\mathcal{A}_1(s_0, s_+)\mathcal{A}_2^*(s_0, s_+)\right] \sin\left(\frac{xt}{\tau}\right) \Bigg]$$

$$\frac{d\Gamma(\overline{D}^0)}{ds_0 ds_+ dt} = e^{-t/\tau} \Bigg[\left|\overline{\mathcal{A}}_1(s_0, s_+)\right|^2 e^{(1+y)} \qquad (19.2.43)$$

$$+ \left|\overline{\mathcal{A}}_2(s_0, s_+)\right|^2 e^{(1-y)}$$

$$+ 2\mathrm{Re}\left[\overline{\mathcal{A}}_1(s_0, s_+)\overline{\mathcal{A}}_2^*(s_0, s_+)\right] \cos\left(\frac{xt}{\tau}\right)$$

$$+ 2\mathrm{Im}\left[\overline{\mathcal{A}}_1(s_0, s_+)\overline{\mathcal{A}}_2^*(s_0, s_+)\right] \sin\left(\frac{xt}{\tau}\right) \Bigg],$$

where $\tau = 1/\Gamma$ is the D^0 lifetime, s_0 and s_+ are the invariant masses squared of K^+K^- and $K_S K^+$ pairs, respectively. The decay amplitudes $\mathcal{A}_1$ and $\mathcal{A}_2$ can be expressed with D^0 and $\overline{D}^0$ decay amplitudes $\mathcal{A}$ and $\overline{\mathcal{A}}$ as $\mathcal{A}_1(s_0, s_+) = [\mathcal{A}(s_0, s_+) + \overline{\mathcal{A}}(s_0, s_+)]/2$ and $\mathcal{A}_2(s_0, s_+) = [\mathcal{A}(s_0, s_+) - \overline{\mathcal{A}}(s_0, s_+)]/2$. In the isobar model (see Chapter 13) the amplitudes $\mathcal{A}$ and $\overline{\mathcal{A}}$ are written as the sum of intermediate decay channel amplitudes (denoted by the subscript r) with the same final state, $\mathcal{A}(s_0, s_+) = \sum_r a_r e^{i\phi_r} \mathcal{A}_r(s_0, s_+)$ and $\overline{\mathcal{A}}(s_0, s_+) = \sum_r \overline{a}_r e^{i\overline{\phi}_r} \overline{\mathcal{A}}_r(s_0, s_+) = \sum_r a_r e^{i\phi_r} \mathcal{A}_r(s_0, s_-)$, where CP conservation in decay has been assumed in the final step. If r is a CP eigenstate, then $\mathcal{A}_r(s_0, s_-) = \pm\mathcal{A}_r(s_0, s_+)$, where the sign $+(-)$ holds for a CP-even(-odd) eigenstate. Hence the amplitude $\mathcal{A}_1$ is CP-even, and the amplitude $\mathcal{A}_2$ is CP-odd. According to our current knowledge of the decay dynamics of $D^0 \rightarrow K_S^0 K^+ K^-$ decays, their Dalitz model includes five CP-even intermediate states: $K_S^0 a_0^0(980)$, $K_S^0 f_0(1370)$, $K_S^0 f_2(1270)$, $K_S^0 a_0^0(1450)$, $K_S^0 f_0(980)$); one CP-odd intermediate state ($K_S^0 \phi(1020)$); and three flavor-specific intermediate states ($K^- a_0^+(980)$, $K^- a_0^+(1450)$, $K^+ a_0^-(980)$) (Aubert, 2008l).

Upon squaring Eqs (19.2.42) and (19.2.43) and integrating over s_+, we obtain for the time-dependent decay rates of initially produced D^0 and $\overline{D}^0$ (e.g. untagged sample):

$$\frac{d\Gamma}{dt ds_0} \propto a_1(s_0) e^{-\frac{t}{\tau}(1+y)} + a_2(s_0) e^{-\frac{t}{\tau}(1-y)}, (19.2.44)$$

where $a_{1,2}(s_0) = \int |\mathcal{A}_{1,2}(s_0, s_+)|^2 ds_+$. When integrating the time-dependent decay rate over s_+, all terms depending on the mixing parameter x (e.g. $\mathrm{Re}\,[A_1 A_2^*]\cos(xt/\tau)$) drop out (see the Appendix in Zupanc, 2009). The two terms in Eq. (19.2.44) have a different time dependence as well as a different s_0 dependence (see Fig. 19.2.17). In any given s_0 interval, $\mathcal{R}$, and assuming $y \ll 1$, the effective D^0 lifetime is

$$\tau_{\mathcal{R}} = \tau \left[1 + (1 - 2f_{\mathcal{R}}) y_{CP}\right], \qquad (19.2.45)$$

where $f_{\mathcal{R}} = \int_{\mathcal{R}} a_1(s_0) ds_0 / \int_{\mathcal{R}} (a_1(s_0) + a_2(s_0)) ds_0$, which represents the effective fraction of the events in the interval $\mathcal{R}$ due to the $\mathcal{A}_1$ amplitude. In Eq. (19.2.45) we introduced the usual notation y_{CP} for the mixing parameter y to indicate that we assumed CP conservation in deriving Eq. (19.2.44).

The mixing parameter y_{CP} can thus be determined from the relative difference in the effective lifetimes of the two s_0 intervals, one around the $\phi(1020)$ peak (interval ON) and the other in the sideband (interval OFF). Using Eq. (19.2.45) and taking into account the fact that $[1 - (f_{\text{ON}} + f_{\text{OFF}})]y_{CP} \ll 1$, we obtain

$$y_{CP} = \frac{1}{f_{\text{ON}} - f_{\text{OFF}}} \left(\frac{\tau_{\text{OFF}} - \tau_{\text{ON}}}{\tau_{\text{OFF}} + \tau_{\text{ON}}}\right). \qquad (19.2.46)$$

According to the Dalitz model of $D^0 \rightarrow K_S^0 K^+ K^-$ decays given in (Aubert, 2008l), the difference in $f_{\text{ON}} - f_{\text{OFF}}$ is -0.753 ± 0.004 for the ON region given by $M_{K^+K^-} \in$

$[1.015, 1.025]\,\mathrm{GeV}/c^2$ and the OFF region given by the union of intervals $M_{K^+K^-} \in [2m_{K^\pm}, 1.010]\,\mathrm{GeV}/c^2$ and $M_{K^+K^-} \in [1.033, 1.100]\,\mathrm{GeV}/c^2$.

The advantage of this method over the time-dependent Dalitz analysis (described in Section 19.2.4) is that it can be performed on the much larger untagged sample of D^0 decays providing better sensitivity on the mixing-related parameter y_{CP}. The disadvantage is that the sensitivity to the mixing parameter x is lost.

Belle performed a measurement of y_{CP} using this method on a data sample corresponding to 673 fb^{-1} (Zupanc, 2009). They find $(72.3 \pm 0.4) \times 10^3$ untagged signal D^0 candidates in the ON region and $(62.3 \pm 0.7) \times 10^3$ events in the OFF region. The proper decay time of the D^0 candidate is reconstructed as described in Section 19.2.1.5. However it is worth noting, that Belle determines the D^0 decay position by fitting only one of the charged kaons with the neutral kaon to a common vertex. The reason for using only $K_S^0 K^\pm$ pairs for the D^0 decay vertex reconstruction, despite the worse resolution, is the strong correlation between the K^+K^- invariant mass $M_{K^+K^-}$ and the mean proper decay time $\bar{t}$ of D^0 mesons that has been observed around m_ϕ in simulations if the vertex was reconstructed from $K_S^0 K^+ K^-$ or from $K^+ K^-$ pairs (see Fig. 19.2.18). If not accounted for, this correlation could have biased the measurement of y_{CP}, and it may be explained as follows. Consider a K^+K^- pair from the decay of a ϕ resonance. The reconstructed invariant mass $M_{K^+K^-}$ of the pair is determined from the relation $M_{K^+K^-}^2 = 2m_{K^\pm}^2 + 2E_{K^+}E_{K^-} - 2p_{K^-}p_{K^+}\cos\alpha_{\mathrm{rec}}$, where $p_{K^\pm}$ and $E_{K^\pm}$ are the momenta and energies of $K^\pm$, and α_{rec} is the reconstructed opening angle between K^+ and K^-. If α_{rec} is bigger (smaller) than the true opening angle α because of, for example, the Coulomb multiple scattering of $K^\pm$ in the detector material, $M_{K^+K^-}$ is shifted to higher (lower) values. Conversely, because of the narrow ϕ resonance, $m(K^+K^-) \lesssim m_\phi$ implies $\alpha_{\mathrm{rec}} \lesssim \alpha$ for the majority of K^+K^- pairs from $\phi(1020)$. In addition, $\alpha_{\mathrm{rec}} \lesssim \alpha$ also implies $L_{\mathrm{rec}} \lesssim L$ and thus $t_{\mathrm{rec}} \lesssim t$, which then explains the correlation between $M_{K^+K^-}$ and $\bar{t}$.

The uncertainties on the vertices of the production and decay of D^0 mesons are reflected in the uncertainties on the reconstructed decay time t_{rec}. The widths (RMS) of the resolution function are $1.35\tau_{D^0}$ and $1.65\tau_{D^0}$ when using the $K_S^0 K^+ K^-$ vertex and the $K_S^0 K^\pm$ vertex, respectively.

In Section 19.2.1.5 a typical p.d.f. used in a likelihood fit to the decay time distribution in charm mixing measurements is given (see Eq. 19.2.21). There exists a simpler and more robust method adopted in the analysis by Belle which has similar statistical sensitivity but does not require detailed knowledge of the resolution function or the time distribution of backgrounds. The average of the convolution is the sum of the averages of the convolved functions. The mean of the proper decay time distribution of a sample consisting of signal decays with lifetime τ_{s} and signal fraction p and of background is thus given by

$$\langle t \rangle = p(\tau_s + t_0) + (1 - p)\langle t \rangle_b, \qquad (19.2.47)$$

where $\langle t \rangle$ and $\langle t \rangle_b$ are the mean decay times of all and of background events, respectively. The latter was estimated using the events in the sideband regions in the plane of D^0 and K_S^0 invariant masses. The parameter t_0 represents a possible non-zero mean of the signal resolution function. Any effect that may cause bias in the lifetime extraction ($t_0 \neq 0$) such as misalignment of the vertex detector is canceled by the use of kinematically equal decays – those in the ON and OFF region.

Belle measured $\tau_{\mathrm{ON}} + t_0^{\mathrm{ON}} = (413.4 \pm 2.5)$ fs and $\tau_{\mathrm{OFF}} + t_0^{\mathrm{OFF}} = (412.7 \pm 3.0)$ fs (Zupanc, 2009). The measured values for $\tau + t_0$ are close to the world average for τ_{D^0}, and, since $y_{CP} \ll 1$, this implies t_0/τ is $\sim 1\%$ or less. Since the topology of events in the ON and OFF intervals is almost identical, Belle assumes $t_0^{\mathrm{ON}} = t_0^{\mathrm{OFF}}$ and includes a systematic error to account for this assumption. Using Eq. (19.2.46) Belle finds $y_{CP} = (+0.11 \pm 0.61 \pm 0.52)\%$, where the first uncertainty is statistical and the second systematic. This is so far the only measurement of the mixing parameter y_{CP} using a CP-odd final state in D^0 decays. The value agrees with the measurements using CP-even final states described in Section 19.2.3.2.

19.2.3.4 Summary on y_{CP}

Measurements of y_{CP} have been at the forefront of the searches and subsequently precise measurements of $D^0 - \bar{D}^0$ mixing. Recent individual measurements exhibit significances between three and five standard deviations. Furthermore, they still exhibit larger statistical than systematic uncertainties. However, a good control of the systematic effects will be needed in future measurements at super flavor factories to significantly improve the accuracy of results. Main sources of systematic errors have been identified in the measurements performed at the B Factories and several methods used to reduce the errors were successfully exploited.

Since the main systematic uncertainties are experimental, and method dependent, one can calculate the average

Figure 19.2.18. The mean proper decay time dependence on $M_{K^+K^-}$, where the D^0 decay point is determined with a (a) $K_S^0 K^+ K^-$ and (b) $K_S^0 K^\pm$ vertex constrained fit for signal $D^0 \to K_S^0 K^+ K^-$ decays. The two vertical red dashed lines indicate the borders of the ON $m(K^+K^-)$ interval. Belle internal, from the (Zupanc, 2009) analysis.

value of the parameter y_{CP} performed by the B Factories assuming uncorrelated errors. The result is

$$y_{CP} = (0.86 \pm 0.16)\% \ . \qquad (19.2.48)$$

In the limit of CP conservation $y_{CP} = y$, and hence the result points to a significant decay width difference for the two D meson mass eigenstates.

19.2.4 t-dependent Dalitz analyses

19.2.4.1 $K^+\pi^-\pi^0$ final state

For WS decays $D^0 \to K^+\pi^-\pi^0$, with an additional π^0, the phase space of possible final states is greatly increased. Each state can be represented as a point in a Dalitz plot with coordinates (s_+, s_0), where $s_{+,0}$ are the squared invariant masses for the $K\pi^{+,0}$ systems. Ignoring CP violation, each point is populated by decays with a time evolution described by Eq. (19.2.13) with values for δ_f and the ratio of $|\bar{A}_f/A_f|$ that are unique to that point (*i.e.* they depend on $s_{+,0}$). The interference term in Eq. (19.2.13), linear in xt and yt, provides the greatest sensitivity to x and y. As for all WS decay channels, the measurement profits from the interference of the doubly-Cabibbo-suppressed (DCS) decay amplitude and the Cabibbo-favored (CF) one preceded by mixing. The interference term is, therefore, comparable in magnitude to each of the other two terms. Furthermore, a model for the Dalitz plane point-to-point variations in δ can be used that allows, in principle, both x and y to be determined. For the two-body WS decays discussed in Section 19.2.2.1, there is just a single value for δ that allows a determination only of the combination $y' = y\cos\delta - x\sin\delta$ (and of x'^2).

Unfortunately, while a model can be found for the variations in δ across the separate Dalitz planes of D^0 and $\bar{D}^0$ decays, no model exists for the unknown relative strong phase ($\delta_{K\pi\pi}$) between one point in the D^0 and another in the $\bar{D}^0$ Dalitz plane. Therefore, only values for $x' = x\cos\delta_{K\pi\pi} + y\sin\delta_{K\pi\pi}$ and $y' = y\cos\delta_{K\pi\pi} - x\sin\delta_{K\pi\pi}$, rotated by this unknown phase, can be measured.

To date only *BABAR* has carried out a mixing analysis of this channel (Aubert, 2009u). The models for the complex decay amplitudes $\mathcal{A}_{DCS}$ and $\overline{\mathcal{A}}_{CF}$, respectively for DCS and CF decays, are based on the isobar model constructed from relativistic Breit-Wigner functions. The $K\pi$ S-wave components are described in a way suggested by $K\pi$ scattering in (Aston et al., 1988). This features a Breit-Wigner phase variation for the scalar $K_0^*(1430)$ added to a slowly varying background phase. Parameters (for the $K\pi$ S-wave and the complex coefficients for the isobars $K^*\pi$, $K\rho$, etc.) are determined from fits to the RS and WS samples. For $\overline{\mathcal{A}}_{CF}$ a fit to the time-integrated Dalitz plot for RS decays $\bar{D}^0 \to K^+\pi^-\pi^0$ (dominated by this amplitude) is used.

For $\mathcal{A}_{DCS}$, a full time-dependent fit to the WS sample is made. The *p.d.f.* for this has the form given in Eq. (19.2.13) with λ_f taken as

$$\lambda(s_+, s_0) = r_0 e^{i\delta_{K\pi\pi}} \frac{\overline{\mathcal{A}}_{CF}(s_+, s_0)}{\mathcal{A}_{DCS}(s_+, s_0)}. \qquad (19.2.49)$$

In this fit, the mixing parameters are defined in the form $(x'/r_0$ and $y'/r_0)$, where r_0 is the ratio between the CF and DCS amplitudes defined above. These are allowed to vary in the fit.

The time-dependent *p.d.f.* for this fit is convolved with a decay time resolution function derived from a fit to the RS events. The D^0 lifetime is also determined from RS events, and is found to agree with the world average (Beringer et al., 2012).

Signal samples consisting of $658,986$ RS (purity 99%) and $3,009$ WS (purity 50%) candidates are selected. Major sources of background come from a variety of wrongly reconstructed D^0 decays, wrongly associated slow pions or from a combination of both. In the WS sample, a small background also comes from events in which both K^+ and π^- are mis-identified in the PID detectors. Simulated samples of these categories are used to determine the contributions of each in the data. The shape of background events in the RS and WS Dalitz plots are determined from M and Δm sideband regions in the data.

For both the RS and WS fits, efficiency variations over the Dalitz plot are estimated from MC samples generated uniformly over the phase space.

The Dalitz plots for the RS and WS samples, together with the distributions of M and Δm for the WS sample are shown in Fig. 19.2.19. In each of the Dalitz plots, bands due to charged and neutral states for $K^*(890)$ and for charged ρ are easily seen. CF modes preferentially decay via $K^*\pi$ while DCS modes preferentially decay via $K\rho$ amplitudes.

Values for x' and y' are obtained for the combined D^0 and $\bar{D}^0$ samples. Separate values are also obtained from fits to each of the two subsamples (for the latter see more details in Section 19.2.7). In all cases, a value for r_0 is required. This is derived from the ratio N_{WS}/N_{RS}, where N_{WS} (N_{RS}) is the number of wrong-sign (right-sign) signal events observed and their respective time-integrated *p.d.f.*s.

This procedure introduces a correlation between the x' and y' values obtained from the fit. Uncertainties in these mixing parameters are, therefore derived from the values obtained in a similar way for 10^6 pairs of values for $(x'/r_0, y'/r_0)$ randomly generated in accordance with the fit covariance matrix (assuming Gaussian errors and including systematic uncertainties).

The major systematic uncertainties arise from uncertainties in resonance masses and widths, and $K\pi$ S-wave parameters in the decay amplitude models, variations in the estimates for the numbers of WS and RS signal events and in parameters describing the time resolution.

The mixing parameter results obtained are

$$x' = (+2.61^{+0.57}_{-0.68} \pm 0.39)\% \qquad (19.2.50)$$
$$y' = (-0.06^{+0.55}_{-0.64} \pm 0.34)\% \qquad (19.2.51)$$
Figure 19.2.19. From (Aubert, 2009u). Dalitz plots for (a) RS decays $\overline{D}^0 \to K^+\pi^-\pi^0$ and (b) WS decays $D^0 \to K^+\pi^-\pi^0$. Invariant mass distributions for (c) M (D^0 decay products) and (d) $\Delta m = (D^* - D^0)$ mass difference for selected WS event candidates are also shown. Arrows indicate the $M - \Delta m$ region selected for making the Dalitz plot fits described in the text.

where the first uncertainties are statistical and the second are systematic. A Bayesian approach is used to estimate the significance of these values. The data from the D^0 and $\overline{D}^0$ samples are consistent with a hypothesis of no mixing ($x' = y' = 0$) at the 3.2σ level. This constitutes evidence for mixing.

19.2.4.2 $K_S^0 h^+ h^-$ final state

Analyses of these channels are important because the final states are CP self-conjugate. This implies a vanishing phase between two equal points in the Dalitz planes of D^0 and $\overline{D}^0$ decays (analogous to $\delta_{K\pi\pi}$ for $D^0 \to K^+\pi^-\pi^0$ decays, $\delta_{K_S^0 h^+ h^-} = 0$). This allows a determination (modulo sign) of both x and y, and of their relative sign, with no unknown strong phase.

As for WS decays to $D^0 \to K^+\pi^-\pi^0$, the phase space of possible final states is represented by points in a Dalitz plot, with coordinates chosen as (s_+, s_-), where $s_{+,-}$ are the squared invariant masses for the $K_S^0 h^{+,-}$ systems, respectively. Ignoring CP violation, each point is populated by decays with a time evolution described by Eq. (19.2.13) with values for $\delta_{K_S^0 h^+ h^-}$ and $|\lambda| = |\overline{\mathcal{A}}_{K_S^0 h^+ h^-}/\mathcal{A}_{K_S^0 h^+ h^-}|$ that are unique to that point. The largest sensitivity to x and y arises from the interference term in Eq. (19.2.13) which is linear in the two parameters. Unlike the WS decay channel, however, these decays proceed either by a DCS amplitude after mixing or by a CF one with no mixing at all. They are therefore dominated by the latter process

and the interference term is very much smaller. The decay amplitudes for a decay of D^0 and $\overline{D}^0$ tagged at $t = 0$ are written as

$$\mathcal{M}(s_+, s_-, t) = \frac{1}{2p}\big[p\big(e_1(t) + e_2(t)\big)\mathcal{A}(s_+, s_-) \\ + q\big(e_1(t) - e_2(t)\big)\mathcal{A}(s_-, s_+)\big]$$

$$\overline{\mathcal{M}}(s_+, s_-, t) = \frac{1}{2q}\big[p\big(e_1(t) - e_2(t)\big)\overline{\mathcal{A}}(s_+, s_-) \\ + q\big(e_1(t) + e_2(t)\big)\overline{\mathcal{A}}(s_-, s_+)\big], (19.2.52)$$

where $e_{1,2}(t) = e^{-i(m_{1,2}-(i\Gamma_{1,2}/2))t}$. Both *BABAR* (using 486.5 fb^{-1}, (del Amo Sanchez, 2010f)) and Belle (using 540 fb^{-1}, (Abe, 2007b)) have analyzed these channels. The model for the complex decay amplitude $\mathcal{A}(s_+, s_-)$, contains CF and DCS terms. As before, these are based on the isobar model constructed from relativistic Breit-Wigner functions. The *BABAR* collaboration also used a $K\pi$ S-wave prescription similar to that outlined for the WS channel, and also used a K-matrix parameterization for the $\pi\pi$ S-wave. In the Belle analysis the latter was used to estimate systematic uncertainties due to the assumed Dalitz model. Details of these amplitudes are described in Chapter 13. In calculating $\lambda(s_+, s_-)$ in the standard fit, it is assumed that direct CP violation can be ignored so that the amplitude $\overline{\mathcal{A}}(s_+, s_-)$ can be taken as $\mathcal{A}(s_-, s_+)$. Belle also performs a fit, in which direct CP violation is permitted, where separate isobar coefficients are allowed for the definition of $\overline{\mathcal{A}}(s_+, s_-)$. They find, however, no significant differences in these coefficients.

As in the WS $K^+\pi^-\pi^0$ mode, the time-dependent *p.d.f.* is convolved with a decay time resolution function derived from the combined D^0 and $\overline{D}^0$ event samples. This fit is performed for both of these samples, each tagged by the charge of the slow pion from D^* decays.

Belle and *BABAR* each use approximately $540k$ $K_S^0\pi^+\pi^-$ candidates, and *BABAR* also uses $80k$ $K_S^0 K^+K^-$ events. Event purities for these samples range from 95-99%. Major sources of the small backgrounds come from a variety of wrongly reconstructed D^0 decays, wrongly associated slow pions or from a combination of both. In the $K_S^0\pi\pi$ mode, there is also a small, but significant background from $D^0 \to K_S^0 K_S^0$ decays and another from $D^0 \to 4\pi$. Simulated samples of these backgrounds are used to determine the contributions of each in the data. Efficiency variations over the Dalitz plot are estimated from MC samples generated uniformly in phase space.

The decay time distributions are shown in Fig. 19.2.20. Results for the mixing parameters obtained are summarized in Table 19.2.4. They are obtained from fits neglecting CP violation, *i.e.* setting $q = p = 1/\sqrt{2}$ in Eq. (19.2.52). Separate fits are performed taking into account the possibility of CP violation, as discussed further in Section 19.2.7. The *BABAR* values are the most precise at present. Neither Belle nor *BABAR* show results more than 3σ from the "no mixing" point $x = y = 0$. The 95% C.L. contour for (x, y) parameters obtained by Belle is shown in Fig. 19.2.21.

Systematic uncertainties in the measurement can be divided into two groups: uncertainties related to experi-
Figure 19.2.20. From (del Amo Sanchez, 2010f). Decay time distributions for (a) $D^0 \to K_S^0 \pi^- \pi^+$, (b) $D^0 \to K_S^0 K^+ K^-$ decays with the time-dependent Dalitz plot fits described in the text.

Table 19.2.4. Results of fits to $K_S^0 h^+ h^-$ CP self-conjugate states (del Amo Sanchez, 2010f; Abe, 2007b). The first uncertainties are statistical and the second are systematic. The third uncertainties arise from uncertainties in the model for $\mathcal{A}(s_+, s_-)$.

Experiment	Sample	Results [$\times 10^3$]
BABAR	486.5 fb^{-1}	$x = 1.6 \pm 2.3 \pm 1.2 \pm 0.8$
No CP	Signal: 540×10^3	$y = 5.7 \pm 2.0 \pm 1.3 \pm 0.7$
violation	Purity: 98.5%	
Belle	540 fb^{-1}	$x = 8.0 \pm 2.9^{+0.0+1.0}_{-0.7-1.4}$
No CP	Signal: 534×10^3	$y = 3.3 \pm 2.4^{+0.8+0.6}_{-1.2-0.8}$
violation	Purity: 98.5%	
Figure 19.2.21. 95% C.L. contour for the mixing parameters (x, y) as obtained from decay-time dependent analysis of Dalitz distribution of $D \to K_S^0 \pi^+ \pi^-$. From (Abe, 2007b).

mental effects and those related to modeling the Dalitz distribution. The contributions to the systematic error related to the former group are related to the efficiency

variations across the DP, modeling of the DP and proper-time distributions for background events, and the selection criteria. The misidentification of the D^0 flavor from incorrectly assigned slow pions and variations of the time resolution function, including alternative ways to describe the correlation between time and DP position also contribute to this group of uncertainties. An important source of the experimental systematic uncertainty is also the limited statistics of full detector simulations required to study biases from event selection and instrumental effects arising from the small misalignment of the detector.

The second group of systematic uncertainties is estimated using alternative models for the decay amplitudes $\mathcal{A}(s_+, s_-)$. This introduces one of the largest systematic uncertainties that would ultimately limit the precision of these results. Further improvements should be possible, however, using a model-independent method to analyze the Dalitz distribution. The method is based on the measurements of the strong phase variation over the Dalitz plane as measured from the charm threshold data (Libby et al., 2010) and does not require modelling of the Dalitz distribution.

19.2.4.3 Summary

Study of the decay-time dependence of Dalitz distributions in multibody D^0 decays provides an essential tool in studying the charm mesons mixing properties. It is the only method which is sensitive to linear order in both mixing parameters, x and y. Especially the time-dependent Dalitz analysis of self-conjugated states ($K_S^0 h^+ h^-$) enables the determination of the parameters not rotated by an unknown phase. On the other hand such measurements carry a systematic uncertainty arising from modeling the Dalitz distribution. With the increasing statistical power of the data samples the models have been gaining in sophistication. Nevertheless in the future the most accurate measurements of the mixing parameters can be expected using a model independent approach (similar to the measurement of ϕ_3, see Section 17.8.4.3), which has not yet been used by the B Factories.

19.2.5 Semileptonic decays

In the case of semileptonic decays, there are no Doubly Cabibbo Suppressed (DCS) modes as with wrong-sign hadronic decays, and only a pure mixing term modulates the exponential lifetime. In the absence of CP violation, from Eqs (19.2.13) one obtains [131]

$$\frac{d\Gamma(D^0 \to X \ell^+ \nu_\ell)}{dt} \sim |A_{X\ell^+\nu_\ell}|^2 e^{-\Gamma t} \,,$$

$$\frac{d\Gamma(\overline{D}^0 \to X \ell^+ \nu_\ell)}{dt} \sim |A_{X\ell^+\nu_\ell}|^2 \left[\frac{x^2 + y^2}{4} (\Gamma t)^2 \right] e^{-\Gamma t} \,.$$

$$(19.2.53)$$

[131] By taking $f = X\ell^+\nu_\ell$, $A_{\bar{f}} = \overline{A}_f = 0$, $A_f = \overline{A}_{\bar{f}}$.

Integrating $d\Gamma(\overline{D}^0 \to X\ell^+\nu_\ell)/dt$ over all times $t > 0$ and normalizing to the integrated value of $d\Gamma(D^0 \to X\ell^+\nu_\ell)/dt$, one finds that the relative time-integrated mixing rate is

$$R_M = \frac{\Gamma(\overline{D}^0 \to X\ell^+\nu_\ell)}{\Gamma(D^0 \to X\ell^+\nu_\ell)} = \frac{x^2 + y^2}{2}. \qquad (19.2.54)$$

Both *BABAR* and Belle have searched for neutral D mixing in semileptonic $K^{(*)}\ell\nu_\ell$ final states, setting upper limits with two conceptually different analyses using an integrated luminosity of 344 fb^{-1} in the 2007 *BABAR* analysis (Aubert, 2007aq) and 492 fb^{-1} for the 2008 Belle analysis (Bitenc, 2008). The *BABAR* analysis uses the flavor of fully reconstructed hadronic charm decays in the hemisphere opposite the semileptonic signal to provide an additional tag of the production flavor of signal decays (supplemental to the information from the slow pion in the D^* signal decay). This double flavor tag very substantially reduces the rate of incorrectly tagged signal candidates, but it also greatly reduces the overall signal efficiency. Belle's analysis does not use any additional flavor tagging information from the opposite hemisphere, relying instead on a maximum likelihood fit to search for mixed signal events. In both analyses the efficiency corrected ratio of mixed $D^0 \to X\ell^-\overline{\nu}_\ell + \overline{D}^0 \to X\ell^+\nu_\ell$ to un-mixed $D^0 \to \overline{X}\ell^+\nu_\ell + \overline{D}^0 \to \overline{X}\ell^-\overline{\nu}_\ell$ events is used to determine the constraints on $x^2 + y^2$.

19.2.5.1 Belle

Belle reconstructs the decay chain $D^{*+} \to D^0\pi_s^+$, $D^0 \to K^-l^+\nu_l$, where l^+ can be either an electron or a muon. The charge of the slow pion π_s^+ tags the production flavor of the neutral D, with unmixed decays having a lepton and soft pion with identical charge (RS) and mixed decays having a lepton and soft pion with opposite-sign charge (WS). Although the neutrino is not directly detected, the uncertainty due to the missing neutrino four-momentum can be minimized by calculating the mass difference between the D^0 and its D^{*+} parent

$$\Delta M \equiv M(K\ell\nu\pi_s) - M(K\ell\nu). \qquad (19.2.55)$$

Since the Belle detector covers nearly the entire solid angle surrounding the interaction point, the signal neutrino four-momentum can be estimated as

$$P_\nu = P_{\mathrm{CM}} - P_{K\ell} - P_{\mathrm{ROE}}, \qquad (19.2.56)$$

where P_{CM} denotes the CM four-momentum of the initial e^+e^- frame of reference and ROE stands for the "rest of the event", *i.e.* the sum of the CM system four-momenta of all detected neutral and charged candidates in an event except for the signal kaon and lepton. Neutrals with energy less than 70 MeV/c^2 and charged tracks with an impact parameter larger than 5 cm (2 cm) in z (xy) are not used in this context, although they are used in the computation of event-shape variables. Two kinematic constraints are

used to improve the resolution of the neutrino momentum. The invariant mass squared $M^2(K\ell\nu) \equiv (P_\nu + P_{K\ell})^2/c^2$ is computed, and only candidates with $-25 < M^2(K\ell\nu) < 64\,\mathrm{GeV}^2/c^4$ are kept. For these events, P_{ROE} is rescaled by a correction factor ξ requiring that

$$M^2(K\ell\nu) = (P_{\mathrm{CM}} - \xi P_{\mathrm{ROE}})^2/c^2 \equiv M_{D^0}^2. \qquad (19.2.57)$$

Having thus determined ξ, the neutrino four-momentum is then recalculated as $P_\nu = P_{\mathrm{CM}} - P_{K\ell} - \xi P_{\mathrm{ROE}}$, and this new neutrino momentum is used in the calculation of ΔM. The most probable value for ξ is close to 1.0, although there is a long tail in the distribution, which leads to an average value of ~ 1.3.

The square of the missing mass $M_\nu^2 \equiv P_\nu^2 = 0$ is used as an additional kinematic constraint, where P_ν^2 now includes the ξ correction factor. The squared missing mass can be expressed in terms of the energies and magnitudes of the three-momenta of the final state particles, along with the cosine of the angle between the vector momenta of the $K\ell$ system and ξP_{ROE}. This angle is corrected by rotating the vector P_{ROE} in the plane defined by the vectors P_{ROE} and $p_{K\ell}$ so that the null mass condition is enforced. The final neutrino four-momentum is then calculated using the original expression in Eq. (19.2.56) with a corrected P_{ROE} term on the right-hand side, and this neutrino momentum is used to compute the value of ΔM which is subsequently used in the fit to the data. The effect of the kinematic constraints on the ΔM distribution of the simulated WS signal events is shown in Fig. 19.2.22.
Figure 19.2.22. Left: The effect of the kinematic constraints on the ΔM distribution of the simulated $D^0 \to K^-e^+\nu_e$ decays. Right: ΔM distribution for simulated associated signal events (see text for the explanation). From (Bitenc, 2008).

The ratio of WS to RS events $N_{\mathrm{WS}}/N_{\mathrm{RS}} = (x^2 + y^2)/2$ is small (n.b. $x^2 + y^2 \sim \mathcal{O}(10^{-4})$, see Section 19.2.1), or equivalently $N_{\mathrm{WS}} \ll N_{\mathrm{RS}}$. Hence the central value and the statistical uncertainty of the ratio is mainly determined by the number of WS events.[132] The selection criteria for the

---

[132] Note that in the ratio $R_M = N_{\mathrm{WS}}/N_{\mathrm{RS}}$ the statistical error is given by $\sigma_R = R_M\sqrt{(\sigma_{\mathrm{WS}}/N_{\mathrm{WS}})^2 + (\sigma_{\mathrm{RS}}/N_{\mathrm{WS}})^2}$; in case N_{RS} and N_{WS} are simply Poissonian distributed numbers of events $\sigma_R = R_M\sqrt{(1/N_{\mathrm{WS}}) + (1/N_{\mathrm{RS}})}$ and the smaller of the two numbers determines the uncertainty.

WS events can thus be determined using a much larger sample of kinematically equal RS decays in accordance with blind analysis principles described in Chapter 14.

The selection criteria include the requirements on minimum invariant mass and momentum of the kaon and lepton system, which suppress the backgrounds from various B meson decays. Two important sources of background are $D^0 \to K^+K^-$ and $\pi^+\pi^-$ decays, which in case of misidentification of one or both final state mesons produce a peak in the ΔM distribution. These are effectively suppressed by calculating the invariant mass of the $K\ell$ system, assigning an appropriate mass to the kaon and lepton candidate,[133] and requiring that the resulting value is not consistent with the nominal D^0 mass. The requirement on the magnitude of the CM momentum of the $K\ell$ system, $p^*(K\ell) > 2.0\,\text{GeV}/c^2$, improves the resolution on ΔM and rejects a majority of D^0 mesons produced in B meson decays. Events with $\gamma \to e^+e^-$ conversions are also a source of background for electron and slow pion candidates. These are suppressed by calculating the invariant mass of the electron and the pion candidate, assigning the electron mass to both tracks, and requiring the result to be larger than $140\,\text{MeV}/c^2$.

Apart from the aforementioned backgrounds and genuine signal there are other D meson decays with ΔM in the signal region. Despite the fact that the measurement method is not specifically aiming to reconstruct those decays the charge correlation between the lepton and the π_s is the same as in the signal decays and hence they carry similar information on the possible mixing parameters. For this reason they are referred to as the associated signal:

- $D^0 \to K^-\pi^0\ell^+\nu$,
- $D^0 \to K^{*-}\ell^+\nu_\ell$, followed by $K^{*-} \to K^-\pi^0$,
- $D^0 \to \pi^-\ell^+\nu_\ell$,
- $D^0 \to \rho^-\ell^+\nu_\ell$, followed by $\rho^- \to \pi^-\pi^0$,
- $D^0 \to K^{*-}\ell^+\nu_\ell$, followed by $K^{*-} \to \bar{K}^0\pi^-$.

The mass difference distribution of simulated associated signal events is shown in Fig. 19.2.22.

The mixed events have on average a larger decay time than the background WS events. Hence requiring a larger value of the decay time for selected events can improve the sensitivity. This is illustrated in Fig. 19.2.23 showing the decay time distribution of WS (signal) events.

The proper decay time scaled in units of the nominal PDG D^0 lifetime (Yao et al., 2006) is calculated from the D^0 momentum $\boldsymbol{p}_{D^0}$ and flight distance l:

$$t_{D^0} = \frac{m_{D^0}l}{\tau_{D^0}p_{D^0}}. \tag{19.2.58}$$

The D^0 flight distance is the distance between the D^0 production and decay vertices, respectively $\boldsymbol{r}_{\text{prod}}$ and $\boldsymbol{r}_{\text{dec}}$.

The D^0 momentum is calculated by summing the momenta of the daughter particles. The decay vertex is obtained by fitting the kaon and lepton tracks to a common vertex. The production vertex is obtained by extrapolating the D^0 momentum vector to the e^+e^- interaction region. Given the relatively large longitudinal extent of the interaction region as explained in Chapter 6, only the transverse components (x, y) are used. The radial flight distance l_{xy} is calculated as

$$l_{xy} = \frac{(r^x_{\text{dec}} - r^x_{\text{prod}}, r^y_{\text{dec}} - r^y_{\text{prod}}) \cdot (p^x_{D^0}, p^y_{D^0})}{\sqrt{(p^x_{D^0})^2 + (p^y_{D^0})^2}}. \tag{19.2.59}$$

The dimensionless proper decay time is then calculated as

$$t_{xy} = \frac{m_{D^0}l_{xy}}{\tau_{D^0}\sqrt{(p^x_{D^0})^2 + (p^y_{D^0})^2}}. \tag{19.2.60}$$

Because of data recorded by two different Belle SVD detector configurations (Chapter 2) the selected sample is divided into two subsamples. The subsamples are denoted as $\ell - i$, where $\ell = e, \mu$ determines the type of the lepton and $i = 1, 2$ the SVD configuration.
Figure 19.2.23. Left: The distribution of the decay time in the transverse plane for selected WS events (dots). The solid line shows the simulated distribution of signal events and the vertical arrows the interval selected for the signal. Right: An example of the fit to the ΔM data distribution (points) in a single t_{xy} bin for the WS $e-2$ data subsample. The histogram is the fit to the distribution, with the contribution of signal shown along the horizontal axis. From (Bitenc, 2008).

The relative rate of mixed events $N^i_{\text{WS}}/N^i_{\text{RS}}$ is determined separately for $i = 1, 6$ in six intervals of t_{xy} for decay times $1.6 < t_{xy} < 9.0$. An example of the fit to the ΔM distribution of WS events in a single t_{xy} bin is shown in Fig. 19.2.23. The shape of the signal is obtained from the simulation. The background is divided into two categories: the correlated and the un-correlated background. The former is defined as a combination in which either the lepton or the kaon candidate or both originate from the same decay chain as the slow pion. The shape of this background is obtained from MC simulation as well. The

---

[133] Specifically, the invariant mass is calculated assuming the pion mass for the kaon candidate and the pion mass for the lepton candidate, as well as with the kaon mass for the lepton candidate.

majority of events in the WS sample belong to the un-correlated background. The shape of the ΔM distribution for these events is obtained from real data by embedding a slow pion candidate track into another event and following the same analysis procedure as described above.

Averaging the $(N_{WS}^i/N_{RS}^i)(\epsilon_{RS}^i/\epsilon_{WS}^i)$ values over the t_{xy} bins, where $\epsilon_{RS,WS}^i$ are the relative acceptances for the RS and WS events in the corresponding bins, one obtains $R_M \equiv (x^2+y^2)/2$ values for $\ell-i$ subsamples. Those values are shown in Fig. 19.2.24.
Figure 19.2.24. Values of $R_M \equiv (x^2 + y^2)/2$ in subsamples of selected $D^0 \to K^-\ell^+\nu_\ell$ events (dots with error bars representing the statistical and systematic uncertainty). The dashed and dotted lines represent the average value and its $\pm 1\sigma$ interval. The solid line corresponds to no mixing. From (Bitenc, 2008).

The average value of the measurement is

$$R_M = (1.3 \pm 2.2 \pm 2.0) \times 10^{-4} \ , \qquad (19.2.61)$$

including the statistical and systematic uncertainty. The value is consistent with no-mixing and is close to the boundary of the physical region ($R_M > 0$). In order to obtain the upper limit in the vicinity of the physical boundary a Feldman-Cousins (Feldman and Cousins, 1998) method is used. The 90% C.L. upper limit is found to be $R_M < 6.1 \times 10^{-4}$.

One of the largest sources of systematic uncertainty is the finite statistical significance of the samples used to obtain the shapes of the signal and background ΔM distribution. The uncertainty is estimated by variation of those shapes within their statistical uncertainties. Another important source of systematic error is the amount of the correlated background in the WS sample. It is estimated by conservatively varying the branching fractions of the main decay mode contributions to this type of the background.

19.2.5.2 *BABAR*

In the *BABAR* analysis (Aubert, 2007aq), the initial flavor of the neutral D meson is tagged twice, once using the slow pion from a charged D^* decay whose neutral D daughter decays semileptonically, and once using the flavor of a high-momentum D fully reconstructed in the CM

hemisphere opposite the semileptonic candidate. Tagging the flavor at production twice, rather than once, highly suppresses the background from false WS slow pions, but it also reduces the signal by an order of magnitude. Additional signal candidate selection criteria similar to that employed above by Belle are used to minimize the remaining sources of background.

Five hadronic tagging samples are used, where three samples explicitly require a reconstructed D^{*+}: $D^{*+} \to D^0\pi^+$ with $D^0 \to K^-\pi^+$, $D^0 \to K^-\pi^+\pi^0$, and $D^0 \to K^-\pi^+\pi^+\pi^-$, and the other two samples are CF decays with no D^{*+} requirement: $D^0 \to K^-\pi^+$ and $D^+ \to K^-\pi^+\pi^+$. Candidates from the D^{*+} sample are explicitly excluded from the inclusive $D^0 \to K^-\pi^+$ sample to ensure that the tagging samples are disjoint.

The selection criteria for the tagging samples, such as the ΔM ranges for the D^* modes or the use of production and decay vertex separation for the D^+ mode, vary from channel to channel to balance high purity against high statistical significance. To eliminate candidates from $B\bar{B}$ events, the CM momentum of the tag-side D must be at least $2.5\,\mathrm{GeV}/c$.

Using a method similar to that employed above by Belle, the optimal proper decay time range in which to search for mixed decays was similarly found to be $\sim 1.5 - 9.5$ nominal D^0 lifetimes. The *BABAR* fit to the ΔM distribution for double-flavor-tagged RS data events uses a fit model similar to Belle's, which is shown in Figure 19.2.25 before and after additional kinematic selection exploiting correlations between tag and signal hemispheres are applied. The final RS signal yield is 4780 ± 94 events after all event selections are imposed.
Figure 19.2.25. From (Aubert, 2007aq). RS data ΔM distribution. The main plot shows the RS data (points) before imposing the double-tag kinematic selection, and the projections of the total fit *p.d.f.* (solid line) and the background *p.d.f.* (dashed line). The inset plot shows the RS ΔM distribution after the double-tag kinematic selection criteria are applied.

Three regions of ΔM are considered to determine the number of WS mixed events: the signal region, $\Delta M \leq 0.20\,\mathrm{GeV}/c^2$; the near background region, $0.20 < \Delta M \leq 0.25\,\mathrm{GeV}/c^2$; and the far background region, $0.25 < \Delta M \leq 0.35\,\mathrm{GeV}/c^2$. These ΔM ranges are shown in Fig. 19.2.26, and are respectively labeled "1", "2" and "3" in the plot. A blind analysis was performed where the signal region was not examined until after all details of event selection, fit methodology and statistical procedures for setting upper limits were finalized. An estimated 2.85 background events was expected in the signal region and, as shown in Fig. 19.2.26, three events were found there, yielding a net WS signal of 0.15 events. Note the difference in the yields and purities of the selected samples using the Belle single tag method (Fig. 19.2.23) and the *BABAR* double tag method (Fig. 19.2.26).
Figure 19.2.26. From (Aubert, 2007aq). WS data ΔM distribution. The dark histogram shows WS events in the data passing all event selections. The light histogram shows WS events passing all selections except the double-tag kinematic selection. Region "1" is the signal region, "2" is the near sideband, and "3" is the far sideband.

To calculate confidence intervals for the number of mixed events observed, a systematic uncertainty associated with the WS background estimate is determined using ten data/MC background control samples. The largest discrepancy between the data and MC rates, 50%, is assigned as the systematic uncertainty associated with the ratio between the MC estimate of the background rate and its true value. To quantify confidence intervals for the number of WS mixed events, a likelihood function is used, $\mathcal{L}(n, n_b; s, b)$, for the number of events observed in the signal region of the WS data sample, n, and the cor-

responding number observed in the MC sample, n_b. The likelihood $\mathcal{L}(n, n_b; s, b)$ depends upon the true signal rate s and the true background rate b in the signal region, and also accounts for the systematic uncertainty in the ratio of the true background rate in data to that estimated from MC. The value of (s, b) which maximizes the likelihood function, $\mathcal{L}_{\max}$, is denoted by $(\hat{s}, \hat{b})$. As one might naïvely expect, $\hat{b}$ is equal to n_b times the ratio of data and MC luminosities, while $\hat{s} = n - \hat{b}$. A scan is made for the values of s where $-\ln\mathcal{L}(s)$ changes by 0.50 [1.35]; here $\mathcal{L}(s)$ denotes the likelihood at s maximized with respect to b. The lower and upper values of s which satisfy this condition define the nominal 68% [90%] confidence interval for s, assuming Gaussian uncertainties. The confidence intervals produced using this procedure provide frequentist coverage accurate to within a few percent. A central value of $R_M = 0.4 \times 10^{-4}$ is found, with 68% and 90% confidence intervals $[-5.6, 7.4] \times 10^{-4}$ and $[-13, 12] \times 10^{-4}$, respectively.

19.2.5.3 Summary

In summary, semileptonic decays of D^0 mesons can be exploited to determine the time integrated mixing rate. By determining the yield of WS decays $D^0 \rightarrow X\ell^-\bar{\nu}_\ell$ relative to the RS decays $D^0 \rightarrow X\ell^+\nu_\ell$ one determines $R_M = N_{\mathrm{WS}}/N_{\mathrm{RS}} = (x^2 + y^2)/2$. Both single and double tagged event selections, thereby isolating samples differing in their statistical power and purity, have been used by Belle and *BABAR*. Averaging the two measurements described results in

$$R_M = (0.011 \pm 0.027)\% \qquad (19.2.62)$$

where the error contains statistical and systematic uncertainties (all individual errors are assumed to be uncorrelated).

Though wrong-sign semileptonic decays are a sure sign of mixing, the low mixing rate ($\simeq 10^{-5}$) and the need to apply strong background suppression requirements will continue to limit the use of these decays in the mixing measurements for some time to come.

19.2.6 t-integrated CP violation measurements

In studies of CP violation in the decays of D mesons one usually measures time-integrated asymmetries of partial decay rates, defined as

$$A_{CP}^f \equiv \frac{\Gamma(D \rightarrow f) - \Gamma(\overline{D} \rightarrow \overline{f})}{\Gamma(D \rightarrow f) + \Gamma(\overline{D} \rightarrow \overline{f})} \ . \qquad (19.2.63)$$

The underlying CP violating parameters, see Eqs (19.2.17, 19.2.18, and 19.2.19) upon which such asymmetries depend are determined by the specific final state f and by the type of D meson. For charged D mesons, for example, only mode specific CP violation in the decays is possible.

On the other hand, for neutral D mesons, these asymmetries can include direct (a_{dir}^f) and indirect (a_{ind}) asymmetry contributions (see Section 19.2.1.3):

$$A_{CP}^f = a_{\mathrm{dir}}^f + a_{\mathrm{ind}}. \qquad (19.2.64)$$

The direct asymmetry term corresponds to the CP violation in decays. The indirect asymmetry in decays to CP eigenstates (like K^+K^- or $\pi^+\pi^-$) consists of the term due to the CP violation in mixing, $-\eta_f(y/2)A_M\cos\phi$, and of the term due to the mixing induced CP violation, $\eta_f x \sin\phi$. η_f denotes the CP eigenvalue of the final state ($\eta_f = +1$ for CP-even and $\eta_f = -1$ for CP odd states). Hence

$$A_{CP}^f = a_{\mathrm{dir}}^f - \eta_f(y/2)A_M\cos\phi + \eta_f x \sin\phi. \quad (19.2.65)$$

As a result of $D^0 - \overline{D}^0$ mixing, CP asymmetries for D^0 mesons depend upon the interval of decay time, t, over which the asymmetry is integrated. At the B Factories, time resolution is comparable with the D^0 lifetime, τ_{D^0}. Therefore, no D^0 decay vertex separation requirement is imposed on the samples used in any of the analyses and integration times include $t = 0$. In contrast, hadron collider experiments (CDF, LHCb, etc.) impose decay length based selections to reduce large combinatorial backgrounds. There, the integration times begin at $t = t_{\min} > 0$. In all cases, the upper end of the range, $t_{\max}$ is large and can be taken as infinite. To first order in the small parameter y, the values for A_{CP}^f measured can be approximated (see, for example Gersabeck, Alexander, Borghi, Gligorov, and Parkes, 2012) as combinations of a_{dir}^f and a_{ind} that are linear in $t_{\min}$, thereby allowing separate values for a_{dir}^f and a_{ind} to be estimated.[134]

The feasibility of using measurements of CP asymmetries as a function of time (as distinct from values A_{CP} integrated over finite time periods) has also been studied (Bevan, Inguglia, and Meadows, 2011). Many decay modes can be used to study weak phases in D^0 meson decays in much the same way that such measurements were used in the B Factory measurements of the CKM phases ϕ_{1-3}. Such measurements will be feasible using samples about 100 times larger than those of the B Factory's.

19.2.6.1 Using data to measure detector induced asymmetries

In the experimental determination of the physics parameter A_{CP}^f other asymmetries not originating from the CP violation may enter and have to be corrected for. These include detector induced asymmetries, for example an asymmetry in the reconstruction efficiencies of positively and negatively charged tracks, as well as the forward-backward (FB) asymmetry due to the $\gamma^* - Z^0$ interference in $e^+e^- \to c\bar{c}$. The former may be induced by different cross-sections for the interaction of particles and anti-particles in the

material of the detector.[135] Such subtle effects are not described to a sufficient accuracy in the simulated data samples — note that as explained in Section 19.2.1.3 in the search for the CP violation in the charm sector one is interested in effects of the order of 10^{-3} — and hence they must be estimated using data control samples.

To explain ideas used in the corrections for the non-CP violating asymmetries mentioned above let us first consider an example of a charged D meson decay, $D^\pm \to Xh^\pm$, where X denotes a neutral hadronic system which is self-conjugated (and hence the same for the D^+ and D^-) and $h^\pm$ represents a charged hadron. The experimentally determined asymmetry is

$$A_{\mathrm{rec}} = \frac{N(D^+ \to Xh^+) - N(D^- \to Xh^-)}{N(D^+ \to Xh^+) + N(D^- \to Xh^-)}, \quad (19.2.66)$$

where N denotes the number of observed decays. Taking into account small magnitudes of all CP and non-CP violating asymmetries (i.e. neglecting quadratic and higher terms) the measured asymmetry can be expressed as the sum of various contributions

$$A_{\mathrm{rec}} = A_{CP} + A_{FB} + A_\epsilon^{h^+}, \qquad (19.2.67)$$

where A_{FB} and $A_\epsilon^{h^+}$ are the forward-backward asymmetry and the detection efficiency asymmetry between positively and negatively charged tracks.

In order to correct for these one has to use real data as much as possible to minimize systematic uncertainty associated with the correction. The control samples and the technique used vary from mode to mode. For example, if two appropriate control samples can be found, for which CP violation is negligible and the asymmetry due to A_{FB} is equal between the two (both assumptions must be satisfied at least to the level below the A_{CP} measurement sensitivity), then

$$A_{\mathrm{rec}}^{\mathrm{cont1}} = A_{FB}^{\mathrm{cont1}} + A_\epsilon^{h^+},$$
$$A_{\mathrm{rec}}^{\mathrm{cont2}} = A_{FB}^{\mathrm{cont2}} \qquad (19.2.68)$$

The above equation assumes that the second control sample does not receive a contribution from the detection efficiency asymmetry (for example the control sample consists of neutral D meson decays). Hence from the difference $A_{\mathrm{rec}}^{\mathrm{cont1}} - A_{\mathrm{rec}}^{\mathrm{cont2}}$ one can determine the detection efficiency asymmetry $A_\epsilon^{h^+}$ (with some additional complications as explained below).

After correcting for $A_\epsilon^{h^+}$ using an appropriate control data samples, one arrives at

$$A_{\mathrm{rec}}^{\mathrm{corr}} = A_{CP} + A_{FB}, \qquad (19.2.69)$$

where the superscript corr denotes that the measured asymmetry has already been corrected for $A_\epsilon^{h^+}$. The remaining

---

[134] For the final states that are CP eigenstates a_{ind} does not depend on decay mode f while a_{dir}^f does.

[135] Note, for example, that the cross-section for π^-p interaction through the Δ^0 resonance at $p_\pi \approx 1\,\mathrm{GeV}/c$ is three times smaller than the cross-section for the π^+p interaction through the Δ^{++}, as can be easily seen using the isospin decomposition.

two contributions can be separated using the fact that A_{FB} is antisymmetric with respect to the cosine of the D meson production polar angle in CM system ($\cos\theta^*$), while the intrinsic CP asymmetry A_{CP} is independent of this angle. At tree level the asymmetry in the number of produced fermions (c quarks) and anti-fermions ($\bar{c}$ quarks) as a function of the angle between the fermion and the incoming electron in the CM system, θ_c, is [136]

$$\frac{N_c(\cos\theta_c) - N_{\bar{c}}(\cos\theta_c)}{N_c(\cos\theta_c) + N_{\bar{c}}(\cos\theta_c)} = \frac{8A_{FB}^0\cos\theta_c}{3(1+\cos^2\theta_c)} \; . \quad (19.2.70)$$

A_{FB}^0 is the forward-backward asymmetry parameter, depending on the axial and vector weak couplings of the electrons and charm quarks (Eidelman et al., 2004). Assuming the fragmentation of the primary quark into a charmed meson does not significantly affect the angular distribution (*i.e.* that $\theta^* \approx \theta_c$) the quark asymmetry above is just the asymmetry A_{FB} of Eq. (19.2.69) induced by the forward backward asymmetry:

$$A_{\rm rec}^{\rm corr}(\cos\theta^*) = A_{CP} + \frac{8A_{FB}^0\cos\theta^*}{3(1+\cos^2\theta^*)} \; . \quad (19.2.71)$$

Hence one can determine A_{FB} and A_{CP} separately from

$$\begin{aligned} A_{CP} &= [A_{\rm rec}^{\rm corr}(\cos\theta^*) + A_{\rm rec}^{\rm corr}(-\cos\theta^*)]/2 \\ A_{FB} &= [A_{\rm rec}^{\rm corr}(\cos\theta^*) - A_{\rm rec}^{\rm corr}(-\cos\theta^*)]/2. \end{aligned}$$
$$(19.2.72)$$

The method of correction for the A_{FB} assumes $\theta^* = \theta_c$ and $A_{FB}^{\rm cont} = A_{FB}$. The expressions can, however, be modified when instead of the quark direction one measures the experimentally accessible polar angle of a D meson (in other words, the assumption $\theta^* = \theta_c$ may not be completely justified). Also, the control data samples often involve decays of different charmed mesons from the ones for which A_{CP} is being measured. Hence another assumption is that A_{FB} is the same for all charmed mesons. Due to slightly different fragmentation when an initial c quark hadronizes into various types of D mesons, the asymmetry can also differ slightly for different D mesons. These assumptions have been tested. The differences between A_{FB}'s for different D mesons are small (Staric, 2012b) justifying the method used to correct for the residual asymmetry arising from A_{FB}.

For measurements of A_{CP} in $D^0 \to K^+K^-, \pi^+\pi^-$ decays, the flavor of neutral D mesons at production is tagged by reconstructing $D^{+*} \to D^0\pi_s^+$ decays. The measured asymmetry can be written as

$$A_{\rm rec} = A_{CP} + A_{FB} + A_\epsilon^{\pi_s}. \quad (19.2.73)$$

To determine $A_\epsilon^{\pi_s}$ (Staric, 2008; Aubert, 2008aq), one reconstructs two $D^0 \to K^-\pi^+$ samples: one consisting of D mesons with tagged initial flavor, and one consisting of

untagged candidates. The measured asymmetries for these modes can be written as

$$\begin{aligned} A_{\rm rec}^{\rm tag} &= A_{CP}^{K\pi} + A_{FB} + A_\epsilon^{K\pi} + A_\epsilon^{\pi_s}, \\ A_{\rm rec}^{\rm untag} &= A_{CP}^{K\pi} + A_{FB} + A_\epsilon^{K\pi}. \end{aligned} \quad (19.2.74)$$

One first uses the difference of the two measurements in Eq. (19.2.74) to determine $A_\epsilon^{\pi_s}$.

After correcting for $A_\epsilon^{\pi_s}$, one corrects for A_{FB} from Eq. (19.2.73) as explained above. An additional complication arises due to the fact that $A_\epsilon^{\pi_s}$, which at least partially arises from the difference of charged particle interactions in the detector material, depends on the momentum and the laboratory polar angle of the pion. Hence $A_\epsilon^{\pi_s}$ is examined as a function of $(p_{\pi_s}, \cos\theta_\pi)$ which denote the magnitude of the momentum and the cosine of the polar angle of the slow pion, respectively. The asymmetry values for various decays are thus calculated in bins of $(p_{\pi_s}, \cos\theta_\pi)$, as well as in bins of the D meson polar angle, as explained below.

Graphically the method of correction is illustrated in Fig. 19.2.27. A similar method has been used in the analysis of $D^0 \to K_S^0 P^0$ ($P^0 = \pi^0$, η, or η') decays (Ko, 2011). An attentive reader may wonder why the treatment of the
Figure 19.2.27. Graphical presentation of the method to correct the measurement of the CP asymmetry in D meson decays. In the case of $D^0 \to h^+h^-$ the difference between the measured asymmetries for $D^{*+} \to D^0(\to K^-\pi^+)\pi_s^+$ (a) and $D^0 \to K^-\pi^+$ (b) decays in a given bin of π_s momentum, its polar angle θ_{π_s} and the D meson polar angle in the CM system θ^*, yields the detector induced asymmetry $A_\epsilon^{\pi_s}$. This can be used to correct the measured asymmetry for the decays $D^{*+} \to D^0(\to h^-h^+)\pi_s^+$ (c) resulting in the sum $A_{CP} + A_{FB}$ (d). The latter can be distinguished according to their $\cos\theta^*$ dependence.

asymmetries as a function of the D meson polar angle in the CM system, $\cos\theta^*$, is needed. The forward-backward

---

[136] The asymmetry follows from the angular distribution of produced fermions in the e^+e^- collisions, $d\sigma/d\cos\theta_f \propto 1 + \cos^2\theta_f + (8/3)A_{FB}^0\cos\theta_f$ (Eidelman et al., 2004).

asymmetry would vanish when integrated over this variable. A subtle reason lies in the fact that the pion polar angle in the laboratory frame, θ_π, on which the detector induced asymmetries depend upon [137] is correlated with θ^*. Hence in a given bin of $\cos\theta_\pi$ the integration over $\cos\theta^*$ does not assure a vanishing A_{FB} contribution.

In $D^+_{(s)} \to K^0_S h^+$ decays ($h^+ = \pi^+$ or K^+), the reconstructed asymmetries can be written as

$$A_{\rm rec}^{D^+_{(s)} \to K^0_S h^+} = A_{CP}^{D^+_{(s)} \to K^0_S h^+} + A_{FB}^{D^+_{(s)}} + A_\epsilon^{h^+}. \quad (19.2.75)$$

To correct for $A_{FB}^{D^+_{(s)}}$ and $A_\epsilon^{h^+}$, Belle (Ko, 2010) uses reconstructed samples of $D^+_s \to \phi\pi^+$ and $D^0 \to K^-\pi^+$ decays, assuming that A_{CP} in Cabibbo favored decays is negligibly small at the current experimental sensitivity (note that within the SM CP violation in charm decays is expected only for Cabibbo suppressed decays, see Section 19.2.1.3). Another assumption is that A_{FB} is the same for all charmed mesons.

The measured asymmetry for $D^+_s \to \phi\pi^+$ is the sum of $A_{FB}^{D^+_s}$ and $A_\epsilon^{\pi^+}$. Hence one can extract the A_{CP} value for the $K^0_S \pi^+$ final states by subtracting the measured asymmetry for $D^+_s \to \phi\pi^+$ from that for $D^+_{(s)} \to K^0_S \pi^+$. The subtraction is performed in bins of π^+ momentum, p_π, and polar angle in the laboratory system, $\cos\theta_\pi$ and the charmed meson's polar angle in the center-of-mass system, $\cos\theta^*_{D^+_{(s)}}$. The three-dimensional (3D) binning is determined in such a way to avoid large statistical fluctuations in each bin. The statistical precision of the $D^+_s \to K^0_S \pi^+$ sample is too low to allow for a 3D correction to $A_{\rm rec}^{D^+_s \to K^0_S \pi^+}$ at present. For this mode one corrects for the forward backward and detection efficiency asymmetries with an inclusive correction obtained by subtracting $A_{\rm rec}^{D^+ \to K^0_S \pi^+}$ from $A_{CP}^{D^+ \to K^0_S \pi^+}$ after integrating over the entire $(p_\pi, \cos\theta_\pi, \cos\theta^*_{D^+})$ space. This technique yields a systematic uncertainty of 0.18%, which originates from the statistical uncertainty of the selected $D^+_s \to \phi\pi^+$ sample. Similar methods have been used in the analysis of $D^+ \to \pi^+ \eta^{(\prime)}$ decays (Won, 2011).

Recently, the *BABAR* collaboration has developed another data-driven method (del Amo Sanchez, 2011i) to determine the charge asymmetry in the track reconstruction as a function of the magnitude of the track momentum and its polar angle, in the analysis of $D^+ \to K^0_S \pi^+$ decays. B mesons are produced in the process $e^+ e^- \to \Upsilon(4S) \to B\bar{B}$. This production mechanism is free of any physics-induced charge or flavor asymmetry. The CP violation in the later decays of B mesons must vanish if one takes a completely inclusive sample of B meson decay products. Hence the inclusive $\Upsilon(4S) \to B\bar{B}$ events provide a very large control sample in which any asymmetry is detector induced. However, data recorded at the $\Upsilon(4S)$ resonance also include continuum production $e^+ e^- \to q\bar{q}$ ($q = u, d, s, c$), where there is a non-negligible

FB asymmetry due to the interference between the single virtual photon process and other production processes, as described above. The continuum contribution is estimated using the off-resonance data rescaled to the same luminosity as the on-resonance data sample. Subtracting the number of reconstructed tracks in the rescaled off-resonance sample from the number of tracks in the on-resonance one, *BABAR* obtains the number of tracks corresponding to the B meson decays only. Therefore, the relative detection and identification efficiencies of the positively and negatively charged particles for given selection criteria can be determined using the numbers of positively and negatively reconstructed tracks directly from data. This technique yields a smaller systematic uncertainty of 0.08%. The obtained π^+/π^- asymmetry map as a function of the pion momentum and polar angle is shown in Fig. 19.2.28. Deviations from unity are largest at low polar angles (due to the amount of the material traversed by the pions) and at relatively low momenta (where the difference between the π^+ and π^- cross-sections for interactions with nucleons is the largest).
Figure 19.2.28. Charged pion reconstruction efficiency ratio $\epsilon(\pi^+)/\epsilon(\pi^-)$ (top) obtained using the method of (del Amo Sanchez, 2011i) as described in the text, and the corresponding statistical errors (bottom).

The method for the measurement of A_{CP} in the $K^0_S K^+$ final state is different from that for the $K^0_S \pi^+$ final state. The $A_{FB}^{D^+_{(s)}}$ and $A_\epsilon^{\pi^+}$ components in $A_{\rm rec}^{D^+_{(s)} \to K^0_S \pi^+}$ are obtained directly from the $D^+_s \to \phi\pi^+$ sample, but there is no corresponding large statistics decay mode that can be used to directly measure the $A_{FB}^{D^+_{(s)}}$ and $A_\epsilon^{K^+}$ components in $A_{\rm rec}^{D^+_{(s)} \to K^0_S K^+}$. Thus, to correct the reconstructed asymmetry in the $K^0_S K^+$ final states, one uses samples of $D^0 \to K^-\pi^+$ and $D^+_s \to \phi\pi^+$ decays.

---

[137] More precisely, the amount of the material traversed by the pion depends on this angle.

The measured asymmetry for $D^0 \to K^-\pi^+$ is a sum of $A_{FB}^{D^0}$, $A_\epsilon^{K^-}$, and $A_\epsilon^{\pi^+}$. Thus, one can extract $A_\epsilon^{K^-}$ by subtracting the measured asymmetry for $D_s^+ \to \phi\pi^+$ from that for $D^0 \to K^-\pi^+$. An $A_\epsilon^{K^-}$ correction map is obtained as follows; $N_{\rm rec}^{D^0 \to K^-\pi^+}$ and $N_{\rm rec}^{\overline{D}^0 \to K^+\pi^-}$ are corrected according to the reconstructed asymmetry for $D_s^+ \to \phi\pi^+$ in bins of $(p_\pi, \cos\theta_\pi, \cos\theta_{D_{(s)}}^*)$. Subsequently, corrected $N_{\rm rec}^{D^0 \to K^-\pi^+}$ and $N_{\rm rec}^{\overline{D}^0 \to K^+\pi^-}$ values are determined in bins of $K^\mp$ momentum and polar angle in the laboratory frame, $(p_{K^\mp}, \cos\theta_{K^\mp})$. From the corrected values of $N_{\rm rec}^{D^0 \to K^-\pi^+}$ and $N_{\rm rec}^{\overline{D}^0 \to K^+\pi^-}$ one obtains an $A_\epsilon^{K^-}$ map that is used to correct for $A_\epsilon^{K^+}$ in the $K_S^0 K^+$ final state. By subtracting $A_\epsilon^{K^+}$ from the reconstructed asymmetry of $D_{(s)}^+ \to K_S^0 K^+$, one obtains the corrected reconstruction asymmetry $A_{\rm rec,corr}^{D_{(s)}^+ \to K_S^0 K^+}$ for $D_{(s)}^+ \to K_S^0 K^+$:

$$
\begin{aligned}
A_{\rm rec,corr}^{D_{(s)}^+ \to K_S^0 K^+} &= A_{\rm rec}^{D_{(s)}^+ \to K_S^0 K^+} - A_\epsilon^{K^+} \\
&= A_{FB}^{D_{(s)}^+} + A_{CP}^{D_{(s)}^+ \to K_S^0 K^+}.
\end{aligned}
\qquad (19.2.76)
$$

As shown in Eq. (19.2.76), $A_{\rm rec,corr}^{D_{(s)}^+ \to K_S^0 K^+}$ includes not only an A_{CP} component but also the A_{FB} component. Since A_{CP} is independent of all kinematic variables, while A_{FB} is an odd function of $\cos\theta_{D_{(s)}^+}^*$, as explained above, one extracts the two components from $A_{\rm rec,corr}^{D_{(s)}^+ \to K_S^0 K^+}$ as a function of $\cos\theta_{D_{(s)}^+}^*$ through Eq. (19.2.72).

In the most recent measurement of $A_{CP}(D^+ \to K_S^0\pi^+)$ Belle (Ko, 2012) uses two different control samples instead of $D_s^+ \to \phi\pi^+$, composed of selected $D^+ \to K^-\pi^+\pi^+$ and $D^0 \to K^-\pi^+\pi^0$ decays. These decays have larger branching fractions and hence the systematic uncertainty arising from the correction due to the charged pion efficiency asymmetry is reduced. The two aforementioned decay modes are Cabibbo favored and hence one does not expect any observable CP violation (see Section 19.2.1.3).[138] Writing out the detector and forward-backward induced contributions to the measured asymmetries in $D^+ \to K^-\pi^+\pi^+$ and $D^0 \to K^-\pi^+\pi^0$ (and assuming the latter is the same for the two modes) it's easy to see that the comparison of the two yields the $A_\epsilon^{\pi^+}$ necessary to correct the measured asymmetry in $D^+ \to K_S^0\pi^+$:

$$
A_{\rm rec}^{D^+ \to K^-\pi^+\pi^+} = A_{FB}^{D^+} + A_{\epsilon_1}^{\pi^+} + A_{\epsilon_2}^{\pi^+} + A_\epsilon^{K^-}
$$

---

[138] The CP violation in decay is expected only in singly Cabibbo suppressed decays, and this is the only possible type of violation appearing in D^+ decays. On the other hand for D^0 decays there's also a possibility of CP violation in mixing and mixing induced CP violation, as explained in Section 16.6. Comparison of the decay-time integrated rates of $D^0 \to K^-\pi^+\pi^0$ and $\overline{D}^0 \to K^+\pi^-\pi^0$ shows that the contribution of this type of CP violation to the A_{CP} measurement is $-y\sqrt{R_D^{K\pi\pi^0}}\sin\delta_{K\pi\pi^0}\sin\phi$. This small quantity is included as one of the systematic uncertainties for this result.

$$
A_{\rm rec}^{D^0 \to K^-\pi^+\pi^0} = A_{FB}^{D^0} + A_{\epsilon_1}^{\pi^+} + A_\epsilon^{K^-} \qquad (19.2.77)
$$
$$
A_{\epsilon_2}^{\pi^+} = A_{\rm rec}^{D^+ \to K^-\pi^+\pi^+} - A_{\rm rec}^{D^0 \to K^-\pi^+\pi^0},
$$

assuming $A_{FB}^{D^+} = A_{FB}^{D^0}$.

Another correction must be applied to the measured asymmetries with a K_S^0 in the final state. In specific decays of charm hadrons either K^0 or $\overline{K}^0$ mesons are produced which propagate in time and are at some later time reconstructed as a K_S^0 decaying to $\pi^+\pi^-$. The K^0 and $\overline{K}^0$ have, however, very different cross-sections for interactions with nucleons in the material of the detector that they traverse (mainly the beam pipe and the material of the silicon vertex detector, see Chapter 2 for the description of the detectors and (Beringer et al., 2012) for the differences in the cross-sections). If a neutral kaon interacts in the material, it normally cannot be reconstructed. Hence the efficiency for the reconstruction of a K_S^0 arising in, for example, a $D \to \overline{K}^0 X$ decay may differ from the efficiency of the K_S^0 reconstruction arising in a $\overline{D} \to K^0\overline{X}$ decay. This asymmetry is not related to the CP violation in charm meson decays and must be corrected for. The asymmetry depends on the amount of material traversed by the neutral kaon as well as (due to the energy dependence of the cross-section) on its momentum. The effect is not included in the simulation packages used by Belle and *BABAR* (Agostinelli et al., 2003) and hence a dedicated study has been performed (Ko, Won, Golob, and Pakhlov, 2011) for various detector geometries. The additional contribution to the asymmetry due to this source is found to be of the order of 0.1% and is included in the measurements with K_S^0 in the final state either as an additional correction or a systematic uncertainty.

Furthermore, Grossman and Nir (2012) have pointed out a non negligible effect of the $K_S^0 - K_L^0$ interference in decays with neutral kaons in the final state. It depends on the acceptance dependence on the neutral kaon decay time. For the analysis in (Ko, 2012) this effect results in a correction factor of 1.022 ± 0.007 for $A_{CP}(D^+ \to K_S^0\pi^+)$.

19.2.6.2 Results

All results of t-integrated CP violation measurements for charm mesons together with the control data samples used for various corrections are listed in Table 19.2.5. In the following some specifics of selected measurements are described.

$D^+ \to K_S^0\pi^+$, $D^0 \to K_S^0 P^0$

A time-integrated CP violation search in $D^+ \to K_S^0\pi^+$ is carried out by both the Belle and *BABAR* collaborations (Ko, 2012; del Amo Sanchez, 2011i). In both experiments corrections for non-CP violating asymmetries are performed as explained in the previous section. Specifically, one expects a non-vanishing asymmetry due to the presence of neutral kaons in the final state. The asymmetry measured by Belle is $A_{CP}(D^+ \to K_S^0\pi^+) = (-0.363 \pm$

$0.094 \pm 0.067)\%$ where the main systematic uncertainty (0.062%) is due to the statistical uncertainty of the control samples used for the $A_\epsilon^{\pi^+}$ correction. In contrast, *BABAR* uses inclusive on- and off-resonance data for the correction and this enables them to achieve a systematic uncertainty of 0.08% despite the significantly lower total integrated luminosity of the sample used for the measurement. The corrected asymmetry value from *BABAR* is $A_{CP}(D^+ \to K_S^0 \pi^+) = (-0.44 \pm 0.13 \pm 0.10)\%$. The *CP* asymmetry from *BABAR* is shown in Fig. 19.2.29 as a function of $|\cos \theta_D^*|$.

If results from the two experiments are combined assuming uncorrelated systematic uncertainties, one obtains $A_{CP}(D^+ \to K_S^0 \pi^+) = (-0.389 \pm 0.094)\%$ (where the last error is combined statistical and systematic uncertainty) and this is one of the first hints of *CP* violation in charm decays. It should be noted, however, that this is consistent with *CP* violation due to neutral kaon mixing in the final state. Namely $D^+ \to K_S^0 \pi^+$ decays receive a contribution from the CF process $D^+ \to \overline{K}^0 \pi^+$ as well as from the DCS process $D^+ \to K^0 \pi^+$. Either $\overline{K}^0$ or K^0 at a later time decays as a K_S^0 reconstructed through the $K_S^0 \to \pi^+ \pi^-$ decay. Hence, even in the absence of any *CP* violation in D meson decays, there is an additional contribution to the measured asymmetry due to the *CP* violation in the neutral kaon system. One expects

$$A_{\overline{K}^0} = \left| \frac{|\langle \pi^+ \pi^- | \overline{K}^0 \rangle|^2 - |\langle \pi^+ \pi^- | K^0 \rangle|^2}{|\langle \pi^+ \pi^- | \overline{K}^0 \rangle|^2 + |\langle \pi^+ \pi^- | K^0 \rangle|^2} \right|^2$$
$$\simeq -\frac{1 - |(p/q)_{K^0}|^2}{1 + |(p/q)_{K^0}|^2} = -\frac{2\mathrm{Re}(\epsilon)}{1 + |\epsilon|^2}. \quad (19.2.78)$$

The expected asymmetry in this decay mode due to the *CP* violation in the neutral kaon system is $(-0.332 \pm 0.006)\%$ (Beringer et al., 2012). The average result for $A_{CP}(D^+ \to K_S^0 \pi^+)$ is in good agreement with this expectation, implying no significant *CP* violation in the charged D meson sector. The results from both collaborations also show a remarkable precision achieved despite the need for significant corrections (several corrections of the order of 0.1% to measure the final central value of the same order) in evaluating the intrinsic *CP* asymmetry.

$A_{CP}(D^0 \to K_S^0 P^0)$, where P^0 is π^0 or $\eta^{(\prime)}$ is measured by the Belle experiment (Ko, 2011). Assuming no *CP* violation in decay for the $K_S^0 \pi^0$ mode (a mixture of CF and DCS decays) it can be used to test the universality of indirect *CP* violation, as explained further in Section 19.2.7.

$D^0 \to KK/\pi\pi$

Searches for time-integrated *CP*-violating asymmetries in decays $D^0 \to K^+ K^-$ and $D^0 \to \pi^+ \pi^-$ are carried out by the *BABAR* and Belle collaborations (Aubert, 2008aq; (Staric, 2008)) using 386 fb^{-1} and 540 fb^{-1} of data, respectively. The analysis is similar in both cases, except that the *BABAR* collaboration extracts the signal yields by fitting the mass distributions, while the Belle collaboration uses the method of sideband-subtraction.
Figure 19.2.29. *CP* asymmetries for $D^+ \to K_S^0 \pi^+$ candidates as a function of $|\cos \theta_D^*|$. The solid line represents the central value of A_{CP} and the hatched region is the $\pm 1\sigma$ interval, obtained from a minimization assuming no dependence on $|\cos \theta_D^*|$ (del Amo Sanchez, 2011i).

As already discussed in Section 19.2.6.1 the measured (or raw) asymmetry can be expressed with a sum of three contributions $A_{\mathrm{rec}} = A_{CP} + A_{FB} + A_\epsilon^{\pi_s}$, where the first one is constant, the second one is an odd function of $\cos \theta^*$ and the last one depends on the slow pion phase space $(p_{\pi_s}, \cos \theta_{\pi_s})$, since this asymmetry is due to detector effects. In Section 19.2.6.1 we also discussed that the term $A_\epsilon^{\pi_s}$ can be obtained from data by using tagged and untagged $D^0 \to K^- \pi^+$ decays. Both experiments use this method; *BABAR* has determined the slow pion detection asymmetry $A_\epsilon^{\pi_s}$ in 3×3 bins, while Belle uses a 5×5 binning in the same momentum range (0.1–$0.6\,\mathrm{GeV}/c$).

The slow pion asymmetry map is used to correct the raw asymmetry. This is done by weighting the $D^0/\overline{D}^0$ candidates with the following weights:

$$w_{D^0} = 1 - A_\epsilon^{\pi_s}(p_{\pi_s}, \cos \theta_{\pi_s}),$$
$$w_{\overline{D}^0} = 1 + A_\epsilon^{\pi_s}(p_{\pi_s}, \cos \theta_{\pi_s}). \quad (19.2.79)$$

Note that only candidates in bins with valid $A_\epsilon^{\pi_s}$ measurements are taken into account. This procedure results in a corrected asymmetry $A_{\mathrm{rec}}^{\mathrm{cor}}$, which is free of the contribution due to the slow pion detection asymmetry. It is calculated as,

$$A_{\mathrm{rec}}^{\mathrm{cor}}(\cos \theta^*) = \frac{m(\cos \theta^*) - \overline{m}(\cos \theta^*)}{m(\cos \theta^*) + \overline{m}(\cos \theta^*)}, \quad (19.2.80)$$

where $m(\overline{m})$ represent the sum of weights of the $D^0(\overline{D}^0)$ candidates in each bin of $\cos \theta^*$.

Finally, taking into account their specific dependence on $\cos \theta^*$, the asymmetries A_{CP} and A_{FB} are extracted by adding or subtracting bins at $\pm \cos \theta^*$, see Eq. (19.2.72).

The systematic uncertainties arise from the signal counting method (*BABAR*: choice of *p.d.f.*, Belle: non-linear background shape), from slow pion corrections
Figure 19.2.30. From (Staric, 2008). Measurement of CP-violating asymmetries in (a) KK and (b) $\pi\pi$ final states, and forward-backward asymmetries in (c) KK and (d) $\pi\pi$ final states. The solid curves represent the central values obtained from the least square minimizations; the dashed curves in (c) and (d) show the leading order expectation.

(statistics of $K^-\pi^+$ samples, binning) and from the A_{CP} extraction procedure (binning, $\cos\theta^*$ range).

The results of both measurements are presented in Table 19.2.5. Figure 19.2.30 is a graphical representation of the Belle results. For individual decay modes the results agree within the uncertainties. The $BABAR$-Belle averages (assuming uncorrelated systematic uncertainties) are

$$A_{CP}(\pi\pi) = (+0.11 \pm 0.39)\%$$
$$A_{CP}(KK) = (-0.24 \pm 0.24)\% . \qquad (19.2.81)$$

The measured values are consistent with no CP violation at the level of $\sim 0.3\%$.

Both experiments obtain forward-backward asymmetries that are consistent with each other (see Fig. 19.2.30), but do not agree well with the leading order calculations. Similar is true for measurements of other decay modes. Unfortunately due to lack of reliable predictions at $E_{\rm CM} \approx$ 10 GeV it is difficult to quantify the level of disagreement in the A_{FB} measurements.

Multibody decays

Direct CP violation is expected to depend on f, the final state for each decay. For multibody decays, therefore, the phenomenon will depend on sub modes. $BABAR$, in performing t-integrated measurements of $D^0 \rightarrow K^+K^-\pi^0$ and $D^0 \rightarrow \pi^+\pi^-\pi^0$ decays (Aubert, 2008ap) also exploited the possibility of normalizing D^0 and $\overline{D}^0$ rates separately to their total 3-body systems, thereby eliminating the most significant experimental uncertainty (the charge asymmetry in efficiency).

They adopt four different methods, three of which are independent of any decay model. The model-dependent method, introduced by the CLEO collaboration in a study of $D^+ \rightarrow K^+K^-\pi^+$ decays (Rubin et al., 2008) compares results of fits to the Dalitz plot distributions of D^0 and $\overline{D}^0$ decays to a model based upon the isobar (quasi two-body) approximation with Breit-Wigner parameterizations for the various intermediate resonances (see Chapter 13). Neither magnitude nor phase of any intermediate 2-body mode shows a significant difference between the charge conjugated modes. As an illustration, the intermediate state with the largest contribution to the $\pi^+\pi^-\pi^0$ final state, $\rho^\pm(770)\pi^\mp$, exhibits a relative difference of amplitude magnitudes of $(-3.2 \pm 1.7 \pm 0.8)\%$ and of phases $(-0.8 \pm 1.0 \pm 1.0)°$.

The first model-independent method is, perhaps, the most obvious. Bin by bin differences between efficiency corrected, background subtracted yields of D^0 and $\overline{D}^0$ Dalitz plot distributions (see Chapter 13) are examined. The yields are normalized so that there are equal numbers of D^0 and $\overline{D}^0$ events. A χ^2 is defined as

$$\chi^2 = \sum_i \chi_i^2 = \sum_i \frac{(n_i^{\overline{D}^0} - R n_i^{D^0})^2}{(\sigma_i^{\overline{D}^0})^2 + R^2 (\sigma_i^{D^0})^2} , \qquad (19.2.82)$$

where $\sigma_i^{D^0}$ and $\sigma_i^{\overline{D}^0}$ are the uncertainties of the corresponding yields $n_i^{D^0}$ and $n_i^{\overline{D}^0}$ in the i-th bin of the Dalitz plot distribution. The renormalization factor R is introduced to remove the possible overall asymmetry in the total number of reconstructed D^0 and $\overline{D}^0$ events. The method is sensitive to possible differences in the shapes of Dalitz distributions but not in the total populations. Using an ensemble of simulated experiments it is found that the value of χ^2/ν, where ν is the number of the Dalitz plot bins, is consistent with no CP violation at the confidence levels of 33% and 17% for the $D^0 \rightarrow \pi^+\pi^-\pi^0$ and $D^0 \rightarrow K^+K^-\pi^0$ decays, respectively. The normalized differences in yields for the $D^0 \rightarrow \pi^+\pi^-\pi^0$ decays are shown in Fig. 19.2.31.[139]

In the second model independent method the angular distributions for the same, normalized, efficiency corrected, background subtracted yields are studied to extract information on the partial wave content of any differences between D^0 and $\overline{D}^0$ decays. The differences $(n_i^{\overline{D}^0} - R n_i^{D^0})$ are weighted by Legendre polynomial functions $P_\ell(\cos\theta)$ normalized over the range $-1 < \cos\theta \le 1$. For the AB "channel" (quasi two-body mode $D^0 \rightarrow r+C, r \rightarrow A + B$) θ is the angle between the momenta of B and C in the r rest frame. The resulting "Legendre difference moments",

$$X_\ell = \frac{(\overline{P}_\ell - R \cdot P_\ell)}{\sqrt{\sigma_{\overline{P}_\ell}^2 + R^2 \cdot \sigma_{P_\ell}^2}}, \qquad (19.2.83)$$

(where the σ^2's are variances for the indicated quantities) are highly correlated. This is because any partial wave

---

[139] An almost identical method is discussed in a later paper (Bediaga et al., 2009) and is commonly referred to as the "Miranda method".

Table 19.2.5. Summary of results of time-integrated *CP* violation measurements for charm mesons. The decay modes are grouped to singly Cabibbo suppressed (SCS), Cabibbo favored (CF) and doubly Cabibbo suppressed (DCS) modes. The third column lists the control data samples used to correct for non-*CP* asymmetries appearing in the measurements.

arising from *CP* violation in *D* decay to any of the resonances in any of the three channels would stimulate nonzero moments in several related values of ℓ.

A statistical test for *CP* violation estimates the probability for any moment (which is chosen to be within the range $0 - 7$) to be inconsistent with no *CP* violation. For this, the quantity

$$\chi^2/\nu = \sum_0^k \sum_{\ell=0}^7 \sum_{m=0}^7 (X_\ell \rho_{\ell m} X_m)/\nu \qquad (19.2.84)$$

summed over each of the k invariant mass ranges in various channels is defined. The number of degrees of freedom $\nu = 8k$.

Five hundred Dalitz plots consistent with no *CP* violation are simulated from actual *BABAR* data in which each event is taken randomly as either D^0 or $\overline{D}^0$. The resulting moments X_ℓ and their correlations $\rho_{\ell m}$ are computed for each sample. The χ^2/ν for the actual *BABAR* sample, with D^*-tagged assignments as D^0 or $\overline{D}^0$ is then compared with the distribution of 500 simulated samples to obtain a one-sided Gaussian C.L. for no *CP* violation. The C.L.'s obtained are 28.2% for the $\pi^+\pi^-$ channel, 28.4% for $\pi^+\pi^0$, 63.1% for K^+K^-, and 23.8% for the $K^+\pi^0$ channels, each consistent with no *CP* violation.

The final method, also model independent, consists of comparison of the total number of D^0 and $\overline{D}^0$ decays in the quoted modes and was also used by Belle for $D^0 \to \pi^+\pi^-\pi^0$ (Arinstein, 2008). The correction for $A_\epsilon^{\pi_s}$ is, in the *BABAR* case, made as described in Section 19.2.6.1

while Belle uses partially reconstructed $D^{*+} \to D^0(\to K_s^0\pi^+\pi^-)\pi^+$ decays to estimate the tracking efficiency systematics (see Chapter 15), but separately for the negative and positive pions. The values of A_{CP} obtained by this method are quoted in Table 19.2.5.
Figure 19.2.31. From (Aubert, 2008ap). χ_i^2 defined in Eq. (19.2.82) calculated from efficiency corrected and background subtracted $D^0 \to \pi^+\pi^-\pi^0$ and $\overline{D}^0 \to \pi^+\pi^-\pi^0$ yields across the Dalitz plane.

19.2.6.3 T-odd correlations

The study of T-odd correlations provides a powerful tool to indirectly search for CP violation. It is straight forward to show that any triple product of momenta (TP), given by $\boldsymbol{v}_1 \cdot (\boldsymbol{v}_2 \times \boldsymbol{v}_3)$, is odd under the time-reversal symmetry operator T. It is clearly also odd under the spatial inversion (parity operator P). The kinematics of a four-body decay can be described by a TP, and so in the usual way one can construct an asymmetry from T conjugate pairs of triple products, namely $\boldsymbol{v}_1 \cdot (\boldsymbol{v}_2 \times \boldsymbol{v}_3) > 0$ and $\boldsymbol{v}_1 \cdot (\boldsymbol{v}_2 \times \boldsymbol{v}_3) < 0$. The choice of T-odd correlations to search for CP violation is proposed by many authors (Bensalem, Datta, and London, 2002a,b; Bensalem and London, 2001; Bigi, 2001; Kayser, 1990; Valencia, 1989) and studies in D decays follow on from similar measurements made for neutral kaon decays.[140] One can construct a T-odd observable using the spin or the momentum ($\boldsymbol{v}_i$) of the final state particles in the D CM frame. The TP asymmetry observable of interest is

$$A_{TP} = \frac{\Gamma(\boldsymbol{v}_1 \cdot (\boldsymbol{v}_2 \times \boldsymbol{v}_3) > 0) - \Gamma(\boldsymbol{v}_1 \cdot (\boldsymbol{v}_2 \times \boldsymbol{v}_3) < 0)}{\Gamma(\boldsymbol{v}_1 \cdot (\boldsymbol{v}_2 \times \boldsymbol{v}_3) > 0) + \Gamma(\boldsymbol{v}_1 \cdot (\boldsymbol{v}_2 \times \boldsymbol{v}_3) < 0)}$$

(19.2.85)

where Γ represents the number of signal events and is measured for D decays only.

However, this is not a true P violating observable, due to final state interaction (FSI) effects that can introduce asymmetries (Bigi and Li, 2009). In order to remove these effects one needs to measure the CP conjugate of this observable ($\overline{A}_{TP}$) using the $\overline{D}$ decays and evaluate the CP violating observable:

$$a_{TP} \equiv \frac{1}{2}(A_{TP} - \overline{A}_{TP}).$$

(19.2.86)

This can be explained considering that the asymmetry A_{TP} has a phase that is the sum of a complex CP violating weak phase and a real strong phase (introduced by FSI). Under the operation of CP conjugation the weak phase changes its sign, while the strong phase does not. Thus, the difference between A_{TP} and $\overline{A}_{TP}$ removes the strong phase and the factor $1/2$ is required for normalization. The exact definition of $\overline{A}_{TP}$ is given in Eq. (19.2.89).

This method requires three independent momentum vectors, thus at least four different particles are reconstructed in the final state unless the spin of the decaying particle is known. In this last case, the spin of the mother can be used in Eq. (19.2.85).

---

[140] Some of the literature refers to CP violating T-odd observables as T-violating observables; however, this is not a correct nomenclature. T-violation in kaon decays is discussed in the PDG (Beringer et al., 2012). Section 17.6 discusses T-violation measurements by BABAR for B decays, and it has been pointed out by Bevan, Inguglia, and Zoccali (2013) that similar measurements are possible using pairs of entangled D mesons produced at the $\psi(3770)$. A recent article discussing TP asymmetries in K, B and D decays has been written by Gronau and Rosner (2011).

The search for CP violation by means of the T-odd correlations at the B Factories has been performed by BABAR in $D^0 \to K^+ K^- \pi^+ \pi^-$, $D^+ \to K^+ K^0_S \pi^+ \pi^-$ and $D^+_s \to K^+ K^0_S \pi^+ \pi^-$ decays. The latter is a Cabibbo favored decay and no effect is expected, while the others are Cabibbo suppressed decays and the effect could be as large as 0.1%, considering Standard Model processes only (Buccella, Lusignoli, Miele, Pugliese, and Santorelli, 1995). The sensitivity reached at the B Factories for these observables is comparable to the higher SM expectations. Observing an asymmetry would be a signal for processes beyond the SM.

The variable used to build the T-odd correlation observable is defined using the momenta of the final state particles in the D CM frame:

$$C_{TP} = \boldsymbol{p}_{K^+} \cdot (\boldsymbol{p}_{\pi^+} \times \boldsymbol{p}_{\pi^-}).$$

(19.2.87)

The asymmetry parameters to be measured are then:

$$A_{TP} = \frac{\Gamma(D, C_{TP} > 0) - \Gamma(D, C_{TP} < 0)}{\Gamma(D, C_{TP} > 0) + \Gamma(D, C_{TP} < 0)},$$

(19.2.88)

$$\overline{A}_{TP} = \frac{\Gamma(\overline{D}, -\overline{C}_{TP} > 0) - \Gamma(\overline{D}, -\overline{C}_{TP} < 0)}{\Gamma(\overline{D}, -\overline{C}_{TP} > 0) + \Gamma(\overline{D}, -\overline{C}_{TP} < 0)}.$$

(19.2.89)

All three analyses have measured the asymmetry parameters through a simultaneous maximum likelihood fit to the four samples obtained by splitting the data set using the D flavor and the C_{TP} ($\overline{C}_{TP}$) value. Furthermore, a blind analysis has been performed: the asymmetry parameters A_{TP} and $\overline{A}_{TP}$ have been masked adding unknown random offsets, and all the selection criteria and systematic effects have been evaluated before unveiling the final result.

The $D^0 \to K^+ K^- \pi^+ \pi^-$ analysis (del Amo Sanchez, 2010n) makes use of 471 fb^{-1} data recorded by the BABAR detector at the $\Upsilon(4S)$ energy and 40 MeV below. The decay chain

$$e^+ e^- \to X D^{*+}; \, D^{*+} \to \pi^+_s D^0; \, D^0 \to K^+ K^- \pi^+ \pi^-,$$
where X indicates any system composed of charged and neutral particles, has been reconstructed from the sample of events having at least five charged tracks. At first, the D^0 has been reconstructed, requiring the momentum in the CM frame $p^*(D^0) > 2.5 \, \text{GeV}/c$ to suppress the background. Then, the successful D^0 candidate has been combined with any charged track having momentum less than $0.65 \, \text{GeV}/c$ (π^+_s) to form the D^{*+} candidate. A contamination from $D^0 \to K^0_S K^+ K^-$ has been removed applying a mass veto to the $K^0_S \to \pi^+ \pi^-$ candidates. This procedure selects about 50,000 signal events.

The two-dimensional distribution of $m(K^+ K^- \pi^+ \pi^-)$ vs. $\Delta m = m(K^+ K^- \pi^+ \pi^- \pi^+_s) - m(K^+ K^- \pi^+ \pi^-)$ has been described by five components: (i) true D^0 signal originating from a D^{*+} decay (signal); and backgrounds comprised of (ii) random π^+_s events where a true D^0 is combined to an incorrect π^+_s (D^0-peaking); (iii) misreconstructed D^0 decays, where one or more of the D^0 decay products are either not reconstructed or reconstructed

with the wrong particle hypothesis (Δm-peaking); (iv) combinatorial; (v) $D_s^+ \to K^+ K^- \pi^+ \pi^- \pi^+$ contamination. The functional forms of the probability density functions for the signal and background components are based on studies of the generic $e^+ e^- \to c\bar{c}$ Monte Carlo (MC) sample. However, all parameters related to these functions are determined from a two-dimensional likelihood fit to data over the full $m(K^+ K^- \pi^+ \pi^-)$ vs. Δm region, shown in Fig. 19.2.32. Combinations of Gaussian and Johnson SU (Johnson, 1949) lineshapes are used for peaking distributions, and polynomials and threshold functions for the non-peaking backgrounds.

Many possible sources of systematic effect have been considered in this analysis, for each of them the related selection criteria have been varied by a small amount to evaluate the deviations with respect to the asymmetries obtained applying the nominal criteria. Among them, the largest contributions to systematic error are due to the particle identification, the selection on $p^*(D^0)$ and the fit bias.

The results are

$$A_{TP}(D^0) = (-68.5 \pm 7.3(\text{stat}) \pm 5.8(\text{syst})) \times 10^{-3},$$
$$\overline{A}_{TP}(\overline{D}^0) = (-70.5 \pm 7.3(\text{stat}) \pm 3.9(\text{syst})) \times 10^{-3},$$
$$a_{TP}(D^0) = (1.0 \pm 5.1(\text{stat}) \pm 4.4(\text{syst})) \times 10^{-3}.$$
$$(19.2.90)$$

No CP violation is found, even though A_{TP} and $\overline{A}_{TP}$ are significantly different from zero, indicating the effect of FSIs.

The reconstruction of the $D_{(s)}^+ \to K^+ K_S^0 \pi^+ \pi^-$ decays in the other *BABAR* analysis (Lees, 2011i), that used $520\,\text{fb}^{-1}$ recorded around a CM energy of $10.6\,\text{GeV}$, is similar. After the reconstruction of the $K_S^0 \to \pi^+ \pi^-$ decay, the K_S^0 candidates are combined into a vertex with three other charged tracks in the event to reconstruct inclusive $D_{(s)}^+$ decays. A kinematic selection on $p^*(D_{(s)}^+) > 2.5\,\text{GeV}/c$ is required to suppress the background. Possible background contamination from $D_{(s)}^+ \to K^+ K_S^0 K_S^0$ decays have been removed by applying a K_S^0 veto.

The signal to background ratio has been then optimized using a likelihood ratio. The probability density functions used to build the likelihood ratio are taken from the distributions of three kinematic variables: (i) $p^*(D_{(s)}^+)$; (ii) $\Delta p = P_1 - P_2$, the difference between the probability of the nominal fit (P_1) and the probability of the fit obtained constraining the $D_{(s)}^+$ vertex into the interaction region (P_2); and (iii) $L_T(D_{(s)}^+)$, the flight distance of the $D_{(s)}^+$ meson in the transverse plane. The signal distributions are obtained from the signal regions of two control samples, the Cabibbo favored $D^+ \to K_S^0 \pi^+ \pi^+ \pi^-$ and $D_s^+ \to K^- K_S^0 \pi^+ \pi^+$ decays, for D^+ and D_s^+, respectively. The background distributions are taken from data sidebands.

A likelihood ratio, optimized on $S/\sqrt{S+B}$ (see Chapter 4) for the signal region, has been applied to obtain the best significance of the mass peak. About 20,000 (30,000) D^+ (D_s^+) signal events have been reconstructed.

The model to fit the $K^+ K_S^0 \pi^+ \pi^-$ mass spectrum has been developed and validated on large samples of inclusive MC processed using the same reconstruction and analysis chain as that used for real events. The mass spectrum has been separated in two regions centered on D^+ and D_s^+ peak, respectively, and the specific requirement on likelihood ratio has been applied.

The model used to simultaneously fit the four samples obtained separating the events by charge and C_{TP} ($\overline{C}_{TP}$) value is composed of two Gaussians for the peak and a second order polynomial for D^+ (D_s^+) background.

The simultaneous fit on the four data subsamples allows one to measure directly the asymmetries:

$$A_{TP}(D^+) = (+11.2 \pm 14.1(\text{stat}) \pm 5.7(\text{syst})) \times 10^{-3},$$
$$\overline{A}_{TP}(D^-) = (+35.1 \pm 14.3(\text{stat}) \pm 7.2(\text{syst})) \times 10^{-3},$$
$$A_{TP}(D_s^+) = (-99.2 \pm 10.7(\text{stat}) \pm 8.3(\text{syst})) \times 10^{-3},$$
$$\overline{A}_{TP}(D_s^-) = (-72.1 \pm 10.9(\text{stat}) \pm 10.7(\text{syst})) \times 10^{-3},$$
$$(19.2.91)$$

from which the CP violation parameters can be obtained

$$a_{TP}(D^+) = (-12.0 \pm 10.0(\text{stat}) \pm 4.6(\text{syst})) \times 10^{-3},$$
$$a_{TP}(D_s^+) = (-13.6 \pm 7.7(\text{stat}) \pm 3.4(\text{syst})) \times 10^{-3}.$$
$$(19.2.92)$$

The sources of systematic error that have been considered are the fit model, the particle identification, the fit bias measured on MC and the selection based on the likelihood ratio. The procedure to evaluate the systematic error follows the same strategy of the D^0 analysis. A slightly different behavior is observed for the A_{TP} and $\overline{A}_{TP}$ asymmetries in D^+ and D_s^+. Even if the final state is the same, a different resonant sub-structure may be responsible for this difference (Gronau and Rosner, 2011).

The CP violation results obtained at the B Factories in four-body D decays are consistent with zero to a precision of 0.5%. These results are in agreement with expectations from SM predictions. Nevertheless, the relative simplicity of the analyses based on T-odd correlations and the results that can be obtained allow one to consider this tool as fundamental to search for CP violation in four-body decays. Furthermore, the study of T-odd correlations allows one to probe FSI in four-body D decays.

19.2.6.4 Summary

Numerous t-integrated searches for CP violation in charm meson decays have been performed by the B Factories and these show no significant intrinsic effect at the levels of sensitivity achieved. These differ from a few percent for the DCS decays to over a few tenths of a percent for SCS decays to 0.1% for CF decays (see Table 19.2.5). Because of the various detector induced and physics (forward-backward) asymmetries the measurements require careful calibration of the data using control samples and hence represent one of the most demanding measurements performed at the B Factories. *BABAR* and Belle developed
Figure 19.2.32. From (del Amo Sanchez, 2010n). The distribution of selected events in the $m(K^+K^-\pi^+\pi^-)$ vs. Δm plane (a) is shown together with the projections of the events with overlaid the fit results for $m(K^+K^-\pi^+\pi^-)$ (b) and Δm (c), with the shaded areas indicating the different contributions. In the bottom, the distribution of the normalized residuals (Pull), is shown for each fit projection.

several methods for such calibrations which assure a satisfactory control of measurement uncertainties that are applicable for the next generation of flavor factories (note that the main systematic uncertainties, arising from limited statistics of control data samples, will be reduced with increased luminosity). It is a remarkable demonstration that both experiments can measure subtle effects such as the asymmetry arising from the CP violation in the neutral kaon system in charm meson decays involving K_S^0's. In combination with t-dependent measurements, CP violating asymmetries represent interesting tests of the SM, as described further in Section 19.2.7.

19.2.7 t-dependent CP violating asymmetries

A general aspect of the possible CP violation effects in the charm sector as well as various parameterizations were discussed in Section 19.2.1.3. In the time dependence of D^0 decays one can search for the effects of all three types of CP violation.

19.2.7.1 Decays to CP eigenstates

Let us start by examining the decays into CP eigenstates, like K^+K^-. The measurements of the mixing-related parameter y_{CP} in this decay mode are described in Sections 19.2.3.1 and 19.2.3.2. In order to search for CP violating effects one has to distinguish between decays of particles and anti-particles. Squaring the modulus in Eqs (19.2.11) and (19.2.12) (keeping the parameter q/p, *i.e.* not setting $q = p = 1/\sqrt{2}$), and using the parameterization as defined in Eqs (19.2.17), (19.2.18) and (19.2.20), we arrive at the time evolution of $D^0 \to K^+K^-$ decays

$$|\langle K^+K^-|D^0(\Gamma t)\rangle|^2 = e^{-\Gamma t}|A_{KK}|^2$$

$$[1 - (1 + \frac{A_M - A_D^{KK}}{2})(x\sin\phi - y\cos\phi)\,\Gamma t],$$
(19.2.93)

and an equivalent expression for $|\langle K^+K^-|\overline{D}^0(t)\rangle|^2$. It is valid to linear order in the dimensionless decay time Γt. One can see that in the above dependence parameters describing all three types of CP violation are present: A_M (CP violation in mixing), A_D^{KK} (CP violation in decay) and ϕ (CP violation in the interference between decays with and without mixing). If Eq. (19.2.93) is regarded as the first term in the expansion of an exponential function,[141] we arrive at separate expressions for the inverse of the effective lifetime of neutral meson decays in this mode:

$$\frac{1}{\tau_{KK}} = \frac{1}{\tau}\left[1 \mp \left(1 \pm (A_M - A_D^{KK})/2\right)(x\sin\phi \mp y\cos\phi)\right],$$
(19.2.94)

where the upper sign corresponds to D^0 and the lower one to $\overline{D}^0$ decays. Hence by measuring separately the effective lifetimes of neutral D meson decays (using tagging of the initial D meson flavor with D^* mesons, as described in Section 19.2.1.5) one can determine the lifetime asymmetry:

$$A_\Gamma \equiv \frac{\tau(\overline{D}^0 \to KK) - \tau(D^0 \to KK)}{\tau(\overline{D}^0 \to KK) + \tau(D^0 \to KK)} =$$

$$= \frac{A_M - A_D^{KK}}{2}y\cos\phi - x\sin\phi \ . \quad (19.2.95)$$

A non-zero value of the asymmetry A_Γ would be a sign of CP violation in the D^0 system - at least one parameter,

---

[141] This is equivalent to the derivation of the y_{CP} parameter, see Eq. (19.2.30) – (19.2.34), but now separately for D^0 and $\overline{D}^0$ decays.

A_D^{KK}, A_M or ϕ, must be different from zero. The sensitivity of A_Γ to the CP violating parameters is limited by the small magnitude of the mixing parameters x and y.

Measurements of this asymmetry were typically performed together with the measurements of y_{CP}. The average of measurements (Staric, 2012a; Lees, 2013d) using the K^+K^- and $\pi^+\pi^-$ final states is found to be

$$A_\Gamma = (0.02 \pm 0.17)\% \quad, \tag{19.2.96}$$

where the error includes statistical and systematic uncertainties.[142]

The main contributions to the systematic uncertainty on A_Γ arise from similar sources as in the y_{CP} measurements, from possible biases in the acceptance dependence on the decay time and the assumption of an equal mean of the resolution function in both decay modes used (see Section 19.2.3.1). From the A_Γ value one can conclude there is currently no significant sign of CP violation at the sensitivity level of 0.25%.

It should be noted that the decay time integrated CP violating asymmetry, as defined in Eq. (19.2.63) of Section 19.2.6, also receives contributions from all the types of CP violation, and the CP violation in decay (A_D^f) appears in the linear order. Upon the summation of Eq. (19.2.65) and Eq. (19.2.95) we get

$$A_{CP}^{KK} + A_\Gamma = A_D^{KK} \tag{19.2.97}$$

(in the above equation the CP violation in decays to K^+K^- is denoted by A_D^{KK}). Hence one can estimate the amount of CP violation in decay by summing the two corresponding results. Using the averages of the $A_{CP}^{KK(\pi\pi)}$ measurements (see Section 19.2.6.2), and assuming the systematic uncertainties due to completely different methods of measurements are uncorrelated, one obtains results for the K^+K^- and $\pi^+\pi^-$ final states:

$$\begin{aligned} A_D^{KK} &= (-0.22 \pm 0.29)\% \quad, \\ A_D^{\pi\pi} &= (+0.13 \pm 0.43)\% \quad, \end{aligned} \tag{19.2.98}$$

including both types of uncertainties.

19.2.7.2 Hadronic wrong-sign decays

The measurements of the mixing parameters in this type of decay are described in Section 19.2.2. Since the fit to the decay time dependence of the wrong-sign decays involves parameters x'^2 and y', a similar fit is repeated by

---

[142] Note that A_Γ can in principle differ for various different final states due to the A_D^f term in Eq. (19.2.95). Hence the averaging of the A_Γ values obtained in D meson decays to K^+K^- and $\pi^+\pi^-$ final states is not justified. However, the difference between $(1/2)(A_M - A_D^{KK})y\cos\phi$ and $(1/2)(A_M - A_D^{\pi\pi})y\cos\phi$, i.e. $(1/2)(A_D^{\pi\pi} - A_D^{KK})y\cos\phi$, is only $(1\pm1)\times10^{-5}$ using the average values (Amhis et al., 2012) of parameters involved. As long as the accuracy of A_Γ measurement doesn't reach that level the approximation done in the averaging is justified.

applying Eq. (19.2.22) separately for D^0 and $\bar{D}^0$ decays. One introduces separate parameters $x'^{2\pm}$ and $y'^\pm$, where $+$ and $-$ denote parameters for D^0 and $\bar{D}^0$ decays, respectively. Any difference between corresponding parameters denoted by $+$ or $-$ represents a sign of CP violation. Parameters $x'^{2\pm}$ and $y'^\pm$ can of course be related to the CP violating parameters in mixing and in the interference introduced in Section 19.2.1.3:

$$x'^\pm = \left[\frac{1 \pm A_M}{1 \mp A_M}\right]^{1/4} (x'\cos\phi \pm y'\sin\phi),$$

$$y'^\pm = \left[\frac{1 \pm A_M}{1 \mp A_M}\right]^{1/4} (y'\cos\phi \mp x'\sin\phi). \tag{19.2.99}$$

Apart from the above parameters, R_D is also duplicated to $R_D^\pm$ using an analogous notation. Any difference between R_D^+ and R_D^- is related to CP violation in decay:

$$A_D = \frac{R_D^+ - R_D^-}{R_D^+ + R_D^-} \quad. \tag{19.2.100}$$

Inclusion of more free parameters to describe the CP violation leads to a reduced statistical accuracy of the obtained results. This can be seen in Fig. 19.2.11, comparing the 95% C.L. regions of x'^2 and y' as obtained from the fits allowing or neglecting the CP violation.

Fits allowing for CP violation were performed by Zhang (2006) and Aubert (2007j). They are given in Table 19.2.6.

Table 19.2.6. CP violation results using $D^0 \to K\pi$ WS decays from BABAR (Aubert, 2007j) and Belle (Zhang, 2006). When two uncertainties are given, the first is statistical and the second systematic. Results with a single uncertainty have both statistical and systematic components combined. Limits correspond to 95% C.L.

Parameter	Fit Results ($\times 10^{-3}$)	
	BABAR	Belle
Assuming both mixing and CP violation		
R_D	$3.03 \pm 0.16 \pm 0.10$	—
A_D	$-21 \pm 52 \pm 15$	23 ± 47
A_M	—	670 ± 1200
x'^{2+}	$-0.24 \pm 0.43 \pm 0.30$	—
y'^+	$9.8 \pm 6.4 \pm 4.5$	—
x'^{2-}	$-0.20 \pm 0.41 \pm 0.29$	—
y'^-	$9.6 \pm 6.1 \pm 4.3$	—
x'^2	—	< 0.72
y'	—	$-28 < y' < 21$

Taking the averages of the measurements [143] and assuming uncorrelated systematic errors one obtains

$$x'^{2+} - x'^{2-} = (0.011 \pm 0.041)\%$$

---

[143] Also converting the results from Belle to $x'^{2\pm}$ and $y'^\pm$, according to (Amhis et al., 2012).

$$y'^+ - y'^- = (-0.19 \pm 0.64)\% \ , \qquad (19.2.101)$$

consistent with no *CP* violation.

In the study of the $D^0 \to K^+\pi^-\pi^+\pi^-$ decays (see Section 19.2.2.3) *BABAR* (Aubert, 2006ap) also performs a fit allowing for *CP* violation. The D^0 and $\overline{D}^0$ decay-time distributions are treated separately, by making a substitution in Eq. (19.2.26):

$$\alpha\widetilde{y}' \to |p/q|^{\pm 1}(\alpha\widetilde{y}'\cos\widetilde{\phi} \pm \beta\widetilde{x}'\sin\widetilde{\phi})$$
$$x^2 + y^2 \to |p/q|^{\pm 2}(x^2 + y^2), \qquad (19.2.102)$$

choosing the "+" ("−") sign for D^0 ($\overline{D}^0$) candidate decays, respectively. *CP* violation in mixing is parameterized by $|p/q|$ and a *CP*-violating phase $\widetilde{\phi}$ is introduced to account for *CP* violation in the interference between mixing and DCS decay. The resulting values of the *CP* violating parameters are consistent with no *CP* violation:

$$R_M = [0.017^{+0.017}_{-0.016}(\text{stat}) \pm 0.003(\text{syst})]\%,$$
$$|p/q| = 1.1^{+4.0}_{-0.6}(\text{stat}) \pm 0.1(\text{syst}),$$
$$\alpha\widetilde{y}'\cos\widetilde{\phi} = -0.006^{+0.008}_{-0.006}(\text{stat}) \pm 0.006(\text{syst}),$$
$$\beta\widetilde{x}'\cos\widetilde{\phi} = 0.002^{+0.005}_{-0.003}(\text{stat}) \pm 0.006(\text{syst}).$$
$$(19.2.103)$$

19.2.7.3 *t*-dependent Dalitz Analyses

Violation of the *CP* symmetry can also be searched for in the analyses of the decay time dependence of the Dalitz distributions in multi-body final states. As for the hadronic wrong-sign decays one can perform a fit to separate D^0 and $\overline{D}^0$ samples (see the previous section). Any difference in the resulting mixing parameters can be ascribed to *CP* violation. This is done in the measurement of the $K^+\pi^-\pi^0$ final state (see Section 19.2.4.1) by *BABAR* (Aubert, 2009u). The resulting x', y' parameters are shown in Table 19.2.7. Within the uncertainties they are consistent between the two samples indicating no significant *CP* violation.

Table 19.2.7. *CP* violation results using separate D^0 and $\overline{D}^0$ samples in the analysis of $K^+\pi^-\pi^0$ final state (Aubert, 2009u).

D^0 only	$x' = (+2.53^{+0.54}_{-0.63} \pm 0.39)\%$
	$y' = (-0.05^{+0.63}_{-0.67} \pm 0.50)\%$
$\overline{D}^0$ only	$x' = (+3.55^{+0.73}_{-0.83} \pm 0.65)\%$
	$y' = (-0.54^{+0.40}_{-1.16} \pm 0.41)\%$

In the Belle search for *CP* violation in the $K^0_S\pi^+\pi^-$ final state (Abe, 2007b) the measurement consists of an extension of the fit procedure described in Section 19.2.4.2. The time evolution of the Dalitz distribution as given in Eq. (19.2.52) is used without setting $q = p = 1/\sqrt{2}$. The possibility of *CP* violation in mixing and mixing induced

CP violation is parameterized by $q/p = |q/p|e^{i\phi}$ with $|q/p|$ and ϕ as free parameters of the fit. The *CP* violation in decay would be manifest as a difference between the magnitudes or phases of the individual intermediate states contributing. This type of the *CP* violation is searched for first by allowing these amplitudes to differ for D^0 and $\overline{D}^0$ decays, while not (yet) introducing additional parameters describing the other two types of the *CP* violation. Such an approach is used due to possible complications in the fitting procedure.[144] In this measurement no significant deviations between the amplitudes of intermediate-state contributions to D^0 and $\overline{D}^0$ decays were found, and hence one can conclude that no sign of *CP* violation in decay was observed. Following this, the individual amplitudes are fixed to be the same for D^0 and $\overline{D}^0$ and the parameters $|q/p|$ and ϕ are introduced. The results are listed in Table 19.2.8.

BABAR (del Amo Sanchez, 2010f) uses the same approach for the $K^+\pi^-\pi^0$ final state, fitting separately D^0 and $\overline{D}^0$ tagged samples with duplicated mixing parameters denoted as x^+, y^+ and x^-, y^-, respectively. The results are given in Table 19.2.8.

Table 19.2.8. Results of search for *CP* violation in time dependent Dalitz analysis of $K^0_S h^+ h^-$ final state (del Amo Sanchez, 2010f; Abe, 2007b).

Experiment	Sample	Results [$\times 10^3$]
BABAR	486.5 fb^{-1}	
CP violation	Purity: 98.5%	$x^+ = 0.0 \pm 3.3$
		$y^+ = 5.5 \pm 2.7$
		$x^- = 3.3 \pm 3.3$
		$y^- = 5.9 \pm 2.8$
Belle	540 fb^{-1}	
CP violation	Purity: 95.0%	$x = 8.1 \pm 3.0^{+1.0+0.9}_{-0.7-1.6}$
		$y = 3.7 \pm 2.5^{+0.7+0.7}_{-1.3-0.8}$
		$|q/p| = 0.86^{+0.30+0.06}_{-0.29-0.03} \pm 0.08$
		$\phi = (-14^{+16+5+2}_{-18-3-4})°$

The results show that parameters x^+, y^+ are consistent with x^-, y^-, $|q/p|$ is consistent with unity and ϕ is consistent with 0. Hence the measurements show no significant sign of *CP* violation.

19.2.8 Summary

Mixing of neutral charm mesons has been established by the *B* Factories. The first results were reported in 2007 and published as back-to-back articles. Mixing was established through the study of wrong sign decays by *BABAR* (Aubert, 2007j) (see Section 19.2.2), and via the measurement of y_{CP} by Belle (Staric, 2007) (see Section 19.2.3). The accuracy achieved by the *B* Factories is well beyond the expectations before the start of data taking in 1999. By

---

[144] Note that by allowing magnitudes and phases of the D^0 and $\overline{D}^0$ decays to differ essentially doubles the number of free parameters in the fit.

the time data taking was well under way, the full potential of *B* Factories as charm factories was realized and interest in charm physics, especially in the FCNC's of *D* mesons, was greatly increased. The reason for this was the physics interest in constraints on NP arising from an up-type quark (charm) FCNC's as well as the availability of large samples of reconstructed charm hadrons. Mixing parameters in the $D^0 - \bar{D}^0$ system are now known to an accuracy of $\mathcal{O}(10^{-3})$ from measurements done at the *B* Factories. The average of results from *B* Factories on the mixing parameters x and y, shown in the upper part of Table 19.2.9, are

$$x = (0.59^{+0.21}_{-0.22})\%$$
$$y = (0.78 \pm 0.12)\% . \qquad (19.2.104)$$

Graphically they are depicted in Fig. 19.2.33. The no-mixing hypothesis is rejected with a significance of $\mathcal{O}(10)\sigma$.
Figure 19.2.33. Likelihood contours of the HFAG-like fit to various measurements of mixing and *CP* violation parameters in the D^0 system, in the (x, y) plane.

The average is calculated according to the Heavy Flavor Averaging Group (Amhis et al., 2012) method, using a χ^2 fit assuming uncorrelated systematic errors, but taking into account statistical correlations among the observables as provided by the experiments. Free parameters of the fit are listed in the lower part of Table 19.2.9.

Because the long-distance contributions to the $D^0 - \bar{D}^0$ mixing amplitude are difficult to calculate, the measured values are difficult to interpret. They may receive some contribution from unknown NP processes, although the measured values can be accommodated within the SM.

For several years observation of *CP* violating asymmetries in the charm sector at the level of $\mathcal{O}(10^{-2})$ was considered as rather clear signature for NP. Measurements performed at the *B* Factories achieved the sensitivity level

of $\mathcal{O}(10^{-3})$. They are probably some of the most demanding measurements as far as the systematic uncertainties are concerned because one needs to control detector induced asymmetries using various control data samples. Several *CP* violating asymmetries are measured to be at the few per mille level but consistent with no *CP* violation. Averages of the most important *CP* violation parameters are given in Table 19.2.9. In Fig. 19.2.34 the likelihood contours of the average are shown in the $(|q/p|, \phi)$ plane. No deviations from *CP* conservation in the charm sector have been observed. Measurements at the *B* Factories have triggered an increased activity also on the theoretical side providing more accurate predictions.
Figure 19.2.34. Likelihood contours of the HFAG-like fit to various measurements of mixing and *CP* violation parameters in the D^0 system, in the $(|q/p|, \phi)$ plane.

Results on mixing and especially *CP* violation in the charm sector have not dried up with the end of the data taking at *B* Factories. The LHCb collaboration recently presented a very precise measurement of the *CP* violation in $D^0 \to h^+ h^-$ decays (Aaij et al., 2013c). One can hope for more precise (statistically significant) measurements of *CP* violation in the charm sector from this and future flavor physics experiments.

Table 19.2.9. Results on mixing and *CP* violation parameters for neutral charm mesons from *B* Factories. Averages are calculated using the HFAG method assuming uncorrelated systematic errors.

19.3.1 Introduction

In ordinary conditions of temperature and baryon density, quantum chromodynamics (QCD) describes colored quarks permanently bound in colorless hadrons. Accounting for the non-perturbative strong dynamics producing the outstanding phenomenon of confinement represents a difficulty which has been faced in several ways, using methods with various degrees of theoretical soundness, reliability and a variety of results. The main approaches to describe bound states of quarks are the constituent quark models, QCD sum rules and lattice QCD. Moreover, it is possible to formulate effective theories of QCD in limits in which particular symmetries, not present in the full QCD Lagrangian, become apparent and can be exploited. Comparing the outcome of the various calculations (mass spectra, decay rates, etc.) to the measurements has allowed the interpretation of many experimental results. On the other hand, it has been possible to test the accuracy of the theoretical methods and of the procedures adopted to obtain quantitative predictions. The wealth of new information in charm spectroscopy collected at the B Factories has allowed a remarkable progress in the description of the strong dynamics of quarks, as it is briefly described below. A few puzzling features of the observed states deserve further investigations.

19.3.1.1 Constituent quark models

Quark models are traditionally a method to compute properties like hadron masses and couplings. In such approaches the hadrons are approximately described in terms of rest-frame valence quark configurations, the dynamics of which is governed by a Hamiltonian derived from (or inspired by) QCD. In particular, quark confinement is implemented by a flavor-independent, linearly increasing Lorentz-scalar interquark interaction at large distances, while the short-distance quark dynamics is described by a one-gluon exchange interaction. For a system comprising a heavy quark $Q = c$ and a light antiquark $\bar{q} = \bar{u}, \bar{d}, \bar{s}$, the Hamiltonian is written as (Godfrey and Isgur, 1985)

$$H = H_0 + V, \qquad (19.3.1)$$

where

$$H_0 = (p^2 + m_Q^2)^{1/2} + (p^2 + m_{\bar{q}}^2)^{1/2} \qquad (19.3.2)$$

is the kinetic term, with p the modulus of the quark three-momentum in the meson rest frame. The potential V includes spin-independent and spin-dependent terms:

$$V = V_0 + V^{\mathrm{hyp}} + V^{\mathrm{so}}. \qquad (19.3.3)$$

V_0 is the sum of the confining and Coulomb potentials

$$V_0 = -\frac{4}{3}\frac{\alpha_s(r)}{r} + c + \sigma^2 r \qquad (19.3.4)$$

with c and σ^2 as free parameters. V^{hyp} describes the spin-spin interaction

$$V^{\mathrm{hyp}} = \frac{4}{3}\frac{\alpha_s(r)}{m_Q m_{\bar{q}}}\left[\frac{8\pi}{3}\boldsymbol{s}_Q \cdot \boldsymbol{s}_{\bar{q}}\,\delta^3(\boldsymbol{r}) \right.$$
$$\left. + \frac{1}{r^3}\left(3\frac{(\boldsymbol{s}_Q \cdot \boldsymbol{r})(\boldsymbol{s}_{\bar{q}} \cdot \boldsymbol{r})}{r^2} - \boldsymbol{s}_Q \cdot \boldsymbol{s}_{\bar{q}}\right)\right] \quad (19.3.5)$$

with $\boldsymbol{s}_Q$ and $\boldsymbol{s}_{\bar{q}}$ the heavy quark and light antiquark spin, respectively. V^{so} describes the spin-orbit interaction, expressed as a sum of the chromomagnetic and Thomas-precession contributions:

$$V^{\mathrm{so(cm)}} = \frac{4}{3}\frac{\alpha_s(r)}{r^3}\left(\frac{1}{m_Q} + \frac{1}{m_{\bar{q}}}\right)\left(\frac{\boldsymbol{s}_Q}{m_Q} + \frac{\boldsymbol{s}_{\bar{q}}}{m_{\bar{q}}}\right) \cdot \boldsymbol{L},$$
$$(19.3.6)$$

$$V^{\mathrm{so(Tp)}} = -\frac{1}{2r}\left(\frac{\partial}{\partial r}V_0\right)\left(\frac{\boldsymbol{s}_Q}{m_Q^2} + \frac{\boldsymbol{s}_{\bar{q}}}{m_{\bar{q}}^2}\right) \cdot \boldsymbol{L}. \quad (19.3.7)$$

$\boldsymbol{L}$ is the orbital angular momentum. The solution of a Schrödinger-like equation with the Hamiltonian (19.3.1) allows to obtain the mass spectrum and the wave functions for the states $n^{2J+1}L_{2S+1}$ classified according to the orbital angular momentum $\boldsymbol{L}$, the total spin of the quarks $\boldsymbol{S} = \boldsymbol{s}_Q + \boldsymbol{s}_{\bar{q}}$, the total angular momentum $\boldsymbol{J} = \boldsymbol{L} + \boldsymbol{S}$, and the radial quantum number n. From the wave functions, other quantities can be computed, *e.g.* the meson decay constants, form factors, the hadron strong couplings.

A few remarks are in order.

– The ("constituent") quark masses in the wave equation are input parameters, and do not coincide with the ("current") masses appearing in the QCD Lagrangian. For the light u and d quarks the constituent masses are fixed to values of $\mathcal{O}(100\,\mathrm{MeV})$, and of $\mathcal{O}(300\,\mathrm{MeV})$ for the strange quark, well above the values of the current masses in the QCD Lagrangian.
– The running of the strong coupling α_s can be implemented as a dependence on the interquark distance, $\alpha_s = \alpha_s(r)$; each model is characterized by its implementation of $\alpha_s(r)$.
– Spin dependent terms in the potential present singularities of the type $1/r^n$ with $n > 1$, corresponding to "illegal" operators in the wave equation. This is a consequence of reducing the relativistic quark-antiquark interaction to an instantaneous potential. The treatment of such singularities introduces a model dependence in the calculation of the meson properties.

– The effect of nearby multi-hadron thresholds (or quark unquenching) is not taken into account in the calculation of, *e.g.*, the mass spectrum. Although such an approximation is legitimate in the limit of large number of colors, in real QCD it represents a systematic uncertainty affecting, in particular, the determination of the masses of the orbital and radial excitations.

In a quark model approach the $c\bar{q}$ spectrum ($q = u, d, s$) was already computed long ago with results shown in Table 19.3.1, namely in (Godfrey and Isgur, 1985). These are in rather close agreement (within 20–30 MeV) with the data in the case of the lightest S-wave ($L = 0$) states and of two $J^P = 2^+$ and $J^P = 1^+$ P-wave ($L = 1$) states, as one can argue considering the experimental measurements reported in Tables 19.3.2 and 19.3.3. As for the state with $J^P = 0^+$ and the second state with $J^P = 1^+$ (both with $L = 1$), in the $c\bar{s}$ case the predicted masses are larger (by about 100 MeV) than the masses of the scalar and axial vector D_{sJ} mesons discussed below in this chapter. Several modifications and improvements have been implemented, namely in models based on the expansion of the Hamiltonian (19.3.1) in the inverse mass of the charm quark, in the spirit of the heavy quark limit described in Section 19.3.1.2 (Di Pierro and Eichten, 2001), and in determinations of the $c\bar{q}$ Regge trajectories (Ebert, Faustov, and Galkin, 2010), but the resulting masses of the scalar and of one of the axial vector D_{sJ} mesons remain larger than in the experiment. A few quark models also predict spin-orbit inversion for the excited states (Godfrey and Kokoski, 1991; Isgur, 1998), which is not observed in data.

To quantitatively assess the accuracy of quark model predictions is not an easy task, due to the assumptions needed to formulate a wave equation for quark-antiquark bound states starting from the QCD Lagrangian; in particular, the effect of quark unquenching is poorly known. Nevertheless, the discrepancy between the predictions of various models and the mass measurements has prompted

the idea that some observed states could not be simple quark-antiquark configurations, but more complex structures, like bound state ("molecules") of other mesons (Barnes, Close, and Lipkin, 2003) or mixtures of conventional quark-antiquark with four-quark components (Vijande, Fernandez, and Valcarce, 2006). A discrimination between the different possibilities is feasible considering the results not only for the masses, but also for the widths of the various decay modes. Within the quark models the calculation of the latter quantities presents further uncertainties: in the infinite heavy quark mass limit a different formalism can be developed to study the classification, the spectrum and some decay processes of heavy-light hadrons, as discussed below.

19.3.1.2 Exploiting symmetries of QCD in particular limits: the Heavy Quark Chiral Effective Theory

In the limit in which the masses of the heavy quarks (*i.e.* quarks with $m_Q \gg \Lambda_{\text{QCD}}$) is sent to infinity, two symmetries emerge in the QCD Lagrangian. The first one is a flavor symmetry, since the dependence on the flavor in QCD is only encoded in the quark mass, and for $m_Q \to \infty$ the heavy flavors are identically described. The second one is a spin symmetry, arising from the decoupling of the spin of a heavy quark from the spin of the light quarks and of the gluons (usually denoted as light degrees of freedom) (Neubert, 1994b). The two symmetries can be recognized at a simple inspection of the Hamiltonian (19.3.1)-(19.3.7); both spin and flavor symmetries are commonly denoted as the "heavy quark symmetry".

A consequence of the heavy quark symmetry is that, in the infinite heavy quark mass limit, heavy-light $Q\bar{q}$ mesons can be classified in doublets labeled by the value of the total angular momentum $\boldsymbol{j}_q$ of the light degrees of freedom with respect to the heavy quark Q (Isgur and Wise, 1991). The spin of each member of the doublet is obtained combining the spin of the heavy quark with the $\boldsymbol{j}_q$: $\boldsymbol{J} = \boldsymbol{s}_Q + \boldsymbol{j}_q$; in the quark model $\boldsymbol{j}_q$ would be given by $\boldsymbol{j}_q = \boldsymbol{s}_{\bar{q}} + \boldsymbol{L}$. Spin symmetry implies that in each doublet the two states are degenerate in mass.

For $L = 0$ the doublet has $j_q = \dfrac{1}{2}$ and consists of two states (P, P^*) (P refers to a generic heavy meson) with spin-parity $J^P_{j_q} = (0^-, 1^-)_{1/2}$. P-wave states, with $L = 1$, form two doublets: (P_0^*, P_1') with $J^P_{j_q} = (0^+, 1^+)_{1/2}$, and (P_1, P_2^*) with $J^P_{j_q} = (1^+, 2^+)_{3/2}$. D-wave states give rise to two other doublets: (P_1^*, P_2) with $J^P_{j_q} = (1^-, 2^-)_{3/2}$, and $(P_2'^*, P_3)$ with $J^P_{j_q} = (2^-, 3^-)_{5/2}$. Notice that the parity of the doublets has been identified with the parity of the corresponding mesons, $P = (-1)^{L+1}$.

This construction is applied to both open beauty and open charm mesons. In the case of charm, the (P, P^*) doublet is filled by the D_q and D_q^* states, with $q = u, d$ and s. The finite heavy quark mass corrections are responsible for removing the mass degeneracy in each doublet (which holds in the light $SU(3)_F$ limit), and are larger in the case of charm than in the case of beauty mesons.

Table 19.3.1. Masses (in GeV) of charmed mesons computed in (Godfrey and Isgur, 1985). The corresponding $L = 1$ experimental findings for D_J and D_{sJ} states are reported in Table 19.3.2 and Table 19.3.3 respectively.

$c\bar{q}$ ($L=0$)	Mass	$c\bar{q}$ ($L=1$)	Mass	$c\bar{q}$ ($L=2$)	Mass
$D(^1S_0)$	1.88	$D(^3P_0)$	2.40	$D(^3D_1)$	2.82
$D(^3S_1)$	2.04	$D(^3P_1)$	2.49	$D(^3D_3)$	2.83
		$D(^3P_2)$	2.50		
		$D(^1P_1)$	2.44		
$c\bar{s}$ ($L=0$)	Mass	$c\bar{s}$ ($L=1$)	Mass	$c\bar{s}$ ($L=2$)	Mass
$D_s(^1S_0)$	1.98	$D_s(^3P_0)$	2.48	$D_s(^3D_1)$	2.90
$D_s(^3S_1)$	2.13	$D_s(^3P_1)$	2.57	$D_s(^3D_3)$	2.92
		$D_s(^3P_2)$	2.59		
		$D_s(^1P_1)$	2.53		

The conservation of angular momentum and parity in strong interactions, together with the heavy quark symmetry, imposes constraints on the transitions between the members of the various doublets with the emission of a light pseudoscalar meson (Isgur and Wise, 1991). In particular, the transitions of the excited states with $j_q^P = \frac{1}{2}^+$ into states with $j_q^P = \frac{1}{2}^-$ and a pion or kaon occur in S-wave, while the transitions of the states with $j_q^P = \frac{3}{2}^+$ into $j_q^P = \frac{1}{2}^-$ ones and a pion or kaon are in D-wave. The consequence is that, if such transitions are kinematically allowed, the $j_q^P = \frac{1}{2}^+$ resonances are expected to be broader than the $j_q^P = \frac{3}{2}^+$ ones. At the next-to-leading order in the $1/m_Q$ expansion, the axial vector states in the $j_q^P = \frac{3}{2}^+$ doublet can also decay in S-wave. An example is provided by the D_2 meson, which decays to $D\pi$ in D-wave; at the leading order in the heavy quark expansion, its spin partner D_1 decays to $D^*\pi$ also in D-wave, and their widths, which depend on the three momentum of the emitted pion as $|\boldsymbol{p}|_\pi^5$, are quite narrow.[145] On the other hand, the scalar D_0^* meson decays to $D\pi$ in S-wave, which explains its broad width.

The strong transitions between states belonging to the various doublets or within the same doublet, can be studied in an effective field theory formalism. An effective QCD Lagrangian is constructed in the infinite heavy quark mass limit, hence exploiting the heavy quark symmetry, and in the limit in which the light quark masses (u, d and s) vanish and another symmetry holds for QCD, the chiral $SU(3)_L \times SU(3)_R$ symmetry. The various heavy meson doublets are represented by fields of 4×4 matrices. The doublets with $j_q^P = \frac{1}{2}^-$ and $j_q^P = \frac{1}{2}^+$ are described by the fields H_a and S_a, respectively, while the doublets with $j_q^P = \frac{3}{2}^+$, $j_q^P = \frac{3}{2}^-$ and $j_q^P = \frac{5}{2}^-$ by the fields T_a^μ, X_a^μ and $X_a'^{\mu\nu}$ (a is a light flavor index):

$$H_a = \frac{1+\slashed{v}}{2}[P_{a\mu}^* \gamma^\mu - P_a \gamma_5],$$

$$S_a = \frac{1+\slashed{v}}{2}[P_{1a}'^\mu \gamma_\mu \gamma_5 - P_{0a}^*], \qquad (19.3.8)$$

$$T_a^\mu = \frac{1+\slashed{v}}{2}$$
$$\times \left\{ P_{2a}^{*\mu\nu} \gamma_\nu - P_{1a\nu} \sqrt{\frac{3}{2}} \gamma_5 \left[g^{\mu\nu} - \frac{\gamma^\nu}{3}(\gamma^\mu - v^\mu) \right] \right\},$$

and analogous expressions for X_a^μ and $X_a'^{\mu\nu}$, with v the meson four-velocity. The doublet with $j_q^P = \frac{1}{2}^-$ corresponding to the first radial excitations is described by H_a'

---

[145] On very general grounds, the matrix element for the transition involving the orbital momentum L depends on the spatial integration of a $(kr)^L$ term, where $k = p/\hbar$, p is the momentum of the final state particle in the rest frame of the decaying particle, and L is the orbital momentum quantum number. Hence the matrix element is proportional to p^L. Furthermore the phase space of a two-body decay is proportional to p. Hence the decay width is proportional to $|\mathcal{M}|^2 \propto p^{2L+1}$.

---

with structure identical to H_a. The various operators P_i in Eq. (19.3.8) annihilate mesons of four-velocity v which is conserved in strong interaction processes.

The octet of light pseudoscalar mesons is introduced through the fields $\xi = e^{\frac{i\mathcal{M}}{f_\pi}}$, with $\mathcal{M}$ containing π, K and η fields:

$$\mathcal{M} = \begin{pmatrix} \sqrt{\frac{1}{2}}\pi^0 + \sqrt{\frac{1}{6}}\eta & \pi^+ & K^+ \\ \pi^- & -\sqrt{\frac{1}{2}}\pi^0 + \sqrt{\frac{1}{6}}\eta & K^0 \\ K^- & \bar{K}^0 & -\sqrt{\frac{2}{3}}\eta \end{pmatrix}$$

$$(19.3.9)$$

and $f_\pi = 132$ MeV the pion decay constant. The strong interaction of the heavy mesons with the octet of light pseudoscalar mesons is described by an effective Lagrangian invariant under chiral transformations of the light fields, and under heavy-quark spin-flavor transformations of the heavy fields. At the leading order in the heavy quark mass and light meson momentum expansion, the transition $F \to HM$ ($F = H, S$ and T, and M a light pseudoscalar meson) can be described by the Lagrangian terms (Burdman and Donoghue, 1992; Wise, 1992; Yan et al., 1992)

$$\mathcal{L}_H = g \, \text{Tr}[\bar{H}_a H_b \gamma_\mu \gamma_5 \mathcal{A}_{ba}^\mu],$$
$$\mathcal{L}_S = h \, \text{Tr}[\bar{H}_a S_b \gamma_\mu \gamma_5 \mathcal{A}_{ba}^\mu] + h.c., \qquad (19.3.10)$$
$$\mathcal{L}_T = \frac{h'}{\Lambda_\chi} \text{Tr}[\bar{H}_a T_b^\mu (iD_\mu \slashed{\mathcal{A}} + i\slashed{D}\mathcal{A}_\mu)_{ba} \gamma_5] + h.c.,$$

with $\mathcal{A}_{\mu ba} = \frac{i}{2}\left(\xi^\dagger \partial_\mu \xi - \xi \partial_\mu \xi^\dagger\right)_{bq}$, D the covariant derivative $D_{\mu ba} = -\delta_{ba}\partial_\mu + \mathcal{V}_{\mu ba}$ and $\mathcal{V}_{\mu ba} = \frac{1}{2}\left(\xi^\dagger \partial_\mu \xi + \xi \partial_\mu \xi^\dagger\right)_{ba}$. Λ_χ is a chiral symmetry-breaking scale (which can be set to $\Lambda_\chi = 1$ GeV), and g, h and h' are effective couplings, which can be determined from experiment or from theoretical calculations (see Section 19.3.1.4).

A set of other Lagrangian terms for the strong transitions among the various heavy quark doublets can be constructed analogously, including a few $\mathcal{O}(m_Q^{-1})$ corrections (Colangelo, De Fazio, and Ferrandes, 2006), from which the decay widths and ratios of decay branching fractions can be computed and compared to experiment. The results are useful to cast light on the $Q\bar{q}$ spectrum, providing support to the classification of the observed resonances.

In the $c\bar{q}$ ($q = u, d$) system, the mesons $D^{+,0}$ and $D^{*+,0}$ fill the $J_{j_q}^P = (0^-, 1^-)_{1/2}$ doublets. The properties of the positive parity states, collected in Table 19.3.5, follow the expectations based on the classification scheme outlined above, with a mixing between the two $J^P = 1^+$ states. A set of heavier states has been observed in the $D\pi$ and $D^*\pi$ distributions: $D(2550)^0$, $D^*(2600)^0$, $D^*(2600)^{0,+}$, $D(2750)^0$ and $D^*(2760)^{0,+}$ (del Amo Sanchez, 2010i); for them, a tentative assignment is proposed in the following.

Also the observed $c\bar{s}$ mesons fit in the classification scheme based on the heavy quark expansion. The two lightest mesons $D_s(1969)$ and $D_s^*(2112)$ fill the $J_{j_q}^P = (0^-, 1^-)_{1/2}$ doublet. There are four positive parity states:

Table 19.3.2. Properties of neutral $L = 1$ D_J mesons.

	J^P	Mass (MeV)	Width (MeV)	Observed decays
D_0^*	0^+	2352 ± 50	261 ± 50	$D\pi$
D_1'	1^+	2427 ± 36	384^{+130}_{-105}	$D^*\pi$
D_1	1^+	2421.3 ± 0.6	27.1 ± 2.7	$D^*\pi, D^0\pi^+\pi^-$
D_2^*	2^+	2462.6 ± 0.7	49.0 ± 1.4	$D^*\pi, D\pi$

$D_{s0}^*(2317)$ and $D_{s1}'(2460)$ which can be identified with the members of the doublet $J_{j_q}^P = (0^+, 1^+)_{1/2}$, and $D_{s1}(2536)$ and $D_{s2}^*(2573)$ filling the $J_{j_q}^P = (1^+, 2^+)_{3/2}$ doublet (Becirevic, Fajfer, and Prelovsek, 2004; Colangelo and De Fazio, 2003; Colangelo, De Fazio, and Ozpineci, 2005), with a $\mathcal{O}(\frac{1}{m_Q})$ mixing between the two 1^+ states. Both the $(0^+, 1^+)_{1/2}$ states have masses below the DK and the D^*K thresholds, respectively, and this explains their very narrow width (Swanson, 2006).[146] Their properties are collected in Tables 19.3.7 and 19.3.8.

The meson $D_{sJ}(2710)$ has been observed in the DK final state, and its spin-parity $J^P = 1^-$ has been determined (Brodzicka, 2008). A resonance $D_{sJ}(2860)$ has also been found in the DK spectrum (Aubert, 2006ag). Since both resonances also appear in the D^*K spectrum (Aubert, 2009au), they have natural parity, $J^P = 1^-, 2^+, 3^-, \cdots$. The decay mode into D^*K excludes the assignment $J^P = 0^+$ for $D_{sJ}(2860)$, and is compatible with the assignment $J^P = 3^-$ with radial quantum number $n = 1$, so that $D_{sJ}(2860)$ could be a member of the doublet $J_{j_q}^P = (2^-, 3^-)_{5/2}$ (Colangelo, De Fazio, and Nicotri, 2006). The rather narrow width of this resonance would be justified by this assignment, since the two-body decay to DK would occur in F-wave. The classification of the broad structure $D_{sJ}(3040)$ observed in the D^*K mass spectrum (Aubert, 2009au), has to be done on the basis of the available information on the mass, the width and the decay modes, together with the full set of information about the other doublets (Colangelo and De Fazio, 2010). Important observables are ratios of branching fractions, namely $\mathcal{B}(D_{sJ}(2710) \to D^*K)/\mathcal{B}(D_{sJ}(2710) \to DK)$ and $\mathcal{B}(D_{sJ}(2860) \to D^*K)/\mathcal{B}(D_{sJ}(2860) \to DK)$ (with $D^{(*)}K$ the sum over $D^{(*)0}K^+$ and $D^{(*)+}K_S^0$): the comparison of the measurement (Aubert, 2009au) with the theoretical results favors the interpretation of $D_{sJ}(2710)$ as the first radial excitation of $D_s^*(2112)$ and a member of the excited doublet $J_{j_q}^P = (0^-, 1^-)_{1/2}$ with radial quantum number $n = 2$ (Colangelo, De Fazio, Nicotri, and Rizzi, 2008; Close, Thomas, Lakhina, and Swanson, 2007). In the case of $D_{sJ}(2860)$ the measured ratio

of branching fractions is larger than the theoretical prediction, leaving the classification still an open issue.

Table 19.3.3. Properties of $L = 1$ D_{sJ} mesons.

	J^P	Mass (MeV)	Width (MeV)	Observed decays
D_{s0}^*	0^+	2317.8 ± 0.6	< 3.8	$D_s^+\pi^0$
D_{s1}'	1^+	2459.5 ± 0.6	< 3.5	$D_s^{*+}\pi^0, D_s^+\gamma, D_s^+\pi^+\pi^-$
D_{s1}	1^+	2535.28 ± 0.20	< 2.5	$D^{*+}K^0, D^{*0}K^+$
D_{s2}^*	2^+	2572.6 ± 0.9	20 ± 5	D^0K^+

The classification of $D_{s0}^*(2317)$ and $D_{s1}'(2460)$ as members of the spin doublet $j_q^P = \frac{1}{2}^+$, together with the observation that the mass splitting $M(D_{s1}') - M(D_{s0}^*)$ coincides with the mass splitting between $D_s(1969)$ and $D_s^*(2112)$ which belong to the negative parity $j_q^P = \frac{1}{2}^-$ doublet, has inspired the notion of chiral heavy-light meson doublets (Bardeen, Eichten, and Hill, 2003; Nowak, Rho, and Zahed, 2004). The idea is that the hadrons comprising a single heavy quark can be considered as "tethered" systems. In a scenario in which (explicitly and spontaneously broken) chiral symmetry is restored in QCD maintaining confinement, the heavy-light hadrons might appear in parity-doubled bound states which transform as linear representations of the chiral symmetry. An effective field theory, constrained by the heavy quark symmetry, can be formulated for such parity-doubled states, and as a consequence the mass difference ΔM between the $j_q^P = \frac{1}{2}^{\pm}$ parity doublets can be related to g_π, the $0^+ \to 0^- \pi$ coupling constant, and to the pion decay constant f_π by a relation similar to the Goldberger-Treiman formula: $\Delta M = g_\pi f_\pi$ (Bardeen, Eichten, and Hill, 2003).

The notion of heavy parity doublets needs to be further explored and confirmed, both in the case of the lightest doublets and for the other excited states. It has various consequences for the strong and radiative decay modes. The radiative E1 transitions $(1^+, 0^+) \to (1^-, 0^-)\gamma$, for example, as well as the $(1^+, 1^-) \to (0^+, 0^-)\gamma$ M1 transitions, are governed by similar combinations of the quark masses and electric charges, so that predictions for the various modes can be elaborated and compared to experiment. In Table 19.3.4 a tentative classification of all the observed mesons with open charm in HQ doublets is shown (Colangelo, De Fazio, Giannuzzi, and Nicotri, 2012).

As a last remark, the heavy quark symmetry allows to use the information available in the charm sector to predict properties in the beauty sector. For example, a doublet $J_{j_q}^P = (0^+, 1^+)_{1/2}$ of narrow positive parity $b\bar{s}$ mesons is expected with masses $M(B_{s0}^*) = (5.71 \pm 0.03)$ GeV and $M(B_{s1}') = (5.77 \pm 0.03)$ GeV below the BK and B^*K thresholds and possible decays into $B_s\pi^0$ and $B_s^*\pi^0$, respectively (Colangelo, De Fazio, and Ferrandes, 2006).

---

[146] Other interpretations of $D_{s0}^*(2317)$ and $D_{s1}'(2460)$ (molecules, multiquarks) are reviewed in (Colangelo, De Fazio, and Ferrandes, 2004) and (Swanson, 2006); the dynamical generation of such states has been proposed in (Guo, Shen, Chiang, Ping, and Zou, 2006; Guo, Shen, and Chiang, 2007).

Table 19.3.4. Tentative classification in HQ doublets of the observed mesons with open charm. States with uncertain assignment are indicated with $(*)$.

Doublet	j_q^P	J^P	$c\bar{q}$ $(n=1)$	$c\bar{q}$ $(n=2)$	$c\bar{s}$ $(n=1)$	$c\bar{s}$ $(n=2)$

19.3.1.3 Results from QCD sum rules

The masses of the open charm mesons, as well as other hadronic quantities like the decay constants, can be computed in QCD by QCD Sum Rules. Two-point correlation functions of quark currents with the quantum numbers of the mesons of interest (Shifman, Vainshtein, and Zakharov, 1979),

$$\Pi(Q^2) = i \int d^4x\, e^{iq\cdot x}\, \langle T[J(x)J^\dagger(0)]\rangle \qquad (19.3.11)$$

with $J = J_{c\bar{q}}$, are expressed in QCD at short distances $(Q^2 \to \infty)$ in terms of the quark masses, the strong coupling constant α_s and of the vacuum matrix elements $\langle O_n \rangle$ of gauge-invariant quark and gluon operators (vacuum condensates). The latter parameters appear in the $1/(Q^2)^n$ corrections to the perturbative expression of the correlation functions $\Pi^{\text{pert}}(Q^2)$,

$$\Pi^{\text{QCD}}(Q^2) = \Pi^{\text{pert}}(Q^2) + \sum_n c_n \frac{\langle O_n \rangle}{(Q^2)^n}. \qquad (19.3.12)$$

The same correlation functions are represented in terms of hadronic states,

$$\Pi(Q^2) = \Pi^{\text{had}}(Q^2), \qquad (19.3.13)$$

and the contributions of the lowest lying states are isolated from the excited states and the hadronic continuum. Matching the two (QCD and hadronic) representations on the basis of analyticity and of (global) quark-hadron duality, expressions can be worked out for, $e.g.$, the meson masses in terms of QCD parameters (Colangelo and Khodjamirian, 2000). The method can be formulated also for the effective theories of QCD, namely the Heavy Quark Effective Theory (Neubert, 1994b). The same approach can be applied to investigate multiquark configurations, using correlation functions of currents composed by several quark fields.

The accuracy of the QCD Sum Rule predictions is related to the separation of the various particle contributions in the hadronic representation of the two-point correlation functions, to the procedure of exploiting quark-hadron duality and to the errors in the parameters, in particular the vacuum condensates. Within the uncertainties, the masses of the lightest $c\bar{q}$ and $c\bar{s}$ mesons have been predicted in agreement with experiment (Reinders, Rubinstein, and Yazaki, 1985). Also the masses of the positive parity open charm mesons turn out to be compatible with measurement, and the main features of the radiative and strong decays are reproduced if they are described as ordinary quark-antiquark configurations (Colangelo, De Fazio, and Ozpineci (2005); Dai, Li, Zhu, and Zuo (2008)).

19.3.1.4 Lattice QCD results

The hadron properties can be computed $ab\ initio$ from the QCD Lagrangian by lattice calculations, analyzing correlation functions of quark currents of suitably chosen quantum numbers. The resulting $c\bar{q}$ and $c\bar{s}$ mass spectrum can be compared to the measurement, addressing the issue of the classification of the observed resonances. However, the calculation of hadronic quantities for dynamical light quarks with masses close to the QCD values is still a challenging task. Different results for the meson masses have been found by different groups, leading to a different classification of, $e.g.$, $D_{s0}^*(2317)$ and $D_{s1}'(2460)$. In (Bali, 2003) the mass $M(D_{s0}^*) = 2.57(11)\,\text{GeV}$ is obtained for the scalar $c\bar{s}$ state, hence a value larger than the measured mass of $D_{s0}^*(2317)$, suggesting a non quark-antiquark interpretation for this state. On the other hand, in the calculations in (Dougall, Kenway, Maynard, and McNeile, 2003) and (Lin, Ohta, Soni, and Yamada, 2006) the mass splitting $M(D_s(0^+)) - M(D_s(0^-))$ turns out to be compatible with experiment. The results of more recent analyses, with overlap fermions for both light and heavy quarks and only one lattice spacing, are consistent with the experimental masses, in particular for $D_{s0}^*(2317)$ described as a $c\bar{s}$ state (Dong et al., 2009). The same conclusion is drawn

in (Gong et al., 2011), where the tetraquark interpretation of $D^*_{s0}(2317)$ is tested and found to be inconsistent with data.

19.3.2 Production of charmed mesons at B Factories

Charmed mesons are copiously produced at B Factories either directly in e^+e^- collisions or as products of B meson decays. Both mechanisms allow for complementary measurements of the charmed multiplets.

Charm production in B decays is governed by the CKM-favored $b \rightarrow c$ transition, thus B mesons are an abundant source of charmed mesons. The restricted kinematics of $B\bar{B}$ production at the $\Upsilon(4S)$ enable a selection of clean B meson samples, while the zero spin of the parent B constrains possible quantum numbers of the daughter particles and makes their spin-parity measurements easier. Depending on the quantum numbers of charmed mesons, theory predicts certain patterns in their production rates in B meson decays (Section 17.3), which is helpful in clarifying the nature of the produced particles. Charmed mesons bearing high spin or being highly excited are suppressed in B meson decays, thus their studies with $e^+e^- \rightarrow c\bar{c}$ continuum data are more feasible.

At the center-of-mass (CM) energy of the B Factories, the cross-section of prompt $c\bar{c}$ pair production provides a large fraction of the total hadronic cross-section, resulting in large samples of ground and excited charmed mesons from the hadronization of the produced c quarks (see Section 24.1). The produced hadrons are usually studied inclusively *i.e.* without reconstruction of the other particles in the event. Such an approach allows high efficiency but often suffers from large background, while charmed hadrons coming from strongly decaying excited states cannot be distinguished from those originating directly from the e^+e^- annihilation.

19.3.3 Non-strange charm spectroscopy

19.3.3.1 Introduction

Charm spectroscopy to this date has still not been fully explored as there are many D meson states predicted in the 1980s, which have not been observed experimentally. Figure 19.3.1 shows the predicted spectrum for a $c\bar{u}$ system (The spectrum of the $c\bar{d}$ system is almost identical.). The ground states, $D^{0,+}$ (Goldhaber et al., 1976; Peruzzi et al., 1976), and spin excitations, $D^{*(0,+)}$ (Feldman et al., 1977), were first observed respectively in 1976 and 1977 by the Mark-I experiment at SLAC. Their properties are quite well known, though they are still being studied with increasing precision. Recent measurements of D^0 and D^+ masses come from CLEO (Cawlfield et al., 2007) and KEDR (Anashin et al., 2010). As for the total widths, only the D^{*+} width has been measured (96 ± 22 keV), as it is enlarged by strong D^{*+} decays. The widths of the other D and D^* mesons are consistent with zero, because they decay either mainly weakly, or in the case of the D^{*0} mainly
Figure 19.3.1. Modified Godfrey-Isgur predictions (Godfrey and Isgur, 1985). The plot shows the $c\bar{u}$ spectrum where the masses have been scaled down so that the ground state matches the D^0 mass. Also, the 2^- states, not shown in the original paper, have been inserted following the splitting structure of the $1P$ states.

radiatively. Therefore, experiments set only upper limits for them. Decays of $D^{(*)}$ mesons are described in detail in Section 19.1. Spin-parities of $D^{(*)}$ quoted in the PDG are assigned based on the quark-model predictions, though many studies performed, especially of $D^{(*)}$ produced in B decays, confirm these assignments (Sections 17.3 and 17.6).

Within the $L = 1$ orbital excitations labeled as D^{**}, the narrow doublet was not observed until 1989 owing to its lower production rates and larger widths. Eventually neutral D^0_1 and D^{*0}_2 mesons were observed in $D^{*+}\pi^-$ final states by ARGUS (Albrecht et al., 1989d) and CLEO (Avery et al., 1990). Their widths of about $20-30$ MeV/c^2 and masses around 2.4 GeV/c^2, were in agreement with the model predictions (Rosner (1986); Godfrey and Kokoski (1991); Falk and Peskin (1994)). The broad $L = 1$ states have only recently been observed by Belle and *BABAR* in B decays where they could be separated from the background, as it will be described in the following.

19.3.3.2 D^{**} in B decays

$\bar{B}$ decays to the $D\pi$ and $D^*\pi$ final states are two of the dominant hadronic decays and have been measured quite well (Section 17.3). Similar processes, $\bar{B} \rightarrow D^{**}\pi$, are expected to be a dominant source of D^{**} mesons. At the quark level such decays proceed through a $b \rightarrow cW^- \rightarrow c\bar{u}d$ transition for which the underlying diagrams are shown in Fig. 19.3.2. As D^{**} mesons are expected to decay dominantly in the $D^{(*)}\pi$ modes, processes like $\bar{B} \rightarrow D^{(*)}\pi\pi$ provide the best way to study them.
Figure 19.3.2. From (Kuzmin, 2007). Quark-line diagrams for charged (left and middle) and neutral (right) $\overline{B} \to D^{**}\pi$ decays.

19.3.3.3 Neutral D^{**} via $B^- \to D^{(*)+}\pi^-\pi^-$ Dalitz analysis

The production of neutral D^{**} resonances was studied through a full Dalitz-plot analysis of the three-body decay $B^- \to D^+\pi^-\pi^-$ (Abe, 2004f; Aubert, 2009g) and $B^- \to D^{*+}\pi^-\pi^-$ (Abe, 2004f). Thus, for the first time, interference between intermediate states is taken into account in measuring properties of the D^{**} mesons. First Belle performed such a Dalitz analysis using a data sample of about 65×10^6 of $B\overline{B}$ pairs; a BABAR analysis, based on 383×10^6 $B\overline{B}$ pairs, followed. The $D^{(*)+}$ are reconstructed in the clean decay modes: $D^+ \to K^-\pi^+\pi^+$, $D^{*+} \to D^0\pi^+$ with $D^0 \to K^-\pi^+$ and $K^-\pi^+\pi^+\pi^-$, ensuring good purity over the Dalitz diagram. Reconstructed B candidates are identified by their ΔE and m_{ES}. In addition a thrust angle requirement, $\cos\theta_T < 0.8$, is applied to suppress continuum background (see Section 9). Signal yields, obtained from fits to the ΔE distributions, of about 1100 events (Belle) and 3500 events (BABAR) for $B^- \to D^+\pi^-\pi^-$ and 560 events for $B^- \to D^{*+}\pi^-\pi^-$ (Belle) have been obtained.

The Dalitz plots for the $B^- \to D^+\pi^-\pi^-$ candidates within the ΔE-m_{ES} signal region are shown in Fig. 19.3.3. The plot from BABAR is symmetric in the $D\pi$ masses because of the two identical pions. Belle used as the Dalitz variables the lower and higher values of the two $D\pi$ mass combinations, denoted as $m^2_{\min}(D\pi)$ and $m^2_{\max}(D\pi)$; intermediate resonances emerge in $m^2_{\min}(D\pi)$. The distributions clearly display the structure of nodes characteristic of the spin-2 resonance $D^*(2460)^0$, while an accumulation of events in the threshold mass region are attributed to the scalar D_0^{*0}.

Principles of Dalitz-plot analysis are described in detail in Section 13. The signal density of the decay $B^- \to D^+\pi^-\pi^-$ are parameterized as a coherent sum of amplitudes corresponding to the following intermediate states forming the $D^+\pi^-$ system: D_2^{*0}, D_0^{*0} and off-shell vector D^{*0} (labeled as D_v^{*0}). Also a virtual B^{*0}, contributing as $\overline{B} \to \overline{B}_v^{*0}\pi$ with $\overline{B}_v^{*0} \to D\pi$, and a constant amplitude for a non-resonant component are included. Such virtual contributions are of phenomenological origin and are introduced to obtain a better description of the Dalitz distributions. Both Belle and BABAR analyses employed an isobar model in which resonance amplitudes are parameterized with Breit-Wigner (BW) functions with a mass dependent width and angular dependence related to resonance decay with given orbital momentum ($L = 0, 1, 2$ respectively for the D_0^{*0}, D_v^{*0}, D_2^{*0}). The latter introduces
Figure 19.3.3. Dalitz plot for $B^- \to D^+\pi^-\pi^-$ from Abe (2004f) (left) and (Aubert, 2009g) (right).

an amplitude dependence on the helicity angle (Θ_h) defined as the angle between the momentum vectors of the bachelor pion from the B decay and the pion of the $D\pi$ system in the $D\pi$ rest frame. The signal parameterization is convoluted with the experimental mass resolution, typically of order of a few MeV/c^2. The background shape is obtained from a fit to the Dalitz distribution for the ΔE sideband region.

With such models for signal and background densities, an unbinned maximum-likelihood fit to the Dalitz plot is performed. The D^{**} parameters, all the amplitudes and relative phases are free parameters in the fit. The fit likelihood value is significantly improved by the inclusion of the broad scalar resonance, thus Belle claimed the first observation of the D_0^{*0} meson (Abe, 2004f).

Figure 19.3.4 shows the $m^2_{\min}(D\pi)$, $m^2_{\max}(D\pi)$ and $m^2(\pi\pi)$ projections with the fit result and contributions from the intermediate resonances superimposed, as obtained by BABAR. The D_0^{*0} signal and the reflection of D_2^{*0} can easily be distinguished in the $m^2_{\min}(D\pi)$ and $m^2_{\max}(D\pi)$ projections, respectively. The resonance masses and widths as well as branching ratio products measured in both analyses are very consistent, and are summarized in Table 19.3.5.

Figure 19.3.5 shows $M(D^+\pi^-)_{\min}$ (previously labeled also as $m_{\min}(D\pi)$) for different helicity angle regions, as measured by Belle. The D_2^{*0} is clearly seen for $|\cos\Theta_h| > 0.67$ where the D-wave component peaks, the D_0^{*0} is visible for $0.33 < |\cos\Theta_h| < 0.67$ where the D-wave is suppressed with respect to the S-wave, the range $|\cos\Theta_h| < 0.33$ demonstrates an interference pattern.

The $B^- \to D^{*+}\pi^-\pi^-$ decay contains a vector particle in the final state, therefore, assuming a negligible D^* width, there are two more variables needed to specify the final state in addition to $M^2(D^*\pi)_{\min}$ and $M^2(D^*\pi)_{\max}$. The following ones are chosen in the analysis performed by Belle (Abe, 2004f): the D^* helicity angle (α) between the momenta of pions from the D^* and D^{**} decays in the

Table 19.3.5. From Abe (2004f) (A4), Kuzmin (2007) (K), (Abe, 2005i) (A5) and Aubert (2009g) (A9). The fitted parameters of the D^{**} mesons and products of branching ratios $\mathcal{B}(B \to D^{**}\pi) \times \mathcal{B}(D^{**} \to f)$. The first error is statistical, the second one is systematic and the third one is model related. World average (WA) values are taken from (Eidelman et al., 2004). "fixed" indicates parameters which were fixed to values obtained from other fits.

D^* rest frame and the azimuthal angle (γ) of the pion from the D^* relative to the $\overline{B} \to D^*\pi\pi$ decay plane.

Figure 19.3.6 shows the Dalitz distribution, $M^2(D^*\pi)_{\min}$ vs. $M^2(D^*\pi)_{\max}$, for the ΔE-m_{ES} signal region B candidates. The significant increase of the event density in $M^2(D^*\pi)_{\min}$ at about $5.8 \text{ GeV}^2/c^4$ corresponds to the narrow D_1 and D_2^* states. The broad D_1' meson, unobserved at the time the analysis was performed, can also contribute to the $D^*\pi$. The $B^- \to D^{*+}\pi^-\pi^-$ signal is thus parameterized as a coherent sum of the relativistic Breit-Wigner amplitudes of these three intermediate states.

The HQET predicts that the two 1^+ mesons, with $j_q = \frac{1}{2}$ and $j_q = \frac{3}{2}$, decay into the $D^*\pi$ final state via S- and D-wave, respectively. Due to the finite c-quark mass, the observed (physical) states can be a mixture of such pure states. The mixing can occur for instance via the common $D^*\pi$ decay channel and the resulting D_1' and D_1 amplitudes are superpositions of the S- and D-wave amplitudes:

$$|D'_1\rangle = |1S\rangle \cos\omega - e^{+i\psi}|1D\rangle \sin\omega$$
$$|D_1\rangle = |1S\rangle \sin\omega + e^{-i\psi}|1D\rangle \cos\omega, \quad (19.3.14)$$

where ω is a mixing angle and ψ is a complex phase. Such an amplitude representation is used in the signal model.

Like in the $B^- \to D^+\pi^-\pi^-$ analysis, virtual D_v^{*0} and B_v^{*0} components, as well as the constant term are also included in the signal function, while the background is estimated with events from the ΔE sidebands.

Amplitudes and phases of the intermediate states are extracted through an unbinned maximum-likelihood fit in the four-dimensional ($M^2(D^*\pi)_{\min}$, $M^2(D^*\pi)_{\max}$, α, γ) phase space. The broad 1^+ meson significantly improves the fit likelihood and, thus, Belle claimed its discovery. Figure 19.3.6 shows the background-subtracted $M(D^{*+}\pi^-)_{\min}$ distribution with the resonance contributions obtained from the fit. The fitted parameters of the axial mesons are summarized in Table 19.3.5, along with the branching ratio products. The mixing angle between the two 1^+ mesons and their relative phase were measured as $\omega = (-0.10 \pm 0.03 \pm 0.02 \pm 0.02)$ rad and $\psi = (0.05 \pm 0.20 \pm 0.04 \pm 0.06)$ rad. Such a measurement is performed for the first time for the charmed mesons. Decomposition of the S- and D-waves was before attempted for the $D_1(2420) \to D^*\pi$ by CLEO. They set a limit on the S-wave contribution to the total width as a function of the relative phase (Avery et al., 1994b; Bergfeld et al., 1994).

For better illustration of the fit results, the measured angular distributions along with MC simulations performed
Figure 19.3.4. From (Aubert, 2009g). Result of the Dalitz plot fit to the $B^- \to D^+\pi^-\pi^-$ signal candidates: projections on (a) $m^2_{\min}(D\pi)$, (b) $m^2_{\max}(D\pi)$ and (c) $m^2(\pi\pi)$. The points with error bars are data, the solid curves represent the nominal fit. The shaded areas show the D_2^{*0} contribution, the dashed curves show the D_0^{*0} signal, the dash-dotted curves show the D_v^* and B_v^* signals, and the dotted curves show the background.

with the fitted parameters, are shown in Fig. 19.3.7 for the $M^2(D^*\pi)_{\min}$ regions populated by the $D_1^{\prime 0}$ or D_1^0.

19.3.3.4 Charged D^{**} via $\overline{B}^0 \to D^{(*)0}\pi^+\pi^-$ Dalitz analysis

The Dalitz analysis of the $\overline{B}^0 \to D^0\pi^+\pi^-$ decay has been performed by Belle (Kuzmin, 2007) using 388×10^6 $B\overline{B}$ pairs. After excluding a subsample of the $\overline{B}^0 \to D^{*+}\pi^-$ with $D^{*+} \to D^0\pi^+$, Belle obtains a signal yield of about
Figure 19.3.5. From (Abe, 2004f). Efficiency-corrected $M(D^+\pi^-)_{\min}$ distribution in $B^- \to D^+\pi^-\pi^-$ for different helicity angle ranges. Curves correspond to the fit to the total distribution (upper blue) and background (lower black) component.
Figure 19.3.6. From (Abe, 2004f). Left: Dalitz plot for the $B^- \to D^{*+}\pi^-\pi^-$ signal candidates. Right: Background-subtracted $M(D^*\pi)_{\min}$ spectrum. Points with error bars correspond to data, hatched histograms show fitted resonance contributions and the open histogram is a coherent sum of all the contributions. In the figure the D_1' is indicated as D_1^*.

2900 events. As intermediate resonances decaying to $D^0\pi^+$ as well as resonances decaying to $\pi^+\pi^-$ can contribute to the $\overline{B}^0 \to D^0\pi^+\pi^-$ reaction, its kinematics is described with the $M^2(D^0\pi^+)$ and $M^2(\pi^+\pi^-)$ invariant masses. The distribution for the reconstructed ΔE-m_{ES} signal region events is shown in Fig. 19.3.8. The *p.d.f.* is comprised of D_0^{*+}, D_2^{*+}, D_v^* and B_v^{*+} components contributing to the $D^0\pi^+$ system, whereas $\rho(770)$, ω, $f_2(1270)$, $f_0(600)$, $f_0(980)$ and $f_0(1370)$ states can be present in the $\pi^+\pi^-$ projection. Parameters of the D_0^{*+} are fixed to the one from the neutral $D_0^{*0} \to D^-\pi^+$ measurement, while light scalar mesons are included in the fit with their parameters fixed to the PDG values (Beringer et al., 2012). An unbinned fit to the Dalitz distribution gives signifi-
Figure 19.3.7. From (Abe, 2004f): Distributions of the D^{**} helicity angle ($\cos\theta$), $\cos\alpha$ and γ in regions of $M^2(D^*\pi)_{\min}$ with dominance of the $D_1'^0$ in $B^- \rightarrow D^{*+}\pi^-\pi^-$ decays: $M^2(D^*\pi)_{\min} < 5.76\,\mathrm{GeV}^2/c^4$ and the D_1^0: $5.76 < M^2(D^*\pi)_{\min} < 5.98\,\mathrm{GeV}^2/c^4$. Points with error bars correspond to data, the histogram is from MC simulation based on the fitted parameters and the hatched histogram shows the background contribution.
Figure 19.3.8. From (Kuzmin, 2007): Dalitz plot for the $\overline{B}^0 \rightarrow D^0\pi^+\pi^-$ signal candidates (left) and $M(D^0\pi^+)$ projection (right) of the events with $\cos\Theta_h > 0$. Points with error bars represent data, the hatched histogram shows background estimated from generic MC events normalized to the sideband data and the open histogram represents the fitted function.

cant contributions from both the charged D_0^{*+}, observed for the first time, as well as the D_2^{*+}. Fig. 19.3.8 shows the $M(D^0\pi^+)$ spectrum with the fitted function superimposed, for the $\cos\Theta_h > 0$ helicity angle region, where the $\pi\pi$ resonance contributions and background are low. Fitted D^{**+} parameters and measured branching ratio products are presented in Table 19.3.5. It can be seen that the production branching fraction for the D_0^{*+} is much smaller than for the D_2^{*+}.

19.3.3.5 The D^{**} production rates

Measurements of the charmed meson production rates in B decays provide tests of HQET and QCD sum rules. The measured branching ratio products (Table 19.3.5) show that the narrow mesons comprise $(36 \pm 6)\%$ of the

$B^- \rightarrow D^+\pi^-\pi^-$ and $(63 \pm 6)\%$ of the $B^- \rightarrow D^{*+}\pi^-\pi^-$ decays, thus the production rates of the $j_q = \frac{1}{2}$ and $j_q = \frac{3}{2}$ $c\bar{u}$ mesons are similar. This is inconsistent with the QCD sum rule which predicts the dominance of the narrow, $j_q = \frac{3}{2}$ states. However, if the color-suppressed amplitude (left diagram in Fig. 19.3.2) contributes significantly, it would be enhanced for the $j_q = \frac{1}{2}$ states. This seems to be supported by the Belle measurements of the color-allowed $\overline{B}^0 \rightarrow D^{(*)0}\pi^+\pi^-$ decays, where production rates of the $j_q = \frac{3}{2}$ states are similar to the ones measured in charged B decays, but are much lower for the broad $j_q = \frac{1}{2}$ states. The measured production rates (Table 19.3.5) give:

$$\frac{\mathcal{B}(B^-\rightarrow D_2^{*0}\pi^-)\mathcal{B}(D_2^{*0}\rightarrow D^+\pi^-)}{\mathcal{B}(B^-\rightarrow D_2^{*0}\pi^-)\mathcal{B}(D_2^{*0}\rightarrow D^{*+}\pi^-)} = \frac{\mathcal{B}(D_2^{*0}\rightarrow D^+\pi^-)}{\mathcal{B}(D_2^{*0}\rightarrow D^{*+}\pi^-)}$$
$$= 1.9 \pm 0.5, \quad (19.3.15)$$

which is consistent with a value predicted by theoretical models (Rosner, 1986; Godfrey and Kokoski, 1991; Falk and Peskin, 1994). Assuming that D_2^* decay is saturated by the $D^{(*)}\pi$ transitions, whereas the D_1 decay is saturated by the $D^*\pi$ mode, one gets:

$$\frac{\mathcal{B}(B^-\rightarrow D_2^{*0}\pi^-)\mathcal{B}(D_2^{*0}\rightarrow D^+\pi^-, D^{*+}\pi^-)}{\mathcal{B}(B^-\rightarrow D_1^0\pi^-)\mathcal{B}(D_1^0\rightarrow D^{*+}\pi^-)} = 0.77 \pm 0.15,$$
$$(19.3.16)$$

which is by a factor of two larger than the HQET prediction calculated in the factorization approximation (Leibovich, Ligeti, Stewart, and Wise, 1998; Neubert, 1998). From these measurements it is impossible to determine the size of the nonfactorized part for the tensor and axial mesons or whether higher order corrections to the leading factorized terms should be taken into account. More accurate measurements of the semileptonic $\overline{B} \rightarrow D^{**}l\nu$ decays (Section 17.1), which are free of nonfactorized contributions, may help to resolve this problem.

19.3.3.6 Other D^{**} decays

Studies of subleading decay modes of the D^{**} mesons are important for understanding heavy-light mesons and to further test theoretical models. Subleading decays could modify the ratio in Eq. (19.3.16). Belle observed the $D_1 \rightarrow D\pi^+\pi^-$ decays in $\overline{B} \rightarrow (D^{(*)}\pi^+\pi^-)\pi^-$, where $D = D^0$ or D^+, in a sample of 152×10^6 $B\overline{B}$ pairs (Abe, 2005i). To suppress the large continuum background, the analysis uses a Fisher discriminant (see Section 9), that is based on the B production angle, the thrust angle, as well as parameters characterizing the momentum flow in the event, originally developed by CLEO (Asner et al., 1996). The $M(D\pi^+\pi^-)$ spectra for the B candidates in the ΔE-$m_{\rm ES}$ signal region, shown in Fig. 19.3.9, demonstrate the prominent D_1 signals. No significant signals are observed for neither $D_1 \rightarrow D^*\pi^+\pi^-$ nor $D_2^* \rightarrow D^{(*)}\pi^+\pi^-$. Except for the D_1 peak, the signal-region data are consistent with the mass distributions for the ΔE sidebands. This suggests that there is no significant contribution from the broad D^{**} mesons. The results of the fits to the $M(D^{(*)}\pi^+\pi^-)$
Figure 19.3.9. From (Abe, 2005i): $M(D\pi^+\pi^-)$ distributions for the $\bar{B} \to (D\pi^+\pi^-)\pi^-$ candidates in the signal region (open histogram) and ΔE sidebands (hatched-yellow).

distributions and the measured $\mathcal{B}$ products are summarized in Table 19.3.5. The observed $D_1 \to D\pi^+\pi^-$ decays lower the ratio in Eq. (19.3.16) to 0.54 ± 0.18 which, thus, becomes consistent with the HQET predictions (see Section 19.3.3.5).

The dynamics of the $D_1 \to D\pi^+\pi^-$ decays are examined in a simplified way by studying one-dimensional projections of mass and angular variables. The data, compared with MC simulations of various D_1 decays models, are found to be well described by the $D_1 \to D_0^*\pi^-$ decay.

19.3.3.7 New excited charmed mesons

To search for new excited charmed mesons, labeled as D_J, BABAR analyzed the inclusive production of the $D^+\pi^-$, $D^0\pi^+$, and $D^{*+}\pi^-$ final states in the reaction $e^+e^- \to c\bar{c} \to D^{(*)}\pi X$, where X is any additional system (del Amo Sanchez, 2010i). They use a data sample consisting of approximately 590×10^6 $c\bar{c}$ events. In the $D\pi$ system, the $D^+ \to K^-\pi^+\pi^+$ and $D^0 \to K^-\pi^+$ decays are reconstructed. The D^0 candidates, when being combined with any additional pion in the event form a D^*, are rejected. To improve the signal purity for $D^0 \to K^-\pi^+$, it is required that $\cos\theta_K > -0.9$, where θ_K is the angle between the K^- direction and the direction opposite to the e^+e^- CM system in the D^0 rest frame. The $D^{*+}\pi^-$ system is reconstructed using the $D^{*+} \to D^0\pi^+$, $D^0 \to K^-\pi^+$ and $K^-\pi^+\pi^-\pi^+$ decay modes. Background from $e^+e^- \to B\bar{B}$ events and much of the combinatorial background, are removed by requiring the CM momentum of the $D^{(*)}\pi$ to be greater than 3.0 GeV/c.

The measured $D^+\pi^-$ and $D^0\pi^+$ mass spectra are presented in Fig. 19.3.10 and show similar features:

- Prominent D_2^* peaks.
- The $M(D^+\pi^-)$ shows a peaking background at about 2.3 GeV/c^2 due to D_1^0 and D_2^{*0} decays to $D^{*+}\pi^-$, with the π^0 from the $D^{*+} \to D^+\pi^0$ missing. Similarly, $M(D^0\pi^+)$ shows feeddown due to the D_1^+ and D_2^{*+} decaying to $D^{*0}\pi^+$ where $D^{*0} \to D^0\pi^0$.
- Both $D^+\pi^-$ and $D^0\pi^+$ mass distributions show new structures around 2.60 and 2.76 GeV/c^2, labeled respectively as $D^*(2600)$ and $D^*(2760)$.
Figure 19.3.10. From (del Amo Sanchez, 2010i). Mass distribution for $D^+\pi^-$ (top) and $D^0\pi^+$ (bottom) candidates produced in the process $e^+e^- \to c\bar{c} \to D\pi X$, Points correspond to data, with the total fit overlaid as a solid curve. The dotted curves are the signal components. The lower solid curves correspond to the smooth combinatoric background and to the peaking backgrounds at 2.3 GeV/c^2. The inset plots show the distributions after subtraction of the combinatoric background.

The $M(D\pi)$ spectra are fitted with contributions from the D_2^*, $D^*(2600)$ and $D^*(2760)$ described with relativistic BW distributions. The smooth background is modeled using an exponential function multiplied by a two-body phase-space factor dropping toward the $D\pi$ mass threshold. The feeddown is described by convolving BW functions with a function describing the resolution and mass shift obtained from the MC simulation. The masses and widths of the D_1 and D_2^* feeddowns are fixed to the values obtained respectively from the same $M(D\pi)$ distribution and from the $M(D^{*+}\pi^-)$ study described below. Finally, although not visible in the $M(D^+\pi^-)$ mass distribution, a BW function is included to account for the broad D_0^*.

The $D^{*+}\pi^-$ mass distribution is shown in Fig. 19.3.11 and exhibits the following features:

- Prominent D_1^0 and D_2^{*0} peaks.
- Two enhancements at 2.60 GeV/c^2 and 2.75 GeV/c^2, which are denoted as $D^*(2600)^0$ and $D(2750)^0$.

The angular analysis of the $M(D^{*+}\pi^-) \approx 2.6\,\text{GeV}/c^2$ region shows that it could not be described by a single resonance, instead two resonances with different helicity-angle distributions could be present. Thus, a new component, labeled as $D(2550)^0$, is included in the $M(D^{*+}\pi^-)$ fit. The $D(2550)^0$ parameters are obtained by requiring $|\cos\theta_H| > 0.75$ in order to suppress the other resonances

Table 19.3.6. From (del Amo Sanchez, 2010i). Summary of the measurements of the old and newly discovered D_J resonances. The first error is statistical and the second is systematic; "fixed" indicates parameters which were fixed to values obtained from other fits. The significance is defined as the yield divided by its total error.

Resonance	Channel	Mass (MeV/c^2)	Width (MeV)	Significance
$D_1(2420)^0$	$D^{*+}\pi^-$	$2420.1\pm0.1\pm0.8$	$31.4\pm0.5\pm1.3$	
$D_2^*(2460)^0$	$D^+\pi^-$	$2462.2\pm0.1\pm0.8$	$50.5\pm0.6\pm0.7$	
$D(2550)^0$	$D^{*+}\pi^-$	$2539.4\pm4.5\pm6.8$	$130\pm12\pm13$	3.0σ
$D^*(2600)^0$	$D^+\pi^-$	$2608.7\pm2.4\pm2.5$	$93\pm6\pm13$	3.9σ
$D(2750)^0$	$D^{*+}\pi^-$	$2752.4\pm1.7\pm2.7$	$71\pm6\pm11$	4.2σ
$D^*(2760)^0$	$D^+\pi^-$	$2763.3\pm2.3\pm2.3$	$60.9\pm5.1\pm3.6$	8.9σ
$D_2^*(2460)^+$	$D^0\pi^+$	$2465.4\pm0.2\pm1.1$	50.5 (fixed)	
$D^*(2600)^+$	$D^0\pi^+$	$2621.3\pm3.7\pm4.2$	93 (fixed)	2.8σ
$D^*(2760)^+$	$D^0\pi^+$	$2769.7\pm3.8\pm1.5$	60.9 (fixed)	3.5σ

(Fig. 19.3.11, top), where the helicity angle (θ_H) is defined in the rest frame of the D^* as the angle between the primary pion and the slow pion from the D^* decay. In this fit, the parameters of the D_2^{*0} and $D^*(2600)^0$ are fixed to those measured in the $D^+\pi^-$. This fit also determined the parameters of the D_1^0. A complementary fit with $|\cos\theta_H| < 0.5$, shown in Fig. 19.3.11 (middle), is performed to discriminate in favor of the $D^*(2600)^0$. To determine the final parameters of the $D(2750)^0$ signal the total $D^{*+}\pi^-$ sample is refitted (Fig. 19.3.11 (bottom)), while fixing the parameters of all other BW components to the values determined in the previous fits. The broad resonance $D_1'^0$ is known to decay to this final state, however, these fits were insensitive to its contribution due to its large width and because the background parameters are free. The fit results are summarized in Table 19.3.6.

The $D^*(2760)^0$ signal observed in its decay to $D^+\pi^-$ is very close in mass to the $D(2750)^0$ signal observed in $D^{*+}\pi^-$.

To have information on the spin of the observed resonances, the data are divided into 10 sub-samples corresponding to $\cos\theta_H$ intervals of 0.2. Each sample is fitted with all shape parameters fixed to the values determined from the fits to the total samples. The yields extracted from these fits are plotted for each resonance in Fig. 19.3.12. The $\cos\theta_H$ distributions of the D_2^* and $D^*(2600)$ are consistent with the expectations for natural parity, defined by $P = (-1)^J$, and leading to a $\sin^2\theta_H$-like distribution. This observation supports the assumption that the enhancement assigned to the $D^*(2600)$ observed in the $D^+\pi^-$ and $D^{*+}\pi^-$ mass spectra belong to the same state, as only states with natural parity can decay to both $D^+\pi^-$ and $D^{*+}\pi^-$. The $\cos\theta_H$ distribution for the $D(2550)^0$ is consistent with pure $\cos^2\theta_H$ as expected for a $J^P = 0^-$ state.

The branching fraction ratios, $\frac{\mathcal{B}(D_J\to D^+\pi^-)}{\mathcal{B}(D_J\to D^{*+}\pi^-)}$, may be used in the identification of the new states. Such ratios, computed using the yields obtained from the fits to the total samples and corrected for the reconstruction efficiency, are measured to be:

$$\frac{\mathcal{B}(D_2^*(2460)^0 \to D^+\pi^-)}{\mathcal{B}(D_2^*(2460)^0 \to D^{*+}\pi^-)} = 1.47 \pm 0.03 \pm 0.16,$$

$$\frac{\mathcal{B}(D^*(2600)^0 \to D^+\pi^-)}{\mathcal{B}(D^*(2600)^0 \to D^{*+}\pi^-)} = 0.32 \pm 0.02 \pm 0.09,$$

$$\frac{\mathcal{B}(D^*(2760)^0 \to D^+\pi^-)}{\mathcal{B}(D(2750)^0 \to D^{*+}\pi^-)} = 0.42 \pm 0.05 \pm 0.11.$$

$$(19.3.17)$$

The $D(2550)^0$ and the $D^*(2600)^0$ have mass values and $\cos\theta_H$ distributions that are consistent with the predicted radial excitations $D_0^1(2S)$ and $D_1^3(2S)$. The $D^*(2760)^0$ and the $D(2750)^0$ (assuming these are two different states) could be some of the four $L = 2$ states, predicted to lie in this mass region.

19.3.4 Charmed-strange mesons

19.3.4.1 Introduction

The unexpected discovery of a narrow state, $D_{s0}^*(2317)^+ \to D_s^+\pi^0$, by the *BABAR* experiment (Aubert, 2003j), and a subsequent discovery of yet another narrow particle, $D_{s1}(2460)^+ \to D_s^*(2112)^+\pi^0$ by CLEO (Besson et al., 2003), Belle (Abe, 2004a) and *BABAR* (Aubert, 2004t) raised considerable interest in the spectroscopy of charmed mesons. These discoveries were a surprise because they contradicted the expectations of HQET which, till then, had been a very successful approach in describing the spectroscopy of $D_{(s)}$ and $B_{(s)}$ mesons. The expected spectrum for the $c\bar{s}$ states is sketched in Fig. 19.3.13. In this scheme, $L = 1$ $c\bar{s}$ excitations consist of a $J^P = (0^+, 1^+)$ doublet carrying the total light-quark angular momentum $j_q = \frac{1}{2}$ and a $(1^+, 2^+)$ doublet having $j_q = \frac{3}{2}$. Figure 19.3.13 shows also a comparison between HQET calculations and experimental measurements of D_s meson masses. The two $j_q = \frac{3}{2}$ states are expected to be narrow and are identified as the 1^+ $D_{s1}(2536)$ and the 2^+ $D_{s2}^*(2573)$ seen in D^*K and DK decays, respectively. These states were first observed in the 1980-90s (Albrecht et al., 1989c; Alexander et al., 1993; Kubota et al., 1994).

Before the observations reported here became available, the two $j_q = \frac{1}{2}$ states were predicted to have masses above the DK and D^*K thresholds, respectively, and
Figure 19.3.12. From (del Amo Sanchez, 2010i). Distribution in $\cos\theta_H$ for each signal observed in the $D^{*+}\pi^-$ final state. The error bars include statistical and correlated systematic uncertainties. The curve is a fit using the function Y shown in the plot; ε_H is the efficiency as a function of $\cos\theta_H$.

rather large widths of order of a few $100\,\mathrm{MeV}/c^2$. The latter was blamed for making their detection hard.

As it can be seen from Fig. 19.3.13, the newly discovered states at 2.32 and 2.46 GeV/c^2 do not fit these predictions. Their masses are considerably lower and are below their relative $D^{(*)}K$ thresholds. The observed decay modes violates isospin conservation and is therefore likely to be of electromagnetic origin. This makes their widths extremely narrow (consistent with zero). Two possibilities then arise: the calculations are flawed, or these states have a parton composition other than the assumed conventional heavy-light $c\bar{s}$ quark-antiquark pair.

19.3.4.2 Discovery of $D^*_{s0}(2317)^+$ and $D_{s1}(2460)^+$

BABAR first investigated the $D_s^+\pi^0$ mass spectrum inclusively produced from e^+e^- interactions, with $92\,\mathrm{fb}^{-1}$ of data used (Aubert, 2003j). The D_s^+ is reconstructed in the $K^+K^-\pi^+$ decay mode, with K^+K^- mass near the $\phi(1020)$ mass or $K^-\pi^+$ mass near the $\overline{K}^*(892)$ mass. The decay products of the $\phi(1020)$ and $\overline{K}^*(892)$ vector states exhibit a $\cos^2\theta_h$ helicity angle behavior and the signal-to-background ratio is improved by requiring $|\cos\theta_h| > 0.5$. Candidates for $\pi^0 \to \gamma\gamma$ are reconstructed using photons which do not belong to another acceptable π^0 candidate ("π^0 veto"). Only $D_s^+\pi^0$ candidates with their CM momenta $p^* > 3.5\,\mathrm{GeV}/c$ are retained to eliminate background from B decays and reduce combinatorial background.

The resulting $D_s^+\pi^0$ mass spectrum, shown in Fig. 19.3.14a, exhibits a clear, narrow signal at a mass near $2.32\,\mathrm{GeV}/c^2$, labeled as $D^*_{s0}(2317)^+$. No such signal is observed in the $M(D_s^+\pi^0)$ distribution obtained using candidates from either the D_s^+ or the π^0 mass sidebands. The same analysis procedure is applied to MC simulations of $e^+e^- \to c\bar{c}$ events which include all known charm states and decays, and yields no $2.32\,\mathrm{GeV}/c^2$ peak. This proves that the $D^*_{s0}(2317)^+$ is not due to reflection from other charmed states.

The $M(D_s^+\pi^0)$ spectrum in Fig. 19.3.14a is fitted using a Gaussian function describing the $D^*_{s0}(2317)^+$ signal and a polynomial background, and yields about 1300 signal events with a mass of $(2316.8 \pm 0.4)\,\mathrm{MeV}/c^2$ and an experimental resolution of $(8.6 \pm 0.4)\,\mathrm{MeV}/c^2$. A clear

$D^*_{s0}(2317)^+ \to D_s^+\pi^0$ signal is also observed for $D_s^+ \to K^+K^-\pi^+\pi^0$ (see Fig. 19.3.14b).

Using $13.5\,\mathrm{fb}^{-1}$ of data, the $D^*_{s0}(2317)^+$ was readily confirmed by CLEO (Besson et al., 2003); in the same analysis they also claimed the discovery of the $D_{s1}(2460)^+ \to D^{*+}_s\pi^0$. In the original paper (Aubert, 2003j), *BABAR* also reports a narrow signal of 2.46 GeV/c^2 in the $M(D_s^+\pi^0\gamma)$ spectrum, with most of the peak events having $D_s^+\gamma$ masses consistent with the D^{*+}_s. However, MC simulations showed a complex kinematic superposition of signals and reflections between $D_{s1}(2460)^+$ and $D^*_{s0}(2317)^+$ (see below), and for this reason *BABAR* did not claim immediately the 2.46 GeV/c^2 structure being a new resonance.

A few months later, Belle confirmed both $D^*_{s0}(2317)^+$ and $D_{s1}(2460)^+$ using 70 fb^{-1} of data sample (Abe, 2004a). The D_{sJ} signals are studied in the $\Delta M(D_s^{(*)+}\pi^0) \equiv M(D_s^{(*)+}\pi^0) - M(D_s^{(*)+})$ mass difference spectra (shown in Fig. 19.3.15) as they have a better resolution than the invariant masses, while the secondary particles are reconstructed as $D^{*+}_s \to D_s^+\gamma$ and $D_s^+ \to \phi\pi^+$. Like in the *BABAR* study, MC simulation reveals that $D_{s1}(2460)^+ \to D^{*+}_s\pi^0$ decays produce a reflection in the $\Delta M(D_s^+\pi^0)$ distribution slightly below the $D^*_{s0}(2317)^+$ signal. On the other hand, the $D^*_{s0}(2317)^+ \to D_s^+\pi^0$ combined with a random photon passing the D^{*+}_s selection, causes a peaking background to the $D_{s1}(2460)^+$. Another feed-down source is the $D_{s1}(2460)^+$ producing a wide structure at its nominal mass, which is due to a random γ in the D^{*+}_s reconstruction. Both these feed-downs are visible in the $\Delta M(D^{*+}_s\pi^0)$ distributions for the D^{*+}_s sidebands in the right upper plot of Fig. 19.3.15.

In the $D^*_{s0}(2317)^+$ fit (left bottom plot in Fig. 19.3.15), both the signal and the feed-down are represented as Gaussian shapes, parameters of the latter are fixed according to MC expectation and normalized by the measured $D_{s1}(2460)^+$ signal. A fit to the $D_{s1}(2460)^+$ mass distribution is performed for the data with the D^{*+}_s sideband subtracted bin-by-bin (right bottom plot in Fig. 19.3.15). Masses corresponding to the fitted peak positions and the upper limits set on the meson widths are summarized in Table 19.3.7.

BABAR developed a different method for solving an overlap between $D_{s1}(2460)^+$ and $D^*_{s0}(2317)^+$ (Aubert, 2004t). Considering the final state $D_s^+\pi^0\gamma$, the
Figure 19.3.11. From (del Amo Sanchez, 2010i). Mass distributions for $D^{*+}\pi^-$ candidates produced in the process $e^+e^- \rightarrow c\bar{c} \rightarrow D^*\pi X$. Top: candidates with $|\cos\theta_H| > 0.75$. Middle: candidates with $|\cos\theta_H| < 0.5$. Bottom: all candidates. Points correspond to data, with the total fit overlaid as a solid curve. The lower solid curve is the combinatoric background, and the dotted curves are the signal components. The inset plots show the distributions after subtraction of the combinatoric background.

$D_{s1}(2460)^+$ may decay through either $D_s^{*+}\pi^0$ or $D_{s0}^*(2317)^+\gamma$. To disentangle these modes and reliably extract the parameters of the signal, *BABAR* applies an unbinned maximum likelihood fit simultaneously to the $M(D_s^+\pi^0\gamma)$, $M(D_s^+\pi^0)$ and $M(D_s^+\gamma)$ spectra of all the $D_s^+\pi^0\gamma$ combinations, using the channel likelihood method (Condon and Cowell, 1974). This fit describes the probability density function of the two $D_{s1}(2460)^+$ decay channels as the product of a Gaussian shape in the $M(D_s^+\pi^0\gamma)$ distribution and a Gaussian shape projected into the $M(D_s^+\pi^0)$ or $M(D_s^+\gamma)$ axes, as appropriate. Background sources included in the fit are: purely combinatorial background, $D_s^{*+} \rightarrow D_s^+\gamma$ decay combined with an unassociated π^0, $D_{s0}^*(2317)^+ \rightarrow D_s^+\pi^0$ decay
Figure 19.3.13. The $c\bar{s}$ spectrum according to the HQET scheme. The P-wave multiplet is shaded. Expectations on the masses according to HQET calculations (lines) are compared with experimental results (dots).
Figure 19.3.14. From (Aubert, 2003j). a) $D_s^+\pi^0$ mass spectrum for $D_s^+ \rightarrow K^+K^-\pi^+$ superimposed with the fit described in the text. b) $D_s^+\pi^0$ mass distribution for $D_s^+ \rightarrow K^+K^-\pi^+\pi^0$. The structure at 2.32 GeV is due to the $D_{s0}^*(2317)^+$ resonance. The narrow peak at threshold is due to the $D_s^{*+} \rightarrow D_s^+\pi^0$ decay. The broad structure is due to reflections from other states (see Section 19.3.4.3).
Figure 19.3.15. From (Abe, 2004a): Distributions of $\Delta M(D_s^+\pi^0)$ (left) and $\Delta M(D_s^{*+}\pi^0)$ (right). In the upper plots data from mass sidebands are also shown: the D_s^+ (left) and D_s^{*+} (right) sideband regions (solid lines), π^0 sidebands (dashed). The bottom plots show fits to the $\Delta M(D_s^+\pi^0)$ (left) and $\Delta M(D_s^{*+}\pi^0)$ distributions after subtraction of the D_s^{*+} sidebands.

combined with a random γ, and a contribution from $D_{s1}(2460)^+ \rightarrow D_s^{*+}\pi^0$ decay with a random γ in D_s^{*+} decay. The $D_{s1}(2460)^+$ signal for a particular decay mode is extracted by calculating for each $D_s^+\pi^0\gamma$ combination a weight proportional to the relative likelihood contributed by the decay mode of interest. Distributions of events so weighted, as well as the unweighted $M(D_s^+\pi^0\gamma)$ spectrum, are compared to the likelihood function in Fig. 19.3.16. The decay $D_{s1}(2460)^+ \rightarrow D_{s0}^*(2317)^+\gamma$ is found to be negligible, whereas the decay $D_{s1}(2460)^+ \rightarrow D_s^{*+}\pi^0$ saturated the $D_s^+\pi^0\gamma$ final state. The results of this study were later superseded by (Aubert, 2006e) described below.

19.3.4.3 High statistics study of $D_{s0}^*(2317)^+$ and $D_{s1}(2460)^+$

BABAR performed a complete analysis of the $D_s^{(*)+}\pi^0$ spectrum using 232 fb^{-1} of data and with some of the selection criteria from the previous analyses reoptimized (Aubert, 2006e).

The invariant mass distribution of the $D_s^+\pi^0$ combinations is shown in Fig. 19.3.17. The π^0 momentum requirement to be greater than 350 MeV/c, removes the majority of the $D_s^{*+} \rightarrow D_s^+\pi^0$ decays, while keeping the entire $D_{s0}^*(2317)^+$ signal. The unbinned likelihood fit applied to the $M(D_s^+\pi^0)$ distribution includes the D_s^{*+} and $D_{s0}^*(2317)^+$ signals and the following peaking components: a reflection at 2.17 GeV/c^2 from $D_s^{*+} \rightarrow D_s^+\gamma$ in which an
Figure 19.3.16. From (Aubert, 2004t). Maximum likelihood fit results overlaid on the $D_s^+\pi^0\gamma$ mass distribution with a) no weights and after applying weights corresponding to b) the $D_s^{*+}\pi^0$ and c) the $D_{s0}^*(2317)^+\gamma$ decays.

unassociated γ forms a false π^0 candidate, as well as a reflection appearing directly under the $D_{s0}^*(2317)^+$ signal. The latter originates from $D_{s1}(2460)^+ \rightarrow D_s^{*+}\pi^0$ with a missing photon from D_s^{*+} decay. Parameters used to describe the former feed-down are determined directly from the data, while the shape of the latter one is based on the MC simulation of the $D_{s1}(2460)^+ \rightarrow D_s^+\pi^0\gamma$ Dalitz distribution. The $D_{s0}^*(2317)^+$ line shape used in the fit is derived from MC simulation configured with an intrinsic width (0.1 MeV/c^2) nearly indistinguishable from zero. Larger intrinsic widths assumed in the MC do not result in any significant improvement of the fit.

A study of the $D_s^+\pi^0\gamma$ mass (see Fig. 19.3.18) is performed with the $D_s^+\gamma$ mass required to be close to the D_s^{*+} mass. Similarly to the Belle analysis, there were two reflections peaking near the $D_{s1}(2460)^+$: from $D_{s0}^*(2317)^+ \rightarrow D_s^+\pi^0$ decays combined with a random γ, and from $D_{s1}(2460)^+ \rightarrow D_s^+\pi^0\gamma$ with a wrong γ chosen. In the fit to the $M(D_s^+\pi^0\gamma)$, these components are combined and described using MC simulations with the rates as measured in the previous analysis. A broad reflection at 2.34 MeV/c^2, coming from $D_s^{*+} \rightarrow D_s^+\gamma$ decays combined with an unassociated γ, is also considered in the fit. The
Figure 19.3.17. From (Aubert, 2006e). The invariant mass distribution for $D_s^+\pi^0$ candidates (solid points) and the equivalent using the D_s^+ sidebands (open points). The curve represents the likelihood fit described in the text and includes a contribution from combinatorial background (light shade) and the reflection from $D_{s1}(2460)^+ \to D_s^{*+}\pi^0$ decay (dark shade). The insert highlights the details near the $D_{s0}^*(2317)^+$ mass. The narrow peak at threshold is due to the $D_s^{*+} \to D_s^+\pi^0$ decay.

$D_{s1}(2460)^+$ signal shape is obtained using MC, similarly to the $D_{s0}^*(2317)^+$ case.

The resulting $D_{s0}^*(2317)^+$ and $D_{s1}(2460)^+$ masses and upper limits on their widths are given in Table 19.3.7. The $D_{s1}(2460)^+$ mass is the average obtained from the $D_s^+\pi^0\gamma$, $D_s^+\gamma$ and $D_s^+\pi^+\pi^-$ final states (see Section 19.3.4.4). The limit on the intrinsic $D_{s1}(2460)^+$ width is taken as the best limit obtained from these three decay modes.

19.3.4.4 Other decay modes

The $D_{s1}(2460)^+$ decays to the $D_s^+\gamma$ and the $D_s^+\pi^+\pi^-$ final states were first observed by Belle (Abe, 2004a) and further confirmed by *BABAR* (Aubert, 2006e). Selected photons are required to pass the π^0 veto, while the $\pi^+\pi^-$ pairs are taken outside of the K_S^0 mass window. The left plot in Fig. 19.3.19 shows the $\Delta M(D_s^+\gamma) = M(D_s^+\gamma) - M(D_s^+)$ distribution measured by Belle. A peak at 490 MeV/c^2 corresponds to the $D_{s1}(2460)^+$, whereas no peak is present in the $D_{s0}^*(2317)^+$ region at 350 MeV/c^2. The observation of the radiative decay of the $D_{s1}(2460)^+$ rules out its spin-parity of $0^\pm$.

The invariant mass distribution of the $D_s^+\pi^+\pi^-$ candidates from *BABAR* presented in right plot in Fig. 19.3.19, shows clear signals from $D_{s1}(2460)^+$ and $D_{s1}(2536)^+$ and
Figure 19.3.18. From (Aubert, 2006e). The $M(D_s^+\pi^0\gamma)$ invariant mass distribution of candidates in the (a) upper, (b) signal, and (c) lower $D_s^+\gamma$ mass selection windows for (solid points) the D_s^+ signal and (open points) D_s^+ sideband samples. The curves represent the fits described in the text. The gray regions correspond to the predicted reflections from $D_{s0}^*(2317)^+$ (dark) and $D_s^*(2112)^+$ (light).

Table 19.3.7. From (Aubert, 2006e) and (Abe, 2004a). The first section summarizes the combined mass and width results from *BABAR*. The $D_{s0}^*(2317)^+$ and $D_{s1}(2536)^+$ mesons are observed in only one decay mode covered by this analysis. The $D_{s1}(2460)^+$ mass is the average of that obtained from the $D_s^+\gamma$, $D_s^+\pi^0\gamma$, and $D_s^+\pi^+\pi^-$ final states, although the latter measurement dominates in the average due to superior systematic uncertainties. The second section gives Belle results based on the $D_s^{(*)+}\pi^0$ modes.

Particle	Mass (MeV/c^2)	Γ (MeV/c^2)
$D_{s0}^*(2317)^+$	$2319.6 \pm 0.2 \pm 1.4$	< 3.8 @ 95 % C.L.
$D_{s1}(2460)^+$	$2460.1 \pm 0.2 \pm 0.8$	< 3.5 @ 95 % C.L.
$D_{s1}(2536)^+$	$2534.6 \pm 0.3 \pm 0.7$	< 2.5 @ 95 % C.L.
$D_{s0}^*(2317)^+$	$2317.2 \pm 0.5 \pm 0.9$	< 4.6 @ 90 % C.L.
$D_{s1}(2460)^+$	$2456.5 \pm 1.3 \pm 1.3$	< 5.5 @ 90 % C.L.

negligible contribution from $D_{s0}^*(2317)^+$. Searches for the decays of $D_{s0}^*(2317)^+$ and $D_{s1}(2460)^+$ to $D_s^+\pi^0\pi^0$ and $D_s^{*+}\gamma$ give no positive results. The branching fraction ratios for the studied channels, given in Table 19.3.8, are measured based on the fitted yields and detection efficiencies estimated with an assumption of the same fragmentation functions for the D_{sJ} states.

The dominant decays observed, $D_{s0}^*(2317)^+ \to D_s^+\pi^0$ and $D_{s1}(2460)^+ \to D_s^{*+}\pi^0$, violate isospin conservation; that is often considered as a property of four-quark states, which have long been proposed (Jaffe, 1977b; Lipkin, 1977). The most unambiguous signature of a molecular interpretation of the $D_{s0}^*(2317)^+$ and the $D_{s1}(2460)^+$ would be an
Figure 19.3.19. Left: The $\Delta M(D_s^+\gamma)$ distribution from (Abe, 2004a). Right: The $M(D_s^+\pi^+\pi^-)$ spectrum from (Aubert, 2006e). The insert focuses on the $D_{s0}^*(2317)^+$ region. The spectra for the D_s^+ sideband candidates are plotted with solid histogram in the left plot and open points in the right one.

Table 19.3.8. A summary of D_s^{**} branching fraction ratios from Belle (first line) and *BABAR* (second line). For the $D_{s0}^*(2317)^+$ meson, only one decay mode has been observed; this is used as the denominator when calculating the $D_{s0}^*(2317)^+$ branching ratios. For the $D_{s1}(2460)^+$ meson, the $D_s^+\pi^0\gamma$ decay mode (consisting of possible decay through either $D_s^*(2112)^+\pi^0$ or $D_{s0}^*(2317)^+\gamma$ is chosen for this role.

	< 0.16 @ 95 % C.L.

observation of their neutral and doubly-charged partners decaying to $D_s^{(*)+}\pi^\pm$. However a search for the $D_{s0}^*(2317)$ partners decaying to $D_s^+\pi^+$ and $D_s^+\pi^-$ resulted in no evidence (Aubert, 2006e).

The observed decay pattern is consistent with the J^P assignments for the $D_{s0}^*(2317)^+$ and $D_{s1}(2460)^+$ of respectively 0^+ and 1^+, as expected by the potential models for the P-wave $c\bar{s}$ mesons with $j_q = \frac{1}{2}$.

19.3.4.5 D_{sJ} production in B decays

To clarify the nature of the $D_{s0}^*(2317)^+$ and $D_{s1}(2460)^+$ states, Belle and *BABAR* searched for their production in $B \to \overline{D}D_{sJ}$ decays. These reactions proceed via $\bar{b} \to \bar{c}W^+ \to \bar{c}c\bar{s}$ transition and are expected to be the dominant exclusive $c\bar{s}$ production mechanism. QCD sum rules predict that P-wave charmed mesons with $j_q = \frac{1}{2}$ should be more readily produced in B decays than ones having $j_q = \frac{3}{2}$ (Le Yaouanc, Oliver, Pène, Raynal, and Morenas, 2001). Thus observation of the $B \to \overline{D}D_{s0}^*(2317)^+$ and $B \to \overline{D}D_{s1}(2460)^+$ would provide a confirmation of the P-wave nature of these D_{sJ} states. Moreover, measurements of B decays to the final states including the $j_q = \frac{3}{2}$ D_{sJ} mesons, or higher orbital or radial $c\bar{s}$ excitations could be a further test of the theoretical predictions on the $c\bar{s}$ spectroscopy.

In a Belle study of the $B \to \overline{D}D_{sJ}$ decays, with 124×10^6 $B\overline{B}$ pairs used, the $\overline{D}$ is reconstructed as: $\overline{D}^0 \to K^+\pi^-$, $K^+\pi^-\pi^-\pi^+$, $K^+\pi^-\pi^0$, $D^- \to K^+\pi^-\pi^-$. The D_{sJ} states are studied in the $D_s^{(*)+}\pi^0$, $D_s^{(*)+}\gamma$ and $D_s^{(*)+}\pi^+\pi^-$ final states, with $D_s^{*+} \to D_s^+\gamma$ and $D_s^+ \to \phi\pi^+, \overline{K}^{(*)0}K^+$ reconstructed (Krokovny, 2003b). To reduce background the B candidates are required to have their $m_{\rm ES}$ consistent with the nominal B mass (see Sections 9 and 7), while the signal events are identified in the ΔE-$M(D_{sJ})$ space. The left plots in Fig. 19.3.20 show invariant mass distributions of the D_{sJ} candidates within the ΔE signal region, for all the D modes combined. The presented spectra are for the D_{sJ} decay final states with significant signals found: $D_{s0}^*(2317)^+ \to D_s^+\pi^0$, $D_{s1}(2460)^+ \to D_s^{*+}\pi^0$ and $D_{s1}(2460)^+ \to D_s^+\gamma$. Unlike the continuum based D_{sJ} studies, cross-feeds between the D_{sJ} decay modes were not found, and thus the $M(D_{sJ})$ spectra are fitted with signal and background described respectively with a Gaussian and linear function. The measured masses of the $D_{s0}^*(2317)^+$ and $D_{s1}(2460)^+$ are respectively $2319.8 \pm 2.1 \pm 2.0 \,{\rm MeV}/c^2$ and $2459.2 \pm 1.6 \pm 2.0 \,{\rm MeV}/c^2$, while the fitted widths are consistent with the experimental resolution.

The ΔE distributions shown in Fig. 19.3.20, are projections for the B candidates having the $M(D_{sJ})$ within the observed D_{sJ} signals. Branching fractions given in Table 19.3.9, are extracted from the ΔE fits of the combined $B \to \overline{D}^0 D_{sJ}^+$ and $B \to D^- D_{sJ}^+$ modes, with efficiencies of the individual modes taken into account and isospin invariance assumed. The determined ratio, $\frac{\mathcal{B}(D_{s1}(2460)^+\to D_s^+\gamma)}{\mathcal{B}(D_{s1}(2460)^+\to D_s^{*+}\pi^0)} = 0.38 \pm 0.11 \pm 0.04$, is consistent with the one obtained from $D_{s1}(2460)^+$ produced in the continuum (see Table 19.3.8).

A helicity angle ($\theta_{D_s\gamma}$) study is performed for the $D_{s1}(2460)^+ \to D_s^+\gamma$ decay, where $\theta_{D_s\gamma}$ is defined as the angle between the D_s^+ momentum and the opposite to the B meson momentum in the $D_{s1}(2460)^+$ rest frame. Figure 19.3.21 shows the background-subtracted $\cos(\theta_{D_s\gamma})$ distribution, where the data points represent signal yields from the ΔE fits performed in respective $\cos(\theta_{D_s\gamma})$ bins.
Figure 19.3.20. From (Krokovny, 2003b): The $M(D_{sJ})$ distribution for the ΔE signal region (left) and the ΔE distribution for the $M(D_{sJ})$ signal region (right) for the $B \to \bar{D}D_{sJ}$ candidates with (a) $D_{s0}^*(2317)^+ \to D_s^+\pi^0$, (b) $D_{s1}(2460)^+ \to D_s^{*+}\pi^0$ and (c) $D_{s1}(2460)^+ \to D_s^+\gamma$ decays observed. Hatched histograms in a given variable distribution show the sidebands of the other variable, lines represent the fit result.

Table 19.3.9. From (Krokovny, 2003b). Measured branching fraction products $\mathcal{B}(B \to \bar{D}D_{sJ}) \times \mathcal{B}(D_{sJ} \to f)$ or 90 % C.L. limits. f is the label of a given final state.

Decay mode	Product $\mathcal{B}$ [10^{-4}]

$B \to \bar{D}D_{s1}(2460)^+,\ D_{s1}(2460)^+ \to D_s^+\pi^+\pi^-$	< 1.6
$B \to \bar{D}D_{s1}(2460)^+,\ D_{s1}(2460)^+ \to D_s^+\pi^0$	< 1.8

As it can be seen from the figure, the $J = 1$ hypothesis fits much better the data than the $J = 2$ hypothesis.

In the *BABAR* approach to the $B \to \bar{D}^{(*)}D_{sJ}^+$ study (Aubert, 2006aw), the $\bar{D}^{(*)} = \bar{D}^{(*)0}$, $D^{(*)-}$ mesons are fully reconstructed ($D_{\rm meas}$), while the invariant mass of the D_{sJ} is inferred from the kinematics of the two-body B decay, as well as the kinematics of the accompanying $\bar{B}$. The analysis used the $\Upsilon(4S) \to B\bar{B}$ events in which the $\bar{B}$ meson ($B_{\rm rec}$) decays into fully reconstructed hadronic final state $B_{\rm rec} \to D^{(*)}Y^-$, with the system Y^- composed of combinations of kaons and pions (see Section 7). The D_{sJ} invariant mass is derived from a missing four-momentum ($p_{\rm miss}$) as:

$$m_X \equiv \sqrt{p_{\rm miss}^2} = \sqrt{(p_{\Upsilon(4S)} - p_{B_{\rm rec}} - p_{D_{\rm meas}})^2},$$
(19.3.18)

with all the momenta measured in the laboratory system. Such a method allows measurements of absolute $B \to \bar{D}^{(*)}D_{sJ}^+$ branching fractions, without any assumptions on the D_{sJ}^+ decays, at the cost of full reconstruction effi-
Figure 19.3.21. From (Krokovny, 2003b): Background-subtracted helicity distribution for the $D_{s1}(2460)^+ \to D_s^+\gamma$. Lines show MC expectations for spin hypotheses $J = 1$ (solid) and $J = 2$ (dashed); $J = 0$ is forbidden.
Figure 19.3.22. From (Aubert, 2006aw). Distributions of the D_{sJ} invariant mass m_X (defined in the text). Fitted $\bar{B} \to D^{(*)+,0}D_s^{(*)-}$ and $\bar{B} \to D^{(*)+,0}D_{s1}(2460)^-$ signal contributions and background components are overlaid to the data points.

ciency of about 0.3 % for $B^0\bar{B}^0$ and 0.2 % for B^+B^-, and the m_X resolution being typically a few times worse than in a direct reconstruction. In the m_X spectra, shown in Fig. 19.3.22, in addition to the $D_s^{(*)+}$, *BABAR* observes the $D_{s1}(2460)^+$ signal.

The measured $B \to \bar{D}^{(*)}D_{s1}(2460)^+$ branching fractions, calculated using PDG values of the $D^{(*)}$ decay rates,

Table 19.3.10. From (Aubert, 2006aw). Absolute branching fractions of the $B \to \overline{D}^{(*)} D_{s1}(2460)^+$ decays.

Decay mode	$\mathcal{B}$ [%]
$B^0 \to D^- D_{s1}(2460)^+$	$0.26 \pm 0.15 \pm 0.07$
$B^0 \to D^{*-} D_{s1}(2460)^+$	$0.88 \pm 0.20 \pm 0.14$
$B^+ \to \overline{D}^0 D_{s1}(2460)^+$	$0.43 \pm 0.16 \pm 0.13$
$B^+ \to \overline{D}^{*0} D_{s1}(2460)^+$	$1.12 \pm 0.26 \pm 0.20$

are summarized in Table 19.3.10. *BABAR* further combined these results with their measurements of the product $\mathcal{B}$ of the $B \to \overline{D}^{(*)} D_{s1}(2460)^+$ decays (Aubert, 2004ad), measured similarly to the described Belle analysis. This allowed a first measurement of the $D_{s1}(2460)^+$ decay rates:

$$\mathcal{B}(D_{s1}(2460)^+ \to D_s^{*+} \pi^0) = (56 \pm 13 \pm 9)\%,$$
$$\mathcal{B}(D_{s1}(2460)^+ \to D_s^+ \gamma) = (16 \pm 4 \pm 3)\%.$$
$$(19.3.19)$$

Belle studied the production of the $D_{s1}(2536)^+$ meson in $B \to \overline{D}^{(*)} D_{s1}(2536)^+$ decays, with $\overline{D}^{(*)}$ being either $\overline{D}^0$ or $D^{(*)-}$, using a data sample of 657×10^6 $B\overline{B}$ pairs (Aushev, 2011). The $D_{s1}(2536)^+$ is reconstructed in its dominant decay modes, $D^{*+} K_S^0$ and $D^{*0} K^+$. Figure 19.3.23 shows the $M(D_{s1}(2536))$ spectra for the B candidates satisfying the ΔE-m_{ES} selection, for each $\overline{D}^{(*)}$ flavor and the $D_{s1}(2536)^+$ decay mode separately. All these distributions are fitted simultaneously, with the signal $D_{s1}(2536)^+$ described as a BW function convolved with a double Gaussian function describing the mass resolution. The measured $D_{s1}(2536)^+$ mass and width were respectively $2534.1 \pm 0.6 \,\text{MeV}/c^2$ and $0.75 \pm 0.23 \,\text{MeV}/c^2$, consistent with their PDG values (Beringer et al., 2012). A fit with the $D_{s1}(2536)^+$ partial width ratio kept as a free parameter, yields:

$$\frac{\mathcal{B}(D_{s1}(2536)^+ \to D^{*0} K^+)}{\mathcal{B}(D_{s1}(2536)^+ \to D^{*+} K^0)} = 0.88 \pm 0.24 \pm 0.08,$$
$$(19.3.20)$$

in agreement with the *BABAR* study (Aubert, 2008bd). Table 19.3.11 summarizes ratios of branching fractions, calculated using the latest measurements of the $B \to \overline{D}^{(*)} D_{s(J)}^{(*)+}$ branching fractions, as well as the $D_{s1}(2536)^+$ measurements by Belle (Aushev, 2011) and *BABAR* (Aubert, 2008bd). In these calculations, 100% branching fractions are assumed for the $D_{s0}^*(2317)^+ \to D_s^+ \pi^0$ and $D_{s1}(2536)^+ \to D^* K$ decay modes. Within the factorization model and in the heavy quark limit, these ratios should be of order unity for the $D_{s0}^*(2317)^+$ and $D_{s1}(2460)^+$, whereas for the $D_{s1}(2536)^+$ they are predicted to be very small (Datta and O'Donnell, 2003b; Le Yaouanc, Oliver, Pène, and Raynal, 1996). The decay pattern for the $D_{s1}(2536)^+$ follows these expectations, whereas for the $D_{s0}^*(2317)^+$ and $D_{s1}(2460)^+$ the ratios are rather different from unity and therefore such an approach

Table 19.3.11. Ratios of B decay branching ratios measured by Belle (Aushev, 2011) and *BABAR* (Aubert, 2008bd).

Ratio	Fraction
$\mathcal{B}(B \to \overline{D} D_{s1}(2536)^+)/\mathcal{B}(B \to \overline{D} D_s^*)$	0.05 ± 0.01
$\mathcal{B}(B \to \overline{D}^* D_{s1}(2536)^+)/\mathcal{B}(B \to \overline{D}^* D_s^*)$	0.04 ± 0.01
$\mathcal{B}(B \to \overline{D} D_{s1}(2460)^+)/\mathcal{B}(B \to \overline{D} D_s^*)$	0.44 ± 0.11
$\mathcal{B}(B \to \overline{D}^* D_{s1}(2460)^+)/\mathcal{B}(B \to \overline{D}^* D_s^*)$	0.58 ± 0.12
$\mathcal{B}(B \to \overline{D} D_{s0}^*(2317)^+)/\mathcal{B}(B \to \overline{D} D_s)$	0.10 ± 0.03
$\mathcal{B}(B \to \overline{D}^* D_{s0}^*(2317)^+)/\mathcal{B}(B \to \overline{D}^* D_s)$	0.15 ± 0.06
Figure 19.3.23. From (Aushev, 2011): The $D_{s1}(2536)^+$ mass distributions for: $B^+ \to \overline{D}^0 D_{s1}(2536)^+$ (a,b,c), $B^0 \to D^- D_{s1}(2536)^+$ (d,e,f), $B^0 \to D^{*-} D_{s1}(2536)^+$ (g,h,i) decays followed by the $D_{s1}(2536)^+$ decays to: $D^{*0} K^+$ with $D^{*0} \to D^0 \gamma$ (a,d,g); $D^{*0} K^+$ with $D^{*0} \to D^0 \pi^0$ (b,e,h) and $D^{*+} K_S^0$ with $D^{*+} \to D^0 \pi^+$ (c,f,i). The curves show results of the simultaneous fit.

Table 19.3.12. From (Aushev, 2011). Fitted product $\mathcal{B}$: $\mathcal{B}(B \to \overline{D}^{(*)} D_{s1}(2536)^+) \times \mathcal{B}(D_{s1}(2536)^+ \to D^{*+} K_S^0 + D^{*0} K^+)$.

Decay mode	Product $\mathcal{B}$ [10^{-4}]
$B^+ \to \overline{D}^0 D_{s1}(2536)^+$	$3.97 \pm 0.85 \pm 0.56$
$B^0 \to D^- D_{s1}(2536)^+$	$2.75 \pm 0.62 \pm 0.36$
$B^0 \to D^{*-} D_{s1}(2536)^+$	$5.01 \pm 1.21 \pm 0.70$

does not really work. One possibility is that these states are not canonical $c\bar{s}$. However, the agreement with theory would be improved for the $D_{s0}^*(2317)^+$, if other prominent decay modes existed in addition to the $D_s^+ \pi^0$.

19.3.4.6 Precision measurements of $D_{s1}(2536)^+$ properties

BABAR measured the mass of the $D_{s1}(2536)^+$ with a significant improvement compared to the world average, and, for the first time, measured directly its decay width, instead of reporting an upper limit only (Lees, 2011d).
Figure 19.3.24. From (Lees, 2011d). $\Delta m(D_{s1}(2536)^+)$ distribution for (left) the $D^0 \to K^-\pi^+$ and (right) the $D^0 \to K^-\pi^+\pi^+\pi^-$ decay modes. The solid line is the fit function as described in the text, the dotted line indicates the background contribution. The normalized fit residuals are shown on top.

Table 19.3.13. From (Lees, 2011d). Combined results for mass and width of the $D_{s1}(2536)^+$.

Parameter	Value [MeV/c^2]
$M(D_{s1}(2536)^+)$	$2535.08 \pm 0.01 \pm 0.15$
$M(D_{s1}(2536)^+) - M(D^{*+})$	$524.83 \pm 0.01 \pm 0.04$
$\Gamma(D_{s1}(2536)^+)$	$0.92 \pm 0.03 \pm 0.04$

The $D_{s1}(2536)^+$ is reconstructed in $D^{*+}K_S^0$, with $D^{*+} \to D^0\pi^+$ and $D^0 \to K^-\pi^+$, $K^-\pi^+\pi^+\pi^-$. To improve the resolution, the mass difference $\Delta m(D_{s1}(2536)^+) = M(D_{s1}(2536)^+) - M(D^{*+}) - M(K_S^0)$ is examined. Combinatorial background and events from B decays are suppressed by requiring a CM momentum $p^* > 2.7$ GeV/c.

The samples for the two D^0 decays are examined separately, the $\Delta m(D_{s1}(2536)^+)$ spectrum for the $K^-\pi^+$ and $D^0 \to K^-\pi^+\pi^+\pi^-$ modes are shown in Fig. 19.3.24. The signal is described with a convolution of a relativistic BW lineshape and a p^* dependent, multi-Gaussian detector resolution parameterization. The dominant systematic uncertainties are related to track reconstruction, the signal lineshape modeling and detector resolution parameterization. Results from the fits to the two $\Delta m(D_{s1}(2536)^+)$ spectra are combined, and the final numbers are given in Table 19.3.13.

The large and clean sample of $D_{s1}(2536)^+$ signal candidates reconstructed by *BABAR*, enables a study of the spin-parity and decay properties of the $D_{s1}(2536)^+$. In this analysis the $D^{*+}K_S^0$ system is produced inclusively, and therefore the origin of the $D_{s1}(2536)^+$ is not known. Thus, for the J^P study, the decay angle of the D^{*+} (θ') is examined. The θ' is measured between the D^0 momentum in the D^{*+} CM system and the D^{*+} momentum in the $D_{s1}(2536)^+$ system; the resulting angular distribution is influenced by the spin of the $D_{s1}(2536)^+$. The $\cos\theta'$ distribution for both subsamples combined, is shown in Fig. 19.3.25 (left). Fits with several models used,
Figure 19.3.25. From (Lees, 2011d). Left: Efficiency-corrected $D_{s1}(2536)^+$ signal yield as function of D^{*+} decay angle θ'. Lines correspond to the following hypotheses fitted to the data: $J^P = 1^+, 2^-, 3^+, \dots$ with S- and D-wave (solid); $1^+, 2^-, 3^+, \dots$ with S-wave only (dash-dotted); 0^- (dashed); $1^-, 2^+, 3^-, \dots$ (dotted). 0^+ is forbidden. Right: Efficiency-corrected $D_{s1}(2536)^+$ signal yield as function of $D_{s1}(2536)^+$ decay angle θ. Assuming $J^P = 1^+$, the data are fitted with hypotheses of pure S-wave (dotted line); S- and D-wave (solid line) $D_{s1}(2536)^+$ decays.

show a clear preference for unnatural spin-parity values ($J^P = 1^+, 2^-, 3^+, \dots$), described by a distribution proportional to $\cos^2\theta' + \beta\sin^2\theta'$. The parameter β is the squared ratio of the D^{*+} amplitudes with helicities 0 and ±1, and its measured value of 0.23 ± 0.02 clearly indicates a D-wave contribution to the decay $D_{s1}(2536)^+ \to D^{*+}K_S^0$ ($\beta = 1$ is the case of a pure S-wave decay.).

The $D_{s1}(2536)^+$ decay angle (θ), defined as the angle between the D^{*+} momentum in the $D_{s1}(2536)^+$ CM system and the $D_{s1}(2536)^+$ momentum in the e^+e^- system, is shown in Fig. 19.3.25. It supports the hypothesis with both S- and D-wave contributing to the $D_{s1}(2536)^+$ decay amplitude. Assuming $J^P = 1^+$ for the $D_{s1}(2536)^+$, the data are expected to have a distribution proportional to $1 + t\cos^2\theta$. The fitted coefficient t in combination with the measured β, yields $\rho_{00} = 0.48 \pm 0.03$, consistent with the Belle result (see below), with ρ_{00} giving the probability that the $D_{s1}(2536)^+$ helicity is zero.

Belle studied the $D_{s1}(2536)^+$ state, inclusively produced in the $e^+e^- \to c\bar{c}$ continuum, using 462 fb^{-1} of data (Balagura, 2008). A new decay mode, $D_{s1}(2536)^+ \to D^+\pi^-K^+$ is observed, with the $D^+\pi^-$ and $K^+\pi^-$ two-body systems consistent with phase-space distributions. Its branching fractions is measured with respect to the normalization mode $D_{s1}(2536)^+ \to D^{*+}K_S^0$ as:

$$\frac{\mathcal{B}(D_{s1}(2536)^+ \to D^+\pi^-K^+)}{\mathcal{B}(D_{s1}(2536)^+ \to D^{*+}K^0)} = (3.27 \pm 0.18 \pm 0.37)\%.$$

$$(19.3.21)$$

This ratio is obtained from the $D_{s1}(2536)^+$ signal yields measured from the $M(D^+\pi^-K^+)$ and $M(D^{*+}K_S^0)$ mass spectra, shown in Figure 19.3.26, with the secondary particles reconstructed as: $D^+ \to K^-\pi^+\pi^+$ and $K_S^0\pi^+$, $D^{*+} \to D^0\pi^+$, $D^0 \to K^-\pi^+$, $K^-\pi^+\pi^+\pi^-$ and $K_S^0\pi^+\pi^-$. Instead of the common p^* cut, the analysts applies a requirement on the scaled momentum (x_p) of the $D_{s1}(2536)$ candidates
Figure 19.3.26. From (Balagura, 2008): Mass spectra of the $D^+\pi^-K^+$ (top) and $D^{*+}K_S^0$ (bottom) final states. The hatched histogram shows a spectrum of the *wrong-sign* $D^+\pi^+K^-$ combinations.

to be larger than 0.8. The scaled momentum is defined as $x_p \equiv p^*/p^*_{\max}$, where p^* is the $D_{s1}(2536)$ momentum in the e^+e^- CM frame, while $p^*_{\max}$ indicates the maximum kinematically allowed momentum in this frame.

The mass distributions in Fig. 19.3.26 are fitted independently with a double Gaussian describing the $D_{s1}(2536)$ signal. The $D_{s1}(2536)$ mass, measured with respect to its PDG value of $2535.35 \pm 0.34 \pm 0.50$ MeV/c^2, is -0.57 ± 0.04 MeV/c^2 for the $D_{s1}(2536) \to D^+\pi^-K^+$ and -0.43 ± 0.02 MeV/c^2 for the $D_{s1}(2536) \to D^{*+}K_S^0$. The mass resolution is about 1.5 MeV/c^2, thus too large to measure the $D_{s1}(2536)$ width.

For the $D_{s1}(2536)^+ \to D^{*+}K_S^0$ sample as shown in Fig. 19.3.26, Belle performed a full three-dimensional angular analysis. Such an analysis allows to study the partial wave structure of the $D_{s1}(2536)$ decay. Assuming $J^P = 1^+$ for the $D_{s1}(2536)$, the kinematics of the $D_{s1}(2536) \to D^{*+}K_S^0$ decay can be described by three angles α, β and γ, defined as shown in Fig. 19.3.27. Then the angular distribution in the helicity formalism is expressed as:

$$N(\alpha,\beta,\gamma) = \frac{9}{4\pi(1+2R_\Lambda)} \times \Big(\cos^2\gamma \big[\rho_{00}\cos^2\alpha + \frac{1-\rho_{00}}{2}\sin^2\alpha\big]$$
$$+ R_\Lambda\sin^2\gamma\big[\frac{1-\rho_{00}}{2}\sin^2\beta + \cos^2\beta\big(\rho_{00}\sin^2\alpha + \frac{1-\rho_{00}}{2}\cos^2\alpha\big)\big]$$
$$+ \frac{\sqrt{R_\Lambda}(1-3\rho_{00})}{4}\sin2\alpha\sin2\gamma\cos\beta\cos\xi\Big),$$
$$(19.3.22)$$

where ρ_{00} is the longitudinal $D_{s1}(2536)$ polarization, and $\sqrt{R_\Lambda}e^{i\xi} \equiv \frac{A_{1,0}}{A_{0,0}}$ denotes the ratio of the D^{*+} amplitudes with helicities of respectively ± 1 and 0, which are related
Figure 19.3.27. Definitions of the angles: α is the $D_{s1}(2536)$ helicity angle measured in the $D_{s1}(2536)$ CM frame as the angle between the boost direction in the e^+e^- CM frame and the K_S^0 momentum; β is the angle between the plane formed by these two vectors and the $D_{s1}(2536)$ decay plane measured also in the $D_{s1}(2536)$ rest frame; γ is the D^{*+} helicity angle between the π^+ and K_S^0 momenta in the D^{*+} rest frame.

to S- and D-wave amplitudes in the $D_{s1}(2536)$ decay:

$$A_{1,0} = (S + D/\sqrt{2})/\sqrt{3} \quad A_{0,0} = (S - \sqrt{2}D)/\sqrt{3}.$$
$$(19.3.23)$$

To measure the phase ξ and, thus, unambiguously determine the partial widths, the full three-dimensional angular analysis is necessary, as after integration over any of the angles, the $\cos\xi$ interference term in Eq. (19.3.22) vanishes.

The probability density function for the $D_{s1}(2536)$ signal is given by Eq. (19.3.22) which includes efficiency corrections obtained in the $(\cos\alpha, \beta, \cos\gamma)$ angular space determined from MC simulation; the background contribution is modeled in that space using the $M(D^{*+}K_S^0)$ sideband regions. The three-dimensional unbinned maximum likelihood fit to the $D_{s1}(2536) \to D^{*+}K_S^0$ signal region data yields:

$$\frac{A_{1,0}}{A_{0,0}} \equiv \sqrt{R_\Lambda}e^{i\xi} = a\,e^{\pm i\cdot b} \qquad (19.3.24)$$

where $a = \sqrt{3.6 \pm 0.3 \pm 0.1}$, $b = 1.27 \pm 0.15 \pm 0.05$, and $\rho_{00} = 0.490 \pm 0.012 \pm 0.004$, showing that the $D_{s1}(2536)$ spin prefers to align transversely to the momentum in the $x_p > 0.8$ region. Figure 19.3.28 shows one-dimensional projections of the fitted data together with the fit result. The good agreement of the data with theoretical predictions for the angular distribution of the axial meson, identifies the spin-parity of the $D_{s1}(2536)$ to be 1^+. The fit results given in Eq. (19.3.24) translate into the partial-wave amplitude ratio of:

$$\frac{D}{S} = c e^{\pm i\cdot d}, \qquad (19.3.25)$$

where $c = 0.63 \pm 0.07 \pm 0.02$ and $d = 0.76 \pm 0.03 \pm 0.01$. This shows that the S-wave amplitude dominates and its contribution to the total width is $\frac{\Gamma_S}{\Gamma_S+\Gamma_D} = \frac{1}{1+|D/S|^2} = 0.72 \pm 0.05 \pm 0.01$, where Γ_S and Γ_D denote the S- and D-wave partial widths.

The result in Eq. (19.3.25) disagrees with HQET which predicts the pure D-wave decay of the $D_{s1}(2536)$. However, HQET breaking caused by finite c-quark mass, can lead to mixing between the axial $c\bar{s}$ states having $j_q = \frac{1}{2}$
Figure 19.3.28. From (Balagura, 2008): Background-subtracted, efficiency-corrected and normalized one-dimensional projections of $(\cos\alpha, \beta, \cos\gamma)$ described in the text. The solid curves show projections of the three-dimensional fit.

and $j_q = \frac{3}{2}$. Then, similarly to Eq. (19.3.14), the physical states, $D_{s1}(2460)^+$ and $D_{s1}(2536)^+$, can be expressed as linear combinations of S- and D-wave amplitudes. As a result, the $D_{s1}(2536)$ can contain an admixture of the $J^P = 1^+$ state with $j_q = \frac{1}{2}$ and decaying in pure S wave. Since the energy release in the $D_{s1}(2536)^+ \rightarrow D^{*+}K_S^0$ decay is small, the D-wave is strongly suppressed by the centrifugal barrier factor $(q/q_0)^5$ and the S-wave contribution, proportional to q/q_0, can be significantly enhanced even if the mixing itself is small. Here q denotes the relative momentum of the $D_{s1}(2536)$ decay products in the $D_{s1}(2536)$ rest frame, while q_0 is a characteristic momentum scale of this reaction. Based on the measured D/S and input on the parameter q_0, theoretical models can calculate the $c\bar{s}$ mixing angle (Godfrey, 2005b).

Some information on the mixing could be also inferred from the ratio of branching fractions of the radiative decays $D_{s1}(2460)^+ \rightarrow D_s^+\gamma$ and $D_{s1}(2460)^+ \rightarrow D_s^{*+}\gamma$. However, only evidence exists for the $D_{s1}(2460)^+ \rightarrow D_s^{*+}\gamma$ (see Section 19.3.4.4), and an average of Belle results $\frac{\mathcal{B}(D_{s1}(2460)^+ \rightarrow D_s^{*+}\gamma)}{\mathcal{B}(D_{s1}(2460)^+ \rightarrow D_s^+\gamma)} = 0.31 \pm 0.14$ (Abe, 2004a; Krokovny, 2003b), gives a constraint of $\tan(\omega + \omega_0) = 0.8 \pm 0.4$, where ω is the mixing angle, while ω_0 is a rotation angle between the j_q and $^{(2S+1)}P_1$ bases, and $\tan\omega_0 = -\sqrt{2}$. The $^{(2S+1)}P_1$ basis is convenient here, as only the $^1P_1$ state in $D_{s1}(2460)^+$ undergoes an electric dipole transition to the D_s^+, while only the $^3P_1$ one to the D_s^{*+} (Godfrey, 2005b; Yamada, Suzuki, Kazuyama, and Kimura, 2005).

19.3.4.7 New D_{sJ}^+ mesons decaying to $D^{(*)}K$.

The potential models predict higher orbitally-excited $c\bar{s}$ states, as well as a spectrum of states belonging to the next level ($n = 2$) of radial excitations. Within the $c\bar{s}$ spectrum above the $D^{(*)}K$ threshold, the radially-excited states $2\,^3S_1$ and $3\,^2S_1$ (possibly with admixtures of D-waves) are predicted to lie respectively at about 2.73 GeV/c^2 and 3.1 GeV/c^2 (Godfrey and Isgur, 1985). One expects a large total production rate of these $2S$ and $3S$ states in B decays, respectively at a level of about 1% and 0.1% (Close and Swanson, 2005). However, since the potential model
Figure 19.3.29. From (Brodzicka, 2008). Left: Background-subtracted $M(D^0K^+)$ distribution for $B^+ \rightarrow \overline{D}^0 D^0 K^+$ with contribution from $D_{s1}^*(2710)^+$ (blue, cross shaded histogram), reflections from $\psi(3770)$ (green, horizontal shaded) and $\psi(4160)$ (yellow, full light) and non-resonant contributions (brown (dark) and red (vertical shaded) obtained from MC simulations based on the fit results. Right: Background-subtracted and efficiency corrected $D_{s1}^*(2710)^+$ helicity-angle distribution compared to predictions for $J = 0$ (green, dashed), 1 (red, full line) and 2 (blue, large dash).

predictions for the P-wave $c\bar{s}$ states have failed, their evaluations must be revised to provide reliable masses and widths of the higher excitations.

The mentioned excitations could appear as intermediate resonances in $B \rightarrow \overline{D}^{(*)}D^{(*)}K$ decays. Belle, in the study of the decay $B^+ \rightarrow \overline{D}^0 D^0 K^+$, observed a new $c\bar{s}$ resonance, the $D_{s1}^*(2710)^+$, decaying to D^0K^+ (Brodzicka, 2008). The $D_{s1}^*(2710)^+$ peak is clearly visible in Figure 19.3.29, showing the $M(D^0K^+)$ distribution of the B signal candidates, which is obtained from fits to the ΔE-m_{ES} distributions for a given $M(D^0K^+)$ bin. A limited reconstructed B signal yield does not allow for a full Dalitz-plot analysis, instead the $D_{s1}^*(2710)^+$ parameters are measured from the fit to the background-subtracted $M(D^0K^+)$ spectrum, where reflections from charmonia decaying to $\overline{D}^0D^0$, $\psi(3770)$ and $\psi(4160)$, are also taken into account. The charmonium yields are estimated from fits to the $M(\overline{D}^0D^0)$ projection, while their shapes are based on $B^+ \rightarrow \psi K^+$ MC simulations. The $D_{s1}^*(2710)^+$ mass is measured to be $(2708 \pm 9^{+11}_{-10})$ MeV/c^2, its width $(108 \pm 23^{+36}_{-31})$ MeV/c^2. The systematic uncertainties include effects of possible interference between the $D_{s1}^*(2710)^+$ and the $\psi(4160)$. The spin-parity of the $D_{s1}^*(2710)^+$ is established to be 1^- from the helicity-angle distribution presented in Figure 19.3.29.

BABAR explored the DK mass spectrum first using 240 fb^{-1} (Aubert, 2006ag) and then, with 470 fb^{-1}, studied also the D^*K system (Aubert, 2009au). In these analyses first observations of $D_{s1}^*(2710)^+$, $D_{sJ}^*(2860)^+$ and $D_{sJ}(3040)^+$ resonances were reported. The measured $D_{s1}^*(2710)^+$ parameters and properties are in agreement with those obtained for this state in B decays, as reported above. The *BABAR* study is performed inclusively, with the $D^{(*)}K$ systems separated from the $B\overline{B}$ background by means of the CM momentum $p^* > 3.5$ GeV/c. To re-
Figure 19.3.30. From (Aubert, 2009au). Sideband-subtracted DK invariant mass distributions for (a) D^0K^+, (c) $D^+K_S^0$; (b) and (d) show the background-subtracted mass spectra, respectively.

Table 19.3.14. From (Aubert, 2009au). Resonance parameters obtained from the fits to the DK and the D^*K mass spectra. Masses and widths are given in units of MeV/c^2. Uncertainties are statistical only.

System	$D_{s1}^*(2710)^+$	$D_{sJ}^*(2860)^+$	$D_{sJ}(3040)^+$
D K	$m = 2710.0 \pm 3.3$	$m = 2860.0 \pm 2.3$	
	$\Gamma = 178 \pm 19$	$\Gamma = 53 \pm 6$	
D^*K	$m = 2712 \pm 3$	$m = 2865.2 \pm 3.5$	$m = 3042 \pm 9$
	$\Gamma = 103 \pm 8$	$\Gamma = 44 \pm 8.3$	$\Gamma = 214 \pm 34$
Figure 19.3.31. From (Aubert, 2009au). (a) Fit to the D^*K invariant mass spectrum, (b) residuals after subtraction of the fitted background.

move combinations of the K and $D^{(*)}$ mesons originating from opposite-side jets, $\cos\theta_K > -0.8$ is required, with θ_K defined as the angle between the K direction and the direction opposite to the laboratory frame in the $D^{(*)}K$ rest frame.

In a study of the D^0K^+ and $D^+K_S^0$ final states, $D^0 \to K^-\pi^+$ and $D^+ \to K^-\pi^+\pi^+$ are reconstructed. The D^0K^+ and $D^+K_S^0$ mass spectra, with D sidebands subtracted, are shown in Fig. 19.3.30(a,c). A single bin peak at 2.4 GeV/c^2 is a reflection from decays of $D_{s1}(2536)^+$ to D^*K in which the π^0 or γ from the D^* decay is missed; the $D_{s1}(2536)^+$ decay to DK is forbidden. In addition to a prominent $D_{s2}^*(2573)^+$ signal, there are also broad structures associated with the $D_{s1}^*(2710)^+$ and $D_{sJ}^*(2860)^+$ mesons. A simultaneous binned χ^2 fit was performed to the two mass spectra, with the background described by a threshold function and the $D_{s2}^*(2573)^+$, $D_{s1}^*(2710)^+$ and $D_{sJ}^*(2860)^+$ peaks parameterized with relativistic BW lineshapes where spin 2 was assumed for $D_{s2}^*(2573)^+$, 1 for $D_{s1}^*(2710)^+$ and spin 0 for $D_{sJ}^*(2860)^+$. Figures 19.3.30(b,d) show the $M(D^0K^+)$ and $M(D^+K_S^0)$ mass distributions with fitted background subtracted. The fit gives the parameters listed in Table 19.3.14.

In a study of the D^*K system, D^* resonances are reconstructed as $D^{*0} \to D^0\pi^0$, $D^{*+} \to D^+\pi^0$ and $D^{*+} \to D^0\pi^+$, with $D^0 \to K^-\pi^+$, $D^0 \to K^-\pi^+\pi^+\pi^-$ and $D^+ \to K^-\pi^+\pi^+$. The total D^*K mass spectrum, D^* sideband-subtracted and summed over all the channels, is shown in Fig. 19.3.31, where above the $D_{s1}(2536)^+$ signal (not shown because out of scale in the figure), there are structures present around 2.71, 2.86 and 3.04 GeV/c^2. A binned

minimum χ^2 fit is performed to the combined D^*K mass spectrum in the region 2.58-3.48 GeV/c^2, with the background parameterized with an exponential function providing a good description of the MC in the same mass range. The D_{sJ}^+ peaks are described with relativistic BW lineshapes, with $J^P = 1^-$ and $J^P = 3^-$ assumed respectively for $D_{s1}^*(2710)^+$ and $D_{sJ}^*(2860)^+$, and an angular momentum $L = 1$, $L = 3$, and $L = 0$ for $D_{s1}^*(2710)^+$, $D_{sJ}^*(2860)^+$ and $D_{sJ}(3040)^+$, respectively. Since the width values for the resonances are much larger than the mass resolutions, effects of the latter are ignored in the fit. The resonance parameters resulting from the fit are given in Table 19.3.14 and the corresponding fitted curves are shown in Fig. 19.3.31. The width of the $D_{s1}^*(2710)^+$ differs somewhat between the $M(DK)$ and $M(D^*K)$ fits, while the parameter of the $D_{sJ}^*(2860)^+$ are consistent for both decay modes.

The observation of both $D_{s1}^*(2710)^+$ and $D_{sJ}^*(2860)^+$ decays to both DK and D^*K, implies that they have natural parity $J^P = 1^-, 2^+, 3^-, \ldots$ ($J^P = 0^+$ is ruled out because of the D^*K decay). A further test of the quantum numbers was performed through analysis of the helicity angle (θ_h), computed as the angle between the π from the D^* decay and the kaon, in the D^* rest frame. The efficiency-corrected $D_{s1}^*(2710)^+$ and $D_{sJ}^*(2860)^+$ yields are plotted in Fig. 19.3.32, together with the normalized expectations for the natural parity $i.e.$ $1 - \cos^2\theta_h$, which give χ^2/NDF of 18.7/5 and 6.3/5, respectively. The large value for the $D_{s1}^*(2710)^+$ is related to the large uncertainties in the background parameterization.
Figure 19.3.32. From (Aubert, 2009au). Distributions of $\cos\theta_h$ for (a) the $D_{s1}^*(2710)^+$ and (b) the $D_{sJ}^*(2860)^+$. The curves are expectations for the natural parity.

BABAR measures the following branching fraction ratios:

$$\frac{\mathcal{B}(D_{s1}^*(2710)^+ \to D^*K)}{\mathcal{B}(D_{s1}^*(2710)^+ \to DK)} = 0.91 \pm 0.13 \pm 0.12 \quad (19.3.26)$$

$$\frac{\mathcal{B}(D_{sJ}^*(2860)^+ \to D^*K)}{\mathcal{B}(D_{sJ}^*(2860)^+ \to DK)} = 1.10 \pm 0.15 \pm 0.19, \quad (19.3.27)$$

using the selected decay channels: $D^{*0}K^+$ with $D^{*0} \to D^0\pi^0$, $D^0 \to K^-\pi^+$, and $D^{*+}K_S^0$ with $D^{*+} \to D^+\pi^0$, $D^+ \to K^-\pi^+\pi^+$, to reduce systematic uncertainties.

The $D_{s1}^*(2710)^+$ can be either a radial excitation or an $L = 2$ orbital excitation, which are both predicted in this mass region. Observation of the $D_{s1}^*(2710)^+ \to D^*K$ decay with rate comparable to that for the DK, suggests that the $D_{s1}^*(2710)^+$ is a radial excitation of the D_s^* state (Colangelo, De Fazio, Nicotri, and Rizzi, 2008). Interpretations of the $D_{sJ}^*(2860)^+$ and $D_{sJ}(3040)^+$ are still unknown.

19.3.5 Conclusions

Results from the B Factories have given an important input to the experimental status of the charm meson spectroscopy. The observation of the broad states belonging to the $L = 1$ $c\bar{u}$ multiplets has validated outstanding predictions of the potential models. Properties of this multiplet need to be refined with higher statistics, while their production has to be studied in various processes. Finding new decay modes, especially radiative ones, could provide further tests of the theory. On the other hand, the $c\bar{s}$ spectroscopy has revealed some surprises. At the moment, it is still not completely clear if the $D_{s1}(2460)^+$ and $D_{s0}^*(2317)^+$ are fully understood in terms of $Q\bar{q}$ mesons, or if we need to include more complex quark configurations to understand their properties. In the simplest scenario, where the $D_{s1}(2460)^+$ and $D_{s0}^*(2317)^+$ are the conventional $L = 1$ $c\bar{s}$ mesons, the potential models may need some serious modifications.

The large data samples collected by Belle and *BABAR* also allowed for precision measurements of already known

mesons, like the $D_{s1}(2536)^+$. The new excited D_J and D_{sJ} mesons observed open a spectrum of the higher orbital and radial excitations that can be studied. They however need confirmation and more studies to allow their final assignment. The LHCb experiment, dedicated charm factories like BES III, and super flavor factories could shed more light on this sector in the future.

19.4 Charmed baryon spectroscopy and decays

Editors:

Matthew Charles (BABAR)
Ruslan Chistov (Belle)

In this section we discuss the physics of charmed baryons at the B Factories. We begin with the spectroscopy of these states, then turn to the weak decays of their lowest-lying ground states. Finally, we consider the use of these decays to study the properties of light baryons.

The data samples analysed include both baryons produced in the decays of B mesons (see Section 17.12) and from the $e^+e^- \to c\bar{c}$ continuum (see Section 24.1). Both produce large samples of charmed baryons. In practice, most of the inclusive analyses discussed in this section use only the continuum sample, since a cut on the center-of-mass momentum of the charmed baryon, p^*, of around $E_{CM}/4$ is very effective at suppressing combinatoric background, but also removes the entire B sample in the process. However, there is an important exception: exclusive B meson decays provide an initial state with known J^P, which is extremely helpful for measuring the J^P quantum numbers of charmed baryons.

19.4.1 Spectroscopy

19.4.1.1 Introduction

Overview

The spectroscopy of charmed baryons is beautiful and intricate. With three quarks there are numerous degrees of freedom, giving rise to many more states than in the charmed meson sector. At the same time, the large difference in mass between the charm quark and the light quarks provides a natural way to classify and understand these states by making use of the symmetries emerging in Heavy Quark Effective Theory (HQET). The spectrum of known singly-charmed states can be thought of in three broad regimes: the ground states, which are a vindication of the constituent quark model; the low-lying excited states, which are described well by heavy quark symmetries; and higher excited states, where the situation is murkier.

The naming convention for charmed baryons is to take a light baryon, replace one or more s quarks with c quarks, and add a c subscript for every quark replaced. Isospin is unchanged. For example, Λ denotes an sud baryon with isospin zero, and so Λ_c^+ denotes a cud baryon with isospin zero. Likewise, Ξ_c^0 denotes a csd baryon and Ξ_{cc}^+ denotes a ccd baryon. A summary of charmed baryon states is given in Table 19.4.1. Following this convention, the experimentally known $C = 1$ baryon states[147] are summarized in

---

[147] Strongly-decaying states are distinguished by their mass following the PDG convention, *e.g.* $\Xi_c(2645)$. The Ξ_c' and Ω_c^* do not decay strongly and are therefore not labelled by

Fig. 19.4.1. Spin-parity assignments follow the PDG (Beringer et al. (2012)); note that in many cases these are assigned based on quark model expectations rather than measurements.

Table 19.4.1. Baryon flavor states, isospin, and quark content. The symbol q denotes a u or d quark. Baryons with beauty are not included for brevity, but follow a similar pattern.

Symbol	I	Content
N (p,n)	1/2	udq
Δ	3/2	qqq
Λ	0	sud
Σ	1	sqq
Ξ	1/2	ssq
Ω	0	sss
Λ_c	0	cud
Σ_c	1	cqq
Ξ_c	1/2	csq
Ω_c	0	css
Ξ_{cc}	1/2	ccq
Ω_{cc}	0	ccs
Ω_{ccc}	0	ccc

---

their mass, although the latter is sometimes referred to as the $\Omega_c(2770)$ in the literature.

Quark model for ground states

In the constituent quark model (Gell-Mann, 1964; Zweig, 1964a,b), baryons composed of u, d, s, c quarks can be classified into $SU(4)$ multiplets according to the symmetry of their flavor, spin, and spatial wavefunctions. All states in a given $SU(4)$ multiplet have the same angular momentum J, and parity P, but can have different quark flavors. For excited states with multiple units of orbital angular momentum the number of possible multiplets becomes large, but for the ground states the picture is much simpler. This $SU(4)$ symmetry is badly broken due to the large charm mass. and thus different states with the same conserved quantum numbers will mix, and baryons are not pure three-quark objects—but it works remarkably well for the ground states.

Quarks are fermions, so the baryon wavefunction must be overall antisymmetric under quark interchange.[148] Baryons are color singlets, and so have an antisymmetric color wavefunction. In the ground state, the orbital angular momentum L is zero (S-wave) and the spatial wavefunction is symmetric. Therefore, the product of the spin and flavor wavefunctions must also be symmetric for ground-state baryons. There are two ways this can be accomplished: both wavefunctions can be fully symmetric, or both can have mixed symmetry with the product being symmetric.

In concrete terms, we can consider a singly-charmed baryon to consist of a heavy c quark and a light diquark with spin-parity j^p. Assuming isospin symmetry and letting q denote a u or d quark, there are four possibilities for the flavor content of the diquark:

- qq with isospin 0 (flavor antisymmetric);
- qq with isospin 1 (flavor symmetric);
- sq with isospin 1/2 (either);
- ss with isospin 0 (flavor symmetric).

These correspond to the Λ_c, Σ_c, Ξ_c, and Ω_c states, respectively. The diquark wavefunction must be antisymmetric under quark interchange. Its color wavefunction is antisymmetric and in the ground state its spatial wavefunction is symmetric, so it may be either flavor-symmetric and spin-symmetric ($j^p = 1^+$) or flavor-antisymmetric and spin-antisymmetric ($j^p = 0^+$). Combining the diquark with the charm quark gives rise to the possible states set out in Table 19.4.2 and illustrated in Fig. 19.4.2, where the multiplets of the full $SU(3)$ symmetry (formed by the u, d, and s quarks) are shown. Those with $J^P = 1/2^+$ are all members of the same multiplet as the proton, and those with $J^P = 3/2^+$ are all members of the same multiplet as the Δ and Ω (Fig. 19.4.3). Note that there is a second isospin doublet of Ξ_c states with $J^P = 1/2^+$, denoted Ξ'_c.

The constituent quark model predicts relations between the masses of these states as well as their existence and quantum numbers. These were expressed for the light baryons as sum rules (see Gell-Mann (1962); Okubo

Figure 19.4.3. The $SU(4)$ multiplets containing the ground state baryons, arranged by spin-parity (J^P), isospin projection (I_3), strangeness (S), and charm (C). A double ring indicates that two states have the same J^P, I_3, S, and C quantum numbers.

(1962)):

$$(m_N + m_\Xi)/2 = (3m_\Lambda + m_\Sigma)/4, \qquad (19.4.1)$$

$$m_{\Sigma^*} - m_\Delta = m_{\Xi^*} - m_{\Sigma^*} = m_\Omega - m_{\Xi^*}, (19.4.2)$$

$$m_{\Sigma^*} - m_\Sigma = m_{\Xi^*} - m_\Xi, \qquad (19.4.3)$$

of which the first is the famous Gell-Mann-Okubo rule. These can be thought of as expressing the mass as the sum of the valence quark masses plus a hyperfine (spin-spin) coupling. This can be parameterized in various ways,[149] such as (De Rujula, Georgi, and Glashow (1975)):

$$M = A + B' \sum_i \Delta m_i + C' \sum_{i>j} \mathbf{s}_i \cdot \mathbf{s}_j (m_q - \Delta m_i - \Delta m_j),$$

$$(19.4.4)$$

where A, B', and C' are constants, m_q is the mass of a light quark, $\Delta m_i = m_i - m_q$ is the mass difference of the ith quark compared to m_q, and $\mathbf{s}_i$ is the spin of the

---

[148] Strictly, it only needs to be antisymmetric under interchange of equal-mass quarks, but in order to build the model we assume $SU(4)$ is a good symmetry.

[149] See also Gasiorowicz and Rosner (1981) for a nice review with a different hyperfine interaction term.

Table 19.4.2. Summary of the ground state singly-charmed baryons. S denotes a wavefunction that is fully symmetric under interchange of any two quarks; M_S and M_A denote mixed overall symmetry with interchange of the two light quarks being symmetric or antisymmetric, respectively; and A would denote a fully antisymmetric wavefunction.

Baryon	Diquark	Diquark I	Diquark j^p	Baryon flavor symmetry	Baryon spin symmetry	Baryon J^P
Λ_c	qq	0	0^+	M_A	M_A	$1/2^+$
Σ_c	qq	1	1^+	M_S	M_S	$1/2^+$
Σ_c^*	qq	1	1^+	S	S	$3/2^+$
Ξ_c	sq	1/2	0^+	M_A	M_A	$1/2^+$
Ξ_c'	sq	1/2	1^+	M_S	M_S	$1/2^+$
Ξ_c^*	sq	1/2	1^+	S	S	$3/2^+$
Ω_c	ss	0	1^+	M_S	M_S	$1/2^+$
Ω_c^*	ss	0	1^+	S	S	$3/2^+$

i^{th} quark. When evaluated for the ground state baryons, the sum rules given in Eq. 19.4.1–19.4.3 are recovered. This simple model can also be extended to baryons with heavy quarks. To illustrate its effectiveness, we note that the spectrum and decay pattern of singly-charmed baryon ground states was mapped out in an essentially correct way within about three months of the discovery of charm but it took three decades before all of the states were seen experimentally (Beringer et al., 2012). The last to be discovered was the Ω_c^*. The equal-spacing mass rule still holds for the singly-charmed $J = 3/2^+$ multiplet:

$$m_{\Omega_c^*} - m_{\Xi_c^*} = m_{\Xi_c^*} - m_{\Sigma_c^*}, \qquad (19.4.5)$$

but with additional flavors the hyperfine terms become more complicated so the analog of Eq. 19.4.3 is:

$$m_{\Omega_c^*} - m_{\Omega_c} = 2\left(m_{\Xi_c^*} - m_{\Xi_c'}\right) - \left(m_{\Sigma_c^*} - m_{\Sigma_c}\right). \ (19.4.6)$$

Substituting in the current world-average experimental masses for states other than the Ω_c^* (Beringer et al., 2012), one would calculate $m_{\Omega_c^*}$ to be approximately 2774 MeV/c^2 from Eq. 19.4.5 or 2770 MeV/c^2 from Eq. 19.4.6. As we will show in Section 19.4.1.4, these simple estimates are in remarkably good agreement with the observed mass.

Higher states

Baryons can be given orbital (l) or radial (k) excitations. Since in the simplest quark model they are three-body systems there are two degrees of freedom in each case (denoted ρ, λ). For baryons with one heavy quark (mass M) and two light quarks (mass m), a natural way to specify these is to divide the system into a light diquark and the heavy quark. Taking a simple potential model based on the harmonic oscillator, the energy levels are given by (Klempt and Richard (2010)):

$$E = \sqrt{\frac{K}{m}}\left(3 + 2l_\rho + 4k_\rho\right) + \sqrt{\frac{K}{\mu}}\left(3 + 2l_\lambda + 4k_\lambda\right),$$

$$(19.4.7)$$

where $l_{\rho,\lambda} = 0, 1, 2, ...$ and $k_{\rho,\lambda} = 0, 1, 2, ...$, and K is a constant describing the potential and $\mu = (2/3M + 1/3m)^{-1} \approx 3m$ in the heavy quark limit. Thus, the ρ excitations (within the diquark) require roughly three times as much energy as the corresponding λ excitations (between quark and diquark). Therefore the lowest-lying excitations are those with $l_\lambda = 1$ and the other quantum numbers zero, *i.e.* $L = 1$. (Within this band there will be further splitting, *e.g.* due to spin-spin and spin-orbit couplings.) The second band will consist of two groups of states that have comparable energy: those with $l_\lambda = 2$ ($L = 2$) and those with $k_\lambda = 1$ ($L = 0$), with the other quantum numbers being zero. Beyond the second band the degeneracy grows further, but we lack useful experimental data in this region in any case.

We can take this quark-diquark separation one step further for singly-heavy baryons by considering the heavy quark to be essentially a spectator and treating the diquark as a distinct object with its own conserved quantum numbers j^p that is the main actor in decays (in HQET, j^p is the total angular momentum of all light degrees of freedom, see Isgur and Wise (1991)). As a consequence, some transitions that would otherwise be allowed are now forbidden. For example, consider a heavier state with $(J^P, j^p) = (1/2^-, 1^-)$ and a lighter state with $(1/2^+, 0^+)$. If we considered only the overall J^P, an S-wave ($L = 0$) strong decay of the heavier state to the lighter state plus a pion, $(1/2^- \rightarrow 1/2^+ 0^-)$, would be allowed. This channel would dominate and, if well above threshold, would lead to a large width for the resonance. However, conservation of angular momentum forbids the corresponding S-wave diquark transition: $(1^- \rightarrow 0^+ 0^-)$. A D-wave ($L = 2$) transition is allowed, but would be kinematically suppressed. The HQET constraints thus have a concrete effect on the decay pattern of excited states, and imply that some will be narrow.

All this said, it is important to bear in mind that states which share all conserved, external quantum numbers (J, P, I, C, S) can mix. Therefore we should be careful when interpreting observed resonances as specific expected states, particularly for higher excitations.

19.4.1.2 Λ_c, Σ_c families

The known Λ_c and Σ_c states are shown in Fig. 19.4.1. The lowest-lying is the Λ_c^+ ground state, which decays weakly (see next section). The most precise measurement of the Λ_c^+ mass was made by *BABAR* (Aubert, 2005a). Since Λ_c^+ are produced copiously at the B Factories, the key challenge is control of the systematic uncertainties. These arise from effects which could change the momentum scale, principally uncertainties in the magnetic field and energy loss in material. By selecting Λ_c^+ decay modes with low energy release (Q value), a large fraction of the reconstructed Λ_c^+ mass comes directly from the rest masses of the final-state daughters, which are known to high precision, and only a small fraction from the measured 3-momenta. Thus, the effect of the momentum uncertainty on the Λ_c^+ is reduced. Using the modes $\Lambda_c^+ \rightarrow \Lambda K_S^0 K^+$ and $\Lambda_c^+ \rightarrow \Sigma^0 K_S^0 K^+$, the mass is found to be $m(\Lambda_c^+) = (2286.46 \pm 0.14)\,\text{MeV}/c^2$. At the time of writing, this is the most precise measurement of an open charm hadron mass and has significantly lower uncertainty than existing theoretical calculations based upon lattice QCD or advanced potential models.

In order of increasing mass, the next states are the ground states $\Sigma_c(2455)$ and $\Sigma_c(2520)$. In both cases these are isotriplets, and the only kinematically allowed strong decay is $\Sigma_c \rightarrow \Lambda_c^+ \pi$. The $\Sigma_c(2455)$ is one of the few charmed baryons whose angular momentum has been measured. This was accomplished with a sample of fully reconstructed $B^- \rightarrow \Lambda_c^+ \bar{p} \pi^-$ decays proceeding via an intermediate $\Sigma_c(2455)^0$ (Aubert, 2008aa). In this exclusive production environment where the initial state is known to have $J = 0$, the angular distributions for different spin hypotheses are fully determined (see Sections 12.1 and 19.4.3 for more on the helicity formalism). In this case the helicity angle, θ_h, is defined as the angle between the direction of the Λ_c^+ in the Σ_c rest frame and the direction of the Σ_c in the B^- rest frame. *BABAR* found that the $\Sigma_c(2455)^0$ is consistent with $J = 1/2$ and inconsistent with $J = 3/2$ as shown in Fig. 19.4.4, in line with the quark model predictions (Section 19.4.1.1).

The lowest-lying excited states are a pair of Λ_c^+ not far above the $\Lambda_c^+ \pi^+ \pi^-$ threshold, the $\Lambda_c(2595)$ and $\Lambda_c(2625)$. These are interpreted as a doublet with the light diquark in a spin-antisymmetric state and one unit of orbital angular momentum between the diquark and the heavy quark ($L = 1$), so that the total j^p of the light degrees of freedom is 1^-. Adding in the spin-1/2 heavy quark, the total J^P of the baryon is $1/2^-$ for the $\Lambda_c(2595)$ and $3/2^-$ for the $\Lambda_c(2625)$ as shown in the first two rows of Table 19.4.3. The pattern of decays seen by ARGUS (Albrecht et al., 1993b, 1997), E687 (Frabetti et al., 1994a, 1996b), and CLEO (Edwards et al., 1995) leads to the following conclusions:

– The states decay to $\Lambda_c^+ \pi^+ \pi^-$ but not to $\Lambda_c^+ \pi^0$, so they have isospin 0 (Λ_c) and not 1 (Σ_c).
– The $\Lambda_c(2595)$ decays predominantly to $\Sigma_c(2455)^0 \pi^+$, which is a favored S-wave decay: $(1^-, 1/2^-) \rightarrow (1^+, 1/2^+)(0^-)$.
Figure 19.4.4. The helicity angle distribution for $\Sigma_c(2455)^0$ candidates in $B^- \rightarrow \Sigma_c(2455)^0 \bar{p}$ at *BABAR*, corrected for efficiency (Aubert, 2008aa). The distributions expected for the spin-1/2 hypothesis (solid, horizontal line) and spin-3/2 hypothesis (dashed curve) are shown. The data are consistent with $J = 1/2$ and exclude $J = 3/2$ at the 4σ level.

– The $\Lambda_c(2625)$ does not decay to the kinematically-allowed $\Sigma_c(2455)^0 \pi^+$ final state, since this would require a D-wave decay: $(1^-, 3/2^-) \rightarrow (1^+, 3/2^+)(0^-)$. Instead, it decays to the 3-body final state $\Lambda_c^+ \pi^+ \pi^-$ via a P-wave transition: $(1^-, 3/2^-) \rightarrow (0^+, 1/2^+)(0^-)(0^-)$.

Table 19.4.3. Possible low-lying excited states in HQET, classified according to the spin-alignment of the two light quarks, the spin-parity of the light degrees of freedom j^p, and the spin-parity of the baryon J^P.

Diquark spin	j^p	J^P
0	1^-	$1/2^-$
0	1^-	$3/2^-$
1	0^-	$1/2^-$
1	1^-	$1/2^-$
1	1^-	$3/2^-$
1	2^-	$3/2^-$
1	2^-	$5/2^-$

Following Table 19.4.3, we would then expect to see a set of five Λ_c states in which the light diquark is in a spin-symmetric arrangement. In these configurations the unit of orbital angular momentum is between the two light quarks (l_ρ in the notation of Eq. 19.4.7) and so the energy levels will be higher than those of the first two $L = 1$ Λ_c states discussed above. These heavier states are often denoted Λ'_c in the literature. We would also expect to see seven corresponding Σ_c states, with an inverted hierarchy due to the different symmetry of the light flavor wavefunction (*i.e.* five lower Σ_c isotriplets with $j = 1$ followed by

two higher Σ_c' isotriplets with $j = 0$). However, looking at Fig. 19.4.1 we see only a handful of known states at higher masses. By implication, the unobserved states either have too small a production cross-section or are too broad to be visible as distinct structures in the current data. Future flavor factories with larger data samples may be able to shed light on them.

Of the remaining known states, two are close in mass: the $\Lambda_c/\Sigma_c(2765)$, seen by CLEO and Belle in the $\Lambda_c^+\pi^+\pi^-$ final state (Artuso et al., 2001; Mizuk, 2007) and the $\Sigma_c(2800)$ isotriplet, seen in $\Lambda_c^+\pi^{+,0,-}$ by Belle (Mizuk, 2005). The isospin of the former state is not known experimentally: the $\Lambda_c^+\pi^+\pi^-$ final state is accessible to both $I = 0$ and $I = 1$, and no results are available for the related $\Lambda_c^+\pi^{\pm}\pi^0$ final states which would be populated for a Σ_c state but not a Λ_c. The peak is also rather broad and could even be due to multiple overlapping resonances (see Fig. 19.4.5). A Σ_c resonance in this region was also observed by *BABAR* in the analysis of $B^- \to \Lambda_c^+\bar{p}\pi^-$ decays mentioned previously. However, the fitted mass was $(2846\pm8\pm10)$ MeV/c^2, higher than the world-average mass of the $\Sigma_c(2800)^0$, (2802^{+4}_{-7}) MeV/c^2 by about 3σ. If this difference is genuine and the states are distinct, the state seen by *BABAR* would be one of the missing Σ_c states.

Finally, we turn to the last states: the $\Lambda_c(2880)$ and $\Lambda_c(2940)$, which were studied by both *BABAR* and Belle and are shown in Fig. 19.4.5. (Aubert, 2007ai; Mizuk, 2007). CLEO discovered the $\Lambda_c(2880)$ in the $\Lambda_c^+\pi^+\pi^-$ final state (Artuso et al., 2001) but did not establish its quantum numbers. *BABAR* observed both states in the D^0p channel. This is notable as the first observation of the strong decay of a charmed baryon to a charmed meson and a light baryon. It also allowed the isospin to be determined straightforwardly: no corresponding resonances were seen in the isospin partner channel D^+p, thus excluding a Σ_c interpretation.

Belle studied the same two resonances in the $\Lambda_c^+\pi^-\pi^+$ final state. The spin of the $\Lambda_c(2880)$, J, was measured by Belle in another application of the helicity formalism (Section 12.1)—but this time with an inclusive production environment. Because the initial state is not fixed, the elements of the density matrix were not known *a priori*. In the case that all diagonal elements were equal (unbiased production environment), one would get a flat distribution independent of J. However, if they were not equal, the result would be an even polynomial in $\cos\theta_h$ of order $\leq (2J - 1)$, where θ_h is the angle between the direction of the Λ_c^+ in the Σ_c rest frame and the direction of the Σ_c in the $\Lambda_c(2880)^+$ rest frame. Thus, a flat distribution would give no discrimination between spins but a higher-order polynomial would exclude lower spins. Belle found that a polynomial of order at least 4 was required, excluding $J = 1/2$ and $3/2$ but consistent with $J = 5/2$ (or higher). They also showed that the relative branching fractions of $\Lambda_c(2880) \to \Sigma_c(2520)\pi$ and $\Lambda_c(2880) \to \Sigma_c(2455)\pi$ were more consistent with HQET predictions for $J^P = 5/2^+$ than $5/2^-$, favoring even parity. This would make the $\Lambda_c(2880)$ an $L = 2$ state from the second excitation band—though, as noted earlier, an

admixture of states with the same external quantum numbers cannot be excluded (see Cheng and Chua (2007) for one example).

19.4.1.3 Ξ_c family

Since all three quark flavors are different for the Ξ_c, there are many allowed configurations. These may be divided into states for which the light diquark wavefunction is flavor-antisymmetric (analogous to Λ_c) or flavor-symmetric (analogous to Σ_c)—for the ground states, we saw this division between the $j = 0$ Ξ_c and the $j = 1$ Ξ_c' and $\Xi_c^*(2645)$ in Table 19.4.2

The masses of the weakly-decaying Ξ_c^0 and Ξ_c^+ were measured by Belle in several decay modes (Lesiak, 2005), and these results now dominate the current world-average. Several decay modes were considered, and as with the Λ_c^+ mass measurement those with smaller energy release (notably $\Xi_c^0 \to pK^-K^-\pi^+$) generally had smaller systematic uncertainties. Combining the decay modes, the mass values obtained were $m_{\Xi_c^+} = (2468.1 \pm 0.4^{+0.2}_{-1.4})$ MeV/c^2 and $m_{\Xi_c^0} = (2471.0 \pm 0.3^{+0.2}_{-1.4})$ MeV/c^2, where the first uncertainty is due to statistical, fitting, and selection effects and the second is due to mass scale uncertainty (evaluated with kinematically similar control modes and with Monte Carlo simulation). The mass splitting was measured to be $m_{\Xi_c^0} - m_{\Xi_c^+} = (2.9 \pm 0.5)$ MeV/c^2. Belle and *BABAR* also performed mass measurements of several of the higher states in a variety of decay modes, summarized in Table 19.4.4.

The Ξ_c' and $\Xi_c(2645)$ ground states form a doublet analogous to the $\Sigma_c(2455)$ and $\Sigma_c(2520)$ with expected (j^p, J^P) of $(1^+, 1/2^+)$ and $(1^+, 3/2^+)$, respectively. The former is too light to decay strongly, but the electromagnetic transition $\Xi_c' \to \Xi_c\gamma$ is allowed. *BABAR* performed an angular analysis of $\Xi_c'^0 \to \Xi_c^0(\Xi^-\pi^+)\gamma$ in the helicity formalism, similar to the $\Lambda_c(2880)$ discussed above, and found the data to be consistent with $J = 1/2$ (Aubert, 2006ba). However, due to the inclusive production environment higher spins could not be ruled out.

The low-lying excited states $\Xi_c(2790)$ and $\Xi_c(2815)$ are analogous to the $\Lambda_c(2595)$ and $\Lambda_c(2625)$, and their decays follow a corresponding pattern: $\Xi_c(2790) \to \Xi_c'\pi$, $\Xi_c(2815) \to \Xi_c(2645)\pi$. They were therefore identified as the $1/2^-, 3/2^-$ doublet with $j^p = 1^-$ and the diquark in a flavor-antisymmetric configuration (Alexander et al., 1999; Csorna et al., 2001). Following the Λ_c/Σ_c analogy, we would then expect to see five low-lying $L = 1$ states with a flavor-symmetric diquark, followed by a small explosion of $L = 2$ states, radially excited states, and higher $L = 1$ states. We have a number of candidates for these states in Fig. 19.4.1, but less information to classify them this time since we cannot use isospin to distinguish them as we do for Λ_c/Σ_c.

The lightest of these, the $\Xi_c(2930)$, was seen in $B^- \to \Lambda_c^+\Lambda_c^-K^-$ decays (Aubert, 2008e). The Dalitz plot[150] is clearly not flat and the $\Lambda_c^+K^-$ projection is consistent

---

[150] See Section 13 for more on Dalitz plots.
Figure 19.4.5. The $\Lambda_c(2880)^+$ and $\Lambda_c(2940)^+$. The two states are visible in the $D^0 p$ mass spectrum (left, *BABAR*) and the $\Lambda_c^+ \pi^- \pi^+$ mass spectrum (center, Belle). The $\Lambda_c/\Sigma_c(2765)$ enhancement is also seen at the lower edge of the $m(\Lambda_c^+ \pi^- \pi^+)$ spectrum. The helicity angle distribution for $\Lambda_c(2880) \to \Sigma_c(2455)\pi$ (right, Belle) is fitted assuming different spin hypotheses for the $\Lambda_c(2880)$: spin-1/2 (dotted line), spin-3/2 (dashed curve), and spin-5/2 (solid curve). The data are consistent with $J = 5/2$ and exclude $J = 1/2$ and $J = 3/2$ at the 5.5σ and 4.8σ levels, respectively. (Aubert, 2007ai; Mizuk, 2007)

Table 19.4.4. Mass and width measurements for strongly-decaying Ξ_c states performed at the B Factories. An asterisk indicates that the measurement has statistical significance below 5σ, and a double-asterisk that the significance is below 3σ.

State	Decay mode	Mass (MeV/c^2)	Width (MeV)	Source
$\Xi_c(2645)^0$	$\Xi_c^+ \pi^-$	$2465.7 \pm 0.2^{+0.6}_{-0.7}$	neg.	Lesiak (2008)
$\Xi_c(2645)^+$	$\Xi_c^0 \pi^+$	$2465.7 \pm 0.2^{+0.6}_{-0.7}$	neg.	Lesiak (2008)
$\Xi_c(2815)^+$	$\Xi_c(2645)^0 \pi^+$	$2817.0 \pm 1.2^{+0.7}_{-0.8}$	neg.	Lesiak (2008)
$\Xi_c(2815)^0$	$\Xi_c(2645)^+ \pi^-$	$2820.4 \pm 1.4^{+0.9}_{-1.0}$	neg.	Lesiak (2008)
$\Xi_c(2930)^0$	$\Lambda_c^+ K^-$	$2931 \pm 3 \pm 5$	$36 \pm 7 \pm 11$	Aubert (2008e)

$\Xi_c(2980)^+$	$\Lambda_c^+ K^- \pi^+$	$2969.3 \pm 2.2 \pm 1.7$	$27 \pm 8 \pm 2$	Aubert (2008f)
$\Xi_c(2980)^+$	$\Xi_c(2645)^0 \pi^+$	$2967.7 \pm 2.3^{+1.1}_{-1.2}$	$18 \pm 6 \pm 3$	Lesiak (2008)
$\Xi_c(3055)^+$	$\Lambda_c^+ K^- \pi^+$	$3054.2 \pm 1.2 \pm 0.5$	$17 \pm 6 \pm 11$	Aubert (2008f)
$\Xi_c(3077)^0$	$\Lambda_c^+ K_S^0 \pi^-$	$3082.8 \pm 1.8 \pm 1.5$	$5.2 \pm 3.1 \pm 1.8$	Chistov (2006b)*
$\Xi_c(3077)^0$	$\Lambda_c^+ K_S^0 \pi^-$	$3079.3 \pm 1.1 \pm 0.2$	$5.9 \pm 2.3 \pm 1.5$	Aubert (2008f)*
$\Xi_c(3077)^+$	$\Lambda_c^+ K^- \pi^+$	$3076.7 \pm 0.9 \pm 0.5$	$6.2 \pm 1.2 \pm 0.8$	Chistov (2006b)
$\Xi_c(3077)^+$	$\Lambda_c^+ K^- \pi^+$	$3077.0 \pm 0.4 \pm 0.2$	$5.5 \pm 1.3 \pm 0.6$	Aubert (2008f)
$\Xi_c(3123)^+$	$\Lambda_c^+ K^- \pi^+$	$3122.9 \pm 1.3 \pm 0.3$	$4.4 \pm 3.4 \pm 1.7$	Aubert (2008f)*

with a single resonance with the parameters given in Table 19.4.4. However, given the small sample size and the inability to rule out other explanations (such as two overlapping Ξ_c resonances or a complicated interference pattern between Ξ_c and charmonium resonances) this is considered unconfirmed.

The remaining resonances were all seen in the $\Lambda_c^+ \overline{K} \pi^+$ isodoublet of final states (and, in the case of the $\Xi_c(2980)$, in $\Xi_c(2645)\pi$). The $\Xi_c(2980)$ and $\Xi_c(3077)$ were discov-

ered by Belle in $\Lambda_c^+ \overline{K} \pi$ (see Fig. 19.4.6) and confirmed by *BABAR*. Since this is a three-body decay it could proceed via an intermediate Σ_c. *BABAR* tested this by fitting a two-dimensional *p.d.f.* in $m(\Lambda_c^+ \pi), m(\Lambda_c^+ \overline{K} \pi)$. It was found that approximately half of the $\Xi_c(2980)$ decays to this final state proceed through an intermediate $\Sigma_c(2455)$ with the rest non-resonant. By contrast, most if not all of the $\Xi_c(3077)$ decays to this final state proceed via $\Sigma_c(2455)$ or $\Sigma_c(2520)$ with approximately equal branching fractions

to each. Because the $\Xi_c(2980)$ is close to threshold on the scale of its natural width, especially with an intermediate Σ_c, the available phase space changes significantly across the resonance. Different handling of this threshold behavior is the reason for the mild tension in the fitted $\Xi_c(2980)$ masses between (Chistov, 2006b) and (Aubert, 2008f). The masses measured in the $\Xi_c(2645)\pi^+$ final state (Lesiak, 2008), which is far from threshold, are consistent with the *BABAR* treatment, although the widths are smaller than either experiment saw in $\Lambda_c^+\overline{K}\pi$. Requiring an intermediate Σ_c reduces the background levels, and by doing this *BABAR* was able to identify two further candidate states, the $\Xi_c(3055)$ and $\Xi_c(3123)$. The latter had a limited statistical significance (3σ), and needs confirmation.
Figure 19.4.6. The $m(\Lambda_c^+K^-\pi^+)$ invariant mass spectrum at Belle. The $\Xi_c(2980)$ and $\Xi_c(3077)$ resonances are visible. (Chistov, 2006b)

No direct measurements of the J^P of any of the excited Ξ_c states are available. Mild constraints on the quantum numbers can be inferred from the decay pattern. For example, the observation of the $\Xi_c(3077)$ in $\Sigma_c(2455)\overline{K}$ and $\Sigma_c(2455)\overline{K}$ excludes states with diquark $j^p = 0^-$ ($0^- \not\to 1^+0^-$ for any L). However, many quantum numbers are still allowed for these states and there is a range of opinions on the best match to the data—see *e.g.* (Alexander et al., 1999; Cheng and Chua, 2007; Rosner, 2007).

19.4.1.4 Ω_c family

The available experimental data on the Ω_c ground states were limited before the B Factories, in contrast to the Λ_c, Σ_c, and Ξ_c families. The weakly-decaying $J = 1/2^+$ Ω_c^0 had been seen in a number of different decay modes and production environments but with only limited statistics (typically samples of order 10 events in a given decay mode, and never more than 100) and the $J = 3/2^+$ Ω_c^{*0} had not been observed.

Belle carried out a precise measurement of the Ω_c^0 mass using a sample of 725 decays to the $\Omega^-\pi^+$ final state (Solovieva, 2009), obtaining $(2693.6\pm0.3^{+1.8}_{-1.5})\,\mathrm{MeV}/c^2$. This decay channel was chosen because it is the most copious and cleanest; due to the limited production rate, it was

not possible to employ low-rate modes close to threshold as was done for the Λ_c^+ in Section 19.4.1.2. As a result, the uncertainty is dominated by the mass scale uncertainty (evaluated based on the observed variation of the mass as a function of kinematic variables).

The Ω_c^{*0} is too light to undergo strong decay and so decays purely to $\Omega_c^0\gamma$ (see Fig. 19.4.7). It was discovered by *BABAR* and confirmed by Belle (Aubert, 2006ah; Solovieva, 2009). Both measured the mass difference $m(\Omega_c^{*0}) - m(\Omega_c^0)$, and the two results are in excellent agreement. The PDG average for the mass difference is $(70.7^{+0.8}_{-1.0})\,\mathrm{MeV}/c^2$. As we saw in equation 19.4.6, the naïve quark model prediction for this is:

$$m_{\Omega_c^*} - m_{\Omega_c} = 2\left(m_{\Xi_c^*} - m_{\Xi_c'}\right) - \left(m_{\Sigma_c^*} - m_{\Sigma_c}\right),$$
$$(19.4.8)$$

which we evaluate as $(74.0\pm4.3)\,\mathrm{MeV}/c^2$ based on current world-average measurements of Ξ_c and Σ_c mass differences (Beringer et al., 2012). This is in beautiful agreement with the experimental result.
Figure 19.4.7. The $m(\Omega_c^0\gamma)$ invariant mass spectrum at *BABAR*, combining four decay modes of the Ω_c^0: $\Omega^-\pi^+$, $\Omega^-\pi^+\pi^0$, $\Omega^-\pi^+\pi^-\pi^+$, $\Xi^-K^-\pi^+\pi^+$. The Ω_c^* resonance is visible. The shaded histogram represents the combinatoric background estimated from the Ω_c^0 mass sidebands. (Aubert, 2006ah)

No radially or orbitally excited Ω_c have yet been discovered, but we would expect their masses to follow a similar pattern to the Σ_c states discussed previously. However, there are fewer options for their decay: transitions of the form $\Omega_c \to \Omega_c\pi$ are isospin-suppressed (whereas $\Xi_c\overline{K}$ and $\Omega_c\pi\pi$ are allowed). This could result in Ω_c states that are narrow but whose Σ_c analogs are too broad to resolve—this will be an interesting area for future flavor factories to search.

19.4.1.5 Searches for Ξ_{cc}

The quark model also predicts baryons with two charm quarks and one lighter quark, as shown in Fig. 19.4.2. Because two quark flavors are identical, fewer distinct configurations are possible than for the $C = 1$ baryons. We expect three weakly-decaying ground states with $J^P = \frac{1}{2}^+$

$(\Xi_{cc}^+, \Xi_{cc}^{++}, \Omega_{cc}^+)$ and three further states with $J^P = \frac{3}{2}^+$ $(\Xi_{cc}^{*+}, \Xi_{cc}^{*++}, \Omega_{cc}^{*+})$. In the baryon mass parameterization of Eq. 19.4.4, the mass splittings between these states can be related to those of singly-charmed baryons:

$$m_{\Xi_{cc}^*} - m_{\Xi_{cc}} = m_{\Sigma_c^*} - m_{\Sigma_c} \approx 64\,\mathrm{MeV}/c^2 \quad (19.4.9)$$

$$m_{\Omega_{cc}^*} - m_{\Omega_{cc}} = m_{\Omega_c^*} - m_{\Omega_c} \approx 71\,\mathrm{MeV}/c^2 (19.4.10)$$

This is well below threshold for strong decay, so the Ξ_{cc}^* and Ω_{cc}^* states should decay electromagnetically like the Ω_c^*.

More ambitiously, we can attempt to relate the masses of the weakly decaying ground states. Applying Eq. 19.4.4 to the Ξ_{cc}, Σ_c, Λ_c, and nucleon, we can write:

$$m_{\Xi_{cc}} = m_N + 2(m_{\Lambda_c} - m_N) + \frac{1}{2}(m_{\Sigma_c} - m_{\Lambda_c}), \quad (19.4.11)$$

where the terms represent the base nucleon mass, the mass offset for two charm quarks, and a hyperfine correction. Evaluating this we obtain $m_{\Xi_{cc}} \approx 3720\,\mathrm{MeV}/c^2$. However, this estimate should be treated with some skepticism: we have assumed that the coefficients A, B', and C' are the same for all baryons, but in practice these terms have some scale dependence (*e.g.* on the spatial extent of the wavefunction). There are numerous more rigorous theoretical predictions (see, *e.g.*, Roberts and Pervin (2008) and the references therein), including increasingly precise estimates from Lattice QCD (Liu, Lin, Orginos, and Walker-Loud, 2010). Most estimates lie between 3600 and 3700 MeV/c^2.

To date, sightings of Ξ_{cc} states have been reported only at the SELEX experiment, a forward spectrometer in which a hyperon[151] beam (composed of Σ^-, p, and π^-) struck a fixed target of copper or diamond. SELEX claimed observation of Ξ_{cc}^+ at a mass of 3519 MeV/c^2 in the $\Lambda_c^+ K^- \pi^+$ and pD^+K^- final states (Mattson et al., 2002; Ocherashvili et al., 2005). In each case the signature is a small, narrow signal on top of a smaller background: an excess of 15.9 events above an estimated background of 6.1 ± 0.5 for $\Lambda_c^+ K^- \pi^+$, and of 5.4 above 1.6 ± 0.4 for pD^+K^-. The observations were controversial (Kiselev and Likhoded, 2002), primarily because the lifetime and the production rate of Ξ_{cc} at SELEX were far from expectations. The theory expectation for the Ξ_{cc}^+ lifetime is approximately 200–250 fs across a number of models (Chang, Li, Li, and Wang, 2008), compared to a reported upper limit of 33 fs. Even more surprising, by comparing the relative yields of Λ_c^+ and Ξ_{cc}^+ and correcting for acceptance and additional decay modes, SELEX estimated that 20% of its sample of 1,630 Λ_c^+ came from Ξ_{cc}^+ decays (presumably with a further contribution of similar order from Ξ_{cc}^{++}). This runs counter to expectations: it is much more difficult to produce a baryon with more than one unit of flavor because two heavy quark-antiquark pairs need to be created within a narrow enough kinematic window

for them to coalesce into a baryon.[152] SELEX also reported preliminary observations of several other peaks in the $\Lambda_c^+ K^- \pi^+$ and $\Lambda_c^+ K^- \pi^+ \pi^+$ mass spectra, claiming a further Ξ_{cc}^+ state at 3443 MeV/c^2 and Ξ_{cc}^{++} states at 3460, 3540, and 3780 MeV/c^2 (Russ, 2002, 2003), but did not publish these results.

BABAR, Belle, and the FOCUS photoproduction experiment carried out searches for Ξ_{cc} in an attempt to reproduce the published SELEX observation (Aubert, 2006ao; Chistov, 2006b; Ratti, 2003). All three examined $\Lambda_c^+ K^- \pi^+$ along with a variety of other final states. None found any signal. Since the integrated luminosity and the production cross-section vary between experiments, upper limits were quoted in the form of a production rate relative to Λ_c^+. At the B Factories this ratio is defined as

$$R_{\Xi_{cc}^+/\Lambda_c^+} \equiv \frac{\sigma(e^+e^- \to \Xi_{cc}^+ X)\,\mathcal{B}(\Xi_{cc}^+ \to \Lambda_c^+ K^- \pi^+)}{\sigma(e^+e^- \to \Lambda_c^+ X)},$$

$$(19.4.12)$$

where X represents the rest of the event and $\mathcal{B}$ the branching fraction, and the ratio is defined in an analogous way for FOCUS. The limits obtained are shown in Table 19.4.5. In each case, the samples of Λ_c^+ events used were much larger than that of SELEX: yields of 19k for FOCUS, 600k for *BABAR*, and 840k for Belle. However, because the production environments differ from that of SELEX it cannot be excluded that the double-charm baryon cross-section is dramatically higher with a hyperon in the initial state for reasons that are not understood theoretically.

Table 19.4.5. Upper limits on the production ratio $R_{\Xi_{cc}^+/\Lambda_c^+}$ defined in Eq. 19.4.12. SELEX reported a ratio of 9.6%.

Experiment	Limit on $R_{\Xi_{cc}^+/\Lambda_c^+}$	Kinematic cuts
BABAR	6.9×10^{-4} @ 95% C.L.	—
BABAR	2.7×10^{-4} @ 95% C.L.	$p^* > 2.3\,\mathrm{GeV}/c$
Belle	1.5×10^{-4} @ 90% C.L.	$p^* > 2.5\,\mathrm{GeV}/c$
FOCUS	2.3×10^{-3} @ 90% C.L.	—

There is one further twist: several of the excited Ξ_c states discussed in Section 19.4.1.3, notably the $\Xi_c(2980)$ and $\Xi_c(3077)$, were discovered in the $\Lambda_c^+ K^- \pi^+$ final state. None of these states were reported by SELEX (although they were not specifically excluded either). This poses a further challenge: if the production cross-section at SELEX were much larger for these excited Ξ_c states than for Ξ_{cc} they should have been seen clearly, so their non-observation raises questions about the Ξ_{cc} signals; conversely, if the cross-section for the excited Ξ_c is smaller than for Ξ_{cc} the mechanism must be highly exotic since the Ξ_c states are not only lighter than Ξ_{cc} but also closer in flavor content to the initial-state Σ^-.

Ultimately, the nature of the Ξ_{cc} states will become clear only when they are observed with high statistics at a

---

[151] A hyperon is a baryon containing at least one strange quark. The term predates the discovery of charm and is not normally used to refer to baryons with heavy flavor.

[152] For example, the production rates of Λ and Λ_c^+ in e^+e^- annihilation events are typically an order of magnitude larger than that of Ξ^- (Beringer et al., 2012).

flavor factory, either vindicating or excluding the SELEX results.

19.4.1.6 Conclusions

The spectroscopy of the ground state $C = 1$ baryons is now well established, and the lowest-lying Λ_c, Σ_c, and Ξ_c excitations are reasonably well understood. There are still question marks about the nature of higher states which have been observed, and about the many states which are predicted but have not yet been seen. To extend our understanding, we need experimental information from three sources: from inclusive production with higher statistics (*e.g.* to be able to see the next Ω_c states, whose production cross-section at the B Factories is bound to be small), from exclusive production in b-meson decays, and from exclusive production in b-baryon decays. The latter will open up angular analyses for some charmed baryon states that are difficult to produce in quasi-two-body decays of B mesons (see Section 17.12), in much the same way that charmed baryon decays allow light baryons to be studied (see Section 19.4.3). We can look forward to results from these studies, as well as searches for doubly-charmed baryons, at LHCb and at future e^+e^- flavor factories.

19.4.2 Weak decays

19.4.2.1 Introduction

The investigation of charmed baryon weak decays is more difficult then for charmed mesons due to their shorter lifetimes and smaller production rate. The reconstruction efficiency is often lower too, due to the frequent presence of hyperons in the final state which are long-lived and commonly have decay modes with a secondary neutron or π^0. The lightest charmed baryon Λ_c^+ was discovered long before the B Factory era. Subsequently, many weak decay modes, mostly Cabibbo-favored tree diagrams, were observed for the Λ_c^+ and $\Xi_c^{0,+}$ baryons. By contrast, little was known about Cabibbo-suppressed and W-exchange decays[153] measurements with more than a dozen signal events had been made even in the early 2000's. Due to this lack of statistics, it was difficult to make definitive tests between theoretical models that predicted charmed baryon decay rates (Korner, Kramer, and Willrodt, 1979; Korner and Kramer, 1992; Uppal, Verma, and Khanna, 1994). Both current data and theoretical models point to non-factorizable amplitudes (*e.g.* W-exchange diagrams) having a significant impact on individual decay rates as well as the total widths and hierarchy of charmed baryon lifetimes. It is therefore important to gather as many measurements as possible on charmed baryon weak decays.

In this section we discuss the many new results on Λ_c^+, $\Xi_c^{0,+}$, and Ω_c^0 weak decays obtained by Belle and *BABAR*.

---

[153] Fig. 17.4.1(E) illustrates the W-exchange decay of a meson; the baryon diagram is the same apart from a second spectator quark.

These measurements make use of the high statistics and the excellent pion-kaon-proton separation, secondary vertex reconstruction, and photon energy resolution available at the B Factories.

19.4.2.2 Results and discussion

Λ_c^+ decays

Belle and *BABAR* measured several ratios of branching fractions, in many cases Cabibbo-suppressed or W-exchange Λ_c^+ decay modes taken relative to topologically similar unsuppressed modes. The numerical results for the analyses discussed below are given in Table 19.4.6.

With the initial 32.6 fb^{-1} of data, Belle observed two new Cabibbo-suppressed decays of Λ_c^+: $\Lambda_c^+ \to \Lambda K^+$ and $\Lambda_c^+ \to \Sigma^0 K^+$ (Abe, 2002h). The Λ_c^+ signals for these modes are shown in Fig. 19.4.8. *BABAR* subsequently confirmed these observarions with 125 fb^{-1} of data, and set limits on two related four-body modes with the same sample: $\Lambda_c^+ \to \Lambda K^+\pi^+\pi^-$ and $\Lambda_c^+ \to \Sigma^0 K^+\pi^+\pi^-$ (Aubert, 2007ag). Both experiments measured the branching fractions relative to the Cabibbo-favored decay modes $\Lambda_c^+ \to \Lambda\pi^+$ and $\Lambda_c^+ \to \Sigma^0\pi^+$. The results were broadly consistent with predictions based on a flavor symmetry approach (Sharma and Verma, 1997):

$$\frac{\mathcal{B}(\Lambda_c^+ \to \Lambda K^+)}{\mathcal{B}(\Lambda_c^+ \to \Lambda\pi^+)} = [0.025 - 0.177], \quad (19.4.13)$$

$$\frac{\mathcal{B}(\Lambda_c^+ \to \Sigma^0 K^+)}{\mathcal{B}(\Lambda_c^+ \to \Sigma^0\pi^+)} = [0.069 - 0.78] \quad (19.4.14)$$

and on the constituent quark model approach (Uppal, Verma, and Khanna, 1994):

$$\frac{\mathcal{B}(\Lambda_c^+ \to \Lambda K^+)}{\mathcal{B}(\Lambda_c^+ \to \Lambda\pi^+)} = [0.039 - 0.056], \quad (19.4.15)$$

$$\frac{\mathcal{B}(\Lambda_c^+ \to \Sigma^0 K^+)}{\mathcal{B}(\Lambda_c^+ \to \Sigma^0\pi^+)} = [0.08 - 0.145] \quad (19.4.16)$$

although both models overshoot the second ratio.

Belle also made the first observation of the Cabibbo-suppressed mode $\Lambda_c^+ \to \Sigma^+ K^+\pi^-$ (Abe, 2002h), measuring the branching fraction relative to $\Lambda_c^+ \to \Sigma^+\pi^+\pi^-$. The invariant mass distribution of the suppressed mode is shown in Fig. 19.4.9. Belle also investigated another Cabibbo-suppressed final state in the same paper: $\Lambda_c^+ \to pK^+K^-$. This was analysed inclusively and also separated into $p\phi$ and $p(K^+K^-)_{\text{non-}\phi}$. Finally, *BABAR* measured the Cabibbo-favored decays $\Lambda_c^+ \to \Sigma^0\pi^+$, $\Xi^- K^+\pi^+$, and $\Lambda\bar{K}^0 K^+$ relative to $\Lambda_c^+ \to \Lambda\pi^+$ (Aubert, 2007ag).

Belle also investigated Cabibbo-favored, W-exchange Λ_c^+ decays to the final state $\Sigma^+ K^+K^-$ (Abe, 2002h) which had previously been observed by CLEO (Avery et al., 1993). As well as measuring the overall branching fraction, they also extracted the rate of $\Lambda_c^+ \to \Sigma^+\phi$. Further, they observed a significant contribution of $\Lambda_c^+ \to \Xi(1690)^0 K^+$

with $\Xi(1690)^0 \to \Sigma^+ K^-$, and confirmed this with the related decay $\Lambda_c^+ \to \Xi(1690)^0 K^+$, $\Xi(1690)^0 \to \Lambda K_S^0$. These demonstrate that W-exchange decays of charmed baryons occur at a non-negligible rate.
Figure 19.4.8. The invariant mass distribution of the selected ΛK^+ (upper) and $\Sigma^0 K^+$ (lower) combinations at Belle. The bumps to the right of the Λ_c^+ signal are due to the reflections from $\Lambda_c^+ \to \Lambda \pi^+$ and $\Lambda_c^+ \to \Sigma^0 \pi^+$, where π^+ is missidentified as K^+. (Abe, 2002h)
Figure 19.4.9. The invariant mass distribution of selected $\Sigma^+ K^+ \pi^-$ combinations at Belle, showing the Λ_c^+ signal. The shaded histogram presents the contribution from the Σ^+ sidebands. (Abe, 2002h)

Ξ_c^0 and Ξ_c^+ decays

In the charm strange baryon sector, Belle measured ratios of branching fractions for a suite of final states: $\Xi_c^+ \to \Xi^- \pi^+ \pi^+$, $\Lambda K^- \pi^+ \pi^+$, and $pK_S^0 K_S^0$; $\Xi_c^0 \to \Xi^- \pi^+$, $\Lambda K^- \pi^+$, ΛK_S^0, and $pK^- K^- \pi^+$ (Lesiak, 2005). The numerical results are given in Table 19.4.7. For the four-body decay $\Xi_c^0 \to pK^- K^- \pi^+$, Belle found that the 3-body resonant mode $\Xi_c^0 \to pK^- \bar{K}^*(892)^0$ was responsible for fully $0.51 \pm 0.03 \pm 0.01$ of the yield.
Figure 19.4.10. Invariant mass distribution for the Ξ_c^0 candidates reconstructed in the $\Xi^- \pi^+$ (upper) and $\Omega^- K^+$ (lower) decay modes at BABAR. (Aubert, 2005z)

BABAR studied the two decay modes $\Xi_c^0 \to \Omega^- K^+$ and $\Xi_c^0 \to \Xi^- \pi^+$. Both are Cabibbo-favored, but the former proceeds through a W-exchange diagram and the latter through a tree diagram. Fig. 19.4.10 shows the invariant mass distribution for Ξ_c^0 candidates in these two modes. The ratio $\mathcal{B}(\Xi_c^0 \to \Omega^- K^+)/\mathcal{B}(\Xi_c^0 \to \Xi^- \pi^+)$ was measured to be $0.294 \pm 0.018 \pm 0.016$ (Aubert, 2005z), and is consistent with a quark model prediction of 0.32 (Korner and Kramer, 1992). Note that this ratio is large, especially when considering that the difference in phase space favors $\Xi_c^0 \to \Xi^- \pi^+$ by a factor of 1.7, showing again that contributions from W-exchange processes cannot be neglected.

Using these modes BABAR measured the Ξ_c^0 production momentum spectrum in two data samples, one at the $\Upsilon(4S)$ resonance and one 40 MeV below. From these spectra the production rate of Ξ_c^0 baryon from B decays was measured to be $\mathcal{B}(B \to \Xi_c^0 X) \times \mathcal{B}(\Xi_c^0 \to \Xi^- \pi^+) = (2.11 \pm 0.19 \pm 0.25) \times 10^{-4}$ (see Section 17.12) and the production cross-section from the continuum was measured to be $\sigma(e^+ e^- \to \Xi_c^0 X) \times \mathcal{B}(\Xi_c^0 \to \Xi^- \pi^+) = (388 \pm 39 \pm 41)$ fb at $\sqrt{s} = 10.58$ GeV (see Section 24.1.2.2). One practical

consequence is that the production rates of Ξ_c from B decays and from the $c\bar{c}$ continuuum are comparable, opening up the possibility of studying these states in B decays.

Ω_c^0 decays
Figure 19.4.11. The invariant mass distributions of Ω_c^0 candidates with 4 different decay modes at BABAR. (Aubert, 2007ao)

A thorough experimental study of the Ω_c, the heaviest weakly-decaying $C = 1, B = 0$ hadron, was long overdue. Because of its heavy mass and triple flavor content, the production rate of Ω_c^0 is low in comparison with other ground state charmed baryons.

BABAR studied four Cabibbo-favored decay modes with 230.5 fb^{-1} of data: $\Omega_c^0 \to \Omega^-\pi^+$, $\Omega^-\pi^+\pi^0$, $\Omega^-\pi^+\pi^+\pi^-$, and $\Xi^-K^-\pi^+\pi^+$ (Aubert, 2007ao). Fig. 19.4.11 shows the Ω_c^0 invariant mass distributions. The number of reconstructed events and the branching fractions relative to $\Omega^-\pi^+$ mode are presented in Table 19.4.7. These measurements represent a significant improvement upon the previous values. The $\Omega_c^0 \to \Omega^-\pi^+$ mode was also used by

BABAR to study the Ω_c^0 momentum spectrum. The pattern was similar to that seen for Ξ_c^0: comparable production rates of Ω_c^0 baryons in the continuum and in the B meson decays (see Fig. 19.4.12), although with overall yields a factor of ~ 40 smaller. At the time of writing, this remains the only observation of Ω_c^0 in B decays.
Figure 19.4.12. The background-subtracted and efficiency-corrected Ω_c^0 yield in $p^*(\Omega_c^0)$ bins at BABAR. The histogram shows continuum contribution from Monte Carlo modelling. The double-peak structure in this spectrum signalizing about two production mechanisms. Lower p^* peak is due to Ω_c^0 production in B decays. Higher-p^* peak is due to Ω_c^0 production in $c\bar{c}$ continuum. (Aubert, 2007ao)

19.4.2.3 Comments on absolute branching fractions

In the preceeding discussion, branching fractions of charmed baryon weak decays were quoted relative to reference modes. However, at present, there is limited experimental information on the absolute branching fractions of those reference modes for Λ_c^+ and none at all for Ξ_c^0, Ξ_c^+, and Ω_c^0. Determining these branching fractions is highly important. At present, this limits many measurements involving charmed baryons, such as production cross-sections and branching fractions of B decays.

The situation for Λ_c^+ is covered in the PDG review (Beringer et al., 2012), which obtains $\mathcal{B}(\Lambda_c^+ \to pK^-\pi^+) = (5.0 \pm 1.3)\%$. This was last updated in 2002 and there has been little progress since. The techniques outlined in the review are limited by systematic or theory uncertainties rather than statistical ones, as are many proposed methods. However, this is not universally true, and we discuss a few possibilities below.

The most direct method would be to operate an e^+e^- collider at the $\Lambda_c^+\bar{\Lambda}_c^-$ threshold. In this environment, observing a Λ_c^+ necessarily implies the existence of a recoiling $\bar{\Lambda}_c^-$ with fully determined kinematics, so the branching fraction can simply be taken as the fraction of cases in which this decays to a particular final state.

Table 19.4.6. Summary of Belle and *BABAR* results on Λ_c^+ Cabibbo-favored (CF), Cabibbo-suppressed (CS) and *W*-exchange (WE) decays.

Λ_c^+ mode	Experiment	Yield	Λ_c^+ reference mode	$\mathcal{B}_{signal}/\mathcal{B}_{ref.}$

$\Omega_c^0 \to \Xi^- K^-\pi^+\pi^-$	*BABAR*	45 ± 12	$\Omega_c^0 \to \Omega^-\pi^+$	$0.46 \pm 0.13 \pm 0.03$

A related method, applicable at *B* Factories operating at the $\Upsilon(4S)$, is to identify events with baryon and charm content and then look for a recoiling $\overline{\Lambda}_c^-$. This approach was used by CLEO, requiring both a D and a p in the event and inferring that a $\overline{\Lambda}_c^-$ is present (Jaffe et al., 2000). However, this comes with two disadvantages: the kinematics of the $\overline{\Lambda}_c^-$ are not known, and there is a problematic background from other event types with the same signature (*e.g.* $e^+e^- \to Dp\overline{DN}X, \, Dp\overline{\Xi}_c\bar{K}X$).[154] Alternatively, it is possible to use $e^+e^- \to \Lambda_c^+\overline{\Lambda}_c^- X$ events in which the Λ_c^+ and the X system are fully reconstructed— the "popcorn" sample identified by *BABAR* in which X consists of a small number of pions and has zero baryon and strangeness content is promising (Aubert, 2010b).

19.4.2.4 Conclusions

The experimental and theoretical investigation of charmed baryon weak decays remains one step behind that of charmed mesons, where both experimental data and theoretical models are more abundant. Nonetheless, the results on charmed baryon weak decays obtained by *BABAR* and Belle could stimulate the development of theoretical models describing charmed baryon weak decays. They could also provide a roadmap for further studies of the charmed baryon sector at future super flavor factories.

---

[154] While we were finalising this book Belle submitted an absolute branching fraction analysis for publication, using a further development of this approach: reconstruction of $D^{(*)-}\bar{p}\pi^+$ events, identification of inclusive Λ_c^+ decays using the missing mass spectrum (the mass of the system recoiling against $D^{(*)-}\bar{p}\pi^+$), and reconstruction of the subset decaying to $pK^-\pi^+$ (Zupanc, 2013a). The result, $\mathcal{B}(\Lambda_c^+ \to pK^-\pi^+) = (6.84 \pm 0.24^{+0.21}_{-0.27})\%$, represents a significant advance on the

precision of this quantity. At the time of writing, this analysis has not yet been published.

Table 19.4.8. Angular distributions for the decay chain $X_c \to RP$, $R \to HP$ for different spin hypotheses J_R. It is assumed that X_c and H have spin 1/2, that P has spin 0^-, and that there is no polarization in the initial state. (Aubert, 2006z)

J_R	$dN/d\cos\theta_h \propto$
1/2	$1 + \beta\cos\theta_h$
3/2	$1 + 3\cos^2\theta_h + \beta\cos\theta_h(5 - 9\cos^2\theta_h)$
5/2	$1 - 2\cos^2\theta_h + 5\cos^4\theta_h + \beta\cos\theta_h(5 - 26\cos^2\theta_h + 25\cos^4\theta_h)$

19.4.3 Applications to light baryon spectroscopy

19.4.3.1 Introduction

A fully exclusive production environment is very helpful for determining the spin or parity of a resonance. We saw this used in Section 19.4.1.2 to measure the spin of the $\Sigma_c(2455)$ in quasi-two-body B decays, for example. In the same way, charmed baryons may be used as a laboratory to study light baryons that are produced as intermediate resonances in their decays. The helicity formalism, discussed in Section 12.1, is used here; for more detail the reader is referred to Jacob and Wick (1959), Chung (1971), Richman (1984), and Ziegler (2007).

In the cases considered below, the decay chain is of the form $X_c \to RP$, $R \to HP$, where X_c is a weakly decaying charmed baryon with $J^P = 1/2^+$, R is the intermediate resonance to be studied, H is a hyperon with $J^P = 1/2^+$, and P are pseudoscalars.[155] The decay helicity angle θ_h is defined as the angle between the direction of H in the rest frame of R and the direction of R in the rest frame of X_c, as illustrated in Fig. 19.4.13. The angular distributions expected under spin hypotheses $J_R = 1/2, 3/2, 5/2$ are given in Table 19.4.8. Parity violation is allowed in weak decays and introduces an asymmetry in the distributions, expressed by the parameter β:

$$\beta = \left[\frac{\rho_{\frac{1}{2},\frac{1}{2}} - \rho_{-\frac{1}{2},-\frac{1}{2}}}{\rho_{\frac{1}{2},\frac{1}{2}} + \rho_{-\frac{1}{2},-\frac{1}{2}}}\right] \left[\frac{|A_{\frac{1}{2}}^J|^2 - |A_{-\frac{1}{2}}^J|^2}{|A_{\frac{1}{2}}^J|^2 + |A_{-\frac{1}{2}}^J|^2}\right], \quad (19.4.17)$$

where the transition matrix element $A_{\lambda_f}^J$ represents the coupling of R to the final state with net helicity λ_f, and $\rho_{i,i}$ are the diagonal density matrix elements inherited from the charmed baryon. If $R \to HP$ is a strong decay then $|A_{\frac{1}{2}}^J| = |A_{-\frac{1}{2}}^J|$ and so β vanishes.

In addition to the technique outlined above for measuring the spin of a resonance, charmed baryon decays can be used more generally to measure properties such as the mass and width of intermediate resonances in multi-body decays.

19.4.3.2 Spin of the Ω^-

The method introduced in Section 19.4.3.1 was used by *BABAR* in an elegant way to measure the spin of the Ω^-

---

[155] Strictly speaking, the spin-parity of the charmed baryons themselves has not been measured—and indeed, some of the papers cited in this section allow for spins other than 1/2. But we do not consider that possibility here.
a) All decay products in the Ξ_c^0 rest-frame.
b) All decay products in the Ω^- rest-frame; in this frame, $\vec{\Omega}_1^- \to \vec{\Omega}_2^- = \vec{0}$, $\vec{\Lambda}_1 \to \vec{\Lambda}_2$, $\vec{K}_1^- \to \vec{K}_2^-$.

Figure 19.4.13. Illustration of the helicity angle θ_h for the case of $\Xi_c^0 \to \Omega^- K^+$, $\Omega^- \to \Lambda K^-$. θ_h is defined as the angle between the Λ direction in the Ω^- rest frame and the Ω^- in the Ξ_c^0 rest frame. (Aubert, 2006z)

(Aubert, 2006z). $J_\Omega = 3/2$ is a key prediction of the quark model and was assumed to be correct, but had proved difficult to test definitively. A sample of approximately 770 decays of the form $\Xi_c^0 \to \Omega^- K^+$, $\Omega^- \to \Lambda K^-$ was selected. The mass distribution of these events is shown in Fig. 19.4.14(a), and the helicity angle distribution of these events after background subtraction and efficiency correction is shown in Fig. 19.4.14(b) and (c). The data are fully consistent with the $J_\Omega = 3/2$ hypothesis, and are highly inconsistent with the $J_\Omega = 1/2$ and 5/2 hypotheses. Higher spins would correspond to an even higher-order polynomial, which would not match the data. *BABAR* therefore concluded that $J_\Omega = 3/2$, as predicted.

As part of the analysis, *BABAR* tested for polarization of the Ξ_c^0 in the lab frame. Polarization would not directly affect the angular distribution, since the angle θ_h is Lorentz-invariant—but a large polarization could affect the weighted efficiency as a function of $\cos\theta_h$ (in particular because the *BABAR* detector is forward-backward asymmetric in the collision center-of-mass frame). In practice, no measureable polarization was found and this simplified
Figure 19.4.14. $\Xi_c^0 \to \Omega^- K^+$, $\Omega^- \to \Lambda K^-$ events at *BABAR*, showing the invariant mass distribution in (a) and the background-subtracted, efficiency-corrected angular distribution in (b) and (c). The curves in (b) show the distribution expected for $J_\Omega = 3/2$, with the asymmetry parameter β fixed to zero (solid line, p-value 0.69) or floated (dashed line, p-value 0.64). The curves in (c) show other spin hypotheses: $J_\Omega = 1/2$ (solid line, p-value 1×10^{-17}), $J_\Omega = 5/2$ (dashed curve, p-value 3×10^{-7}). (Aubert, 2006z)

the analysis considerably. However, similar measurements at colliders such as the Tevatron and LHC would need to take polarization into account.

19.4.3.3 Properties of $\Xi(1530)$ and $\Xi(1690)$

BABAR also applied the method to study the $\Xi(1530)$ resonance, which is predicted by the quark model to have $J^P = 3/2^+$, in the decay $\Lambda_c^+ \to \Xi^- \pi^+ K^+$ (Aubert, 2008w). In the limit that the decay is pure quasi-two-body, the formalism described above applies—and superficially it is indeed quasi-two-body, as shown in Fig. 19.4.15(a) where the $\Xi(1530)^0$ is the only visible resonance. However, while the angular distribution is roughly quadratic and is clearly inconsistent with spin-1/2 or spin-5/2, it is not fully described by the spin-3/2 hypothesis either, as shown in Fig. 19.4.15(b). This implies interference with another resonance, which the paper speculates may be a high-mass Λ or Σ^0 in the $\Xi^- K^+$ channel. The spin-3/2 hypothesis is corroborated with studies of the moments of the $m(\Xi^- \pi^+)$ distribution (weighting candidates by the nth-order Legendre polynomial in $\cos\theta_h$).

A similar study of the $\Xi(1690)$ resonance was made in $\Lambda_c^+ \to \Lambda \overline{K}^0 K^+$ (Aubert, 2006y). As with the $\Xi(1530)$ analysis, interference from other resonances in the Dalitz plot was found to be significant and diluted the power of the angular analysis. Correcting for these effects, it was found that $J = 1/2$ was favored (p-value 0.30), but that higher spins could not be excluded (p-value 0.02 for 3/2, 0.01 for 5/2).

19.4.3.4 Conclusions

As illustrated in the previous sections, charmed baryons can be used as a clean, exclusive production environment to study the properties of light baryons. This allows angular analyses which would be nigh impossible in inclusive production. When applied to strongly decaying resonances in multi-body charmed baryon decays, however, interference effects cannot be neglected even for narrow states.
Figure 19.4.15. $\Lambda_c^+ \to \Xi^- \pi^+ K^+$ events at *BABAR*, showing (a) the Dalitz plot, and (b) the angular distribution in the $\Xi(1530)$ region. Curves are superimposed for the $\Xi(1530)$ spin hypotheses $J = 3/2$ (solid, p-value 3×10^{-4}) and $J = 5/2$ (dashed, p-value 6×10^{-44}). The hypothesis $J = 1/2$ would correspond to a flat distribution. Color online. (Aubert, 2008w)

Chapter 20
Tau physics

Swagato Banerjee, Kiyoshi Hayasaka, George Lafferty, Alberto Lusiani, Boris Shwartz

The e^+e^- B Factories, owing to the large cross section for producing tau lepton pairs, are also de facto "tau factories". The contributions to our understanding of a variety of sectors of the Standard Model and Beyond-the-Standard Model theories from studies of the tau lepton at Belle and *BABAR* are presented here. Following an introductory section that reviews the history of the tau lepton and some basics of its production and decay, this chapter proceeds with discussions of the status of tests of *CPT* and charged current lepton universality involving the tau in Section 20.2 and Section 20.3. We then discuss searches for new physics via lepton flavor violating processes in Section 20.4 and *CP* violation in tau production and decay in Section 20.5. Section 20.6 presents studies of hadronic decays of the tau. That section begins with a theoretical introduction before proceeding with presentations of measurements of branching fractions, measurements of hadronic mass spectra and spectral functions, and searches for second-class currents. These results are then interpreted in terms of tests of the Conserved Vector Current(CVC) hypothesis and used to extract the hadron vacuum polarization contribution to muonic $g-2$ in Section 20.7. Section 20.8 summarises values of $|V_{us}|$ extracted from strange decays of the tau. We close with a brief summary.[156]

20.1 Introduction

In this section, we give a brief history of the tau from its discovery to the status before B Factory experiments. We also discuss the cross section of the tau-pair production in the e^+e^- collisions, $e^+e^- \to \tau^+\tau^-$ as well as the commonly used techniques to select tau-pair events.

The tau lepton discovery was reported in 1974 by Martin Perl et al. (1975) using the SPEAR electron-positron collider at SLAC scanning over center-of-mass (CM) energies of 3 GeV to 7.8 GeV. The group initially observed 86 $e^+e^- \to e^\pm \mu^\mp$ + missing energy events above 3.8 GeV in CM with an expected background of 22 events from known non-tau sources using the "SLAC-LBL magnetic detector" (later called Mark I), which had a full 2π azimuthal angle and $50° \le \theta \le 130°$ polar angle acceptance. It consisted of barrels of "trigger counters" at two radii,

cylindrical wire chambers inside a 0.4 T solenoidal magnetic field, lead-scintillator shower counters outside the 3 m×3 m long magnet coil and muon wire chambers surrounding the iron return-yoke of the magnet. The group collected more data and the following year published the cross section and lepton spectra from 105 signal events (above 34 background events) with which they demonstrated that the events were most economically described by $e^+e^- \to U^+U^-$ where $U^\pm$ is a heavy lepton with a mass between 1.6 GeV/c^2 and 1.8 GeV/c^2 decaying via $U^- \to \nu_U \ell^- \overline{\nu}_\ell$ (Perl et al., 1976). Under that hypothesis they also reported a value of the leptonic branching fraction, which was in excellent agreement with Paul Tsai's calculations for a third generation heavy lepton published a few years earlier in the classic and first comprehensive paper on tau physics (Tsai, 1971). Confirmation of the discovery came over the next two years. The Maryland-Princeton-Pavia magnetic detector group operating a single arm spectrometer at SPEAR reported an anomalous muon event rate (Cavalli-Sforza et al., 1976). (Snow, 1976) analysed the charged multiplicity of their "anomalous" events and concluded that a new heavy lepton was the simplest explanation. In 1977 the PLUTO (Burmester et al., 1977a,b) and DASP (Brandelik et al., 1977) groups reported confirmations of the discovery with their experiments operating at DESY's DORIS electron-positron collider in Hamburg. By early 1977 the new particle was being considered a sequential lepton and was first named the τ: "Since there is now substantial evidence that it is a lepton, we wish to designate it by a lower case Greek letter. We use $\tau^\pm$ because it appears to be the third charged lepton to be found and τριτος means third in Greek." (Perl, 1977). Martin Perl was awarded the 1995 Nobel Prize in physics for this discovery.

Since its discovery, properties of the tau have primarily been determined with precision using the $e^+e^- \to \tau^+\tau^-$ process as a source of tau leptons. The cross section for this process at $\sqrt{s} = 10.58$ GeV is 0.919±0.003 nb (Banerjee, Pietrzyk, Roney, and Wąs, 2008).

The text book (Stahl, 2000) is useful to learn more about the history of tau lepton physics.

20.2 Mass of the tau lepton

Masses of quarks and leptons are fundamental parameters of the Standard Model. They cannot be determined by the theory and must be measured. High precision measurements of the mass of the tau lepton are important for testing lepton universality and for calculating branching fractions that depend on the tau mass. Uncertainties in the tau mass have important consequences on the accuracy of the calculated leptonic-decay rate of the tau lepton, since it is proportional to m_τ^5:

$$\Gamma(\tau^- \to \ell^- \nu_\tau \overline{\nu}_\ell) = \frac{G_\mu^2 m_\tau^5}{192\pi^3} f\left(\frac{m_\ell^2}{m_\tau^2}\right)\left(1 + \frac{3}{5}\frac{m_\tau^2}{m_W^2}\right)$$
$$\left(1 + \frac{\alpha(m_\tau)}{2\pi}\left[\frac{25}{4} - \pi^2\right]\right), \tag{20.2.1}$$

---

[156] Through out this section, charge-conjugate τ decays are implied if it is not specified explicitly.

$$f(x) = 1 - 8x + 8x^3 - x^4 - 12x^2 \ln x, \qquad (20.2.2)$$

where $\ell = e, \mu$ and $\alpha^{-1}(m_\tau) = 133.3$. G_μ is the Fermi coupling constant determined precisely from the muon lifetime (Marciano and Sirlin, 1988).

In addition to the fundamental importance of the tau lepton mass in the Standard Model, separate measurements of the masses of the τ^+ and τ^- in B Factory experiments allow us to test the CPT theorem. CPT invariance is a fundamental symmetry of any local field theory, including the Standard Model. Any evidence of CPT violation would be evidence of local Lorentz violation and a sign of physics beyond the Standard Model.

At present the precision of the tau mass is dominated by the KEDR (Shamov et al., 2009) and BES (Bai et al., 1996a) measurements where the mass value was derived from the energy dependence of the $e^+e^- \rightarrow \tau^+\tau^-$ cross section near production threshold. However, both B Factories performed the tau mass determination using a different technique, the so called pseudomass method originally introduced by the ARGUS collaboration (Albrecht et al., 1992a).

In this technique, the pseudomass is defined in terms of the mass, energy and momenta of the tau decay products. For the hadronic decays of the τ^- ($\tau^- \rightarrow h^-\nu_\tau$ and its charge conjugate), the tau mass, m_τ, is given by

$$m_\tau = \sqrt{M_h^2 + 2(E_\tau^* - E_h^*)(E_h^* - P_h^* \cos\theta^*)}, (20.2.3)$$

where M_h, E_h^*, P_h^* are the invariant mass, energy and the magnitude of the three-momentum of the hadronic system h in the e^+e^- CM frame, respectively. The energy of the tau lepton is given by $E_\tau^* = \sqrt{s}/2$, where $\sqrt{s} = 10.58$ GeV. θ^* is the angle between the hadronic system and the ν_τ direction. Since the neutrino is undetected, one can not measure the angle θ^*; thus one defines the pseudomass $M_{\min}$ by setting $\theta^* = 0$:

$$M_{\min} = \sqrt{M_h^2 + 2(E_{\text{beam}} - E_h^*)(E_h^* - P_h^*)}, (20.2.4)$$

which is less than or equal to the tau lepton mass.

Figure 20.2.1 shows the typical pseudomass distribution of the combined τ^+ and τ^- samples for $\tau^\pm \rightarrow \pi^\pm\pi^+\pi^- \nu_\tau$ candidates. A sharp kinematic cutoff is seen at $M_{\min} \sim m_\tau$. The smearing of the endpoint is caused by the initial and final state radiation and the detector resolution.

To determine the endpoint from the pseudomass distribution, a fit was performed to the data with an empirical function of the form

$$F(x) = (p_3 + p_4 x) \tan^{-1}\left(\frac{p_1 - x}{p_2}\right) + p_5 + p_6 x, \qquad (20.2.5)$$

where x is the pseudomass, and the p_i are free parameters of the fit. Only the position of the endpoint, p_1, is important in determining the tau mass. The relation between the estimator p_1 and the true tau lepton mass is obtained by using several Monte Carlo (MC) samples with different
Figure 20.2.1. Pseudomass $M_{\min}$ distribution for $\tau^\pm \rightarrow \pi^\pm\pi^+\pi^- \nu_\tau$ candidates measured by the Belle, shown separately for positively and negatively charged tau decays. The solid points with error bars correspond to τ^+ decays, while the open points with error bars are τ^- decays. The solid curve is the result of the fit to the τ^+ pseudomass distribution (Abe, 2007c).

values of tau mass. In the absence of initial and final state radiation (ISR/FSR) and with perfect detector resolution one expects the relation between the p_1 fit result and the generated tau mass to be linear with a slope of unity and zero offset. With the inclusion of ISR/FSR effects and detector resolution non-zero offset is expected.

The current status of the tau mass measurements is summarized in Table 20.2.1 (see also Figure 20.2.2). In this table, we also include the results from the measurements by the BES and KEDR experiments, where the tau mass is measured from the $\tau^+\tau^-$ cross section around the production threshold. The systematics in the pseudomass technique and the threshold scan are quite different. Nevertheless, the results from the two methods are in good agreement with similar size of errors. The world average of the tau lepton mass is (Asner et al., 2010)

$$m_\tau = (1776.77 \pm 0.15)\,\text{MeV}. \qquad (20.2.6)$$

Table 20.2.1. Summary of recent tau mass measurements.

Experiment	m_τ, MeV	Ref.
BES	$1776.96^{+0.18+0.25}_{-0.21-0.17}$	Bai et al. (1996a)
KEDR	$1776.69^{+0.17}_{-0.19} \pm 0.15$	Shamov et al. (2009)
Belle	$1776.61 \pm 0.13 \pm 0.35$	Abe (2007c)
BABAR	$1776.68 \pm 0.12 \pm 0.41$	Aubert (2009ac)
Average	1776.77 ± 0.15	Asner et al. (2010)
Figure 20.2.2. Measurements and average value of m_τ (Asner et al., 2010).

The mass difference between τ^+ and τ^-, $\triangle m = m_{\tau^+} - m_{\tau^-}$, can be measured precisely since many sources of systematic error are common for τ^+ and τ^- and cancel out in $\triangle m$. The values of $\triangle m$ measured by Belle and *BABAR* collaborations are

$$\triangle m = (\ \ 0.05 \pm 0.23(\text{stat}) \pm 0.14(\text{syst}))\ \text{MeV (Belle)},$$
$$\triangle m = (-0.61 \pm 0.23(\text{stat}) \pm 0.06(\text{syst}))\ \text{MeV } (BABAR).$$
$$(20.2.7)$$

The values of $\triangle m$ obtained for both experiments are consistent with zero within the errors, where the precisions are dominated by statistical uncertainty. The systematic shift in the mass difference has been estimated from the mass differences for charged D and D_s mesons. The *BABAR* result shows some deviation, however this is interpreted as having a 1.2% chance of obtaining a result as different from zero as this under the condition of no *CPT* violation, which has been ascertained using MC simulation.

Combining both Belle and *BABAR* results, we obtain a mass difference of

$$\triangle m = (-0.24 \pm 0.18)\ \text{MeV}, \qquad (20.2.8)$$

where the error is obtained by adding statistical and systematic errors from both experiments in quadrature. The mean value is the weighted average of the two experiments. From these results, we obtain an upper limit on the mass difference,

$$|m_{\tau^+} - m_{\tau^-}|/m_{\text{AVG}}^\tau < 3.0 \times 10^{-4}, \qquad (20.2.9)$$

at 90% C.L. Where m_{AVG}^τ is the averaged mass of m_{τ^+} and m_{τ^-}. The results improve upon the previous OPAL constraint (Abbiendi et al., 2000a) by one order of magnitude (see Table 20.2.2).

(In addition to tau mass, a precise measurement of the tau-lepton lifetime is reported recently by the Belle collaboration (Belous, 2014). For the measurement, they use an

Table 20.2.2. Measured upper limit of the τ^+ and τ^- mass difference at 90% C.L.

Experiment	$|m_\tau^+ - m_\tau^-|/m_{AVG}^\tau$	Ref
OPAL	$< 3.0 \times 10^{-3}$	Abbiendi et al. (2000a)

BABAR	$< 5.5 \times 10^{-4}$	Aubert (2009ac)

unique method that is only applicable in the asymmetric-energy e^+e^- colliders.)

20.3 Tests of lepton universality

20.3.1 Charged current universality between μ-e

Tests of $\mu - e$ universality can be expressed as

$$\left(\frac{g_\mu}{g_e}\right)^2 = \frac{\mathcal{B}(\tau^- \to \mu^- \overline{\nu}_\mu \nu_\tau)}{\mathcal{B}(\tau^- \to e^- \overline{\nu}_e \nu_\tau)} \frac{f(m_e^2/m_\tau^2)}{f(m_\mu^2/m_\tau^2)}, \quad (20.3.1)$$

where $f(x)$ is given by Eq. (20.2.2), assuming that the neutrino masses are negligible (Tsai, 1971). Also, in this equation, small corrections of the order $m_{e,\mu}^2/m_W^2$ and the difference between $\alpha(m_e)$ and $\alpha(m_\mu)$ are ignored, see Eq. (20.2.2). The relation between the weak coupling constant g_l and the Fermi coupling constant G_l, for the lepton l, is given by

$$G_l = \frac{g_l^2}{4\sqrt{2}M_W^2}. \qquad (20.3.2)$$

The HFAG group has performed a constrained fit (Amhis et al., 2012) using 157 branching fraction measurements and 47 constraint equations that fit 86 quantities. For example, there are measurements of the total branching fraction of all decays to three charged pions or kaons plus any number of neutrals. In addition, there are separate measurements of exclusive branching fractions to specific final states that have three identified charged mesons. One constraint is that the sum of exclusive 3-prong decays, the decays involving three charged particles in their final statess, must equal the inclusive 3-prong measurement. The fit is statistically consistent with the constraint that the sum of all base modes is equal to one, referred to as the "unitarity constraint", but the unitarity constraint is not explicitly applied. From that fit, which uses all available data including the recent *BABAR*'s results (Aubert, 2010f), we obtain $\mathcal{B}(\tau^- \to \mu^- \overline{\nu}_\mu \nu_\tau)/\mathcal{B}(\tau^- \to e^- \overline{\nu}_e \nu_\tau) = 0.9761 \pm 0.0028$, which includes a correlation coefficient of 23% between the branching fractions. This yields a value of $\left(\frac{g_\mu}{g_e}\right) = 1.0018 \pm 0.0014$, which is consistent with the SM value.

This prediction from tau decays is more precise than the other determinations:

− We average the measurements of $\mathcal{B}(\pi \to e\nu_e(\gamma))/\mathcal{B}(\pi \to \mu\nu_\mu(\gamma)) = (1.2265 \pm 0.0034\ (\text{stat}) \pm$

0.0044 (syst)) $\times 10^{-4}$ from TRIUMF (Britton et al., 1992) and = $(1.2346 \pm 0.0035 \text{ (stat)} \pm 0.0036 \text{ (syst)}) \times 10^{-4}$ from PSI (Czapek et al., 1993), to obtain a value of $(1.2310 \pm 0.0037) \times 10^{-4}$. Comparing this with the prediction of $(1.2352 \pm 0.0001) \times 10^{-4}$ from recent theoretical calculations (Cirigliano and Rosell, 2007), we obtain a value of $\left(\frac{g_\mu}{g_e}\right) = 1.0017 \pm 0.0015$.

– The ratio $\mathcal{B}(K \to e\nu_e(\gamma))/\mathcal{B}(K \to \mu\nu_\mu(\gamma))$ has recently been measured very precisely by the KLOE (Ambrosino et al., 2009b) and the NA62 (Goudzovski, 2011) collaborations. Using the new world average value of $(2.487 \pm 0.012) \times 10^{-5}$ from Goudzovski (2010), and the predicted value of $(2.477 \pm 0.001) \times 10^{-5}$ from Cirigliano and Rosell (2007), we obtain $\left(\frac{g_\mu}{g_e}\right) = 0.9980 \pm 0.0025$.

– From the report of the FlaviaNet Working Group on Kaon Decays (Antonelli et al., 2010b), we obtain $\left(\frac{g_\mu}{g_e}\right) = 1.0010 \pm 0.0025$ using measurements of $\mathcal{B}(K \to \pi\mu\bar{\nu})/\mathcal{B}(K \to \pi e\bar{\nu})$.

– From the report of the LEP Electroweak Working Group (Alcaraz et al., 2006), we obtain $\left(\frac{g_\mu}{g_e}\right) = 0.997 \pm 0.010$ using measurements of $\mathcal{B}(W \to \mu\bar{\nu}_\mu)/\mathcal{B}(W \to e\bar{\nu}_e)$.

20.3.2 Charged current universality between τ-μ

Tau-muon universality is tested with

$$\left(\frac{g_\tau}{g_\mu}\right)^2 = \frac{\mathcal{B}(\tau^- \to h^- \nu_\tau)}{\mathcal{B}(h^- \to \mu^- \bar{\nu}_\mu)} \frac{2m_h m_\mu^2 \tau_h}{(1+\delta_h) m_\tau^3 \tau_\tau} \left(\frac{1 - m_\mu^2/m_h^2}{1 - m_h^2/m_\tau^2}\right)^2 \tag{20.3.3}$$

where $h = \pi$ or K and the radiative corrections are $\delta_\pi = (0.16 \pm 0.14)\%$ and $\delta_K = (0.90 \pm 0.22)\%$ (Decker and Finkemeier, 1994, 1995; Marciano and Sirlin, 1993).

Using the world average mass and lifetime values and meson decay rates (Nakamura et al., 2010) and our unitarity constrained fit including recent *BABAR* results (Aubert, 2010f), we determine $\left(\frac{g_\tau}{g_\mu}\right) = 0.9966 \pm 0.0030$ and 0.9860 ± 0.0073 from the pionic and kaonic branching fractions, respectively, where the correlation coefficient between these values is 13.10%. Combining these results, we obtain $\left(\frac{g_\tau}{g_\mu}\right) = 0.9954 \pm 0.0029$, which is 1.6 σ below the SM expectation.

We also test lepton universality between τ and μ (e), by comparing the average electronic (muonic) branching fractions of the tau lepton with the predicted branching fractions from measurements of the τ and μ lifetimes and their respective masses (Nakamura et al., 2010), using known electroweak and radiative corrections (Marciano and Sirlin, 1993). This gives $\left(\frac{g_\tau}{g_\mu}\right) = 1.0011 \pm 0.0021$ and $\left(\frac{g_\tau}{g_e}\right) = 1.0030 \pm 0.0021$. The correlation coefficients between the determination of $\left(\frac{g_\tau}{g_\mu}\right)$ from the electronic

branching fraction with the ones obtained from pionic and kaonic branching fractions are 48.16% and 21.82%, respectively. Averaging these three values, we obtain $\left(\frac{g_\tau}{g_\mu}\right) = 1.0001 \pm 0.0020$, which is consistent with the SM value. In Fig. 20.3.1, we compare these above determinations with each other and with the values obtained from W decays (Alcaraz et al., 2006).

20.4 Search for lepton flavor violation in tau decays

In order to progress beyond the Standard Model it is necessary to incorporate results from many different measurements and interpret them within a cohesive theoretical framework. This will include results from direct searches (and discoveries) of new particles at the energy frontier of the LHC, neutrino oscillation measurements, $g - 2$ and electric dipole moment measurements, as well as searches (and discoveries) of LFV in the decays of leptons and mesons. Discoveries at the LHC alone will be insufficient to determine the underlying theoretical structures responsible for New Physics. Moreover, a discovery of $\mu^+ \to e^+\gamma$ alone will not provide sufficient information to nail down the underlying LFV mechanism or even to identify an underlying theory: it is critical to probe all LFV modes and searches for $\mu^+ \to e^+\gamma$ search need to be augmented by studies of $\tau^\pm \to \mu^\pm\gamma$ as well as $\tau^\pm \to e^\pm\gamma$. Even in the presence of the existing and projected $\mu^+ \to e^+\gamma$ bounds, $\tau^\pm \to \mu^\pm\gamma$ decays are predicted to occur at rates that are accessible at current experiments in many models (Aushev et al., 2010; Bona et al., 2007b). In fact, the full set of measurements of μ and τ LFV processes are required as in many models there are strong correlations between the expected rates of the different channels. In a supersymmetric seesaw model describing potential LFV (Babu and Kolda, 2002; Sher, 2002), for example, there is an expectation that the specific relative rates of $\mathcal{B}(\tau^\pm \to \mu^\pm\gamma) : \mathcal{B}(\tau^\pm \to \mu^\pm\mu^+\mu^-) : \mathcal{B}(\tau \to \mu\eta)$ are dependent on the model parameters. In the unconstrained minimal supersymmetric model (MSSM), which includes various correlations between the τ and μ LFV rates, τ LFV branching fractions can be as high as 10^{-7} (Brignole and Rossi, 2004; Goto, Okada, Shindou, and Tanaka, 2008) even with the strong experimental bounds on muon LFV.

20.4.1 Tau lepton data samples and search strategies

With 1,550 fb^{-1} of data currently collected between the Belle and *BABAR* experiments and the $e^+e^- \to \tau^+\tau^-$ cross section of 0.919 nb (Banerjee, Pietrzyk, Roney, and Wąs, 2008), the world sample of τ-leptons produced at the e^+e^- colliders now exceeds 10^9 which allows for experimental probing of LFV processes at the $\mathcal{O}(10^{-7})$ to $\mathcal{O}(10^{-8})$ levels.

The analyses typically select τ-pair events with the appropriate charged-particle topology, removing non-τ events

Figure 20.3.1. Measurements of lepton universality from W, kaon, pion, and tau decays.

can be seen in the *BABAR* detector display of a simulated $e^+e^- \rightarrow \tau^+\tau^-; \tau^+ \rightarrow e^+\bar{\nu}_\tau\nu_e; \tau^- \rightarrow \mu^-\gamma$ event depicted in Figure 20.4.1. Whereas Standard Model τ-decays have at least one neutrino, the LFV decay products have a combined energy, $E_{\ell X}$, equal to the energy of the τ which is approximately equal to the beam energy in the center-of-mass, $\sqrt{s}/2$, and a mass $(m_{\ell X})$ equal to that of the τ. Using a two dimensional signal region in the $m_{\ell X}$ *vs* ΔE plane, the signal is separated from the Standard Model τ-decay backgrounds with minimal loss of efficiency, where $\Delta E = E_{\ell X} - \sqrt{s}/2$. The distributions for the $\tau^\pm \rightarrow e^\pm\gamma$ and $\tau^\pm \rightarrow \mu^\pm\gamma$ decays in that plane are shown in Figure 20.4.2 for the *BABAR* analysis, where the peaking at $\Delta E = 0$ and $m_{\ell X} = m_\tau = 1777\,\text{MeV}/c^2$ is evident. For the lepton-photon invariant mass *BABAR* calculates m_{EC}, which is obtained from a kinematic fit that requires the center-of-mass tau energy to be $\sqrt{s}/2$ after assigning the origin of the γ candidate to the point of closest approach of the signal lepton track to the e^+e^- collision axis. Use of a "signal box" in the ΔE-$m_{\ell X}$ plane encompassing events within approximately two standard deviations of $\Delta E = 0$ and $m_{\ell X} = m_\tau = 1777\,\text{MeV}/c^2$ serves as the most powerful requirement in the searches for LFV in τ decay. The signal peaks near zero in the distribution of $\Delta E = E_{\ell X} - \sqrt{s}/2$ and typically has a standard deviation of around 50 MeV. Using a beam-energy constrained mass and constraining photons to come from the same primary vertex as the charged particles in the event enables a resolution on $m_{\ell X}$ of 9 MeV to be achieved.

The analyses are normally optimized to give the best "expected upper limit" using MC simulations of the signal and backgrounds. Signal efficiency (ϵ) is initially estimated using simulated events and typically lies between 2% and 10%, depending on the channel under study. The components of a generic τ LFV decay selection efficiency are roughly: trigger (90%), acceptance/reconstruction (70%), charged-particle hemisphere topology (1-vs-1 or 1-vs-3: 70%), particle identification (50%), requirements apart from those on ΔE and $m_{\ell X}$ (50%), ΔE vs $m_{\ell X}$ signal box requirements (50%). Data-driven corrections are applied to the simulated signal efficiencies using the results of comparisons between data and simulated control samples.

Estimates of the expected number of background events (N_{bkd}) are usually estimated using the distribution shapes from the Monte Carlo simulation of backgrounds with the normalization obtained from the data in the regions outside the signal box. These *BABAR* and Belle analyses are "blind" in the sense that the analysts have no knowledge of the data in the signal region when optimizing for a best "expected upper limit" and estimating systematic uncertainties. The data in the signal region is "unblinded" only after these steps are completed, and the analyst learns the number of events observed in the signal region (N_{obs}), either making a discovery, or - as has been the case to date - setting an upper limit on the process (see Chapter 14 for a general discussion of blind analysis techniques).

N_{obs} and N_{bkd} together gives the number of signal events (N_{sig}). When N_{obs}-N_{bkd} is consistent with zero,

with an impact as minimal as possible on the signal efficiency. A candidate event is divided into hemispheres in the center-of-mass frame where each hemisphere contains either the τ^+ or τ^- decay products. The τ decay associated with each hemisphere is then considered a possible candidate for the LFV decay under consideration, as
Figure 20.4.1. A *BABAR* event display with a simulated LFV $\tau^\pm \to \mu^\pm \gamma$ decay opposite a Standard Model $\tau^+ \to e^+ \bar{\nu}_\tau \nu_e$ decay
Figure 20.4.2. The 2σ elliptical signal-box for $\tau^\pm \to e^\pm \gamma$ (Left) and $\tau^\pm \to \mu^\pm \gamma$ (Right) decays in the $m_{\rm EC}$ vs. ΔE plane in the *BABAR* analysis. $m_{\rm EC}$ is the invariant mass of the lepton-photon pair as discussed in the text. Data are shown as red dots and contours containing 90% (50%) of signal MC events are shown as the yellow (green) shaded regions (Aubert, 2010i).

an upper limit on $N_{\rm sig}$ (N_{90}^{UL}) is established. Conceptually, the 90%C.L. branching ratio upper limit is obtained from:

$$\mathcal{B}_{90}^{UL} = \frac{N_{90}^{UL}}{2N_{\tau\tau}\epsilon} = \frac{N_{90}^{UL}}{2\mathcal{L}\sigma_{\tau\tau}\epsilon}, \qquad (20.4.1)$$

where $N_{\tau\tau} = \mathcal{L}\sigma_{\tau\tau}$ is the number of τ-pairs produced in e^+e^- collisions obtained from the integrated luminosity, $\mathcal{L}$, and τ-pair production cross section, $\sigma_{\tau\tau}$. In practice, when $N_{\rm bkd}$ is more than a few events, $N_{\rm sig}$ and $N_{\rm bkd}$ are determined from a fit.

20.4.2 Results on LFV decays of the tau from Belle and BABAR

In performing searches, LFV decays can be conveniently classified as $\tau^\pm \to \ell^\pm \gamma$, $\tau^\pm \to \ell_1^\pm \ell_2^+ \ell_3^-$ and $\tau^\pm \to \ell^\pm h^0$

where ℓ is either an electron or muon and h^0 represents a hadronic system. For the *BABAR* and Belle searches, the h^0 has been categorized in three ways: i) a pseudoscalar meson: *e.g.* π^0, η, η', K_S^0; ii) a neutral vector meson: *e.g.* $\rho, \omega, K^*(892), \phi$; and iii) inclusive two charged meson decays, $h^0 = h_1^+ h_2^-$ where $h_{1(2)}^\pm$ is either $\pi^\pm$ or $K^\pm$.

The most recent $\tau^\pm \to \mu^\pm \gamma$ and $\tau^\pm \to e^\pm \gamma$ results reported by Belle (Hayasaka, 2008) use a data sample having an integrated luminosity of 535 fb^{-1} which corresponds to 492×10^6 τ-pair events. Figure 20.4.3 shows the distribution in the $m_{\ell\gamma}$ vs ΔE plane for the selected sample in the Belle experiment. The main $\tau^\pm \to \mu^\pm \gamma$ backgrounds in these searches arise from $e^+e^- \to \mu^+\mu^-\gamma$ events and $e^+e^- \to \tau^+\tau^-\gamma$ events where one of the τ's decays via $\tau \to \mu\nu\bar{\nu}$. In both cases the photon, from initial state radiation in the latter and initial or final state radiation
Figure 20.4.3. The distribution in the $m_{\ell\gamma}$ vs ΔE plane for (a) $\tau^{\pm} \to \mu^{\pm}\gamma$ and (b) $\tau^{\pm} \to e^{\pm}\gamma$ for the selected sample in the Belle analysis. The solid circles and the shaded boxes show the data and the signal MC, respectively. The outer (inner) ellipse shows the 3 (2)σ signal region (Hayasaka, 2008).

Table 20.4.1. Summary of 90% C.L. upper limits on $\mathcal{B}(\tau^{-} \to \ell^{-}\gamma)$ and $\mathcal{B}(\tau^{-} \to \ell_1^{-}\ell_2^{+}\ell_3^{-})$ LFV τ decays. N_{obs} and N_{bkg} are the number of events observed in the signal region and the estimated background, respectively. BF is the upper limit (90% C.L.) on the branching fraction.

Channel	Belle (Hayasaka, 2008, 2010)		BABAR (Aubert, 2010i; Lees, 2010a)	
	N_{obs} (N_{bkg}) events	BF (10^{-8})	N_{obs} (N_{bkg}) events	BF (10^{-8})
$\tau^{-} \to \mu^{-}\gamma$	10 $(13.9^{+6.0}_{-4.8})$	4.5	2 (3.6 ± 0.7)	4.4
$\tau^{-} \to e^{-}\gamma$	5 $(5.14^{+3.86}_{-2.81})$	12	0 (1.6 ± 0.4)	3.3
$\tau^{-} \to \mu^{-}e^{+}e^{-}$	0 (0.04 ± 0.04)	1.8	0 (0.64 ± 0.19)	2.2
$\tau^{-} \to \mu^{-}\mu^{+}\mu^{-}$	0 (0.13 ± 0.06)	2.1	0 (0.44 ± 0.17)	3.3
$\tau^{-} \to e^{-}\mu^{+}\mu^{-}$	0 (0.10 ± 0.04)	2.7	0 (0.54 ± 0.14)	3.2
$\tau^{-} \to e^{-}e^{+}e^{-}$	0 (0.21 ± 0.15)	2.7	0 (0.12 ± 0.02)	2.9
$\tau^{-} \to e^{-}\mu^{+}e^{-}$	0 (0.01 ± 0.01)	1.5	0 (0.34 ± 0.12)	1.8
$\tau^{-} \to \mu^{-}e^{+}\mu^{-}$	0 (0.02 ± 0.02)	1.7	0 (0.03 ± 0.02)	2.6

in the former, combines with a muon to accidentally fall within the signal box. The $e^{+}e^{-} \to \tau^{+}\tau^{-}\gamma; \tau^{-} \to \mu^{-}\nu_{\tau}\bar{\nu}_{\mu}$ events can be classified as "irreducible" because the events are genuine τ-pair events and the μ and γ are correctly identified and measured. A similar irreducible background source from $e^{+}e^{-} \to \tau^{+}\tau^{-}\gamma; \tau^{-} \to e^{-}\nu_{\tau}\bar{\nu}_{e}$ exists. Belle set a 90% C.L. upper limit on the number of signal events for $\tau \to \mu\gamma$ ($\tau \to e\gamma$) of 2.0 (3.34) events. These yield upper limits of $\mathcal{B}(\tau \to \mu\gamma) < 4.5 \times 10^{-8}$ and $\mathcal{B}(\tau \to e\gamma) < 1.2 \times 10^{-7}$. BABAR's 2009 published 90% C.L. upper limits using a 534 fb^{-1} data sample are 4.4×10^{-8} and 3.3×10^{-8} on $\mathcal{B}(\tau \to \mu\gamma)$ and $\mathcal{B}(\tau \to e\gamma)$, respectively (Au-

bert, 2010i). Both experiments report classical frequentist confidence intervals. These are reported in Table 20.4.1.

Belle (Hayasaka, 2010) and BABAR (Lees, 2010a) also searched for $\tau \to \ell_1\ell_2\ell_3$. Fig. 20.4.4 shows the distributions in the $m_{\ell\ell\ell}$ vs ΔE plane for the $\tau \to \ell_1\ell_2\ell_3$ candidate events before the final selection. There is essentially no background in these samples, since the requirement for three leptons is tight and can reduce the background effectively. No evidence for a signal is seen by either experiment and the 90% C.L. upper limits on the branching fractions are presented in Table 20.4.1. Unlike the $\tau^{\pm} \to \mu^{\pm}\gamma$ and $\tau^{\pm} \to e^{\pm}\gamma$ searches, there is no irreducible background

Table 20.4.2. Summary of 90% C.L. upper limit on $\mathcal{B}(\tau^- \to \ell^- h^0)$ in units of (10^{-8}) where $\ell = \mu$ or e and h^0 is either a pseudoscalar (upper half) or vector meson (lower half) from the Belle (Hayasaka, 2011; Miyazaki, 2006, 2010, 2011; Nishio, 2008) and *BABAR* (Aubert, 2007ar, 2008au, 2009o,ao) experiments.

Channel	$\ell = $ e (10^{-8})		$\ell = \mu$ (10^{-8})	
	Belle	*BABAR*	Belle	*BABAR*
$\tau^- \to \ell^- \pi^0$	2.2	13	2.7	11
$\tau^- \to \ell^- \eta$	4.4	16	2.3	15
$\tau^- \to \ell^- \eta'$	3.6	24	3.8	14
$\tau^- \to \ell^- K_S^0$	2.6	3.3	2.3	4.0
$\tau^- \to \ell^- \phi$	3.1	3.1	8.4	19.0
$\tau^- \to \ell^- \rho^0$	1.8	4.6	1.2	2.6
$\tau^- \to \ell^- \omega$	4.8	11	4.7	10
$\tau^- \to \ell^- K^{*0}$	3.2	5.9	7.2	17.0
$\tau^- \to \ell^- \overline{K}^{*0}$	3.4	4.6	7.0	7.3

at the current luminosities. The Belle $\tau \to \ell_1 \ell_2 \ell_3$ analysis uses 719×10^6 τ-pairs whereas *BABAR* reports on an analysis using 431×10^6 τ-pairs. Note that, in addition to the reactions violating flavor, Table Table 20.4.1 also lists bounds of similar magnitude on $\tau^- \to e^- \mu^+ e^-$ and $\tau^- \to \mu^- e^+ \mu^-$, which simultaneously violate the lepton-flavors, L_e, L_μ and L_τ, but the total lepton number is conserved.

Both Belle, using 901 fb^{-1} (Hayasaka, 2011), and *BABAR*, using 339 fb^{-1} (Aubert, 2007ar), have published bounds on LFV τ decays involving a lepton and a π^0, η or η' pseudoscalar. Belle has also published on searches for $\tau \to \ell K_S^0$ and $\tau \to \ell K_S^0 K_S^0$ (Miyazaki, 2010). Searches for LFV involving the ω vector meson, $\tau \to \ell\omega$, have been reported by both experiments with *BABAR* employing a data set of 384 fb^{-1} (Aubert, 2008au) whereas Belle used 854 fb^{-1} (Miyazaki, 2011). From the same data set Belle has also searched for $\tau \to \ell\rho$, $\tau \to \ell\phi$, $\tau \to \ell K^{*0}$ and $\tau \to \ell\overline{K}^{*0}$. The 90% C.L. upper limits on these processes are typically around 5×10^{-8} and are listed in Table 20.4.2. *BABAR*, using a 221 fb^{-1}, sets limits on LFV inclusive decays with two charged mesons, $\tau^\pm \to \ell^\pm h_1^+ h_2^-$, where no assumptions are made on the resonance structure of the hadronic final state (Aubert, 2005ab). These bounds range from 1×10^{-7} to 5×10^{-7}, depending on the final state. Belle's equivalent analysis used 854 fb^{-1} and set bounds ranging from 2.0×10^{-8} to 8.4×10^{-8} (Miyazaki, 2013).

The status of searches for lepton flavor violation in τ decays is summarized in Figure 20.4.5. A table of these results and the corresponding references are provided by the HFAG report of Amhis et al. (2012).

20.4.3 Future Prospects

By the end of 2010 Belle and *BABAR* had collected a combined data sample of roughly 1.5 ab^{-1}, corresponding to

the production of about 1.4×10^9 τ pairs, and those experiments can be expected to update their analyses with their complete data sets over the next year or two. However, SuperKEKB, a new significantly higher luminosity e^+e^- collider designed to operate at the Υ resonances, but mainly on the $\Upsilon(4S)$, is on the horizon. It will provide exciting new opportunities for the discovery and potential study of LFV decays of the τ lepton. The physics potential of a super flavor factory operating with a luminosity of about 10^{36}cm^{-2}s^{-1} has been discussed extensively in (Aushev et al., 2010; Bona et al., 2007b) Such a facility is expected to probe LFV $\tau^\pm \to \ell^\pm \ell^+ \ell^-$ and $\tau^\pm \to \ell^\pm h^0$ decays, which have no irreducible backgrounds, at the $\mathcal{O}(10^{-10})$ level. However, the initial state photon accidental background will prevent the $\tau^\pm \to \ell^\pm \gamma$ decays from being probed below the level of a few 10^{-9}. However it should be noted that this irreducible background can be removed if one were to accumulate a large sample of tau leptons near production threshold (below about 4 GeV).

20.5 *CP* violation in the tau lepton system

Understanding the origin of *CP* violation is one of the most important outstanding questions in particle physics. To date *CP* violation has been observed only in the K and B meson system[157]. In the Standard Model, all observed *CP* violation effects can be accommodated by a single irreducible, complex phase in the CKM quark mixing matrix.

---

[157] The LHCb collaboration reported in 2011 the 3.5σ significance for the difference of the direct *CP* asymmetry $\Delta A_{CP} = A_{CP}(K^+K^-) - A_{CP}(\pi^+\pi^-)$, where $A_{CP}(K^+K^-)$ and $A_{CP}(\pi^+\pi^-)$ are the *CP* asymmetry for $D^0(\overline{D}^0) \to K^+K^-$ and $D^0(\overline{D}^0) \to \pi^+\pi^-$, respectively (Aaij et al., 2012c). However, their recent update does not confirm this observation (Aaij et al., 2013e). So more data are needed to establish *CP* violation in the D meson system.
Figure 20.4.4. Distributions in the $M_{\ell\ell\ell}$ vs ΔE plane for the selected events for (a) $\tau^{\pm} \to e^{\pm}e^{+}e^{-}$, (b) $\tau^{\pm} \to \mu^{\pm}\mu^{+}\mu^{-}$, (c) $\tau^{\pm} \to e^{\pm}\mu^{+}\mu^{-}$ and (d) $\tau^{\pm} \to \mu^{\pm}e^{+}e^{-}$ modes in the Belle analysis (Hayasaka, 2010). The solid circles are data. The shaded boxes show the MC signal distribution with arbitrary normalization. The ellipse is the signal region used for evaluating the signal yield.

The CKM mechanism alone is however not sufficient enough to explain the observed matter-antimatter asymmetry in the universe, and thus new sources of CP violation are necessary. In this regard, one important area is the lepton sector. In the neutral lepton sector, the 3×3 neutrino mixing matrix can accommodate CP violation. A search for signs of CP violation in the neutrino sector is thus a primary task in future neutrino experiments. While in the charged lepton sector, there is no such mixing, so mixing-induced CP violation is not expected. However, physics beyond the Standard Model could produce CP violation in processes involving charged leptons; we would expect such effects to be enhanced for tau leptons because of their large mass.

In this section, we first discuss CP violation in tau-pair production, which is usually parameterized in terms

of the electric dipole moment (EDM) of the tau lepton. We then describe various searches for the CP violation in tau decays.

20.5.1 Electric dipole moment of the tau lepton

If a particle has an EDM value of d, the Hamiltonian H describing a non-relativistic particle of spin S placed in a electric field $\boldsymbol{E}$ can be given by

$$H = -d\,\boldsymbol{E} \cdot \frac{\boldsymbol{S}}{S}. \tag{20.5.1}$$

This interaction violates both parity and time-reversal invariance. Therefore, a non-zero d can exist if and only if both parity and time-reversal invariance (or CP invariance under the CPT theorem) are broken.
Figure 20.4.5. (color online) Limits on the branching fraction at 90 % C.L., obtained from searches for lepton flavor violation in τ decays. Results from CLEO (closed circle), *BABAR* (triangle-down), Belle (triangle-up) and LHCb (square) experiments are shown. The LHCb result is taken from Aaij et al. (2013f).

There are extensive studies of the EDM for electron, muon, neutron and various nuclei such as ^{199}Hg,^{205}Tl, that provide stringent constraints on new *CP*-violating physics (Czarnecki and Marciano, 2010; Roberts and Mar-

ciano, 2010). The current limit on the tau EDM, d_τ, is many orders of magnitude less than that of the electron and nucleons, since it is difficult to measure its EDM due to the short lifetime. However, its size is interesting both theoretically and experimentally. In the Standard Model, the EDM of the tau can arise at the multi-loop level through CKM type quark mixing and is extremely small, $d_\tau < 10^{-34} e$ cm, (Hoogeveen, 1990; Pospelov and Khriplovich, 1991). A much larger contribution to the tau EDM is however predicted by various SM extensions such as supersymmetry (Pospelov and Ritz, 2005), unparticle physics (Moyotl, Rosado, and Tavares-Velasco, 2011), and mirror leptons (Ibrahim and Nath, 2010).

Experimentally, one can measure the tau EDM by using the momentum correlation of decay products in the tau-pair production $e^+ e^- \to \tau^+ \tau^-$ as explained below. The relativistic generalization of the interaction $d\boldsymbol{E} \cdot \boldsymbol{S}$ for a tau lepton (spin 1/2 particle) Ψ can be expressed by an effective Lagrangian as

$$\mathcal{L}_{CP} = -d_\tau \frac{i}{2} \overline{\Psi} \sigma^{\mu\nu} \gamma_5 \Psi \, F_{\mu\nu}, \qquad (20.5.2)$$

where d_τ is the electric dipole moment of the tau lepton. Furthermore, $F^{\mu\nu}$ is the electric field tensor and $\sigma^{\mu\nu} = \frac{i}{2}(\gamma^\mu \gamma^\nu - \gamma^\nu \gamma^\mu)$. From this Lagrangian and the Standard Model one, the squared matrix element, $\mathcal{M} = \mathcal{M}_{\rm SM} + d_\tau \mathcal{M}_{\rm EDM}$, for the tau-pair production

$$e^+(\boldsymbol{p}) + e^-(-\boldsymbol{p}) \to \tau^+(\boldsymbol{k}, \boldsymbol{S}_+) + \tau^-(-\boldsymbol{k}, \boldsymbol{S}_-)(20.5.3)$$

is given by the sum of the SM term $|\mathcal{M}|_{\rm SM}^2$, the EDM term $|d_\tau|^2 |\mathcal{M}|_{\rm EDM}^2$ and the interference between them

$$\begin{aligned}|\mathcal{M}|^2 &= (\mathcal{M}_{\rm SM}^\dagger + d_\tau^\dagger \mathcal{M}_{\rm EDM}^\dagger)(\mathcal{M}_{\rm SM} + d_\tau \mathcal{M}_{\rm EDM}) \\ &= |\mathcal{M}|_{\rm SM}^2 + Re(d_\tau)\mathcal{M}_{Re}^2 + Im(d_\tau)\mathcal{M}_{Im}^2 \\ &\quad + |d_\tau|^2 |\mathcal{M}|_{\rm EDM}^2, \end{aligned} \qquad (20.5.4)$$

where $Re(d_\tau)$ $[Im(d_\tau)]$ is the real [imaginary] part of the EDM. Since these terms vanish for the total integrated cross section, one needs to study CP-odd observables. The interference terms $\mathcal{M}_{Re/Im}$, being proportional to real and imaginary part of d_τ, contain the following combination of spin-momentum correlations:[158]

$$\mathcal{M}_{Re}^2 : (\boldsymbol{S}_+ \times \boldsymbol{S}_-) \cdot \widehat{\boldsymbol{k}} \text{ and } (\boldsymbol{S}_+ \times \boldsymbol{S}_-) \cdot \widehat{\boldsymbol{p}} \qquad (20.5.5)$$

$$\mathcal{M}_{Im}^2 : (\boldsymbol{S}_+ - \boldsymbol{S}_-) \cdot \widehat{\boldsymbol{k}} \text{ and } (\boldsymbol{S}_+ - \boldsymbol{S}_-) \cdot \widehat{\boldsymbol{p}}, \qquad (20.5.6)$$

where $\widehat{\boldsymbol{p}}$ $(\widehat{\boldsymbol{k}})$ is the unit momentum vector of $e^+(\tau^+)$ in the CM frame and $\boldsymbol{S}_\pm$ are the spin vectors for $\tau^\pm$. To measure $Re(d_\tau)$ one needs a CP-odd and T-odd (CPT-even) operator, as shown in the first line. To measure $Im(d_\tau)$ one needs a CP-odd and T-even (CPT-odd) operator, as shown in the second equation (20.5.6).[159] These

---

[158] The complete form is given by Bernreuther, Nachtmann, and Overmann (1993).

[159] Even in the absence of CPT violation, a non-zero value of $Im(d_\tau)$ could be generated through absorptive contributions, *i.e.*, rescattering corrections from on-shell intermediate states.

terms change their sign for the CP transformation (*i.e.* CP-odd terms). So if one of these terms is non-zero, the process violates CP.

In order to optimize the sensitivity to d_τ, Belle employs a so-called optimal observable method, first proposed by Atwood and Soni (1992). In this method, the optimal observables can be defined as

$$\mathcal{O}_{Re} = \frac{\mathcal{M}_{Re}^2}{|\mathcal{M}_{\rm SM}|^2}, \quad \mathcal{O}_{Im} = \frac{\mathcal{M}_{Im}^2}{|\mathcal{M}_{\rm SM}|^2}. \qquad (20.5.7)$$

The mean value of the observable $\mathcal{O}_{Re}$ is given by

$$\begin{aligned}< \mathcal{O}_{Re} > &\propto \int \mathcal{O}_{Re} |\mathcal{M}|^2 d\phi \\ &= \int \mathcal{M}_{Re}^2 d\phi + Re(d_\tau) \int \frac{(\mathcal{M}_{Re}^2)^2}{|\mathcal{M}_{\rm SM}|^2} d\phi, \quad (20.5.8)\end{aligned}$$

where the integration is over the phase space (ϕ) spanned by the relevant kinematic variables. The expression for the imaginary part is similar. The first term containing the integral of $\mathcal{M}_{Re}^2$ and $\mathcal{M}_{Im}^2$ drops out because of their symmetry properties. The means of the observables $< \mathcal{O}_{Re} >$ and $< \mathcal{O}_{Im} >$ are therefore linear functions of d_τ,

$$< \mathcal{O}_{Re} >= a_{Re} \cdot Re(d_\tau), \quad < \mathcal{O}_{Re} >= a_{Im} \cdot Im(d_\tau). \qquad (20.5.9)$$

Eight different final states in the decays of τ-pairs,

$$\begin{aligned}&(e^+ \nu_e \overline{\nu}_\tau)(\mu^- \overline{\nu}_\mu \nu_\tau) \,, (e^+ \nu_e \overline{\nu}_\tau)(\pi^- \nu_\tau), \\ &(\mu^+ \nu_\mu \overline{\nu}_\tau), (\pi^- \nu_\tau) \,, (e^+ \nu_e \overline{\nu}_\tau)(\rho^- \nu_\tau), \\ &(\mu^+ \nu_\mu \overline{\nu}_\tau)(\rho^- \nu_\tau) \,, (\pi^- \nu_\tau)(\rho^+ \overline{\nu}_\tau), \\ &(\rho^- \nu_\tau)(\rho^+ \overline{\nu}_\tau) \,, (\pi^- \nu_\tau)(\pi^+ \overline{\nu}_\tau) \qquad (20.5.10)\end{aligned}$$

and their charge-conjugate modes are analyzed.

Because of the undetectable particles (neutrinos), one can not fully reconstruct the quantities $\boldsymbol{S}_\pm$ and $\widehat{\boldsymbol{k}}$. Therefore, for each event the mean values of $|\mathcal{M}_{\rm SM}|^2$, $\mathcal{M}_{Re}^2$ and $\mathcal{M}_{Im}^2$ are obtained by averaging over all possible kinematic configurations. In the case when both tau leptons decay hadronically, the tau flight direction can be determined with a two-hold ambiguity. In the case of leptonic tau decays, there is an additional ambiguity from the effective mass of the two daughter neutrinos. A Monte Carlo treatment is adopted to take into account the additional ambiguity in the effective mass of the $\nu\bar{\nu}$ system. Explicit formulae for reconstructing the tau's flight direction and the spin vectors are provided in Posthaus and Overmann (1998) and Ackerstaff et al. (1997b).

The obtained optimal observable distributions for the $\tau^+ \tau^- \to (\pi \nu_\tau)(\rho \nu_\tau)$ mode in the Belle experiment (Inami, 2003) are shown in Fig. 20.5.1 (a) and (b) for real and imaginary part, respectively. Note that the width of the distribution is proportional to the sensitivity. The distributions do not show any apparent asymmetry.

The values of the EDM obtained from the mean values of the optimal observables are plotted in Figure 20.5.2 (a) and (b). All results are consistent with the EDM of zero
Figure 20.5.1. Distribution of optimal observables, (a) $\mathcal{O}_{Re}$ and (b) $\mathcal{O}_{Im}$, for $\pi\rho$ events $\tau^-\tau^+ \to (\pi^-\bar{\nu}_\tau)(\rho^+\nu_\tau)$ (Inami, 2003). Dots are Belle data and white and shaded histograms show the MC simulation for signal and background, respectively. If CP is violated, mean values $<\mathcal{O}_{Re}>$, $<\mathcal{O}_{Im}>$ are differ from zero.

within statistical errors. Taking the weighted average of eight different modes, Belle sets the 95% confidence level interval for the tau-lepton EDM (Inami, 2003) as

$$-2.2 \times 10^{-17} e\,\text{cm} < Re(d_\tau) < 4.5 \times 10^{-17} e\,\text{cm} \tag{20.5.11}$$

and

$$-2.5 \times 10^{-17} e\,\text{cm} < Im(d_\tau) < 0.8 \times 10^{-17} e\,\text{cm}. \tag{20.5.12}$$

These limits are ten times more stringent than the previous results given by L3 Acciarri et al. (1998), OPAL (Ackerstaff et al., 1998) and DELPHI (Abdallah et al., 2004) experiments:

$$|d_\tau| < 3.1 \times 10^{-16} \ e\,\text{cm (L3)}, \tag{20.5.13}$$

$$|d_\tau| < 3.7 \times 10^{-16} \ e\,\text{cm (OPAL)}, \tag{20.5.14}$$

$$|d_\tau| < 3.7 \times 10^{-16} \ e\,\text{cm (DELPHI)}. \tag{20.5.15}$$

20.5.2 CP violation in tau decay

In the Standard Model, no observable CP violation is expected in the hadronic decays of tau leptons except for the known CP violation in the neutral kaon system. Observing a signal would then be manifestation of some kind of new physics. For example, the CP violation could originate from the minimal supersymmetric Standard Model (MSSM) (Calderon, Delepine, and Castro, 2007; Ibrahim and Nath, 2008) or from multi-Higgs doublet models (MHDM) (Grossman, 1994; Kiers, Soni, and Wu, 2000; Weinberg, 1976). The charged Higgs bosons in these models
Figure 20.5.2. Results of the tau-lepton EDM for eight modes and the weighted mean for the (a) real and (b) imaginary parts. The error bars include both statistical and systematic errors. The small ticks on the error bars show the statistical errors (Inami, 2003).

play an important role in strangeness changing (Cabibbo-suppressed) processes with $\triangle S = 1$. In the $\tau^- \to K_S^0 \pi^- \nu_\tau$ mode, a Standard Model CP asymmetry of 0.3%, due to the CP violation in $K_L \to \pi^+\pi^-$, is expected in the decay rates (Bigi and Sanda, 2005; Calderon, Delepine, and Castro, 2007). While in new physics models such as MSSM or MHDM, a non-zero CP asymmetry is not expected in the decay rates of $\tau^\pm$ even if the intermediate scalar bosons have CP violating couplings, but the bosons in the models introduce a CP asymmetry in the angular distribution of the tau decays.

20.5.2.1 Decay rate asymmetry

A first search for *CP* violation in the decay rate of the tau lepton is carried out by *BABAR*. They use a dataset of 437 million tau lepton pairs (Lees, 2012q) and measure the decay-rate asymmetry

$$A_{CP} = \frac{\Gamma(\tau^+ \to K_S^0 \pi^+ \overline{\nu}_\tau) - \Gamma(\tau^- \to K_S^0 \pi^- \nu_\tau)}{\Gamma(\tau^+ \to K_S^0 \pi^+ \overline{\nu}_\tau) + \Gamma(\tau^- \to K_S^0 \pi^- \nu_\tau)}$$
(20.5.16)

for a $\tau^- \to K_S^0 \pi^- (\geq 0\pi^0)\nu_\tau$ sample. The signal candidates are selected by dividing the event into two hemispheres using the event thrust axis in the e^+e^- CM system. *BABAR* selects events with a charged track identified as a pion, a $K_S^0 \to \pi^+\pi^-$ and up to three π^0 candidates in the "signal" hemisphere. To reduce background from $q\overline{q}$ continuum, *BABAR* require that the momentum of the charged track in the "tag" hemisphere be less than 4 GeV/c in the CM system and be identified as an electron or muon and the magnitude of the event thrust be between 0.92 and 0.99.

After all selection criteria are applied, a total of 199,064 (140,602) candidates are obtained in the e-tag (μ-tag) sample, of which there are 99842 (70369) in the τ^- and 99222 (70233) in the τ^+ sample. The background is estimated to be at the 1% level. After the subtraction of background composed of $q\overline{q}$ and non-K_S^0 tau decays, the decay-rate asymmetry is measured to be $(-0.32 \pm 0.23 \pm 0.13)\%$ for the e-tag sample and $(-0.05 \pm 0.27 \pm 0.10)\%$ for the μ-tag sample, where the first errors are statistical and the second are systematic.

To these measured rate-asymmetries, two corrections are applied. One is the correction for the different nuclear-interaction cross section of the K^0 and $\overline{K}^0$ mesons with the material in the detector. A correction to the asymmetry is calculated using the momentum and polar angle of the K_S^0 candidate together with the nuclear-interaction cross section for the neutral kaons. The correction is found to be $(0.07 \pm 0.01)\%$ for both the e-tag and μ-tag samples. The other is a correction for the dilution effect. The final sample includes other tau decay modes with one K_S^0. The decay-rate asymmetry for $\tau^- \to K^- K_S^0 \nu_\tau$ is opposite to that of $\tau^- \to K_S^0 \pi^- (\geq 0\pi^0)\nu_\tau$ in the Standard Model because the K_S^0 in the $\tau^- \to K_S^0 \pi^- (\geq 0\pi^0)\nu_\tau$ is produced via a $\overline{K}^0$, whereas the K_S^0 in $\tau^- \to K^- K_S^0 \nu_\tau$ is produced via a K^0. In addition, the decay asymmetry is zero in the Standard Model for the $\tau \to K^0 \overline{K}^0 \nu_\tau$ decay, because the asymmetries due to the K^0 and $\overline{K}^0$ will cancel each other. To obtain the genuine rate asymmetry for $\tau^- \to K_S^0 \pi^- (\geq 0\pi^0)\nu_\tau$, the measured asymmetry is divided by 0.75 ± 0.04.

Finally, by applying these corrections and combining both the e-tag and μ-tag samples, *BABAR* obtain the decay-rate asymmetry for the $\tau^- \to K_S^0 \pi^- (\geq 0\pi^0)\nu_\tau$ decay to be

$$A_{CP} = (-0.36 \pm 0.23 \pm 0.11)\%.$$
(20.5.17)

As pointed out by Grossman and Nir (2012), the predicted decay-rate asymmetry is affected by the K_S^0 decay time dependence of the event selection efficiency. By taking into account the efficiency correction (1.08 ± 0.01) caused by the finite acceptance as a function of K_S^0 decay in the *BABAR* detector, the Standard Model decay-rate asymmetry is predicted to be $(0.36 \pm 0.01)\%$ (Bigi and Sanda, 2005). The sign of the asymmetry is different between experiment and the prediction. The measured value is 2.8 standard deviations from the Standard Model prediction.

20.5.2.2 Asymmetry in angular distribution

A first search for the *CP* asymmetry in the angular distribution has been carried out by the CLEO collaboration for the $\tau^- \to K_S^0 \pi^- \nu_\tau$ mode using 13 fb^{-1} data (Bonvicini et al., 2002). Belle performs a similar search in the same mode using a data sample of 699 fb^{-1} (Bischofberger, 2011).

In this section, we first introduce the generic formula for the *CP* asymmetry in the angular distribution of the tau decays and how the *CP* violating parameters are related to the observables. The relevant SM Hamiltonian for the Cabibbo-suppressed decays $\tau^\pm \to X_s^\pm \nu_\tau$, is given by

$$\mathcal{H}_{SM} = \frac{G_F}{\sqrt{2}} \sin\theta_c [\overline{\nu}_\tau \gamma_\mu (1 - \gamma_5)\tau][\overline{s}\gamma^\mu (1 - \gamma_5)u] + h.c.,$$
(20.5.18)

where the form is determined by the vector-boson $W^\pm$ exchange. On the other hand, the Hamiltonian with scalar- or pseudoscalar-boson exchange has a form

$$\mathcal{H}_{NP} = \frac{G_F}{\sqrt{2}} \sin\theta_c [\overline{\nu}_\tau (1 + \gamma_5)\tau][\overline{s}(\eta_S + \eta_P \gamma_5)u] + h.c.$$
(20.5.19)

where η_P and η_S are the complex parameters, in general, relevant for the pseudoscalar and scalar hadronic system, respectively. If either η_P or η_S has a non-zero imaginary part, *CP* is violated in this process (Kühn and Mirkes, 1997).

Among them, the scalar η_S term can be measured in the modes decaying to two pseudoscalars such as $\tau^- \to K_S^0 \pi^- \nu_\tau$. For $\tau^- \to K_S^0 \pi^- \nu_\tau$, the full differential decay width, in the hadronic rest frame ($\boldsymbol{q}_1 + \boldsymbol{q}_2 = 0$), is given by

$$d\Gamma_{\tau^-} = \frac{G_F^2}{2m_\tau} \sin^2\theta_c \frac{1}{(4\pi)^3} \frac{(m_\tau^2 - Q^2)^2}{m_\tau^2} |\boldsymbol{q}_1|$$
$$\times \frac{1}{2}\left(\sum_X \overline{L}_X W_X\right) \frac{dQ^2}{\sqrt{Q^2}} \frac{d\cos\theta}{2} \frac{d\cos\beta}{2},$$
(20.5.20)

where G_F is the Fermi coupling constant, θ_c is the Cabibbo angle, m_τ is the mass of the tau lepton, $\boldsymbol{q}_1$ and $\boldsymbol{q}_2$ denote the three-momenta of K_S^0 and π^-, respectively, and $Q^2 = (q_1 + q_2)^2$ is the invariant mass squared of the $K_S^0\pi^\pm$ system. β is the helicity angle of K_S^0 in the $K_S^0\pi^\pm$ rest frame while θ is the helicity angle of the $K_S\pi^\pm$ system in the tau rest frame. The angular coefficients L_X with $X = 1$ to 4 are known functions related to the leptonic current. The

four hadronic functions W_X are formed from the vector and scalar form factors $F(Q^2)$ and $F_S(Q^2)$ and are proportional to $|F|^2$, $|F_S|^2$, $Re(FF_S)$, and $Im(FF_S)$, respectively. Among them the last term $Im(FF_S)$ is most important for a CP measurement, which involves the CP-odd term proportional to $Im(\eta_S)$ (Kühn and Mirkes, 1997). This term has an angular dependence of $\cos\beta\cos\psi$, where ψ is the helicity angle of the tau lepton in the $K_S\pi^\pm$ rest-frame. Note that the angles θ and ψ are correlated and their cosine can be determined from the energy of the $K_S\pi^\pm$ system without measuring the tau direction (Kühn and Mirkes, 1997).

In order to extract the CP violating term proportional to $Im(FF_S)$, Belle measure the asymmetry, in bins of Q^2, defined as the difference of the differential τ^+ and τ^- decay width weighted by $\cos\beta\cos\psi$:

$$A_i^{CP} = \frac{\int \cos\beta\cos\psi \left(\frac{d\Gamma_{\tau^-}}{d\omega} - \frac{d\Gamma_{\tau^+}}{d\omega}\right) d\omega}{\frac{1}{2}\int\left(\frac{d\Gamma_{\tau^-}}{dQ^2} + \frac{d\Gamma_{\tau^+}}{dQ^2}\right)dQ^2}$$

$$\simeq \langle\cos\beta\cos\psi\rangle_{\tau^-} - \langle\cos\beta\cos\psi\rangle_{\tau^+} \quad (20.5.21)$$

with $d\omega = dQ^2 d\cos\theta d\cos\beta$. The asymmetry A_i^{CP} is just the difference between the mean values $\langle\cos\beta\cos\psi\rangle$ for τ^+ and τ^- events evaluated in bins of Q^2.

The measured CP asymmetry A_i^{CP} is related to the CP parameter $Im(\eta_S)$ by

$$A_i^{CP} = \langle\cos\beta\cos\psi\rangle_{\tau^-}^i - \langle\cos\beta\cos\psi\rangle_{\tau^+}^i$$

$$= \frac{N_s}{n_i}\frac{1}{\epsilon_{tot}\Gamma}\iiint_{Q_{1,i}^2}^{Q_{2,i}^2}\epsilon(Q^2,\cos\beta,\cos\theta)$$

$$\times \cos\beta\cos\psi\left[\frac{d\Gamma(\tau^-)}{d\omega} - \frac{d\Gamma(\tau^+)}{d\omega}\right]d\omega$$

$$\simeq Im(\eta_S)\frac{N_s}{n_i}\int_{Q_{1,i}^2}^{Q_{2,i}^2}C(Q^2)\frac{Im(FF_H^*)}{m_\tau}dQ^2,$$

$$(20.5.22)$$

with $n_i = (n_i^- + n_i^+)/2$. Where $n_i^\pm$ denotes the observed number of $\tau^- \to K_S^0\pi^-\nu_\tau$ events in the i-th Q^2 bin, $(Q^2 \in [Q_{1,i}^2, Q_{2,i}^2])$, and $N_s = \sum_i n_i$. The function $C(Q^2)$ contains model-independent terms and detector efficiency effects, and is obtained after numerical integration over $\cos\beta$ and $\cos\theta$:

$$C(Q^2) = -\frac{1}{\Gamma}\frac{G_F^2}{2m_\tau}\sin^2\theta_c\frac{1}{(4\pi)^3}\frac{(m_\tau^2 - Q^2)^2}{Q^2}|\boldsymbol{q}_1|^2$$

$$(20.5.23)$$

$$\times \iint\frac{\epsilon(Q^2,\cos\beta,\cos\psi)}{\epsilon_{tot}}\cos^2\beta\cos^2\psi\,d\cos\theta\,d\cos\beta,$$

here the coefficients ϵ_{tot} and $\epsilon(Q^2,\cos\beta,\cos\psi)$ are the total and the three-dimensional detector efficiencies and Γ is the total $\tau^- \to K_S^0\pi^-\nu_\tau$ decay width.

Belle selects events with a charged track identified as a pion, $K_S^0 \to \pi^+\pi^-$ and no additional photons with energy greater than 0.2 GeV in the signal hemisphere, and one

charged track with the number of photons above 0.1 GeV less than five in the tag hemisphere. After all selection criteria are applied, a total of 162000 ± 403 $\tau^- \to K_S^0\pi^-\nu_\tau$ and 162200 ± 403 $\tau^+ \to K_S^0\pi^+\bar{\nu}_\tau$ candidates are selected from a 699 fb^{-1} data sample. The background subtracted asymmetry as a function of $\sqrt{Q^2}$ is shown in Fig. 20.5.3 (a) and (b). The asymmetry is within two standard deviations (σ) from zero for all mass bins.
Figure 20.5.3. (a) Measured CP asymmetry as a function of the mass of the hadron system $W = \sqrt{Q^2}$. The closed squares are data. The triangles indicate the expected asymmetry for $Im(\eta_S) = 0.1$ [$Re(\eta_S) = 0$]. (b) The same data with a zoomed vertical scale ($\times 5$) for the higher mass bins. The vertical lines indicate statistical and systematic errors added in quadrature (Bischofberger, 2011).

In the most precisely measured mass region, 0.9 GeV $< \sqrt{Q^2} <$ 1.1 GeV, the asymmetry is measured to be

$$A_{CP} = (1.8 \pm 2.1 \pm 1.4) \times 10^{-3}. \quad (20.5.24)$$

From the measured values of A_{CP}, the parameter $Im(\eta_S)$ can be extracted from Eq. (20.5.22), where the results on the $K_S\pi^\pm$ mass spectra obtained by Epifanov (2007) are used for the values of the form factors F and F_S. The resultant upper limit for the parameter $Im(\eta_S)$ is

$$|Im(\eta_S)| < (0.012\,\text{to}\,0.026) \quad (20.5.25)$$

at 90% C.L., where the range of the upper limit is due to the uncertainty of the parameterization used to describe the hadronic form factors and the unknown relative phase between the spin-one $|F|$ and the spin-zero $|F_S|$ form factors. The results improve upon the previous limit from the CLEO experiment (Bonvicini et al., 2002) by one order of magnitude.

Theoretical predictions for $Im(\eta_S)$ are available in the context of MHDM with three or more Higgs doublets (Choi, Hagiwara, and Tanabashi, 1995; Grossman, 1994). In such models η_S is related to the model parameters as (Choi, Hagiwara, and Tanabashi, 1995),

$$\eta_S \simeq \frac{m_\tau m_s}{M_{H^\pm}^2} \cdot X^* Z \qquad (20.5.26)$$

if numerically small terms proportional to m_u are ignored. Here, $M_{H^\pm}$ is the mass of the lightest charged Higgs boson and X and Z are the complex coupling constants shown in Fig. 20.5.4 (a). The limits for the $|Im(\eta_S)|$ result in the exclusion region shown in Fig. 20.5.4 (b). For the limit $|Im(\eta_S)| < 0.026$, this is equivalent to $|Im(XZ^*)| < 0.15 \times M_{H^\pm}^2$.
Figure 20.5.4. (a) Feynman diagram for a tau decay via exchange of a Higgs boson in Multi-Higgs-Doublet models. (b) Excluded region of the parameter space in Multi-Higgs-Doublet model from limits for $|Im(\eta_S)|$ (Bischofberger, 2011).

20.6 Hadronic tau decays

20.6.1 Theory

The hadronic tau decays turn out to be a beautiful laboratory for studying strong interaction effects at low energies (Pich, 1998). The tau is the only known lepton massive enough to decay into hadrons. Its semileptonic decays are then ideally suited to investigate the hadronic weak currents. The $\tau^- \to \nu_\tau h^-$ decay amplitude,

$$\mathcal{M}(\tau^- \to \nu_\tau h^-) = \frac{G_F}{\sqrt{2}} \mathcal{H}_h^\mu \left[\overline{\nu}_\tau \gamma_\mu (1 - \gamma_5) \tau \right], \quad (20.6.1)$$

probes the matrix element of the left-handed charged current between the vacuum and the final hadronic state h^-,

$$\mathcal{H}_h^\mu \equiv \langle h^- | \left(V_{ud}^* \, \overline{d} \gamma^\mu (1 - \gamma_5) u + V_{us}^* \, \overline{s} \gamma^\mu (1 - \gamma_5) u \right) |0\rangle . \qquad (20.6.2)$$

For the decay modes with lowest multiplicity, $\tau^- \to \nu_\tau \pi^-$ and $\tau^- \to \nu_\tau K^-$, the relevant hadronic matrix elements are already known from the measured decays $\pi^- \to \mu^- \overline{\nu}_\mu$ and $K^- \to \mu^- \overline{\nu}_\mu$:

$$\langle \pi^- | \overline{d} \gamma^\mu u |0\rangle = -i f_\pi p_\pi^\mu ,$$
$$\langle K^- | \overline{s} \gamma^\mu u |0\rangle = -i f_K p_K^\mu , \qquad (20.6.3)$$

where $f_\pi = (130.4 \pm 0.2)$ MeV and $f_K = (156.1 \pm 0.8)$ MeV are the so-called pion and kaon decay constants (Beringer et al., 2012). The corresponding tau decay widths can then be accurately predicted. The predictions are in good agreement with the measured values and provide a test of lepton universality. Assuming universality in the quark couplings, muonic decays of the pion and kaon determine the ratio (Cirigliano, Ecker, Neufeld, Pich, and Portoles, 2012)

$$\frac{|V_{us}| f_K}{|V_{cd}| f_\pi} = 0.2763 \pm 0.0005 \qquad (20.6.4)$$

to a higher precision than is currently obtained with tau decays. The determination of this ratio by tau decays is presently limited by the measurement of $\Gamma(\tau^- \to \nu_\tau K^-)$, but *BABAR* has significantly improved the precision of this mode, as discussed in Section 20.8.

For the two-pion final state, the hadronic matrix element is parameterized in terms of the so-called pion form factor $F_\pi(s)$, defined through $[s \equiv (p_{\pi^-} + p_{\pi^0})^2]$

$$\langle \pi^- \pi^0 | \overline{d} \gamma^\mu u |0\rangle \equiv \sqrt{2} F_\pi(s) (p_{\pi^-} - p_{\pi^0})^\mu . \qquad (20.6.5)$$

Isospin symmetry relates this quantity to the analogous form factor measured in $e^+ e^- \to \pi^+ \pi^-$. Accurate measurements of $F_\pi(s)$ are a critical ingredient of the Standard Model prediction for the anomalous magnetic moment of the muon.

Owing to the different quarks involved, two form factors are needed to characterize the decays $\tau \to \nu_\tau K\pi$,

$$\langle \overline{K}^0 \pi^- | \overline{s} \gamma^\mu u |0\rangle \equiv f_+^{K\pi}(s) (p_K - p_\pi)^\mu + f_-^{K\pi}(s) (p_K + p_\pi)^\mu \qquad (20.6.6)$$

with $s \equiv (p_\pi + p_K)^2$. The form factor $f_+^{K\pi}(s)$ corresponds to a hadronic final state with $J^P = 1^-$, while the scalar (0^+) combination $f_0^{K\pi}(s) = f_+^{K\pi}(s) + s\, f_-^{K\pi}(s)/(m_K^2 - m_\pi^2)$ vanishes in the $SU(3)$ limit because the vector current is conserved for equal quark masses. In $K \to \pi\ell\nu$ $(K_{\ell3})$ decays one also measures the form factors in the timelike region. More precisely, in the kinematical region $m_\ell^2 < q^2 < (M_K - M_\pi)^2$. In tau decays this is extended up to the tau mass.

Higher-multiplicity modes involve a richer dynamical structure, providing a very valuable experimental window into the non-perturbative hadronization of the QCD currents. While e^+e^- data only test the electromagnetic vector current, tau decays are sensitive to the vector and axial-vector currents, both in the Cabibbo-allowed and Cabibbo-suppressed channels.

A dynamical understanding of the hadronic matrix elements can be achieved using analyticity, unitarity and some general properties of QCD, such as chiral symmetry, the short-distance asymptotic behavior and the limit of a large number of QCD colors (Pich, 2007). The high-statistics B Factory data samples provide very important information on the hadronic structure, allowing one to improve theoretical tools and get a better control of the strong interaction in the resonance region. These data have already triggered extensive theoretical activity (Boito, Escribano, and Jamin, 2009, 2010; Gómez Dumm, Pich, and Portolés, 2004; Gómez Dumm, Roig, Pich, and Portolés, 2010a,b; Guerrero and Pich, 1997; Guo and Roig, 2010; Jamin, Pich, and Portolés, 2006, 2008; Pich and Portolés, 2001). As a result, there has been considerable progress towards the development of a quantum field theory description of the resonance dynamics at the energy scales accessible through tau decays.

20.6.1.1 Inclusive tau decay width

The inclusive character of the total tau hadronic width renders possible an accurate calculation of the ratio (Braaten, 1988, 1989; Braaten, Narison, and Pich, 1992; Le Diberder and Pich, 1992b; Narison and Pich, 1988)

$$R_\tau \equiv \frac{\Gamma(\tau^- \to \nu_\tau\, \text{hadrons})}{\Gamma(\tau^- \to \nu_\tau e^- \overline{\nu}_e)} = R_{\tau,V} + R_{\tau,A} + R_{\tau,S}\,. \tag{20.6.7}$$

$R_{\tau,V}$ $(R_{\tau,A})$ is the Cabibbo-allowed decay width into final states with $J^P = 1^-, 0^+$ $(1^+, 0^-)$, while $R_{\tau,S}$ accounts for decays into states with strangeness $S = -1$.

The inclusive hadronic width,

$$\Gamma(\tau^- \to \nu_\tau\, \text{hadrons}) \propto L_{\mu\nu} \sum_h \int dQ_h\ \mathcal{H}_h^\mu \mathcal{H}_h^{\nu\dagger}\,, \tag{20.6.8}$$

involves a sum over all possible final hadronic states h^- with the corresponding phase-space integration dQ_h. Unitarity and analyticity (optical theorem) relate this spectral distribution with the imaginary parts of the two-point correlation functions for the vector $V_{ij}^\mu = \overline{\psi}_j \gamma^\mu \psi_i$ and axial-

vector $A_{ij}^\mu = \overline{\psi}_j \gamma^\mu \gamma_5 \psi_i$ color-singlet quark currents,

$$\Pi_{ij,\mathcal{J}}^{\mu\nu}(q) \equiv i \int d^4x\, e^{iqx}\, \langle 0|T(\mathcal{J}_{ij}^\mu(x)\mathcal{J}_{ij}^\nu(0)^\dagger)|0\rangle\,, \tag{20.6.9}$$

which have the Lorentz decomposition $(\mathcal{J} = V, A)$,

$$\Pi_{ij,\mathcal{J}}^{\mu\nu}(q) = \left(-g^{\mu\nu}q^2 + q^\mu q^\nu\right) \Pi_{ij,\mathcal{J}}^{(1)}(q^2) + q^\mu q^\nu \Pi_{ij,\mathcal{J}}^{(0)}(q^2)\,. \tag{20.6.10}$$

The superscript $J = 0, 1$ denotes the angular momentum in the hadronic rest frame and $i, j = u, d, s$.

The imaginary parts of $\Pi_{ij,\mathcal{J}}^{(J)}(q^2)$ are proportional to the spectral functions for hadrons with the corresponding quantum numbers. The hadronic decay rate of the tau can be written as an integral of these spectral functions over the invariant mass $s = q^2$ of the final-state hadrons:

$$R_\tau = 12\pi \int_0^{m_\tau^2} \frac{ds}{m_\tau^2} \left(1 - \frac{s}{m_\tau^2}\right)^2$$
$$\times \left[\left(1 + 2\frac{s}{m_\tau^2}\right) \text{Im}\Pi^{(1)}(s) + \text{Im}\Pi^{(0)}(s)\right], \tag{20.6.11}$$

where

$$\Pi^{(J)}(s) \equiv |V_{ud}|^2 \left(\Pi_{ud,V}^{(J)}(s) + \Pi_{ud,A}^{(J)}(s)\right)$$
$$+ |V_{us}|^2 \left(\Pi_{us,V}^{(J)}(s) + \Pi_{us,A}^{(J)}(s)\right)\,. \tag{20.6.12}$$

The contributions coming from the first two terms correspond to $R_{\tau,V}$ and $R_{\tau,A}$, respectively, while $R_{\tau,S}$ contains the remaining Cabibbo-suppressed contributions.

The integrand in Eq. (20.6.11) cannot be calculated at present from QCD. Nevertheless the integral itself can be calculated systematically by exploiting the analytic properties of the correlators $\Pi^{(J)}(s)$. They are analytic functions of s except along the positive real s-axis, where their imaginary parts have discontinuities. R_τ can then be written as a contour integral in the complex s-plane running counter-clockwise around the circle $|s| = m_\tau^2$ (Braaten, Narison, and Pich, 1992):

$$R_\tau = 6\pi i \oint_{|s|=m_\tau^2} \frac{ds}{m_\tau^2} \left(1 - \frac{s}{m_\tau^2}\right)^2$$
$$\times \left[\left(1 + 2\frac{s}{m_\tau^2}\right) \Pi^{(0+1)}(s) - 2\frac{s}{m_\tau^2}\Pi^{(0)}(s)\right]. \tag{20.6.13}$$

Cauchy's theorem guarantees that the integration along the closed contour shown in Fig. 20.6.1 gives zero. Up to a sign the integral along the circle is then equal to the sum of the integrals above and below the real axis, which reproduces Eq. (20.6.11) because $\Pi^{(J)}(s + i\epsilon) - \Pi^{(J)}(s - i\epsilon) = 2i\,\text{Im}\Pi^{(J)}(s)$.

To compute the contour integral Eq. (20.6.13) we only need to know the correlators $\Pi^{(J)}(s)$ for complex values
Figure 20.6.1. Integration contour used to derive Eq. (20.6.13).

of s, with $|s| = m_\tau^2$ which is larger than the scale associated with non-perturbative effects. Therefore, the Operator Product Expansion (OPE) can be used to organize the perturbative and non-perturbative contributions into a systematic expansion in powers of $1/s$:

$$\Pi^{(J)}(s) = \sum_{D=0,2,4,\dots} \frac{C_D^{(J)}}{(-s)^{D/2}} . \quad (20.6.14)$$

$C_D^{(J)}$ parameterizes the contributions from operators with dimension D. Since parity is a symmetry of the strong interactions, only operators with even dimension contribute. The leading $D = 0$ term is the perturbative contribution, while the corrections correspond to non-perturbative effects from operators with dimension $D \geq 4$. Since there are no gauge-invariant operators with D=2, the dominant non-perturbative effects appear at D=4 through the so-called gluon, $\langle \alpha_s G_{\mu\nu} G^{\mu\nu} \rangle$, and quark, $\langle m_q \bar{q} q \rangle$, vacuum condensates.

Inserting Eq. (20.6.14) into the contour integral, R_τ can be expressed as an expansion in powers of $1/m_\tau^2$. The uncertainties associated with the use of the OPE near the timelike axis are heavily suppressed by the presence of a double zero at $s = m_\tau^2$ in Eq. (20.6.13).

In the chiral limit ($m_{u,d,s} = 0$), the vector and axial-vector currents are conserved. This implies $s \, \Pi^{(0)}(s) = 0$. Therefore, only the correlator $\Pi^{(0+1)}(s)$ contributes to Eq. (20.6.13). Since $(1 - x)^2 (1 + 2x) = 1 - 3x^2 + 2x^3$ $[x \equiv s/m_\tau^2]$, up to tiny logarithmic running corrections, the only non-perturbative contributions to the contour integration in Eq. (20.6.13) originate from operators of dimensions $D = 6$ and 8. The usually leading $D = 4$ operators can only contribute to R_τ with an additional suppression factor of $\mathcal{O}(\alpha_s^2)$, which makes their effect negligible (Braaten, Narison, and Pich, 1992).

20.6.1.2 Determination of $\alpha_s(m_\tau)$

The Cabibbo-allowed combination $R_{\tau, V+A}$ can be written as (Braaten, Narison, and Pich, 1992)

$$R_{\tau, V+A} = N_C |V_{ud}|^2 S_{EW} \{1 + \delta_P + \delta_{NP}\}, \quad (20.6.15)$$

where $N_C = 3$ is the number of quark colors and $S_{EW} = 1.0201 \pm 0.0003$ contains the electroweak radiative corrections (Braaten and Li, 1990; Erler, 2004; Marciano and Sirlin, 1988). The dominant correction ($\sim 20\%$) is the perturbative QCD contribution δ_P, which is already known to $O(\alpha_s^4)$ (Baikov, Chetyrkin, and Kühn, 2008; Braaten, Narison, and Pich, 1992). Quark mass effects are tiny for the Cabibbo-allowed current and amount to a negligible correction smaller than 10^{-4}.

Non-perturbative contributions δ_{NP}, are suppressed by six powers of the tau mass and, therefore, are very small. Their numerical size has been determined from the invariant-mass distribution of the final hadrons in tau decay, through the study of weighted integrals (Le Diberder and Pich, 1992a),

$$R_\tau^{kl} \equiv \int_0^{m_\tau^2} ds \left(1 - \frac{s}{m_\tau^2}\right)^k \left(\frac{s}{m_\tau^2}\right)^l \frac{dR_\tau}{ds}, \quad (20.6.16)$$

which can be calculated theoretically in the same way as R_τ, but are more sensitive to OPE corrections. The predicted suppression of the non-perturbative contribution to R_τ has been confirmed by ALEPH (Barate et al., 1998; Buskulic et al., 1993a; Schael et al., 2005), CLEO (Coan et al., 1995) and OPAL (Ackerstaff et al., 1999). The most recent analysis gives (Davier, Hoecker, and Zhang, 2006)

$$\delta_{NP} = -0.0059 \pm 0.0014, \quad (20.6.17)$$

showing that non-perturbative corrections are below 1%.

The QCD prediction for $R_{\tau, V+A}$ is then completely dominated by δ_P; non-perturbative effects being smaller than the perturbative uncertainties from unknown higher-order corrections. Using $|V_{ud}| = 0.97425 \pm 0.00022$ (Hardy and Towner, 2009) and Eq. (20.6.17), the present experimental value $R_{\tau, V+A} = 3.4671 \pm 0.0084$ (Amhis et al., 2012), determines the purely perturbative contribution to R_τ to be

$$\delta_P = 0.1995 \pm 0.0033. \quad (20.6.18)$$

The predicted value of δ_P turns out to be very sensitive to $\alpha_s(m_\tau^2)$, allowing for an accurate determination of the fundamental QCD coupling (Braaten, Narison, and Pich, 1992; Narison and Pich, 1988). The calculation of the $\mathcal{O}(\alpha_s^4)$ contribution (Baikov, Chetyrkin, and Kühn, 2008) has triggered a renewed theoretical interest on the $\alpha_s(m_\tau^2)$ determination, since it allows one to improve the accuracy to the four-loop level (Beneke and Jamin, 2008; Caprini and Fischer, 2009, 2011; Cvetic, Loewe, Martinez, and Valenzuela, 2010; Davier, Descotes-Genon, Höcker, Malaescu, and Zhang, 2008; Maltman and Yavin, 2008; Menke, 2009; Pich, 2011a). The value of δ_P in Eq. (20.6.18) implies (Pich, 2011b)

$$\alpha_s(m_\tau^2) = 0.329 \pm 0.013, \quad (20.6.19)$$

which is significantly larger than the values obtained at higher energies. After evolution up to the scale M_Z (Rodrigo, Pich, and Santamaria, 1998), the strong coupling decreases to

$$\alpha_s(M_Z^2) = 0.1198 \pm 0.0015, \quad (20.6.20)$$

in excellent agreement with the direct measurements at the Z peak and with a better accuracy. The comparison of these two determinations of α_s in two very different energy regimes, m_τ and M_Z, provides a beautiful test of the predicted running of the QCD coupling; i.e., a very significant experimental verification of asymptotic freedom.

20.6.1.3 $|V_{us}|$ Determination

A separate measurement of the $|\Delta S| = 0$ and $|\Delta S| = 1$ tau decay widths provides a very clean determination of V_{us} (Gamiz, Jamin, Pich, Prades, and Schwab, 2003, 2005, 2008). To a first approximation the Cabibbo mixing can be directly obtained from experimental measurements, without any theoretical input. Neglecting the small $SU(3)$-breaking corrections from the $m_s - m_d$ quark-mass difference, the measured ratio $R_{\tau,S} = 0.1612 \pm 0.0028$ (Amhis et al., 2012) implies

$$|V_{us}|^{SU(3)} = |V_{ud}| \left(\frac{R_{\tau,S}}{R_{\tau,V+A}} \right)^{1/2} = 0.210 \pm 0.002 \,. \tag{20.6.21}$$

The new branching ratios measured by *BABAR* and Belle are all smaller than the previous world averages, which translate into a smaller value of $R_{\tau,S}$ and $|V_{us}|$. For comparison, the previous value $R_{\tau,S} = 0.1686 \pm 0.0047$ (Davier, Hoecker, and Zhang, 2006) resulted in $|V_{us}|^{SU(3)} = 0.215 \pm 0.003$.

This rather remarkable determination is only slightly shifted by the small $SU(3)$-breaking contributions induced by the strange quark mass. These effects can be estimated through a QCD analysis of the differences (Baikov, Chetyrkin, and Kühn, 2005; Chen et al., 2001a; Chetyrkin, Kühn, and Pivovarov, 1998; Gamiz, Jamin, Pich, Prades, and Schwab, 2003, 2005, 2008; Kambor and Maltman, 2000; Korner, Krajewski, and Pivovarov, 2001; Maltman and Kambor, 2001; Maltman and Wolfe, 2006, 2007; Pich and Prades, 1998, 1999)

$$\delta R_\tau^{kl} \equiv \frac{R_{\tau,V+A}^{kl}}{|V_{ud}|^2} - \frac{R_{\tau,S}^{kl}}{|V_{us}|^2} \,. \tag{20.6.22}$$

The only non-zero contributions are proportional to the mass-squared difference $m_s^2 - m_d^2$ or to vacuum expectation values of $SU(3)$-breaking operators such as $\delta O_4 \equiv \langle 0|m_s \bar{s}s - m_d \bar{d}d|0\rangle \approx (-1.4 \pm 0.4) \cdot 10^{-3}$ GeV^4 (Gamiz, Jamin, Pich, Prades, and Schwab, 2003; Pich and Prades, 1998, 1999). The dimensions of these operators are compensated by corresponding powers of m_τ^2, which implies a strong suppression of δR_τ^{kl} (Pich and Prades, 1998, 1999),

$$\delta R_\tau^{kl} \approx 24\, S_{EW} \left\{ \frac{m_s^2(m_\tau^2)}{m_\tau^2} \left(1 - \epsilon_d^2\right) \Delta_{kl}(\alpha_s) \right.$$
$$\left. -2\pi^2 \frac{\delta O_4}{m_\tau^4} Q_{kl}(\alpha_s) \right\}, \tag{20.6.23}$$

where $\epsilon_d \equiv m_d/m_s = 0.053 \pm 0.002$ (Leutwyler, 1996). The perturbative corrections $\Delta_{kl}(\alpha_s)$ and $Q_{kl}(\alpha_s)$ are known

to $O(\alpha_s^3)$ and $O(\alpha_s^2)$, respectively (Baikov, Chetyrkin, and Kühn, 2005; Pich and Prades, 1998, 1999).

The $J = 0$ contribution to $\Delta_{00}(\alpha_s)$ shows a rather pathological behavior, with clear signs of being a non-convergent perturbative series. Fortunately, the corresponding longitudinal contribution to $\delta R_\tau \equiv \delta R_\tau^{00}$ can be estimated phenomenologically with a much better accuracy, $\delta R_\tau|^L = 0.1544 \pm 0.0037$ (Gamiz, Jamin, Pich, Prades, and Schwab, 2003, 2005, 2008; Jamin, Oller, and Pich, 2006), because it is dominated by far by the well-known $\tau \to \nu_\tau \pi$ and $\tau \to \nu_\tau K$ contributions. To estimate the remaining transverse component, one needs an input value for the strange quark mass. Taking the conservative value $\delta R_{\tau,\mathrm{th}} = 0.239 \pm 0.030$ (Gamiz, 2013), one obtains

$$|V_{us}| = \left(\frac{R_{\tau,S}}{\frac{R_{\tau,V+A}}{|V_{ud}|^2} - \delta R_{\tau,\mathrm{th}}} \right)^{1/2}$$
$$= 0.2173 \pm 0.0020_{\mathrm{exp}} \pm 0.0010_{\mathrm{th}}. \tag{20.6.24}$$

A larger central value, $|V_{us}| = 0.2217 \pm 0.0032$, is obtained with the old world average for $R_{\tau,S}$, i.e. $R_{\tau,S} = 0.1686 \pm 0.0047$ (Davier, Hoecker, and Zhang, 2006).

Sizeable changes on the experimental determination of $R_{\tau,S}$ could be expected from future analyses. In particular, the high-multiplicity decay modes are not well known at present. The recent decrease of several experimental tau branching ratios is also worrisome, since it could indicate some uncontrolled systematic effect. As pointed out by the PDG (Beringer et al., 2012), 18 of the 20 branching fractions measured at the B Factories for which older non-B Factory measurements exist are smaller than the previous non-B Factory values. The average normalized difference between the two sets of measurements is $-1.30\,\sigma$. Thus, the result in Eq. (20.6.24) could easily fluctuate in the near future. In fact, combining the measured Cabibbo-suppressed tau distribution with hadronic e^+e^- data, a slightly larger value of $|V_{us}|$ is obtained (Maltman, 2009; Maltman, Wolfe, Banerjee, Nugent, and Roney, 2009).

The final error of the $|V_{us}|$ determination from tau decay is dominated by the experimental uncertainties. This is in contrast with the standard determination from $K_{\ell 3}$ decays, where the achievable precision is limited by theoretical errors (Cirigliano, Ecker, Neufeld, Pich, and Portoles, 2012). If $R_{\tau,S}$ is measured with a 1% precision, the resulting $|V_{us}|$ uncertainty will get reduced to around 0.6%, i.e. ± 0.0013, making tau decay the best source of information on $|V_{us}|$.

An accurate measurement of the invariant-mass distribution of the final hadrons could allow one to perform a simultaneous determination of $|V_{us}|$ and the strange quark mass, through a correlated analysis of several weighted differences δR_τ^{kl}. However, the extraction of m_s suffers from theoretical uncertainties related to the convergence of the perturbative series $\Delta_{kl}(\alpha_s)$. A better understanding of these corrections is needed.

20.6.1.4 Spectral Functions

The invariant-mass distribution of the final state hadrons in tau decay contains very important information on the low-energy dynamics of QCD. While the separate measurement of each decay mode allows one to study the resonance structure of hadronic form factors with different J^P and strangeness quantum numbers, the inclusive and semi-inclusive distributions associated with the different quark currents provide direct access to relevant perturbative and non-perturbative QCD parameters.

The precise determination of $\alpha_s(m_\tau^2)$ requires that one pins down the small non-perturbative contribution to $R_{\tau,V+A}$ in Eq. (20.6.17), which can only be done through an accurate measurement of the corresponding spectral distribution. Similarly, a precise experimental determination of the Cabibbo-suppressed distribution would help to improve the extraction of $|V_{us}|$, which at present is mainly obtained from the total decay width. The inclusive distribution of hadrons with $J^P = 1^-$ provides complementary information, which is needed to predict the hadronic contribution to the anomalous magnetic moment of the muon and the running of the electromagnetic coupling from low energies to the electroweak scale. While the present discrepancies between e^+e^- and tau data are limiting the interpretation of the measured muon $g-2$, the uncertainties induced by this hadronic distribution on $\alpha(M_Z^2)$ are the largest source of error in the Higgs mass value extracted from precision electroweak tests, to be compared with its direct measurement at the LHC.

Moreover, the separate measurement of the vector and axial-vector spectral functions allows us to extract valuable information on the dynamical breaking of chiral symmetry. The chiral invariance of massless QCD guarantees that the two-point correlation function of a left-handed and a right-handed quark current vanishes identically to all orders in perturbation theory. The spontaneous breaking of chiral symmetry by the QCD vacuum generates a non-zero value of $\Pi_{LR}(s) = \Pi_{ud,V}^{(0+1)}(s) - \Pi_{ud,A}^{(0+1)}(s)$, which at large momenta manifests in its OPE through operators with dimension $D \geq 6$. At very low momenta, Chiral Perturbation Theory (χPT) dictates the low-energy expansion of $\Pi_{LR}(s)$ in terms of the pion decay constant and some χPT couplings (for a basic review of χPT, see Ecker (1995); Pich (1995)). Analyticity relates the short- and long-distance regimes through the dispersion relation

$$\frac{1}{2\pi i} \oint_{|s|=s_0} ds \, w(s) \, \Pi_{LR}(s) = -\int_{s_{th}}^{s_0} ds \, w(s) \, \rho(s)$$
$$+ 2f_\pi^2 w(m_\pi^2) + \mathrm{Res}[w(s)\Pi_{LR}(s), s=0] \,,$$
$$(20.6.25)$$

where $\rho(s) \equiv \frac{1}{\pi} \mathrm{Im}\Pi_{LR}(s)$ and $w(s)$ is an arbitrary weight function that is analytic in the whole complex plane except at the origin (where it can have poles). The last term in Eq. (20.6.25) accounts for the possible residue at the origin.

For $s_0 \leq m_\tau^2$, the integral along the real axis can be evaluated with the measured tau spectral functions.

The residues at zero are determined by the χPT low-energy couplings and, taking s_0 large enough, the OPE can be applied in the entire circle $|s| = s_0$. Therefore, taking different weight functions one can determine the χPT couplings and the OPE coefficients from the tau spectral data (Davier, Girlanda, Höcker, and Stern, 1998; Gonzalez-Alonso, Pich, and Prades, 2008, 2010a,b). Moreover, one can explicitly check the predicted QCD asymptotic behavior (absence of $D < 6$ contributions in the OPE), which is reflected in the celebrated first and second Weinberg (1967) sum rules. The absence of perturbative contributions makes Eq. (20.6.25) an ideal tool to also investigate possible violations of quark-hadron duality, *i.e.* small departures from the OPE behavior at small values of s_0 (Cata, Golterman, and Peris, 2005; Shifman, 2000).

It is worth noting that the information extracted from $\Pi_{LR}(s)$ through Eq. (20.6.25) is needed to calculate the electromagnetic penguin contribution to the CP-violating ratio $\varepsilon_K'/\varepsilon_K$ in neutral kaon decays. Moreover, since the spontaneous breaking of the Standard Model electroweak symmetry has the same formal pattern as the QCD chiral symmetry breaking, $\Pi_{LR}(s)$ can also be used to investigate strongly-coupled scenarios of electroweak symmetry breaking (Peskin and Takeuchi, 1990, 1992).

Since we lack a B Factory analysis of these spectral distributions, the ALEPH (Barate et al., 1999; Schael et al., 2005) and OPAL (Abbiendi et al., 2004; Ackerstaff et al., 1999) measurements are still being used at present. A change of this unfortunate situation is certainly possible and appears to be mandatory. Significant improvement of the LEP measurements should be possible with the much larger data samples collected at the B Factories .

20.6.2 Tau lepton branching fractions

The B Factories, thanks to the large and clean recorded tau pairs sample, provide improved measurements of hadronic branching fractions for many modes and also provide first measurements of several modes which have small branching fractions.

Table 20.6.1 shows the B Factories results that have been included in the early 2012 HFAG report (Amhis et al., 2012), while Table 20.6.2 shows the results from two recent papers, which have not yet been included in the HFAG averages. The corresponding averages are also listed.

20.6.3 Hadronic spectral functions: Cabibbo-favored modes

A separate measurement of the mass distribution for each decay mode allows one to study the resonance structure of hadronic form factors with different J^P and strangeness quantum numbers. In addition, as discussed in Sections 20.6.1.1 to 20.6.1.4, inclusive invariant-mass distributions of the final state hadrons in tau decay are very important for the determination of fundamental constants,

Table 20.6.1. Hadronic tau lepton branching fractions, $\mathcal{B}$, measured by the B Factory experiments that were used in the early 2012 HFAG report (Amhis et al., 2012). The notation (ex.) K^0 means the branching fraction excludes the contribution $K_S^0 \to \pi^+\pi^-$ to a $\pi^+\pi^-$ contained in its final state.

favored and Cabibbo-suppressed modes with kaons are distinguished by an odd or even number of kaons.

20.6.3.1 $\tau^- \to \pi^- \pi^0 \nu_\tau$

Among the decay channels of the tau lepton, $\tau^- \to \pi^- \pi^0 \nu_\tau$ has the largest branching fraction. From the CVC theorem, the $\pi^- \pi^0$ mass spectrum can be related to the cross section of the process $e^+ e^- \to \pi^+ \pi^-$ and thus used to improve a theoretical error on the anomalous magnetic moment of the muon $a_\mu = (g_\mu - 2)/2$.

Using a sample of 5,430,000 $\tau^- \to \pi^- \pi^0 \nu_\tau$ decays, Belle measures the branching fraction and the $\pi \pi^0$ mass spectrum (Fujikawa, 2010). After unfolding performed using the singular-value-decomposition method (Höcker and Kartvelishvili, 1996), the distribution for the $\pi \pi^0$ mass spectrum shown in Fig. 20.6.2(a) is obtained. This precisely measured spectrum has a shape formed by $\rho(770)$, $\rho(1450)$ and $\rho(1700)$ resonances and their interference. Figure 20.6.2(b) shows the pion form factor in the $\rho(770)$ region obtained from the $\pi \pi^0$ mass spectrum. The measured branching fraction is

$$\mathcal{B}(\tau^- \to \pi^- \pi^0 \nu_\tau) = (25.24 \pm 0.01(\text{stat}) \pm 0.39(\text{syst}))\%. \tag{20.6.26}$$

The discussion of the CVC relation and the evaluation of a_μ using tau-lepton data including this Belle measurement are provided in Section 20.7.

20.6.3.2 $\tau^- \to (3\pi)^- \nu_\tau$

The three-pion final states form a dominant fraction of the axial-vector current. The unfolded 3π mass spectrum given by $(1/\Gamma)(d\Gamma/dM)$, measured in $\tau^- \to \pi^- \pi^+ \pi^- \nu_\tau$ by Belle (Lee, 2010), is shown in Fig. 20.6.3(a). The solid histogram is the spectrum implemented in the current TAUOLA program (Gómez Dumm, Roig, Pich, and Portolés, 2010a). A systematic difference between data and MC is observed at the peak region of the $a_1(1260)$ resonance. Belle (red circle) and ALEPH (solid circles) show very good agreement in this peak region as can be seen in Fig. 20.6.3(b) and (c). This indicates that the model in the current TAUOLA should be updated. Figure 20.6.3(d) shows the ratio ALEPH/Belle-1. Both data show very good agreement for M^2 between 0.7 and 2.0 GeV^2/c^4. Outside this range differences of up to 20% between the experiments have been observed. This can be attributed to the imperfect modeling of the background or the detector effects. Further studies are needed for the high mass region, where the mass spectrum plays an important role as the spectral function of the axial-vector current (see the discussion in Section 20.6.1.4, and 20.6.5 for the recent status).

20.6.3.3 $\tau^- \to (K\bar{K}\pi)^- \nu_\tau$

The $K\bar{K}\pi$ mode has both vector and axial-vector components. The axial-vector component arises from the Wess-Zumino-Witten chiral-anomalous term (Wess and Zumino, 1971; Witten, 1983) and the non-anomalous odd-intrinsic-parity amplitude (Ruiz-Femenia, Pich, and Portoles, 2003).
Figure 20.6.2. (a) Unfolded $\pi^{\pm}\pi^0$ mass spectrum for $\tau^{\pm} \to \pi^{\pm}\pi^0\nu_\tau$ obtained by the Belle experiment (Fujikawa, 2008). Solid circles are the data and the solid line is a fit based on the Gounaris-Sakurai (G&S) parameterization (Gounaris and Sakurai, 1968). The error bars include both statistical and systematic errors. (b) Pion form factor $|F_\pi(s)|^2$ in the $\rho(770)$ region derived from the $\pi^{\pm}\pi^0$ mass spectrum.

See Shekhovtsova, Przedzinski, Roig, and Wąs (2012) for more details.

The unfolded $K\bar{K}\pi$ mass spectrum measured by Belle (Lee, 2010) for the $\tau^- \to K^- K^+ \pi^- \nu_\tau$ is shown in Fig. 20.6.4 (a). In this process there are contributions from both vector and axial-vector currents. The current TAUOLA output (histogram) does not give a satisfactory description of the data. In Fig. 20.6.4 (b), the result is compared with a model prediction based on resonance chiral perturbation theory (Gómez Dumm, Roig, Pich, and Portolés, 2010a). The comparison indicates that a larger axial-vector component than the current prediction is needed to improve the agreement between the data and model.
Figure 20.6.3. (color online) (a) Unfolded mass spectrum $(1/N)dN/dM$ for the $\pi^-\pi^+\pi^-$ system in $\tau^- \to \pi^-\pi^+\pi^-\nu_\tau$ measured by Belle (Lee, 2010). Solid circles with error bars are the data with statistical errors; solid-red histogram is the spectra implemented in the current TAUOLA program; the horizontal green band at the zero entry line shows the size of the systematic uncertainties for data. (b) Comparison of $\pi^-\pi^-\pi^+$ mass spectra as a function of mass-squared between Belle (red circle) and ALEPH (black circles). (c) in log-scale, (d) the ratio ALEPH/Belle-1.

20.6.3.4 $\tau^- \to \pi^-\pi^0\eta\nu_\tau$

Using a data sample of 490 fb^{-1}, Belle has studied the $\tau^- \to \pi^-\pi^0\eta\nu_\tau$ decay where the η meson is reconstructed
Figure 20.6.4. (color online) (a) Unfolded mass spectrum $(1/N)dN/dM$ for the $K^-K^+\pi^-$ system in $\tau^- \to K^-K^+\pi^-\nu_\tau$ measured by Belle (Lee, 2010). Solid circles with error bars are the data with statistical errors; solid-red histogram is the spectra implemented in the current `TAUOLA` program; the horizontal green band at the zero entry line shows the size of the systematic uncertainties for data. (b) Comparison of the result with the theoretical model based on resonance chiral-perturbation theory. Closed circles are Belle data, red-dashed and blue-dashed lines are the axial-vector and vector components from the chiral-perturbation theory, respectively. the pink-solid line is the sum of axial-vector and vector components. While the red-solid line is the model implemented in the `TAUOLA` progarm (Gómez Dumm, Roig, Pich, and Portolés, 2010a).

through its decay into $\gamma\gamma$ or $\pi^+\pi^-\pi^0$ (Inami, 2009) and obtained the new world-average branching fraction of $(0.139 \pm 0.008)\%$. The branching fraction and the mass spectrum are compared with the prediction from the CVC theorem by Cherepanov and Eidelman (2011), using the data from the process $e^+e^- \to \eta\pi^+\pi^-$ including the recent results from *BABAR* (Aubert, 2007bb) and SND (Achasov et al., 2010) collaborations. Belle found that the expected branching fraction $(0.153\pm0.018)\%$ is compatible with the tau result and that the mass spectra of the $\eta\pi^+\pi^-$ system in e^+e^- annihilation and tau decay are consistent with the CVC expectation.

20.6.4 Hadronic spectral functions: Cabibbo-suppressed modes

(b)
Figure 20.6.5. $K_S\pi$ mass distribution measured by (a) Belle (Epifanov, 2007) and by (b) *BABAR* (Adametz, 2011). Points with error bars in both figures are data, the histogram shows the fitted result for the spectrum expected in the model incorporating the $K^*(892) + K_0^*(800) + K^*(1410)$ model. In Belle data, different types of background are also shown, while in the *BABAR* plot, the background is already subtracted.

20.6.4.1 $\tau^- \to (K\pi)^-\nu_\tau$

A data sample of 351 fb^{-1} has been used by Belle to study the $K_S\pi^-\nu_\tau$ final state (Epifanov, 2007). As a result of the analysis, 53,110 lepton-tagged signal events have been selected. The measured branching fraction obtained is

$$\mathcal{B}(\tau^- \to K_S\pi^-\nu_\tau) = (0.404 \pm 0.002 \pm 0.013)\%$$

(20.6.27)

which is the most precise among all the published measurements and is somewhat lower than all of them although within errors consistent with the other results.

An analysis of the $K_S\pi^-$ invariant mass spectrum shown in Fig. 20.6.5 (top) reveals the dominant contribution from the $K^*(892)^-$ with additional contributions of higher-mass states at 1400 MeV. A satisfactory fit is obtained only if the existence of a broad scalar state, $K_0^*(800)$, is assumed. For the first time the $K^*(892)^-$ mass and width have been measured in tau decay:

$$M(K^*(892)^-) = (895.47 \pm 0.20 \pm 0.44 \pm 0.59) \text{ MeV,}$$
$$\Gamma(K^*(892)^-) = (46.2 \pm 0.6 \pm 1.0 \pm 0.7) \text{ MeV,}$$

(20.6.28)

where the first uncertainty is the statistical and the second systematic. The third uncertainty is model-based. The $K^*(892)^-$ mass is significantly higher than the world-average value based on various hadronic experiments and is much closer to the world average for the neutral $K^*(892)$ (Nakamura et al., 2010).

Recently the *BABAR* collaboration presented the $K_S\pi^-$ invariant mass spectrum in the $K_S\pi^-\nu_\tau$ decay (Adametz, 2011). Figure 20.6.5 (bottom) shows the $K_S\pi^-$-invariant mass distribution and the fit result. The mass and width of the $K^*(892)^-$ resonance determined using a $K^*(892) + K_0^*(800) + K^*(1410)$ model yield

$$M(K^*(892)^-) = (894.57 \pm 0.19 \pm 0.19) \text{ MeV,}$$
$$\Gamma(K^*(892)^-) = (45.56 \pm 0.43 \pm 0.57) \text{ MeV.}$$

(20.6.29)

The values of the $K^*(892)^-$ mass and width obtained by the B Factories are in agreement with each other. However, it should be noted that *BABAR* did not present an uncertainty induced by the ambiguity in the model used for the mass spectrum fit.

20.6.4.2 $\tau^- \to (K\pi\pi)^-\nu_\tau$

The unfolded $K^-\pi^+\pi^-$ mass spectrum measured by Belle (Lee, 2010), shown in Fig. 20.6.6 (a), has a peak at $1.25 \text{ GeV}/c^2$ and shoulder at $1.4 \text{ GeV}/c^2$, corresponding to $K_1(1270)$ and $K_1(1400)$, respectively. The model in the `TAUOLA` reproduces the qualitative features of the mass spectra but fails to reproduce their detail.

20.6.5 Inclusive non-strange spectral function

As was discussed in Section 20.6.1.2, the inclusive non-strange (Cabibbo-favored) spectral function plays an important role for the determination of α_s and various theoretical tests of QCD in the transition region between perturbative QCD and resonances. The results obtained by
Figure 20.6.6. (color online) (a) Unfolded mass spectrum $(1/N)dN/dM$ for the $K^-\pi^+\pi^-$ system in $\tau^- \to K^-\pi^+\pi^-\nu_\tau$ measured by Belle (Lee, 2010). Solid circles with error bars are the data with statistical errors; solid-red histogram is the spectra implemented in the current `TAUOLA` program. (b) $K^-\pi^+\pi^-$ spectral function exstructed from the unfolded mass spectrum. The horizontal green band at the zero entry line shown in the both figures indicate the size of the systematic uncertainties for data.

LEP experiments are shown in Fig. 20.6.7 for the vector current, and in Fig. 20.6.8, for the axial-vector current. The statistical errors in the high mass region above $2 \text{ GeV}^2/c^4$, where perturbative QCD plays an important role, are large. Mass spectra data can contribute significantly to the improvement of our knowledge of this region. See Boito et al. (2012) for a recent discussion of the importance of the new data in this region.

20.6.6 Inclusive strange spectral functions

An accurate measurement of strange (Cabibbo-suppressed) spectral function plays an important role in the simultaneous determination of $|V_{us}|$ and the strange quark mass m_s (see Section 20.6.1.3). The strange spectral function available now is obtained from the ALEPH and OPAL experiments at LEP (see Fig. 20.6.9) and has large errors with coarse binning. Exclusive spectral functions for $K^-K^+\pi^-$ (Fig. 20.6.4 (b)) and $K^-\pi^+\pi^-$ (Fig. 20.6.6 (b)) measured by the Belle, show a significant improvement
Figure 20.6.7. Vector spectral functions measured by (a) ALEPH (Davier, Hoecker, and Zhang, 2006; Schael et al., 2005) and (b) OPAL (Ackerstaff et al., 1999) experiments.

Figure 20.6.8. Axial Vector spectral functions measured by (a) ALEPH (Davier, Hoecker, and Zhang, 2006; Schael et al., 2005) and (b) OPAL (Ackerstaff et al., 1999) experiments.

over the previous LEP experiments. The measurements for all Cabibbo-suppressed modes, and their sum, to obtain the total inclusive spectral function are in progress.

20.6.7 Search for second-class currents

Standard Model processes that are mediated by the charged hadronic weak current, such as semihadronic tau decays, produce hadronic systems with a well-defined set of allowed quantum numbers for spin, parity and G-parity. In tau decays these so-called first-class currents (Weinberg, 1958) yield hadronic systems with $J^{PG} = 0^{++}, 0^{--}, 1^{+-}$ or 1^{-+}.

The quantum numbers $J^{PG} = 0^{+-}, 0^{-+}, 1^{++}$ and 1^{--} would be associated with second-class currents. Small contributions to second-class currents, at the level of order 10^{-5} to 10^{-6}, are expected from isospin violation (and hence G-parity violation) due to the mass difference between the up and down quarks (Berger and Lipkin, 1987;

Nussinov and Soffer, 2008, 2009; Pich, 1987). However, second-class currents have not been seen to date in tau decays, nor indeed in any processes mediated by the hadronic weak current. Observation at a level significantly above that expected from isospin violation would be a signal for new physics contributions (Langacker, 1977).

Tau decay modes that have the quantum numbers associated with second-class currents include: $\tau^- \to \eta\pi^-\nu_\tau$ and $\tau^- \to \eta'(958)\pi^-\nu_\tau$, both of which correspond to $J^{PG} = 0^{+-}$ or 1^{--}; and $\tau \to \omega(782)\pi^-\nu_\tau$ with the ω and π^- in a relative S-wave or D-wave. However, the $\omega(782)\pi^-\nu_\tau$ mode is dominated by the P-wave $J^{PG} = 1^{-+}$ $\tau^- \to \rho(770)^-\nu_\tau$ and $\rho'\nu_\tau$ decays, and an angular analysis is required to search for any S-wave or D-wave (second-class) contribution.

Before the B Factory experiments, the best upper limits on second-class currents in tau decays came from CLEO for the η and η' modes (Bartelt et al., 1996) and from ALEPH for the $\omega\pi^-$ mode (Buskulic et al., 1997). *BABAR* has published results for all of the above modes, providing
Figure 20.6.9. Strange spectral functions measured by (a) ALEPH (Davier, Hoecker, and Zhang, 2006) and (b) OPAL (Abbiendi et al., 2004) experiments.

significant improvements in upper limits for the branching fractions, but continues to see no evidence for the existence of second-class currents.

The $\tau^- \to \eta\pi^-\nu_\tau$ channel has been studied by BABAR, using the $\eta \to \pi^+\pi^-\pi^0$ decay mode (del Amo Sanchez, 2011m). The basic method is to select a sample of candidate $\tau^- \to \pi^-\pi^-\pi^+\pi^0\nu_\tau$ decays and to fit the inclusive $\pi^+\pi^-\pi^0$ mass spectrum for the contribution from η. The limiting factors in this analysis are the relatively large combinatorial background in the 3π spectrum from tau decays to $\omega(782)\pi^-\nu_\tau$ and $\rho\pi\pi\nu_\tau$, and the background from $\tau^- \to \eta\pi^-\pi^0\nu_\tau$ where the additional π^0 is undetected. The former background cannot be removed without producing significant distortions of the phase space, and introducing a strong model dependence in any limit. For these reasons, the limit on the branching fraction obtained by BABAR, $< 0.9 \times 10^{-4}$ at 95% C.L., was dominated by systematic errors and represented only a small improvement over the previously existing limit from CLEO (Bartelt et al., 1996). It may be possible to improve limits further at both BABAR and Belle using the $\eta \to \gamma\gamma$ decay mode, but here again large backgrounds may be expected, particularly from $\tau^- \to \eta\pi^-\pi^0\nu_\tau$ and $\tau^- \to \pi^-\pi^0\nu_\tau$.

BABAR has also looked for the second-class current mode $\tau^- \to \eta'(958)\pi^-\nu_\tau$, with the decay mode $\eta' \to \eta\pi^+\pi^-$ and $\eta \to \pi^+\pi^-\pi^0$ (Lees, 2012z). A fit for a possible η' contribution in the inclusive $\eta\pi^+\pi^-$ mass spectrum gave no significant signal above the expected background,
Figure 20.6.10. Distribution of $\cos\theta_{\omega\pi}$ from $\tau \to \omega(782)\pi^-\nu_\tau$ events in BABAR (Aubert, 2009ap). Here $\theta_{\omega\pi}$ is the angle, in the $\omega\pi^-$ rest frame, between the normal to the $\omega \to \pi^+\pi^-\pi^0$ decay plane and the direction of the pion. The curve shows a fit to determine the relative contributions from first-class and second-class currents.

allowing a limit to be set on the branching fraction at $< 4.0 \times 10^{-6}$ at a 90% C.L.. This is the lowest limit obtained for any possible second-class decay mode of the tau and is at the level where the effects of isospin violation may be expected to appear.

Figure 20.6.10 is taken from the BABAR analysis of the channel $\tau \to \omega(782)\pi^-\nu_\tau$ (Aubert, 2009ap), and shows the distribution of $\cos\theta_{\omega\pi}$, where $\theta_{\omega\pi}$ is the angle, in the $\omega\pi^-$ rest frame, between the normal to the $\omega \to \pi^+\pi^-\pi^0$ decay plane and the direction of the pion. This distribution has been corrected for the combinatorial background, using distributions from the ω mass sidebands. The curve is a fit to a sum of S-wave and P-wave contributions. It is apparent that the data correspond to an almost pure $\sin^2\theta_{\omega\pi}$ distribution, as expected from a P-wave decay. The fit allows a limit to be put on an possible S-wave (*i.e.* second-class current) contribution to this mode at a level of < 0.0069 at a 95% C.L.. This corresponds to an absolute limit on the branching fraction for the decay $\tau \to \omega(782)\pi^-\nu_\tau$ via a second-class current of $< 1.4 \times 10^{-4}$ at 95% C.L.

20.7 Tests of CVC and vacuum hadronic polarization determination

The hypotheses of the CVC and isospin symmetry relate the isovector part of $e^+e^- \to$ hadrons and corresponding (vector current $J^P = 1^-$) hadronic decay of the tau

lepton. This follows from the deep relation between weak and electromagnetic interactions. The weak vector current and the isovector part of the electromagnetic vector current are different components of the same vector current, so that the matrix element of these currents must be identical assuming $SU(2)$ symmetry. In this case the weak isovector current is assumed to be conserved in analogy with the electromagnetic current. This assumption is the CVC hypothesis and was first introduced by Feynman and Gell-Mann into their theory of weak interaction (Feynman and Gell-Mann, 1958).

As a consequence, hadronic currents describing the Cabibbo-allowed vector part of the tau hadronic decays, such as 2π, 4π, $\pi\pi\eta$ and $\pi\omega$ channels, and low-energy e^+e^- annihilation are closely related to each other (Gilman and Rhie, 1985). In fact, this relation was used to predict the decays of a heavy lepton even before the discovery of the tau lepton (Thacker and Sakurai, 1971; Tsai, 1971).

20.7.1 CVC and vacuum hadronic polarization contribution in $(g-2)_\mu$

In addition, the CVC relations allow one to use an independent high-statistics data sample from tau decays for increasing accuracy of the prediction of the hadronic contributions to the muon anomalous magnetic moments $a_\mu = (g-2)/2$ (Alemany, Davier, and Hoecker, 1998). Here, we briefly review the basic formula required for this.

The leading-order hadronic contribution $a_\mu^{\mathrm{had,LO}}$ can be obtained by using a combination of experimental data and perturbative QCD for the hadronic vacuum polarization (HVP) of the photon. At low energies, where QCD does not provide a reliable calculation, the HVP can be obtained as a sum over the production cross section of each $e^+e^- \to X^0$ channel (Jegerlehner and Nyffeler, 2009; Miller, de Rafael, and Roberts, 2007).

$$a_\mu^{\mathrm{had,LO}}(e^+e^-) = \frac{\alpha^2}{3\pi^2} \int_{4m_\pi^2}^\infty ds \frac{K(s)}{s} R_{X^0}^{(0)}(s), \quad (20.7.1)$$

where s is the CM energy squared of the hadron system and $R_{X^0}^{(0)}$ is the ratio of hadronic X^0 to point-like $\mu^+\mu^-$ bare cross sections in e^+e^- annihilation given by

$$R_{X^0}^{(0)}(s) = \frac{3s\sigma_{X^0}(s)}{4\pi\alpha^2} = 3v_0(s). \quad (20.7.2)$$

The behavior of the QED kernel $K(s) \sim 1/s$ enhances the low-energy contributions to $a_\mu^{\mathrm{had,LO}}$ (Jegerlehner and Nyffeler, 2009).

In the limit of isospin invariance ($v_0 = v_1$) and taking into account the isospin breaking effects, the spectral function of the vector current decay $\tau \to X^- \nu_\tau$ is related to the $e^+e^- \to X^0$ cross section of the corresponding isovector final sate X^0,

$$\sigma_{X^0}(s) = \frac{4\pi\alpha^2}{s} v_{1,X^-}(s), \quad (20.7.3)$$

where s is the invariant mass squared of the tau final state X^- and α is the electromagnetic fine structure constant. The term $v_{1,X^-}(s)$ is the vector spectral function in the Cabibbo-allowed decays, which is given by

$$v_{1,X^-}(s) = 3Im\left[\Pi_V^{(1)}(s)\right]$$
$$= \frac{m_\tau^2}{6|V_{ud}|^2} \frac{\mathcal{B}_{X^-}}{\mathcal{B}_e} \frac{1}{N_X} \frac{dN_x}{ds} \quad (20.7.4)$$
$$\times \left(1 - \frac{s}{m_\tau^2}\right)^{-2} \left(1 + \frac{2s}{m_\tau^2}\right)^{-1} \frac{R_{IB}(s)}{S_{EW}},$$

where, $(1/N_X)dN_X/ds$ is the normalized invariant mass spectrum of the hadronic final state, $\mathcal{B}_{X^-}$ denotes the branching fraction of $\tau^- \to X^- \nu_\tau$. The values of other parameters, tau mass m_τ, the CKM matrix element $|V_{ud}|$ and the electron branching fraction $\mathcal{B}_e$ are known precisely.

The last term $R_{IB}(s)/S_{EW}$ represents the correction for the isospin-breaking (IB) effects. Short-distance electroweak radiative effects lead to the correction $S_{EW} = 1.0235 \pm 0.0003$ (Davier, Eidelman, Hoecker, and Zhang, 2003b). All the s-dependent isospin-breaking corrections are included in $R_{IB}(s)$. In the dominant $\pi^+\pi^-$ decay channel, $R_{IB}(s)$ is given by

$$R_{IB}(s) = \frac{FSR(s)}{G_{EM}(s)} \frac{\beta_0^3(s)}{\beta_-^3(s)} \left|\frac{F_0(s)}{F_-(s)}\right|^2, \quad (20.7.5)$$

where the subscripts $i = 0, -$ refer to the electric charge of the 2π system produced in e^+e^- annihilation, and in τ^- lepton decay, respectively. $FSR(s)$ refers to the final state radiative corrections in the $e^+e^- \to \pi^-\pi^-$ channel, and $G_{EM}(s)$ denotes the long-distance radiative corrections to the inclusive $\pi^-\pi^0$ spectrum in $\tau \to \pi^-\pi^0\nu_\tau$. The second correction of the ratio of the pion velocities, $\beta_0^3(s)/\beta_-^3(s)$, arises from $\pi^\pm - \pi^0$ mass difference. The third IB correction term $|F_0/F_-|^2$ involves the ratio of electromagnetic (F_0) to weak (F_-) form factors and needs to be considered carefully. This ratio involves two sources of IB: (a) $\rho - \omega$ mixing effects and (b) the mass and width difference of neutral and charged ρ mesons.

Taking these IB corrections into account, the shift in the lowest order hadronic contribution to the muon $g-2$ using tau data in the dominant $\pi\pi$ channel can be evaluated as

$$\triangle a_\mu^{\mathrm{had,LO}}[\pi^+\pi^-, \tau] = \frac{\alpha^2}{3\pi^2} \int_{4m_\pi^2}^\infty ds \frac{K(s)}{s} 3v_-(s)$$
$$\times \left[\frac{R_{IB}(s)}{S_{EW}} - 1\right]. \quad (20.7.6)$$

The most recent estimates for these effects are summarized in Table 20.7.1 (Castro, 2010; Davier et al., 2010). In the table, the last term, the radiative corrections for photon-inclusive $\rho \to \pi\pi$ is different from the previous estimate in (Davier, Eidelman, Hoecker, and Zhang, 2003b).

Using all available $\pi^+\pi^-$ data from tau lepton decays, ALEPH, CLEO, OPAL and Belle, and applying these IB

Table 20.7.1. Contributions to $\triangle a_\mu^{\mathrm{had,LO}}[\pi\pi,\tau](\times 10^{-10})$ from the isospin-breaking correction $R_{IB}(s)$. Corrections shown in two separate columns correspond to the results obtained using the Gounaris and Sakurai (1968)(GS), and Kuhn and Santamaria (1990)(KS) parameterization of pion form factors (Davier et al., 2010).

corrections, the lowest order hadronic contributions obtained are summarized in the 2nd column of Table 20.7.2. The new tau-based estimate of $a_\mu^{\mathrm{had,LO}}$ is found to be 1.9 σ lower than the results based on the e^+e^- data. This updated estimate makes the difference between tau and e^+e^- based estimates closer than the previous ones reported by Davier, Eidelman, Hoecker, and Zhang (2003b).

In addition to these IB corrections, the importance of the other effect that was not discussed is recently demonstrated by Jegerlehner and Szafron (2011). They argue that, in addition to $\rho - \omega$ mixing, $\rho - \gamma$ interference exists in the e^+e^- reaction and they contribute to $a_\mu^{\mathrm{had,LO}}$, but that effect does not exist in tau-lepton decays. The size of the $\rho - \gamma$ interference effects is about 5% to 10% in the ρ-resonance region and changes the sign in the lower and upper side of the ρ mass peak (see Fig.6 in Jegerlehner and Szafron (2011)). After taking this effect into account, the results of $a_\mu^{\mathrm{had,LO}}$ obtained from e^+e^--based and tau-based data are summarized in the 3rd column of Table 20.7.2. The table shows a good agreement between the e^+e^- and tau-based results, if the $\rho - \gamma$ effects are taken into account. A similar estimation based on a Hidden Local Symmetry model is given by Benayoun, David, DelBuono, and Jegerlehner (2012). To confirm this interesting proposal, further investigation at the higher 2π mass region as well as precise experimental tests of the CVC relation for other modes such as 4π, $\omega\pi$ and $\eta\pi\pi$ are important.

20.7.2 CVC and $\pi\pi$ branching fraction

The CVC relation allows one to predict the branching fraction of the decay $\tau \to \pi\pi^0\nu_\tau$ ($\mathcal{B}_{\pi\pi}$) in terms of the isovector part of the $e^+e^- \to \pi^+\pi^-$ cross section after taking into account the IB correction:

$$\mathcal{B}_{\pi\pi}^{CVC} = \frac{3}{2}\frac{\mathcal{B}_e|V_{ud}|^2}{\pi\alpha^2 m_\tau^2}\int_{s_{min}}^{m_\tau^2} ds \; s\sigma_{\pi^+\pi^-}^0(s)$$

Table 20.7.2. $a_\mu^{\mathrm{had,LO}}[ee]$	690.9 ± 5.2	690.8 ± 4.7
$a_\mu^{\mathrm{had,LO}}[\tau,ee]$	705.3 ± 4.5	691.0 ± 4.7

$$\times \left(1 - \frac{2}{m_\tau^2}\right)^2 \left(1 + \frac{2s}{m_\tau^2}\right)\frac{S_{EW}}{R_{IB}}, \quad (20.7.7)$$

where $s_{min} = (m_{\pi^-} + m_{\pi 0})^2$. The meaning of the other parameters is the same as for Eq. (20.7.5). The result using all e^+e^- data including recent *BABAR* (Lees, 2012n) and KLOE (Ambrosino et al., 2009a; Babusci et al., 2013) results is

$$\mathcal{B}_{\pi\pi}^{CVC} = (24.78 \pm 0.17 \pm 0.22)\%, \quad (20.7.8)$$

while the average of the measured $\mathcal{B}_{\pi\pi}$ is $(25.42 \pm 0.10)\%$ (Davier et al., 2010). The difference is $(0.64 \pm 0.10 \pm 0.28)\%$, which is still substantial, but less significant than the previous results (Davier, Eidelman, Hoecker, and Zhang, 2003b).

If the $\rho - \gamma$ mixing effect is included, the result is $\mathcal{B}_{\pi\pi}^{CVC} = (25.20 \pm 0.17 \pm 0.28)\%$ (Jegerlehner and Szafron, 2011), which is in good agreement with the measured branching fraction.

20.8 Measurement of $|V_{us}|$

Here we describe three ways to determine $|V_{us}|$ using tau decays : $\mathcal{B}(\tau^- \to K^-\nu_\tau)$, $\mathcal{B}(\tau^- \to K^-\nu_\tau)/\mathcal{B}(\tau^- \to \pi^-\nu_\tau)$, and the inclusive sum of tau branching fractions having net strangeness of unity in the final state:

1) We use the lattice QCD value of the kaon decay constant $f_K = 157 \pm 2\,\mathrm{MeV}$ (Follana, Davies, Lepage, and Shigemitsu, 2008), and our value of

$$\mathcal{B}(\tau^- \to K^-\nu_\tau) = \frac{G_F^2 f_K^2 |V_{us}|^2 m_\tau^3 \tau_\tau}{16\pi\hbar}$$
$$\times \left(1 - \frac{m_K^2}{m_\tau^2}\right)^2 S_{EW}, \quad (20.8.1)$$

where $S_{EW} = 1.0201 \pm 0.0003$ (Erler, 2004), to determine $|V_{us}| = 0.2204 \pm 0.0032$ from results of the unitarity constrained fit. This value is consistent with the estimate of $|V_{us}| = 0.2255 \pm 0.0010$ obtained using the unitarity constraint on the first row of the CKM matrix.

2) We use $f_K/f_\pi = 1.189 \pm 0.007$ from lattice QCD (Follana, Davies, Lepage, and Shigemitsu, 2008), $|V_{ud}| =$

0.97425 ± 0.00022 (Hardy and Towner, 2009), and the long-distance correction $\delta_{LD} = (0.03 \pm 0.44)\%$, estimated (Banerjee, 2008) using corrections to $\tau \to h\nu_\tau$ and $h \to \mu\nu_\mu$ (Decker and Finkemeier, 1994, 1995; Marciano, 2004; Marciano and Sirlin, 1993), for the ratio

$$\frac{\mathcal{B}(\tau^- \to K^- \nu_\tau)}{\mathcal{B}(\tau^- \to \pi^- \nu_\tau)} = \frac{f_K^2 |V_{us}|^2}{f_\pi^2 |V_{ud}|^2} \frac{\left(1 - \frac{m_K^2}{m_\tau^2}\right)^2}{\left(1 - \frac{m_\pi^2}{m_\tau^2}\right)^2} (1 + \delta_{LD}),$$

$$(20.8.2)$$

where short-distance electroweak corrections cancel in this ratio.

From the unitarity constrained fit, we obtain $\mathcal{B}(\tau^- \to K^- \nu_\tau)/\mathcal{B}(\tau^- \to \pi^- \nu_\tau) = 0.0643 \pm 0.0009$, which includes a small correlation (coefficient of -0.5%) between the branching fractions. This yields $|V_{us}| = 0.2229 \pm 0.0021$, which is also consistent with the value of $|V_{us}|$ from the CKM unitarity prediction.

3) The total hadronic width of the τ normalized to the electronic branching fraction, $R_{\mathrm{had}} = \mathcal{B}_{\mathrm{had}}/\mathcal{B}_{\mathrm{e}}$, can be written as $R_{\mathrm{had}} = R_{\mathrm{non-strange}} + R_{\mathrm{strange}}$. We can then measure

$$|V_{us}| = \sqrt{R_{\mathrm{strange}} / \left[\frac{R_{\mathrm{non\text{-}strange}}}{|V_{ud}|^2} - \delta R_{\mathrm{theory}}\right]}.$$

$$(20.8.3)$$

Here, we use $|V_{ud}| = 0.97425 \pm 0.00022$ (Hardy and Towner, 2009), and $\delta R_{\mathrm{theory}} = 0.240 \pm 0.032$ (Gamiz, Jamin, Pich, Prades, and Schwab, 2007) obtained with the updated average value of $m_s(2\,\mathrm{GeV}) = 94 \pm 6$ MeV (Jamin, Oller, and Pich, 2006), which contributes to an error of 0.0010 on $|V_{us}|$. We note that this error is equivalent to half the difference between calculations of $|V_{us}|$ obtained using fixed order perturbation theory and contour improved perturbation theory calculations of $\delta R_{\mathrm{theory}}$ (Maltman, 2010), and twice as large as the theoretical error proposed in Gamiz, Jamin, Pich, Prades, and Schwab (2008).

As in Davier, Hoecker, and Zhang (2006), we improve upon the estimate of the electronic branching fraction by averaging its direct measurement with its estimates of $(17.899 \pm 0.040)\%$ and $(17.794 \pm 0.062)\%$ obtained from the averaged values of muonic branching fractions and the averaged value of the lifetime of the tau lepton $= (290.6 \pm 1.0) \times 10^{-15}$ s (Nakamura et al., 2010), assuming lepton universality and taking into account the correlation between the leptonic branching fractions. This gives a more precise estimate for the electronic branching fraction: $\mathcal{B}_{\mathrm{e}}^{\mathrm{uni}} = (17.852 \pm 0.027)\%$.

Assuming lepton universality, the total hadronic branching fraction can be written as: $\mathcal{B}_{\mathrm{had}} = 1 - 1.972558\, \mathcal{B}_{\mathrm{e}}^{\mathrm{uni}}$, which gives a value for the total τ hadronic width normalized to the electronic branching fraction as $R_{\mathrm{had}} = 3.6291 \pm 0.0086$.

The non-strange width is $R_{\mathrm{non-strange}} = R_{\mathrm{had}} - R_{\mathrm{strange}}$, where the estimate for the strange width $R_{\mathrm{strange}} = $

0.1613 ± 0.0028 is obtained from the sum of the strange branching fractions with the unitarity constrained fit as listed in Table 199 in the HFAG report (Amhis et al., 2012). This gives a value of $|V_{us}| = 0.2174 \pm 0.0022$, which is 3.3 σ lower than the CKM unitarity prediction.

A similar estimation using results from the unconstrained fit to the branching fractions gives $|V_{us}| = 0.2166 \pm 0.0023$, which is 3.6 σ lower than the CKM unitarity prediction. Since the sum of base modes from our unconstrained fit is less than unity by 1.6 σ, instead of using $\mathcal{B}_{\mathrm{non-strange}} = 1 - \mathcal{B}_{\mathrm{leptonic}} - \mathcal{B}_{\mathrm{strange}}$, we also evaluate $|V_{us}|$ from the sum of the averaged non-strange branching fractions. This gives $|V_{us}| = 0.2169 \pm 0.0023$, which is 3.5 σ lower than the CKM unitarity prediction.
Figure 20.8.1. Measurements of $|V_{us}|$ from kaon, hyperon and tau decays (Asner et al., 2010).

A summary of these $|V_{us}|$ values is shown in Figure 20.8.1, where we also include values from kaon decays obtained from Antonelli et al. (2010b) and from hyperon decays obtained from Jamin (2007). The $|V_{us}|$ determination from hyperon decays was done in Mateu and Pich (2005).

20.9 Summary of the tau section

In summary, B Factory experiments contribute to various aspects of physics related to tau leptons: The tau mass

is measured with an accuracy of 0.15 MeV, and the mass difference of τ^+ and τ^- is tested at the level of 0.03%. The charged current universality is tested at the level of $0.1 - 0.2$ %. Two orders of magnitude more stringent limits are set for 50 lepton flavor violating tau-lepton decays. Measurements of the tau-EDM and tau mass-difference are improved significantly. For the *CP* violation of tau-lepton decays, the *BABAR* result shows a 2.8σ deviation from the Standard Model prediction for $\tau^- \to K_S^0 \pi^- \nu_\tau$, while Belle find no indication of *CP* asymmetry in the decay angular distribution.

The hadronic tau decays provide a beautiful laboratory to measure the CKM matrix V_{us} and to study the strong interactions. The values of V_{us} have been estimated via various methods. The value derived from the inclusive strange branching fraction provides a result somewhat smaller than the one obtained from kaon decays. The branching fractions and the precise spectral functions have been measured for various decay modes. The second-class current has been searched for at the level of $< 4.0 \times 10^{-6}$ in the mode $\tau \to \eta'(958)\pi^- \nu_\tau$.

Yet, there are several on-going analyses, which include precise measurements of the tau-lepton lifetime, Michel parameters and Cabibbo-allowed and Cabibbo-suppressed inclusive spectral functions.

In addition, a set of form factors based on "Resonance Chiral Theory"($R\chi T$) is recently implemented in the `TAUOLA` MC program (Shekhovtsova, Przedzinski, Roig, and Wąs, 2012). The formulae of $R\chi T$ is designed to reproduce chiral perturbation theory at the low energy limit and has a smooth transition to the perturbative QCD results in the high energy region. They rely on the large-N_C expansion of QCD. It is nice since these formulae are designed so that one can fit the data without violating the basic requirements of QCD. Tests of $R\chi T$ and the determination of the model parameters by the data may provide a new insight into the resonance region from QCD (see references in Shekhovtsova, Przedzinski, Roig, and Wąs (2012) for detailed discussion).

In the near future, an additional two orders of magnitude increase in available data sets is expected to be accumulated by future flavor factories.

Chapter 21
Initial state radiation studies

21.1 Introduction

Low energy e^+e^- annihilation are among the most powerful ways to study the nature of hadrons, because of the very clean environment — with the perfectly known initial state and the low multiplicity of the produced final states — as has been shown since the first e^+e^- accumulation ring, ADA, was built in Frascati (Bernardini, Corazza, Ghigo, and Touschek, 1960; Cabibbo and Gatto, 1961).

At low energies, the hadrons observed in the final state come from the hadronization of the original quark pair produced by the e^+e^- annihilation via a single intermediate virtual photon. The process of hadronization is well described by Quantum Chromodynamics (QCD) for a relatively high center-of-mass (CM) energy of the e^+e^- system. However, QCD fails to describe the low energy region, which is characterized by intense final state interactions and rich production of resonant states. Experimental data in this energy region are of fundamental importance both as an input and as validation for the various QCD-based theoretical models of hadronic interactions.

The total cross section of e^+e^- annihilation into hadrons is also the experimental input to the calculation of the hadronic contribution to both the anomalous magnetic moment of the muon and the value of the running fine-structure constant at the Z^0 pole. Therefore, it provides high precision tests of the Standard Model and searches for New Physics effects.

Studies of the nature of known light and heavy vector mesons, and searches for new resonant states, can be performed measuring exclusive final states over a wide energy range.

A novel method of studying e^+e^- annihilation using initial state radiation (ISR) has been developed in the last decade at various high-luminosity e^+e^- colliders. Most of the results presented in this chapter rely on the ISR technique (exceptions include $D^{(*)+}D^{(*)-}$ production far from threshold, Section 21.4.1, and dark force searches, Section 21.6). The experimental method, with its theoretical foundations, is described in the next section. Section 21.3 reports on the measurement of a number of light meson final states, with implications for the value of $(g-2)_\mu$ discussed in Section 21.3.2. Measurements of time-like baryon form factors are presented in Section 21.3.7,

while Sections 21.4 and 21.5 report on the studies of open-charm production via e^+e^- annihilation and the searches for new, possibly exotic, vector states, respectively. A detailed discussion of the results of these two sections can be found in sections 18.2 and 18.3. Finally, Section 21.6 presents a search for e^+e^- annihilation into multi-lepton final states at a CM energy of ~ 10.6 GeV, which could be a manifestation of dark boson decays.

21.2 The Initial State Radiation method

The e^+e^- annihilation process is described at lowest order by the Feynman diagram shown in Fig. 21.2.1. The center-of-mass energy squared is given by $s = 4E_b^{*2}$, for a collider operating with beams of CM energy E_b^*. Exclusive and total hadronic cross sections as a function of s have usually been obtained by scanning the accessible energy range, and collecting a certain amount of data at each value of the beam energies.
Figure 21.2.1. The lowest-order Feynman diagram describing the process of e^+e^- annihilation into hadrons.

However, the colliding electrons can emit one or several photons from the initial state, so that the effective CM energy of the e^+e^- collision can take any value from m_{th}, the production threshold of the hadronic system, up to $\sqrt{s} = 2E_b^*$. The process effectively studied is thus $e^+e^- \to f + n\gamma$, $n = 0, 1, 2, ...$, where f is a given final state; the cross section depends on the Born cross section at all energies below $\sqrt{s}$ (Kuraev and Fadin, 1985):

$$\sigma(s) = \int_0^{1-m_{\text{th}}^2/s} W(s,x)\, \sigma_0(s(1-x))\, dx\,. \qquad (21.2.1)$$

Here, x is the fraction of the beam energy carried by the photons emitted from the initial state, the radiator function $W(s,x)$ is the photon emission probability density function, which is fully calculable in QED (see *e.g.* Actis et al. (2010) and references therein), and $\sigma_0(s(1-x))$ is the Born cross section for the process $e^+e^- \to f$ at the reduced center-of-mass energy squared

$$s' = s(1-x)\,. \qquad (21.2.2)$$

In energy-scan experiments, the contribution of ISR is normally suppressed by requiring energy and momentum balance between the final hadronic state and the initial e^+e^- state. This limits the fraction of energy carried by radiated photons within the experimental resolution, and Eq.(21.2.1) can then be written as

$$\sigma(s) = \sigma_0(s)\,(1 + \delta(s)), \qquad (21.2.3)$$

where the factor $1 + \delta(s)$ summarizes the QED radiative corrections, which can be as large as 10% for slowly varying cross sections.

On the other hand, the emission of initial state radiation allows the study of e^+e^- annihilation for a continuous spectrum of energies below the nominal beam energy, without changing the operating conditions of the collider, as outlined long ago (Baier and Khoze, 1965; Bonneau and Martin, 1971). This becomes clear when we write the differential form of the cross section

$$\frac{d\sigma(s,x)}{dx} = W(s,x)\,\sigma_0(s(1-x)), \qquad (21.2.4)$$

and note that the reduced CM energy after photon emission is just the invariant mass of the hadronic system: $m = \sqrt{s(1-x)}$. In terms of m, the differential cross section becomes

$$\frac{d\sigma(s,m)}{dm} = \frac{2m}{s}\,W(s,m)\,\sigma_0(m). \qquad (21.2.5)$$

It should also be noted that the dominant contribution from ISR processes comes from the diagram shown in Fig. 21.2.2, with a single photon emitted. From the experimental point of view, the Born differential cross section for the process $e^+e^- \to f$ as a function of m is obtained from the measurement of the cross section for $e^+e^- \to \gamma_{\mathrm{ISR}} + f$.
Figure 21.2.2. The lowest-order Feynman diagram describing the process of $e^+e^- \to \gamma_{\mathrm{ISR}} + $ hadrons.

The experimental method, and the potential for precise measurements of the hadronic cross sections and for low-energy spectroscopy at the forthcoming ϕ- and B Factories, were discussed in several papers at the end of the 90's: Arbuzov, Kuraev, Merenkov, and Trentadue (1998); Benayoun, Eidelman, Ivanchenko, and Silagadze (1999); Binner, Kühn, and Melnikov (1999); Konchatnij and Merenkov (1999). The high luminosities reached in these colliders provide substantial datasets despite the suppression due to the additional QED vertex in Fig. 21.2.2.

21.2.1 Radiator function and Monte Carlo generators

The dependence of the radiator function on the polar angle of the ISR photon with respect to the beam axis in the CM system is given at lowest order by (Bonneau and Martin, 1971)

$$W_0(s,x,\theta) = \frac{\alpha}{\pi x}\left[\frac{(2-2x+x^2)\sin^2\theta - \frac{x^2}{2}\sin^4\theta}{\left(\sin^2\theta + \frac{4m_e^2}{s}\cos^2\theta\right)^2}\right.$$
$$\left. - \frac{4m_e^2}{s}\frac{(1-2x)\sin^2\theta - x^2\cos^4\theta}{\left(\sin^2\theta + \frac{4m_e^2}{s}\cos^2\theta\right)^2}\right], \quad (21.2.6)$$

where α is the fine-structure constant, and m_e is the electron mass. The ISR photons are emitted predominantly at small angles, however a significant fraction of them have large angles. In particular, at CM energies $\sqrt{s} \sim 10$ GeV more than 10% of the high-energy ISR photons are emitted within the fiducial volume of the detector. These features provide the basis for two different experimental approaches to the study of ISR processes: The *tagged* approach, with detection of the ISR photon, and the *untagged* one, where the detection of the ISR photon is not explicitly required. These two approaches will be discussed in detail in Section 21.2.4.

The radiator function at lowest order is obtained by integration of Eq.(21.2.6) over the polar angle in the CM frame, in the range appropriate to the experimental situation. In the tagged approach, $\theta_0 < \theta < \pi - \theta_0$, where $\theta_0 \gg m_e/\sqrt{s}$ is chosen to cover the fiducial volume of the electromagnetic calorimeter. Writing $C = \cos\theta_0$, the radiator function becomes

$$W_0(s,x,\theta_0) = \frac{\alpha}{\pi x}\left[(2-2x+x^2)\ln\frac{1+C}{1-C} - x^2C\right], \quad (21.2.7)$$

while for an untagged analysis $(0 < \theta < \pi)$

$$W_0(s,x) = \frac{\alpha}{\pi x}(2-2x+x^2)\left[\ln\frac{s}{m_e^2} - 1\right]. \qquad (21.2.8)$$

Radiative corrections to W_0 are as large as 15% (Kuraev and Fadin, 1985). It is therefore necessary to include higher-order diagrams to reach the desired level of accuracy in the calculation of $W(s,x)$. The study of radiative corrections to ISR processes has been pursued in several theoretical works, some of which have been used as the basis for Monte Carlo (MC) generators to be used in analysis of experimental data.

Two different MC generators are used at the B Factories: `AfkQed` and `PHOKHARA` . The `AfkQed` package is based on the `EVA` event generator (Binner, Kühn, and Melnikov, 1999; Czyz and Kühn, 2001). It was initially designed to simulate 2π and 4π production with the ISR photon emitted at large angles. Soft multi-photon emission in the initial state is generated with the structure function technique (Caffo, Czyz, and Remiddi, 1994), while final state radiation (FSR) is generated using the `PHOTOS` simulation

package (Barberio, van Eijk, and Wąs, 1991). The `AfkQed` package provides the generation of a number of hadronic final states, including $\pi^+\pi^-$, $\pi^+\pi^-\pi^0$, 4π, 5π, 6π, and modes with kaons and light baryons. Additional modes can be easily implemented. It also includes the process $e^+e^- \rightarrow \mu^+\mu^-\gamma$, for which both ISR and FSR diagrams and their interference are taken into account. This generator is used by *BABAR*, for all the analyses where a tagged ISR photon is required. In order to properly calculate the radiator function the ISR photon is generated in an angular range slightly larger than the acceptance of the electromagnetic calorimeter, typically with $20° < \theta < 160°$. The achieved accuracy, of the order of 1%, is sufficient for all the measured final states, with the exception of the $\pi^+\pi^-$ channel, for which sub-percent precision is required. This particular case will be discussed in detail in Section 21.3.3

The `PHOKHARA` event generator is based on theoretical work by Rodrigo, Czyz, Kühn, and Szopa (2002) and Czyz, Grzelinska, Kühn, and Rodrigo (2003). The calculations include one-loop corrections and next-to-leading order (NLO) ISR radiative corrections: that is, up to two hard ISR photons are generated. For the processes $e^+e^- \rightarrow \pi^+\pi^-\gamma$, $e^+e^- \rightarrow K^+K^-\gamma$, and $e^+e^- \rightarrow \mu^+\mu^-\gamma$, NLO FSR corrections are also implemented, with interference between ISR and FSR. The accuracy in the determination of the radiator function is estimated to be about 0.5%. The `PHOKHARA` generator is used for both tagged and untagged ISR studies, and it is particularly appropriate for measurement of the $\pi^+\pi^-$ and K^+K^- final states. It is used in both *B* Factory experiments, as well as in the KLOE experiment at the ϕ factory DAΦNE.

In the latest `PHOKHARA` version, several multi-hadron final states are implemented. However it should be noted that for these more complex channels the main theoretical uncertainty does not come from the treatment of the radiative corrections, but from the dependence of the matrix element on the hadronic model used to describe the process. Detection efficiencies estimated via MC simulation depend in fact on the angular and momentum distributions generated by the chosen model. In order to determine a systematic uncertainty due to the model dependence, the hadron distributions from MC simulations are reweighted with those from data, and the detection efficiencies resulting from different theoretical models are compared.

21.2.2 Cross section

Experimentally, the Born cross section as a function of m for the process $e^+e^- \rightarrow f$, $\sigma_0(m)$, is obtained from the measured mass spectrum of the corresponding ISR process $e^+e^- \rightarrow \gamma_{\text{ISR}}f$, taking into account the detection efficiency $\varepsilon(s,m)$, and the integrated luminosity $\mathcal{L}$:

$$\frac{dN(s,m)}{dm} = \varepsilon(s,m)\,\frac{d\sigma(s,m)}{dm}\,\mathcal{L}. \qquad (21.2.9)$$

Replacing the differential cross section by the expression in Eq. (21.2.5), we obtain

$$\frac{dN(s,m)}{dm} = \varepsilon(s,m)\,(1+\delta_r(s,m))\,\sigma_0(m)\,\frac{d\mathcal{L}_{\text{ISR}}(m)}{dm},$$
$$(21.2.10)$$

where $1 + \delta_r(s,m) = W(s,m)/W_0(s,m)$ is the radiative correction factor mentioned in the previous subsection, and we have introduced the so-called effective ISR differential luminosity:

$$\frac{d\mathcal{L}_{\text{ISR}}(m)}{dm} = \frac{2m}{s}\,W_0(s,m)\,\mathcal{L}. \qquad (21.2.11)$$

The Born radiator function is given by Eq.(21.2.7) or Eq.(21.2.8) depending on the experimental conditions.

The mass spectrum is then subdivided in small mass bins of width Δm, within which both W and σ_0 vary little, and the cross section is extracted for each bin from the number of events ΔN falling in that bin:

$$\sigma_0(m_i) = \frac{\Delta N(m_i)}{\Delta m}\,\frac{1}{\varepsilon(s,m_i)\,(1+\delta_r)\,d\mathcal{L}_{\text{ISR}}(m_i)/dm}. \qquad (21.2.12)$$

The ISR luminosity is the quantity to be compared with the luminosity integrated by previous experiments via conventional energy scan. The solid line in Fig. 21.2.3 reports the mass dependence of the ISR differential luminosity calculated at an e^+e^- CM energy of 10.58 GeV, for a tagged analysis, assuming a typical acceptance of 10% and the integrated luminosity of the *BABAR* data set of 470 fb^{-1}. The ISR luminosity, calculated considering an energy-bin width of 0.02 GeV, increases from about 0.2 pb^{-1} at the $\pi^+\pi^-$ production threshold up to more than 3 pb^{-1} at 3.5 GeV. Only part of this range has been covered by energy scans at previous experiments. In particular the region below $\sqrt{s} = 1.4$ GeV has been investigated with high precision by the SND and CMD-2 experiments at the VEPP-2M collider in Novosibirsk. They have collected a sample similar in size to that available at *BABAR*, in particular in the regions around the peaks of the vector meson resonances. There is much less data available at energies above 1.4 GeV, most of it collected by the experiments DM1 and DM2 at the DCI collider in Orsay. The histograms in the figure report the luminosity integrated by CMD-2 and DM2. Precise measurements of the $e^+e^- \rightarrow \pi^+\pi^-$ cross section have also been performed by the KLOE experiment by means of both ISR untagged and tagged analyses. Information about the data collected by energy scan experiments has been extracted from several published papers, whose main results are reported in comparison with *B* Factories results in the following sections.

In the mass region of charm production the ISR luminosity ranges from tens to hundreds of pb^{-1} per 100 MeV/c^2 wide mass bin, significantly exceeding the integrated luminosity collected by direct e^+e^- experiments. By comparison the recent CLEO-c (Cronin-Hennessy et al., 2009) energy scan collected a total of 60 pb^{-1} in twelve points between 3.97 and 4.26 GeV, and BESIII ac-
Figure 21.2.3. *BABAR* ISR luminosity versus equivalent CM energy calculated in energy bins 20 MeV wide, for an integrated machine luminosity of 470 fb^{-1} and an angular acceptance for the ISR photon between 0.35 and 2.4 rad. For comparison, the histogram reports the luminosity integrated by the CMD-2 and DM2 experiment with a conventional energy scan, at energies below and above 1.4 GeV, respectively; these data are presented in many separate papers, as discussed in the text. The two high, narrow peaks correspond to the energy regions around the mass of the ρ and ϕ resonances, where most of the data were collected.

cumulated 53 pb^{-1} data at 3.900 GeV and 482 pb^{-1} data at 4.009 GeV (Ablikim et al., 2013b).

In conclusion, the current data samples of ISR events available at the *B* Factories are larger than those produced directly in e^+e^- collisions for all masses with the exceptions of the regions around the narrow resonances (ω, ϕ, J/ψ, and $\psi(2S)$). In particular, the data in the mass regions above 1.4 GeV/c^2 for light quarks, and in the charm region, are unique both in terms of quantity and quality.

21.2.3 Mass resolution and energy scale

Mass resolution and absolute energy scale have to be kept under control in order to assess the accuracy of the cross sections measured with the ISR method.

The mass resolution is determined by the precision of the measurement of the parameters (angles and momenta) of the reconstructed tracks, and of the energy and direction of the photons from π^0 and η decays. It is therefore expected that the mass resolution is best in the vicinity of the production threshold, due to the lower particle momenta, and degrades with increasing mass. The mass resolution is measured with simulated events, fitting the distribution of the difference between the reconstructed and generated invariant masses. It is then checked with

experimental data by fitting the line shape of narrow resonances, such as the ϕ or the J/ψ.

For multi-hadron systems with only charged particles, typical values of the invariant mass resolution obtained at the *B* Factories range from 4 up to 7 MeV/c^2, when the mass increases from 1.5 to 3 GeV/c^2. The presence of neutral pions worsens the resolution by a few MeV/c^2. The width of the mass bin chosen for the majority of the analyses in this energy region is 25 MeV/c^2, reducing in this way the effect of the mass resolution on the measured mass spectrum. A bin size of only 2 MeV/c^2 has been used by *BABAR* for the $\pi^+\pi^-$ final state close to the peak of the ρ meson (Aubert, 2009ah), requiring a specific procedure for unfolding the resolution effects from the $\pi^+\pi^-$ mass-spectrum (Malaescu, 2009). A small bin size of 5 MeV/c^2 was also used for the process $e^+e^- \to p\bar{p}\gamma$ in the $p\bar{p}$ mass region close to the production threshold, where the resolution is less than 2 MeV/c^2, as shown in Fig. 21.2.4, allowing the study of the proton electromagnetic form factor with unprecedented accuracy (Aubert, 2005ah; see also the discussion in Section 21.3.7.3 below). In the charm mass region, the final-state hadrons have smaller momenta, and the mass resolution is of the order of 5 MeV/c^2, which is much smaller than the typical bin sizes used of 20–25 MeV/c^2.
Figure 21.2.4. Mass resolution of the $p\bar{p}$ system as a function of the reconstructed $p\bar{p}$ mass obtained by *BABAR* for the process $e^+e^- \to p\bar{p}\gamma_{\rm ISR}$. *BABAR* internal, prepared for (Aubert, 2006d) analysis.

The absolute mass scale is calibrated by comparison of the reconstructed mass values for known resonances with their nominal peak positions. In all cases a relative accuracy significantly better than 10^{-3} has been measured.

21.2.4 Comparison of tagged and untagged ISR measurements with direct e^+e^- measurements

As already outlined, analyses of processes with hard photon emission in the initial state can be performed with or without detection of the ISR photon. In this section we discuss the general features of the two approaches, and compare them to direct e^+e^- measurements.

One of the main issues with measurements of exclusive cross sections at e^+e^- experiments is that each collider is able to scan only a limited range of center-of-mass energies. Significant normalization uncertainties are therefore present when data from different experiments, or even data from the same experiment at different energies, are combined. In the ISR technique, by contrast, exclusive cross sections are measured simultaneously over a continuous and very wide range of energies, with the same experimental conditions.

The requirement that the ISR photon is emitted within the detector angular acceptance results in an efficiency loss of about an order of magnitude relative to the full ISR production. In some cases, tagging of the ISR photon allows for analyses with partial reconstruction of the hadronic system, increasing the global detection efficiency while keeping the background at an affordable level.

In untagged analyses, the detection of the ISR photon is not required, while the hadronic system must be fully reconstructed. The detection efficiency is typically higher in this case with respect to the tagged analyses; however this is not true for all experimental conditions. In particular, for low invariant masses the hadronic system is subject to a strong boost, and the hadrons are produced in a narrow cone centered around the direction opposite to the ISR photon momentum. As a consequence, most of the events with the ISR photon emitted roughly collinear with the beam axis are rejected also in the case of an untagged analysis, because a fraction of the hadrons falls outside the detector acceptances. The overall detection efficiencies are therefore very similar for the tagged and untagged approach up to an invariant mass of about $3-3.5 \,\text{GeV}/c^2$, where the final state hadrons are emitted at large enough angles to be within the angular acceptance of the calorimeter and tracking system, and the small-angle ISR begins to contribute significantly.

The previous considerations about detection efficiencies constitute the main reason why, at the B Factories, the untagged approach is used for measurements of exclusive cross sections of hadronic final states with an invariant mass above 3.5 GeV/c^2, in particular to study the production of open charm and charmonium. By contrast, all the studies of e^+e^- annihilation into light hadrons are performed requiring the detection of the ISR photon.

In ISR events, the final state hadrons have a measurable momentum even at production threshold, because of the boost of the hadronic system recoiling against the radiated high-energy photon. As a consequence, the detection efficiency differs from zero at threshold and, generally, varies smoothly over the whole measured range of invariant masses, unlike in direct e^+e^- measurements where the detection efficiency drops to zero close to threshold. As

an example, Fig. 21.2.5 shows the detection efficiency as a function of the $p\bar{p}$ mass, obtained at BABAR for the process $e^+e^- \to p\bar{p}\gamma_{\text{ISR}}$ with the photon detected (Aubert, 2006d).
Figure 21.2.5. The detection efficiency, as measured by BABAR for the process $e^+e^- \to p\bar{p}\gamma_{\text{ISR}}$ in a tagged analysis, varies slowly as a function of the reconstructed $p\bar{p}$ mass (Aubert, 2006d).

As we have already observed, for tagged ISR analyses the hadrons, produced in a cone around the direction opposite to the tagged photon, generally fall in an instrumented region of the detector. The detection efficiency is thus only weakly dependent on the final state hadrons' angular distribution in the reference frame where the hadronic system is at rest, and the uncertainties related to the theoretical models used for simulation are significantly reduced. This is in contrast with both untagged ISR analyses and direct e^+e^- measurements, for which the region at small polar angles is largely inaccessible.

There are also prices to pay for using the ISR technique. As discussed in Section 21.2.3, a good mass resolution and absolute mass scale are obtained in ISR analyses, but in direct e^+e^- measurements these quantities are given respectively by the beam energy spread and by the beam energy setting, which are determined far more precisely.

The sources of background events for ISR measurements are significantly larger than those for direct e^+e^- measurements. In the latter case, the main backgrounds to a given final state come from other $e^+e^- \to hadrons$ reactions, due to undetected low momentum particles or to wrong particle identification, but such backgrounds are limited by the requirement of four-momentum conservation. For ISR events, a source of background of the same kind is due to mis-reconstructed events from other ISR processes where one or more particles escape detection. The constraint of four-momentum conservation is much less effective in this case because of the relatively poor resolution on the measurement of the energy of the ISR

photon and the emission of secondary photons, which degrade the kinematic fits in both the tagged and untagged analyses.

A background source affecting mainly the tagged analyses comes from e^+e^- annihilations at full energy (that is, without the emission of an ISR photon) but containing a high-energy π^0. If the π^0 is not correctly reconstructed because the two decay-photons are not resolved and therefore *merged* by the reconstruction algorithm, or one of them is undetected, the process $e^+e^- \to X\pi^0$ can mimic the ISR process $e^+e^- \to X\gamma_{\text{ISR}}$. The contribution of this background to distributions needed in an analysis is estimated for each process from generic light quark continuum MC samples using for normalization a sample of $e^+e^- \to X\pi^0$ with a reconstructed π^0 selected from data. The background contribution is then subtracted. This is the dominant source of background at masses of the hadronic system higher than about 2 GeV/c^2, and limits the measurable mass range for light hadron final states to $m < 4.0$–4.5 GeV/c^2.

For untagged analyses, the background due to non-ISR events only partially reconstructed can be suppressed by requiring that the missing momentum of the event is collinear with the beam axis. Another significant source of background for untagged analysis is due to two-photon processes $e^+e^- \to e^+e^-\gamma^*\gamma^* \to e^+e^-X$, where the colliding electron and positron are scattered predominantly at small angles, and are therefore undetected (see Chapter 22 for a discussion of the two-photon reactions). In such events the missing momentum is roughly along the beam axis, but the missing mass is large, so effective suppression of this kind of background is obtained requiring a missing mass close to zero, as expected if the only missing particle is the hard ISR photon.

21.3 Exclusive hadronic cross-sections

The precision of the Standard Model calculation of the muon anomalous magnetic moment is limited by the uncertainty on the hadronic contribution; for many years this contribution was determined using only data from e^+e^- scan experiments (Davier, Eidelman, Hoecker, and Zhang, 2003b). The discrepancy between $(g-2)_\mu$ calculations and the direct measurement by the E821 experiment (Bennett et al., 2006), on the order of three standard deviations, called for new and more precise measurements of the e^+e^- hadronic cross section.

This has been the main physics motivation for the intensive *BABAR* program of measurements of exclusive e^+e^- annihilation to light-quark hadrons, using ISR. In addition, the large data sample and good detector performance enable spectroscopic studies of unprecedented accuracy in the energy region below 3 GeV.

Many final states have already been studied at *BABAR*: from $\pi^+\pi^-$ (Aubert, 2009ah), the most important channel for $(g-2)_\mu$, to almost all of the possible channels with up to six hadrons in the final state. Exclusive production $e^+e^- \to \mathfrak{B}\overline{\mathfrak{B}}$ (where $\mathfrak{B} = p, \Lambda, \Sigma$) has also been measured

in order to extract the time-like electromagnetic form factors of the corresponding baryons. Belle investigated the $\phi\pi^+\pi^-$ ($\phi \to K^+K^-$) final state (Shen, 2009). A few more states are under study at the time of writing of this book, which are essential to complete the main part of the program for the estimate of the hadronic contribution to the value of $(g-2)_\mu$, namely $\pi^+\pi^-\pi^0\pi^0$, K^+K^-, $K_S^0 K_L^0 + n\pi$, and $K_S^0 K^\pm \pi^\mp + n\pi^0$, with $n = 0, 1, 2$.

This section is organized as follows. The general features common to most of these analyses are described in Section 21.3.1. The hadronic contribution to $(g-2)_\mu$, the measurement of the $\pi^+\pi^-$ cross-section, and the impact of this and other ISR results on $(g-2)_\mu$ and $\alpha(M_Z)$ are discussed in Sections 21.3.2–21.3.4 respectively. Light meson spectroscopy results from the study of multi-hadron final states are presented in Section 21.3.5; the search for the $f_J(2220)$ is discussed separately in Section 21.3.6. Finally, time-like baryon form factor measurements are described in Section 21.3.7.

21.3.1 Common analysis strategy

All the aforementioned analyses are performed with the ISR tagged approach. A loose pre-selection is applied to filter out ISR candidate events: The ISR event is tagged by the detection of a photon of CM energy $E_\gamma^* > 3$ GeV. A rough balance between the beam energies and the energy of the reconstructed event, and a well reconstructed primary vertex from the charged tracks are required. Additional photons are considered only if they have an energy above 0.03 GeV. In any case, the photon with highest energy is assumed to be the ISR photon. The above pre-selection works for most of the final states with a few exceptions, such as processes with long-lived particles or with only neutral particles in the final state, for which a dedicated selection has been implemented.

Each candidate event is then subject to a set of constrained kinematic fits, under different hypotheses for the final state. The fit results, along with information on charged-particle identification, are used to both select the final states of interest and measure backgrounds from other processes. The kinematic fits use the ISR photon direction and energy along with the four-momenta and covariance matrices of the colliding electrons and of the selected tracks and photons in the final state. Masses of narrow resonances, such as π^0, η and ϕ mesons, are constrained in the fit to their nominal values.

In general, the main background at low invariant masses comes from other ISR processes; at higher masses the background is due to continuum $q\bar{q}$ production, as explained in Section 21.2.4 above.

21.3.2 Hadronic vacuum polarization

Here we briefly describe polarization of the vacuum due to fluctuations (Section 21.3.2.1), and its effects on the running of the electromagnetic coupling (Section 21.3.2.2) and on the muon magnetic anomaly (Section 21.3.2.3). The

hadronic cross section in e^+e^- annihilation is a crucial input to the calculation of both quantities. The measurement of the $e^+e^- \to \pi^+\pi^-$ cross section, and the effect of this and other ISR exclusive results on $(g-2)_\mu$ and $\alpha(M_Z)$, are then discussed in Sections 21.3.3 and 21.3.4 respectively.

21.3.2.1 Quantum fluctuations

A virtual photon exchanged in an electromagnetic process can fluctuate into particle-antiparticle pairs leading to a polarization of the vacuum. While the effect of lepton pairs can be readily calculated with QED, hadronic effects can be treated with QCD only at large energies (quark-antiquark pairs). At low energies perturbative QCD cannot be employed any more, but fortunately hadronic vacuum polarization can still be evaluated with a dispersion integral (Bouchiat and Michel, 1961) involving experimental data on the cross section for $e^+e^- \to hadrons$, usually expressed in terms of its ratio R to the point like cross section. This technique applies to two situations of great importance in particle physics: the running of the electromagnetic coupling $\alpha(s)$, particularly its value at the Z pole where precision tests of the electroweak physics are performed, and the calculation of the Standard Model prediction for the lepton magnetic anomaly, especially in the case of the muon because of its sensitivity to new physics.

The conservation of the vector current (CVC) allows one to use τ decay data to compute the dispersion integral (Alemany, Davier, and Hoecker, 1998), but in this case small corrections must be applied in order to take into account isospin symmetry breaking between the weak charged and electromagnetic hadronic currents. This subject is discussed in Section 20.7.

21.3.2.2 The running of the electromagnetic coupling

The running of the electromagnetic fine structure constant $\alpha(s)$ is governed by the renormalized vacuum polarization function, $\Pi_\gamma(s)$. For the spin 1 photon, $\Pi_\gamma(s)$ is given by the Fourier transform of the time-ordered product of the electromagnetic currents $j_{em}^\mu(s)$ in the vacuum:

$$(q^\mu q^\nu - q^2 g^{\mu\nu})\,\Pi_\gamma(q^2) = i \int d^4x\, e^{iqx} \langle 0 | T(j_{em}^\mu(x) j_{em}^\nu(0)) | 0 \rangle .$$
$$(21.3.1)$$

With $\Delta\alpha(s) = -4\pi\alpha\,\mathrm{Re}\left[\Pi_\gamma(s) - \Pi_\gamma(0)\right]$ and $\Delta\alpha(s) = \Delta\alpha_{lep}(s) + \Delta\alpha_{had}(s)$, which subdivides the running contributions into a leptonic and a hadronic part, one has

$$\alpha(s) = \frac{\alpha(0)}{1 - \Delta\alpha_{lep}(s) - \Delta\alpha_{had}(s)} , \qquad (21.3.2)$$

where $4\pi\alpha(0)$ is the square of the electron charge in the long-wavelength Thomson limit.

The leptonic contribution at $s = M_Z^2$ is known precisely at three-loop order (Steinhauser, 1998): $\Delta\alpha_{lep}(M_Z^2) =$

314.98×10^{-4}. Using analyticity and unitarity, the dispersion integral for the contribution from the hadronic vacuum polarization reads

$$\Delta\alpha_{had}(M_Z^2) = -\frac{\alpha(0)M_Z^2}{3\pi}\,\mathrm{Re}\int_{4m_\pi^2}^\infty ds\, \frac{R(s)}{s(s - M_Z^2) - i\epsilon} ,$$
$$(21.3.3)$$

and, employing the identity $1/(x' - x - i\epsilon)_{\epsilon \to 0} = \mathrm{P}\{1/(x' - x)\} + i\pi\delta(x' - x)$, the above integral is evaluated using the principal value integration technique. Here, $R(s) \equiv R^{(0)}(s)$, denotes the ratio of the 'bare' cross section for e^+e^- annihilation into hadrons to the point like muon-pair cross section. The 'bare' cross section, $\sigma^{(0)}(s) = \sigma(s)\left[\alpha(0)/\alpha(s)\right]$, is defined as the measured cross section with vacuum polarization effects from the photon propagator removed.

21.3.2.3 The muon magnetic anomaly

A prediction from Dirac theory is that charged leptons have a magnetic moment equal to the Bohr magneton $(e\hbar/2m)$, corresponding to a gyromagnetic ratio $g = 2$. However the magnetic anomaly, defined as $a = (g-2)/2$, deviates from zero because of virtual corrections from higher orders in QED and from other interactions. It is convenient to separate the Standard Model prediction for the anomalous magnetic moment of the muon a_μ^{SM} into its different contributions,

$$a_\mu^{SM} = a_\mu^{QED} + a_\mu^{had} + a_\mu^{weak} ; \qquad (21.3.4)$$

the hadronic term is dominated by lowest-order (LO) vacuum polarization (VP), whose Feynman diagram is shown in Fig. 21.3.1. But a_μ^{had} receives further contributions, smaller by a factor ~ 30, from higher-order (HO) vacuum polarization (several loops in photon propagators including at least one hadronic loop) and the so-called light-by-light (LBL) contribution, where the hadronic loop is connected to the QED part by four photon legs.
Figure 21.3.1. The Feynman diagram for the lowest-order contribution of hadronic vacuum polarization to the muon magnetic anomaly.

As in the case of $\alpha(M_Z)$, by virtue of the analyticity of the vacuum polarization correlator, the LO contribution of the hadronic vacuum polarization to a_μ can be calculated via a dispersion integral

$$a_\mu^{had,LO} = \frac{\alpha^2(0)}{3\pi^2}\int_{4m_\pi^2}^\infty ds\, \frac{K(s)}{s} R(s) . \qquad (21.3.5)$$

The QED kernel, $K(s)$ is given by (Brodsky and De Rafael, 1968)

$$
\begin{aligned}
K(s) \; = \; & x^2 \left(1 - \frac{x^2}{2} \right) + (1+x)^2 \left(1 + \frac{1}{x^2} \right) \\
& \times \left(\ln(1+x) - x + \frac{x^2}{2} \right) + \frac{(1+x)}{(1-x)} x^2 \ln x \; ,
\end{aligned}
\tag{21.3.6}
$$

with $x = (1 - \beta_\mu)/(1 + \beta_\mu)$ and $\beta_\mu = (1 - 4m_\mu^2/s)^{1/2}$. The function $K(s)$ decreases monotonically with increasing s. It gives a strong weight to the low energy part of the integral (21.3.5). About 92% of the total contribution to a_μ^{had} is accumulated at CM energies $\sqrt{s}$ below 1.8 GeV, and 73% of a_μ^{had} is covered by the two-pion final state which is dominated by the $\rho(770)$ resonance.

21.3.3 Measurement of $e^+ e^- \to \pi^+ \pi^- (\gamma)$

Precise results on the $e^+ e^- \to \pi^+ \pi^- (\gamma)$ cross section have been obtained by *BABAR* (Aubert, 2009ah), using 232 fb^{-1} of recorded data. In this analysis, two-body ISR processes $e^+ e^- \to \gamma_{\mathrm{ISR}} X$ with final states $X = \pi^+ \pi^- (\gamma)$ and $X = \mu^+ \mu^- (\gamma)$ are measured, where the charged particle pair can be accompanied by a final state radiation (FSR) photon. The $\pi\pi$ cross section is obtained from the ratio of pion to muon yields, thereby significantly reducing the systematic uncertainty. Furthermore the measured muon cross section can be compared to the QED prediction, providing a powerful cross check of the analysis.

In this approach the measurement of the cross section $\sigma_{\pi\pi(\gamma)}$ uses the effective ISR luminosity provided by the measured mass spectrum of $\mu\mu\gamma_{\mathrm{ISR}}(\gamma)$ events. For the muon QED test, the measurement of $\sigma_{\mu\mu(\gamma)}$ uses the ISR luminosity calculated from the $e^+ e^-$ integrated luminosity and the radiator function obtained from PHOKHARA .

In addition to the pre-selection requirements, two-body ISR events are selected requiring exactly two tracks of opposite charge, each with a momentum $p > 1\,\mathrm{GeV}/c$ and within the polar angle range 0.40 to 2.45 rad in the laboratory frame. The charged-particle tracks are required to have at least 15 hits in the DCH, to originate within 5 mm of the collision axis, and to extrapolate to DIRC and IFR active areas, excluding low-efficiency regions.

MC simulation is used to compute acceptance and mass-dependent efficiencies for trigger, reconstruction, PID, and event selection. Corrections for differences between data and MC efficiencies amount to at most a few percent and are known to the few permill level or better.

The precision aimed for by this analysis requires dedicated studies of the detector performance, particularly regarding track reconstruction and particle identification efficiencies. These are determined taking advantage of the kinematic constraints of pair production. Two-prong ISR candidates are selected on the basis of the ISR photon and one detected track, and subjected to a kinematic fit to estimate the expected parameters of the second track. Comparison with the sample of reconstructed second-track candidates allows the measurement of the track reconstruction efficiency.

Pure samples of muon, pion, and kaon pairs are obtained from two-prong ISR events where one track is selected as a μ-, π-, or K-candidate respectively, according to the output of cut-based and likelihood selectors (see Section 5.2). The other track is used to determine the efficiency and misidentification probabilities of the PID algorithm under test, as a function of momentum and position in the IFR or the DIRC. The efficiencies for μ are of the order of 90%, with 10% misidentified as π. The π efficiency depends strongly on momentum, with the fraction of pions misidentified as K increasing from 1% at 1 GeV/c to 20% at 6 GeV/c; the fraction misidentified as μ is 5–6%, and that as e around 2%.

The multi-hadronic background from $e^+ e^- \to q\bar{q}$ is estimated as explained in Section 21.2.4. The background from other ISR processes is dominated by the $e^+ e^- \to \pi^+ \pi^- \pi^0 \gamma_{\mathrm{ISR}}$ and $e^+ e^- \to \pi^+ \pi^- 2\pi^0 \gamma_{\mathrm{ISR}}$ reactions, which are estimated using MC simulation. Residual background sources from the $e^+ e^- \to \gamma\gamma$ process with photon conversion and radiative Bhabha events are studied and taken into account.

The analysis allows for one additional ISR or FSR photon, and is thus effectively performed at NLO in α. Each event is subjected to two kinematic fits to the $e^+ e^- \to X \gamma_{\mathrm{ISR}}$ hypothesis, where X allows for an additional photon from the initial or final state, detected or not. The first fit, called the 'ISR' fit, tests the consistency of the reconstructed event with the presence of an undetected ISR photon collinear with the collision axis. The second fit, called the 'FSR' fit, is performed only if an additional photon with $E_\gamma > 25\,\mathrm{MeV}$ is detected, and tests the hypothesis that this photon is radiated by the final state tracks. Misreconstructed events and residual background generally have large χ^2 values for both fits, and can be separated from signal events. If the 'FSR' fit has the smaller χ^2, the mass of the hadronic final state is calculated including the 4-momentum of the additional detected photon.

The computed detector acceptance and the selection efficiency of the kinematic fit procedure are sensitive to an imperfect description of radiative effects in the generator. The estimated rates of FSR for data and MC simulation are found to be consistent at better than the one permill level. The AfkQed generator simulates additional ISR production in the collinear approximation and applies an energy cut-off for very hard photons. The effects of these approximations are estimated by comparing the AfkQed generator at four-vector level with the PHOKHARA generator, which gives a full description of the process at next-to-leading order. Corrections to the acceptance of the order of a few percent are found for the individual $\pi^+ \pi^- (\gamma)$ and $\mu^+ \mu^- (\gamma)$ processes, but since photon emission from the initial state is common to the two channels, the $\pi^+ \pi^- (\gamma)/\mu^+ \mu^- (\gamma)$ ratio is affected only at the few permill level. Therefore the measurement of the pion cross section is to a large extent insensitive to the description of NLO effects in the generator.

A QED test is performed by comparing the $\mu^+\mu^-(\gamma)$ mass spectrum in data with that in MC-simulated events. In particular, the distribution of the data is background-subtracted, and the distribution of the `AfkQed`-based full simulation, normalized to the data luminosity, is corrected for all known data/MC detector and reconstruction differences and for the generator NLO limitations determined from the comparison between `PHOKHARA` and `AfkQed`. The ratio, shown in Fig. 21.3.2, is rather flat from threshold to $3\,\text{GeV}/c^2$ and consistent with unity, as found by a fit to a constant value which returns

$$\frac{\sigma_{\mu\mu\gamma(\gamma)}^{\text{data}}}{\sigma_{\mu\mu\gamma(\gamma)}^{\text{NLO QED}}} - 1 = (40 \pm 20 \pm 55 \pm 94) \times 10^{-4} \,, \quad (21.3.7)$$

with $\chi^2/n_{\text{dof}} = 55.4/54$; the errors are statistical, systematic from this analysis, and systematic from the integrated luminosity respectively. The QED test is thus satisfied within an overall accuracy of 1.1%.

Figure 21.3.3. The bare cross section for $e^+e^- \to \pi^+\pi^-(\gamma)$ measured by *BABAR* (Aubert, 2009ah) in the full energy range. The inset shows an enlarged view of the energy region around the ρ and ω masses. Total uncertainties are shown.

Figure 21.3.3 shows the $e^+e^- \to \pi^+\pi^-(\gamma)$ bare cross section including FSR measured by *BABAR* as a function of the CM energy. It is dominated by the ρ resonance, and shows the effect of the $\rho - \omega$ interference at 0.78 GeV, a clear dip at 1.6 GeV resulting from interference with a heavier ρ state, and additional structure above 2 GeV. The systematic uncertainty ranges from 0.5% in the energy region around the ρ mass, up to 5% at the highest measured energies, and is smaller than the statistical error in the corresponding energy interval over the whole spectrum. The contributions of the various sources to the systematic uncertainties are shown in Table 21.3.1 for the central energy region $0.4 < \sqrt{s'} < 1.2\,\text{GeV}$.

The square of the pion form factor is defined as usual by the ratio of the dressed cross section without FSR, and

Figure 21.3.2. The ratio of the $e^+e^- \to \mu^+\mu^-\gamma(\gamma)$ cross section measured by *BABAR* to the NLO QED prediction (Aubert, 2009ah). The solid line and the shaded band represent the central value and errors given in Eq. (21.3.7).

Before extraction of the final cross section, an unfolding procedure, described in detail in Malaescu (2009), is applied to the background-subtracted and efficiency-corrected $m_{\pi\pi}$ spectrum. A mass-transfer matrix obtained using simulation provides the probability that an event generated in an interval i of the reduced e^+e^- CM energy $\sqrt{s'}$ is reconstructed in a $m_{\pi\pi}$ interval j. In the energy region around the ρ peak, where the cross section is measured in energy intervals 2 MeV wide, the significant elements of the mass-transfer matrix lie near the diagonal over a typical range of 6 MeV, which corresponds to the energy resolution.

Table 21.3.1. Relative systematic uncertainties (in 10^{-3}) in the $e^+e^- \to \pi^+\pi^-(\gamma)$ cross section by $\sqrt{s'}$ intervals up to 1.2 GeV (Aubert, 2009ah). The statistical part of the efficiency uncertainties is included in the total statistical uncertainty in each interval, and, therefore, it is not reported in the table.

source of uncertainty	$\sqrt{s'}$ (GeV)			
	0.4–0.5	0.5–0.6	0.6–0.9	0.9–1.2
trigger/ filter	2.7	1.9	1.0	0.5

the lowest-order cross section for point-like spin 0 charged particles. Thus,

$$|F_\pi|^2(s') = \frac{3s'}{\pi\alpha^2(0)\beta_\pi^3}\,\sigma_{\pi\pi}(s')\,, \qquad (21.3.8)$$

with the pion velocity $\beta_\pi = \sqrt{1 - 4m_\pi^2/s'}$. A vector-meson-dominance (VMD) model is used to fit the *BABAR* pion form factor, correlating the observed structures to the effects from higher-mass isovector vector mesons. In addition to the ρ and ω (isoscalar, but interfering with the ρ through its isospin-violating $\pi^+\pi^-$ decay), three higher ρ states at (1493 ± 15) MeV/c^2, (1861 ± 17) MeV/c^2, and (2254 ± 22) MeV/c^2 are required to fit the data. The fit is shown in Fig. 21.3.4.
Figure 21.3.4. The pion form factor squared measured by *BABAR* (Aubert, 2009ah) as a function of $\sqrt{s'}$ in the full range, with details of the $\rho-\omega$ interference region shown in the inset. The line represents a VMD fit with the ρ, the ω, and three higher ρ states.

21.3.4 Impact of ISR results on $(g-2)_\mu$ and $\alpha(M_Z)$

21.3.4.1 The *BABAR* $\pi^+\pi^-$ contribution

The *BABAR* 2π results discussed above can be used in a straightforward way to compute the dispersion integral of Eq. 21.3.5. The errors are computed using the full statistical and systematic covariance matrices. The systematic uncertainties for each source are taken to be fully correlated over all mass regions. The upper range of integration (1.8 GeV) is chosen in accordance with previous evaluations (Davier, Eidelman, Hoecker, and Zhang, 2003a,b) in which the contribution of the higher energy region was computed using QCD. This procedure was justified by detailed studies using τ decay data (Barate et al., 1998). The contribution to a_μ in the 1.8–3 GeV range, obtained with the present *BABAR* data, is $(0.21 \pm 0.01) \times 10^{-10}$, thus negligible with respect to the uncertainty in the main region.

The contribution from threshold to 1.8 GeV is obtained for the first time from a single experiment:

$$a_\mu^{\pi\pi(\gamma),\mathrm{LO}} = (514.1 \pm 2.2 \pm 3.1) \times 10^{-10}\,, \qquad (21.3.9)$$

where the errors are statistical and systematic.

21.3.4.2 Comparison to other determinations

Direct comparison with the results from other experiments is complicated by two facts: (i) e^+e^- scan experiments provide cross section measurements at discrete and unequally spaced energy values, while the ISR method provides a continuous spectrum and, (ii) unlike *BABAR* no other experiment covers the complete mass spectrum from threshold up to energies where the contributions become negligible. Wherever gaps remain, they have been filled by using the weighted-average cross section values from the other experiments. This approach has been followed by Davier, Hoecker, Malaescu, Yuan, and Zhang (2010) from which the relevant integrals are extracted.

Correlations between systematic uncertainties have been taken into account, particularly for radiative corrections, when combining the results from all experiments. The combination is performed in small energy bins at the cross section level, taking into account possible disagreements leading to an increased uncertainty of the resulting average. The contribution of the $\pi^+\pi^-$ channel to a_μ obtained from the combination of all measurements of the $e^+e^- \to \pi^+\pi^-$ cross section is $(507.8 \pm 3.2) \times 10^{-10}$. It is compared in Fig. 21.3.5 with the determinations of a_μ calculated using the data form the individual experiments. All determinations are indeed consistent within the uncertainties, *BABAR* and CMD-2 (Akhmetshin et al., 2006, 2007; Aulchenko et al., 2005) being almost a factor of two more precise than SND (Achasov et al., 2006) and KLOE (Ambrosino et al., 2009a, 2011).

The *BABAR* result is also consistent with determinations using τ decay with isospin-breaking corrections from Davier et al. (2010), which are also reported in Fig. 21.3.5. This reduces the previous tension between e^+e^- and τ values (Davier, Eidelman, Hoecker, and Zhang, 2003a). Looking at the full picture it is important to note that the four inputs (CMD-2/SND, KLOE, *BABAR*, τ) have completely independent systematic uncertainties.

21.3.4.3 Other exclusive channels

Remaining contributions from other exclusive channels up to 1.8 GeV amount to about 18% of $a_\mu^{\mathrm{had},LO}$. Previous results were obtained by CMD-2/SND from the ω and ϕ resonances, and from multihadrons up to 1.4 GeV. Data between 1.4 GeV and 2 GeV from the DM2 experiment were rather poor. However it was shown by the LEP experiments that perturbative QCD could be used at the τ mass scale with accuracies of about 1% (Ackerstaff et al., 1999;
Figure 21.3.5. Evaluation of LO hadronic vacuum polarization 2π contributions to the muon magnetic anomaly in the energy range $[2m_\pi, 1.8\,\text{GeV}]$ from *BABAR*, other e^+e^- experiments (Davier, Hoecker, Malaescu, Yuan, and Zhang, 2010), and τ experiments (Davier et al., 2010); see the text for details. The errors include both statistical and systematic sources. For the τ values, a common systematic error of 1.9 is included to account for uncertainties in the isospin-breaking corrections. The vertical bands represent the combined result, which amount to $(507.8 \pm 3.2) \times 10^{-10}$ for the $\pi\pi$ value, and $(515.2 \pm 3.0 \pm 1.9) \times 10^{-10}$ for the τ value. They are not obtained as the weighted average of the different values, but originate from a local combination of the respective spectral functions.

Barate et al., 1998), so it became advantageous (Davier and Hoecker, 1998) to use theory above 1.8 GeV.

The situation between 1 GeV and 1.8 GeV changed drastically with the advent of ISR *BABAR* data. In fact an almost complete set of precise measurements is available and a few remaining channels are being analyzed. These measurements benefit from the excellent particle identification, providing access to many previously unmeasured cross sections. They help to discriminate between older, less precise and sometimes contradictory results. Figure 21.3.6 gives a few examples of measured cross sections and demonstrates the impact of the *BABAR* results. The band shown on all these plots represents the combination by Davier, Hoecker, Malaescu, and Zhang (2011) of all existing data using the `HVPTools` package (Davier, Hoecker, Malaescu, Yuan, and Zhang, 2010): it is clearly dominated by the *BABAR* results.

The measurement using the full available data set of the production cross section for several final states are in progress at *BABAR*. Particularly relevant for the calculation of the muon anomaly are $\pi^+\pi^-\pi^0\pi^0$, K^+K^-, $K_S K_L$, and $K_S K_L \pi^+\pi^-$. Some channels involving π^0 multiplicities larger than 2 will probably remain unmeasured. The estimate of the missing channels, obtained using isospin

relations or inequalities (Davier, Hoecker, Malaescu, and Zhang, 2011), is greatly facilitated by the studies of produced final states performed by *BABAR* on the related channels as discussed in the following sections.

21.3.4.4 The complete muon anomaly prediction

Measurements from all experiments have been combined in the recent analysis of Davier, Hoecker, Malaescu, and Zhang (2011). The weight of the ISR *BABAR* data in the combination is the largest of all experiments: 41% for 2π and from 58 to 100% for the other measured exclusive channels below 1.8 GeV. More recently an independent analysis using the same data has been presented (Hagiwara, Liao, Martin, Nomura, and Teubner, 2011) with similar results. Adding all contributions (QED, electroweak, hadronic LO VP, hadronic HO VP, hadronic light-by-light) as given in Davier, Hoecker, Malaescu, and Zhang (2011), using for hadronic LO VP the combined result, one obtains the predicted value

$$a_\mu^{\text{SM}} = (11\,659\,180.2 \pm 4.2 \pm 2.6 \pm 0.2) \times 10^{-10} , \quad (21.3.10)$$

where the three uncertainties come from hadronic VP (e^+e^- data), the LBL calculations, and the sum of QED and Weak contributions, respectively, for a total uncertainty of $\pm 4.9 \times 10^{-10}$. The Standard Model prediction can be compared to the direct measurement (Bennett et al., 2006), slightly updated in (Nakamura et al., 2010):

$$a_\mu^{\text{exp}} = (11\,659\,208.9 \pm 6.3) \times 10^{-10} . \quad (21.3.11)$$

The experimental value exceeds the theory prediction by $(28.7 \pm 8.0) \times 10^{-10}$, *i.e.* 3.6 standard deviations. Although the deviation is not significant enough to claim a departure from the Standard Model, it confirms the trend of earlier results using previous data (Davier, Eidelman, Hoecker, and Zhang, 2003b; Hagiwara, Martin, Nomura, and Teubner, 2007; Jegerlehner and Nyffeler, 2009).

Such a deviation could originate from new physics beyond the Standard Model. One possibility, much discussed in the literature, is the effect of contributions from supersymmetry (SUSY) involving scalar muons or neutrinos, and gauginos at a few hundred GeV mass scale. For the moment this explanation is not confirmed by the early LHC results as no evidence has yet been found for new particles in this mass range. While under tension this scenario is not yet ruled out as many SUSY versions can still be considered.

However it is clear that the muon $(g-2)$ discrepancy should be further explored. The progress will follow two lines. First, projects are considered at FNAL and J-PARC to extend the direct measurement to higher precision. Second, more precise measurements of $e^+e^- \rightarrow$ hadrons are possible with VEPP2000 and in the longer term with the new generation of B Factories using the ISR method. Combining the two approaches could produce a very significant deviation which would unambiguously signal physics beyond the Standard Model.
Figure 21.3.6. Cross sections versus center-of-mass energy for $e^+e^- \rightarrow \pi^+\pi^-\pi^+\pi^-$, $e^+e^- \rightarrow \pi^+\pi^-\pi^0\pi^0$, $e^+e^- \rightarrow K^+K^-\pi^+\pi^-$, $e^+e^- \rightarrow 2\pi^+2\pi^-\pi^0$, $e^+e^- \rightarrow 3\pi^+3\pi^-$, $e^+e^- \rightarrow 2\pi^+2\pi^-2\pi^0$. The open circles show data from BABAR which dominate in precision. The references for the earlier results displayed are given in Davier, Hoecker, Malaescu, and Zhang (2011). The error bars show the statistical and systematic uncertainties added in quadrature. The shaded (green online) band is the combined result $\pm 1\sigma$ taking all experiments into account using the `HVPTools` package (Davier, Hoecker, Malaescu, Yuan, and Zhang, 2010).

21.3.4.5 The prediction for $\alpha(M_Z^2)$

All hadronic contributions considered above are used as input to compute the dispersion relation in Eq. (21.3.3) with the result

$$\Delta\alpha_{\text{had}}(M_Z^2) = (275.0 \pm 1.0) \times 10^{-4}, \qquad (21.3.12)$$

which, contrary to the evaluation of $a_\mu^{\text{had,LO}}$, is not dominated by the uncertainty in the experimental low-energy data, but by contributions from all energy regions, where both experimental and theoretical errors have similar magnitude. Nevertheless the new ISR data provided by BABAR

permits a significant improvement in precision. The result in Eq. (21.3.12) can be compared with the value obtained in Hagiwara, Liao, Martin, Nomura, and Teubner (2011), $(276.3 \pm 1.4) \times 10^{-4}$.

Adding the leptonic contribution $\Delta\alpha_{\text{lep}}(M_Z^2)$, one finds

$$\alpha^{-1}(M_Z^2) = 128.952 \pm 0.014. \qquad (21.3.13)$$

The running electromagnetic coupling at M_Z enters at various levels the global SM fit to electroweak precision data. It contributes to the radiator functions that modify the vector and axial-vector couplings in the partial Z boson widths to fermions, and also to the SM prediction of
Figure 21.3.7. Overall χ^2 for the Standard Gfitter electroweak fit (Baak et al., 2012; green shaded band) with the result obtained for the new evaluation of $\Delta\alpha_{\mathrm{had}}(M_Z^2)$. The shaded areas represent the excluded regions at 95% C.L. from the LEP and LHC experiments, leaving only a small window near 126 GeV where a very significant signal is observed by the ATLAS (Aad et al., 2012) and CMS (Chatrchyan et al., 2012b) experiments.

the W mass and the effective weak mixing angle. Overall, the fit exhibits a -39% correlation between the Higgs mass (M_H) and $\Delta\alpha_{\mathrm{had}}(M_Z^2)$ (Baak et al., 2012), so that the decrease in the value given in Eq.(21.3.12) and thus in the running electromagnetic coupling strength, with respect to earlier evaluations, leads to an increase in the most probable value of M_H returned by the fit. Figure 21.3.7 shows the standard Gfitter result (green shaded band; Baak et al., 2012), using as the hadronic contribution the result obtained by using Eq. (21.3.12). The fitted Higgs mass shifts from $(84\,^{+30}_{-23})$ GeV/c^2 to $(91\,^{+30}_{-23})$ GeV/c^2. The stationary error of the latter value, in spite of the improved accuracy, is due to the logarithmic M_H dependence of the fit observables. The new 95% upper limit on M_H is 163 GeV/c^2. A new boson with properties compatible with the Higgs particle has been discovered by the ATLAS (Aad et al., 2012) and CMS (Chatrchyan et al., 2012b) experiments at the LHC. The fact that its mass of 126 GeV/c^2 is consistent with the range allowed above can be considered as a triumph for the Standard Model in the so-far hidden sector of gauge symmetry breaking.

21.3.5 Light meson spectroscopy

Most of the multi-hadron final states feature a variety of internal sub-processes, with formation of several intermediate states, whose properties can be measured thanks to the large available statistics at the B Factories.

In some cases, however, these studies are made difficult by the presence of broad interfering intermediate states, and have been performed only in a qualitative way. As an example, the study of the two- and three-pion invariant mass distributions of the process $e^+e^- \to \pi^+\pi^-\pi^0\pi^0$ shows important contributions from $\omega(780)\pi$, $a_1(1260)\pi$, and $\rho^+\rho^-$ intermediate states, which strongly interfere.

A partial-wave analysis combining the data of $e^+e^- \to \pi^+\pi^-\pi^0\pi^0$ and $e^+e^- \to \pi^+\pi^-\pi^+\pi^-$ is required in order to separate the different sub-processes and to study the two excited ρ states, $\rho(1450)$ and $\rho(1700)$, decaying into four pions.

In many other cases, more quantitative results have been obtained. A non-exhaustive summary of these results is presented below.

21.3.5.1 Study of ω-like resonances

The $e^+e^- \to \pi^+\pi^-\pi^0$ cross section is dominated by the production of the well-known vector states ω, ϕ, and J/ψ. Between 1 and 2 GeV the cross section is generally described as the sum of two ω-like resonances: $\omega(1420)$ or ω', and $\omega(1650)$ or ω'', whose parameters are not yet well established. The published BABAR results (Aubert, 2004af) are based on an integrated luminosity of only 89.3 fb^{-1}. Therefore, an update of the study using the full available dataset is desirable. The measured cross section in the 1.05–3.0 GeV/c^2 mass region is shown in Fig. 21.3.8. There is good agreement with previous results by the SND experiment (Achasov et al., 2002) below 1.4 GeV/c^2; significant disagreement with DM2 results (Antonelli et al., 1992) is observed at higher energies.
Figure 21.3.8. The $e^+e^- \to \pi^+\pi^-\pi^0$ cross section measured by the BABAR experiment (Aubert, 2004af; full circles) in the 1-3 GeV/c^2 range compared with the SND (Achasov et al., 2002; open circles) and DM2 (Antonelli et al., 1992; triangles) data. The inset shows the result of a fit to the mass distribution as explained in the text.

The three pion mass spectrum below 1.8 GeV/c^2, obtained by BABAR, is fitted as the sum of the four known vector resonances ω, ϕ, ω', and ω''. The fit result in the ω' and ω'' mass region is shown in the inset to Fig. 21.3.8, superimposed on the experimental data. The resonance parameters from the fit are reported in the first column of Table 21.3.2, together with the corresponding values from studies of ISR processes with five and six hadrons in the final state.

Clear $\eta \to 3\pi$ and $\omega \to 3\pi$ signals are observed in the $e^+e^- \to 2(\pi^+\pi^-)\pi^0$ process. The cross sections for

Figure 21.3.10. The $e^+e^- \rightarrow \omega\eta$ cross section extracted from the $2(\pi^+\pi^-\pi^0)$ final state measured by BABAR (Aubert, 2006az). The solid line is the result of the fit with a Breit-Wigner function.

As can be seen from Table 21.3.2, there is general consistency among the ω' and ω'' parameters measured in the different channels. An update of the three pion final state measurement with the full available BABAR data set, and a combined fit to all channels, could give information on relative decay rates and significantly improve the knowledge of these states.

21.3.5.2 Study of excited ρ and ϕ states in the $K\bar{K}\pi$ and $K\bar{K}\eta$ final states

By studying the Dalitz plots of the $e^+e^- \rightarrow K_S^0 K^\pm \pi^\mp$ and $e^+e^- \rightarrow K^+K^-\pi^0$ final states, the DM1 and DM2 experiments have identified $e^+e^- \rightarrow \bar{K}K^*(892)$ and its charge conjugate as the dominant sub-process, and measured the contributions of the different isospin $(I = 0, 1)$ components. They also observed a resonant structure in the isoscalar component, which was interpreted as the first excitation of the ϕ resonance, thereafter called the $\phi(1680)$ or ϕ' (Bisello et al., 1991; Buon et al., 1982). BABAR performs a similar study of the $K_S^0 K^\pm \pi^\mp$ and $K^+K^-\pi^0$ final states, using a $\simeq 220$ fb^{-1} sample (Aubert, 2008ab). The large amount of data allows the measurement of the cross sections up to a CM energy of 4.5 GeV, and a much more accurate study of the Dalitz plots of the two processes, shown in Fig. 21.3.11. It can be seen that in both processes, the main contributions come from the $\bar{K}K^*(892)$ and $\bar{K}K_2^*(1430)$ intermediate states, and that the Dalitz plot population for the $K_S^0 K^\pm \pi^\mp$ channel is strongly asymmetric. This is because both the neutral $\bar{K}^0 K^{*0}$ and charged $K^\pm K^{*\mp}$ combinations are involved, and these are produced by, respectively, the sum and the difference of the iso-scalar and iso-vector amplitudes. By studying the Dalitz plots, the moduli and relative phase of the isospin components for both the $\bar{K}K^*(892)$ and

Figure 21.3.9. The $e^+e^- \rightarrow \eta\pi^+\pi^-$ (top) and $e^+e^- \rightarrow \omega\pi^+\pi^-$ (bottom) cross sections measured by BABAR (Aubert, 2007bb) in comparison with direct e^+e^- measurements.

production of the $\eta\pi^+\pi^-$ and $\omega\pi^+\pi^-$ final states, measured by BABAR (Aubert, 2007bb), are compared to previous, less precise data (Akhmetshin et al., 2000; Antonelli et al., 1988; Cordier et al., 1981; Druzhinin et al., 1986) in Fig. 21.3.9. Several new features are revealed by the BABAR data. In particular, the study of the $\pi^+\pi^-$ mass distribution shows a clear contribution of the intermediate state $\omega f_0(980)$ to the $\omega\pi^+\pi^-$ cross section. In addition, the $\omega\pi^+\pi^-$ cross section has been fitted, after removal of the $\omega f_0(980)$ contribution, with a sum of two BW functions, referring to the ω' and ω'', as in the case of the $\pi^+\pi^-\pi^0$ final state. The fitted parameters are reported in the third column Table 21.3.2.

Finally, further structure compatible with ω excitations has been observed in $e^+e^- \rightarrow 2(\pi^+\pi^-\pi^0)$ (Aubert, 2006az). In fact, in addition to clear $\eta \rightarrow \pi^+\pi^-\pi^0$ and $\omega \rightarrow \pi^+\pi^-\pi^0$ signals, a small associated production of η and ω is observed in this channel. The cross section for the $e^+e^- \rightarrow \omega\eta$ reaction, reported in Fig. 21.3.10, shows a peak in the $\omega(1650)$ energy region, which is fitted with a Breit-Wigner function.

Table 21.3.2. Summary of the $\omega(1420)$ (or ω') and $\omega(1650)$ (or ω'') resonance parameters obtained from the fits described in the text. m_i and Γ_i are the mass and the full width of state i, respectively, σ_{0i} is the peak cross section, $\Gamma_{ee}B_{if}$ the dielectron width multiplied by the branching fraction for decays into the final state f, and ϕ_i is the phase w.r.t. the ω amplitude. The errors shown are combination of statistical and systematic uncertainties. The values without errors were fixed in the fits.

Figure 21.3.11. The Dalitz plot distribution for the $K^+K^-\pi^0$ (left) and $K_S^0 K\pi$ final state (right) measured by BABAR (Aubert, 2008ab).

$\overline{K}K_2^*(1430)$ cross sections have been obtained as a function of the CM energy. The isoscalar σ_0 and isovector σ_1 cross sections for $e^+e^- \rightarrow \overline{K}K^*(892)$ are shown in Fig. 21.3.12(a,b). The isoscalar component is dominant, and shows a clear resonant peak at a CM energy of $\sim$ 1.7 GeV, consistent with the $\phi(1680)$ meson. The isovector component is also incompatible with a pure phase space shape, and shows a resonant structure, as can be deduced by a study including the information on the relative phase between σ_0 and σ_1.

A global fit has been performed using six different sources of information: σ_0, σ_1 and their relative phase; the $K^+K^-\pi^0$ cross section shown in Fig. 21.3.12(c), and the $\phi\eta$ cross section measured reconstructing two different η decay modes: $\eta \rightarrow \gamma\gamma$ (Aubert, 2008ab), and $\eta \rightarrow \pi^+\pi^-\pi^0$

(Aubert, 2007bb). The $e^+e^- \rightarrow \phi\eta$ reaction is well suited to study excited ϕ states, because the production of any ω-like state, even if allowed by quantum-number conservation, is strongly suppressed by the OZI rule. The measured $\phi\eta$ cross section reported in Fig. 21.3.12(d) shows a broad peak at a CM energy of about 1.7 GeV, which can be identified as a new decay channel of the $\phi(1680)$ meson. The same dominant resonance ϕ' is therefore assumed to fit both the $\phi\eta$ and the isoscalar $\overline{K}K^*(892)$ cross sections. An additional resonance, ϕ'' is included to account for a small peak seen at a CM energy of about 2.15 GeV in the $\phi\eta$ cross section. The fit results are superimposed on the cross section data in Fig. 21.3.12 and are listed in Table 21.3.3. The parameters obtained for the ϕ' and ρ' are compatible with previous measurements (Amsler
Figure 21.3.12. Isoscalar (a) and isovector (b) components of the $e^+e^- \to K_S^0 K\pi$ cross section; the $e^+e^- \to K^\pm K^*(892)^\mp$ cross section obtained by the BABAR experiment, using $e^+e^- \to K^+K^-\pi^0$ events (c), and the $e^+e^- \to \phi\eta$ cross section (d). The points with error bars are data and the gray bands represent the fit and its uncertainty (Aubert, 2008ab).

et al., 2008). Concerning the ϕ'' resonance, which is seen only in the $\phi\eta$ channel with a significance of about 2.5σ, the fitted parameters are close to those for the $Y(2175)$ state observed in the $\phi f_0(980)$ final state (Aubert, 2006c), discussed in Section 21.3.5.3.

An interesting sub-process of the $K^+K^-\gamma\gamma$ final state measured for the first time by BABAR is $e^+e^- \to \phi\pi^0$ (Aubert, 2008ab). The decays of ordinary isovector resonances to $\phi\pi^0$ are suppressed by the OZI rule, so structure in this channel could serve as a signal for exotic resonant states. Two possible descriptions are considered to fit the $\phi\pi^0$ cross section, assuming respectively the presence of one or two radial excitations of the ρ meson (despite being OZI suppressed).[160] In the first case, the parameters obtained for the unique isovector state are 1593 ± 32 MeV/c^2 for the mass and 203 ± 97 MeV for the width, which are compatible with those of the $\rho(1700)$ (Amsler et al., 2008). A slightly better fit quality is obtained if two resonances are assumed, as seen from the results shown in Table 21.3.3. The parameters obtained for the first resonance (indicated by ρ'' in the Table) are consistent with those of the $C(1480)$ state observed in $\pi^-p \to \phi\pi^0 n$ charge-

---

[160] It should be noted that in the region 1 GeV to 2 GeV several wide resonances, mixtures of $s\bar{s}$, $u\bar{u}$ and $d\bar{d}$ states, are present and hence the OZI rule may not be directly applicable.

exchange reaction (Bityukov et al., 1987). However, a firm conclusion cannot be drawn, and an OZI-violating decay of the $\rho(1700)$ is not excluded. The second structure, the $\rho(1900)$, is compatible with the "dip" already observed in other experiments, predominantly in multi-hadron final states (Antonelli et al., 1996; Frabetti et al., 2001), and by BABAR in the ISR production of six-pion final states (Aubert, 2006az). In the last-cited result, however, a significantly larger width has been measured, so the situation is still uncertain.

21.3.5.3 The discovery of the $Y(2175)$ in $K^+K^-\pi\pi$ final states.

The $e^+e^- \to K^+K^-\pi^+\pi^-$ and $e^+e^- \to K^+K^-\pi^0\pi^0$ reactions proceed through the production of numerous intermediate states. The invariant mass distributions of the two- and three-particle combinations indicate that the intermediate states $K^*(892)^0 K^\pm\pi^\mp$ and $K^*(892)^\mp K^\pm\pi^0$ dominate in these reactions. A small $K_2^*(1430)K\pi$ contribution is also seen, while states with two K^*, namely $K^*(892)\bar{K}^*(892)$, $K^*(892)\bar{K}_2^*(1430)$, and $K_2^*(1430)\bar{K}_2^*(1430)$, account for less than 1% of the total reaction yield.

Table 21.3.3. Summary of parameters obtained for the ρ and ϕ radial excitation from the study of the $K\overline{K}\pi$ and $K\overline{K}\eta$ final states (Aubert, 2008ab), including the data on the $\phi\eta$ cross section from Aubert (2007bb). The parameters for the ρ'' are taken from the fit to the $\phi\pi^0$ cross section with two resonances (see the text).

Among the most interesting studies of this final state performed by *BABAR* is the extraction of the relatively small contributions of the $\phi\pi^+\pi^-$ and $\phi\pi^0\pi^0$ ($\phi \to K^+K^-$) intermediate states (Aubert, 2006c, 2007bc). The original motivation was the search for decays of the then recently-discovered vector meson $Y(4260)$. As discussed in Section 18.3, the $Y(4260)$ was discovered by *BABAR* in the process $e^+e^- \to \gamma_{\mathrm{ISR}}Y(4260) \to \gamma_{\mathrm{ISR}}J/\psi\,\pi^+\pi^-$, but was not seen to decay to $D^{(*)}\overline{D}^{(*)}$, although this was expected for a wide conventional charmonium state with a mass well above the $D\overline{D}$ production threshold. A certain exotic-structure model for the $Y(4260)$ predicted a large branching fraction for the decay into $\phi\pi\pi$ (Zhu, 2005).

Since the ϕ resonance is relatively narrow, a clean sample of $\phi\pi\pi$ events can be easily separated. The scatter plot of the reconstructed masses, $m(\pi^+\pi^-)$ versus $m(K^+K^-)$, for selected events in a data sample corresponding to $232\,\mathrm{fb}^{-1}$ is shown in Fig. 21.3.13(a) (Aubert, 2006c): a clear $\phi \to K^+K^-$ vertical band is visible, as well as an accumulation of events indicating correlated production of the ϕ and $f_0(980) \to \pi\pi$ resonances. A wide horizontal band corresponding to $\rho^0 \to \pi^+\pi^-$ production is also seen. The invariant mass distribution of the $\pi\pi$ system in $\phi\pi\pi$ events is obtained using the condition $|m(K^+K^-) - m_\phi| < 10\,\mathrm{MeV}/c^2$, where m_ϕ is the nominal ϕ-mass. The background from true $K^+K^-\pi\pi$ events with non-resonant K^+K^- pair is subtracted using the ϕ mass sidebands $10 < |m(K^+K^-) - m_\phi| < 20\,\mathrm{MeV}/c^2$; other backgrounds are subtracted based on MC simulation. The final mass spectrum for $\pi\pi$ pairs associated with ϕ production is shown in Fig. 21.3.13(b)(Aubert, 2007bc). Besides the clear $f_0(980)$ signal, and a concentration consistent with the $f_2(1270)$ resonance, a broad bump at lower mass values is observed, which can be interpreted as the controversial $f_0(600)$ scalar meson.

The $e^+e^- \to \phi\pi\pi$ mass spectrum is measured in $25\,\mathrm{MeV}/c^2$ wide bins by extracting the number of reconstructed $\phi \to K^+K^-$ decays from a fit to the K^+K^- mass spectrum. The corresponding cross section is then obtained applying Eq. (21.2.12) and taking into account the $\phi \to K^+K^-$ branching fraction. With an analogous procedure, but requiring in addition that $0.85 < m(\pi\pi) < 1.1\,\mathrm{GeV}/c^2$, a 90% pure sample of $\phi f_0(980)$ is selected, and, assuming a decay rate $\mathcal{B}(f_0(980) \to \pi^+\pi^-) = 2/3$,

the cross section is measured. Similar distributions and results are obtained for the $\phi\pi^0\pi^0$ final state.

The cross section for the two $f_0(980)$ decay modes are consistent with each other; both are shown in Fig. 21.3.14. The data are successfully described by a relatively narrow resonance, called the $Y(2175)$, interfering with a non-resonant term. The result of the fit is shown as the solid line in the figure. By contrast, the attempt to fit the data with only the non-resonant term, accounting for the finite width of the ϕ and $f_0(980)$, and for their spin and phase space, is clearly unsatisfactory (see the dashed red line). The histogram is the result of a simulation of the non-resonant $e^+e^- \to \phi(1020)f_0(980)$ reaction, which also fails to reproduce the features seen in the data.

The $Y(2175)$ was confirmed by the BES Collaboration in the $\phi f_0(980)$ invariant mass spectrum from $J/\psi \to \eta\phi f_0(980)$ decays (Ablikim et al., 2008b), as well as in subsequent measurements making use of the full data sets now available to Belle and *BABAR*.

The new analyses at the two B Factories select the $\phi\pi\pi$ and $\phi f_0(980)$ final states in a way similar to the previous *BABAR* analysis and measure rather consistent cross sections, and, thanks to the larger data samples ($674\,\mathrm{fb}^{-1}$ for Belle, and $475\,\mathrm{fb}^{-1}$ for *BABAR*), a more precise study of the $e^+e^- \to \phi\pi\pi$ cross section and of the intermediate states involved is possible. In both cases, the $e^+e^- \to \phi(1020)\pi^+\pi^-$ cross section shows two clear peaks: the first, at about 1.7 GeV, can be attributed to the $\phi(1680)$, and the second, above 2 GeV, to the $Y(2175)$. Different models have been used by the two collaborations to fit the cross section distributions.

Belle (Shen, 2009) uses an incoherent sum of two Breit-Wigner functions, one for the $\phi(1680)$, which is assumed to decay into $\phi\pi^+\pi^-$, and the other for the $Y(2175)$ which decays predominantly into $\phi f_0(980)$. The result of the fit is shown as the solid line in Fig. 21.3.15, while the separate contributions of the two fitted resonances are given by the dotted lines.

In the *BABAR* analysis (Lees, 2012d), it is also noted that the second structure, associated to the $Y(2175)$, completely disappears if events with a dipion mass under the $f_0(980)$ peak are removed. Figure 21.3.16 shows the *BABAR* data and the result of a fit to a VMD-based model. This assumes that two vector mesons contribute to the cross sec-
Figure 21.3.13. (a) The reconstructed $m(\pi^+\pi^-)$ vs $m(K^+K^-)$ distribution for the $e^+e^- \rightarrow K^+K^-\pi^+\pi^-$ reaction measured by *BABAR* (Aubert, 2006c). The vertical lines identify the selected region around the ϕ mass peak. (b) Background subtracted $m(\pi^+\pi^-)$ distribution of selected $e^+e^- \rightarrow \phi(1020)\pi^+\pi^-$ events (Aubert, 2007bc). The solid line is the results of the fit to the data with a coherent sum of two Breit-Wigner functions, referring to the $f_0(600)$ and $f_0(980)$.

tion: the $\phi(1680)$ decaying both to $\phi f_0(600)$ and $\phi f_0(980)$, and the $Y(2175)$ decaying to $\phi f_0(980)$ only. Since the nominal $\phi(1680)$ mass lies below the $\phi f_0(980)$ threshold, the $\phi(1680) \rightarrow \phi f_0(980)$ decay will reveal itself as a smooth bump in the energy dependence of the $e^+e^- \rightarrow \phi f_0(980)$ cross section above 2 GeV, as shown by the dotted line in the plot. The solid line is the result of the total fit to the $\phi\pi\pi$ cross section, which clearly indicates the need for an additional resonance centered at about 2.2 GeV, on top of the dashed line showing the $\phi(1680)$ contribution.

Both collaborations also fitted the selected samples of $\phi f_0(980)$ events, finding results consistent with the fits to the whole $\phi\pi^+\pi^-$ sample. The final quoted values for the
Figure 21.3.14. The $e^+e^- \rightarrow \phi f_0(980)$ cross sections measured in the $K^+K^-\pi^+\pi^-$ (circles) and $K^+K^-\pi^0\pi^0$ (squares) final states using an integrated luminosity of 232 fb^{-1} by *BABAR* (Aubert, 2007bc). The hatched histogram shows the simulated cross section in the no-resonance hypothesis, which is consistent with a fit to the data with only a non-resonant component (dashed line). The solid line represents the result of the fit described in the text assuming the presence of the $Y(2175)$.
Figure 21.3.15. The $e^+e^- \rightarrow \phi\pi^+\pi^-$ cross section measured by Belle (Shen, 2009). The solid line is the result of a fit with two incoherent BW functions, one for the $\phi(1680)$ and the other for the $Y(2175)$. The dashed lines show the individual contributions of the two resonances.

parameters of the $\phi(1680)$ and $Y(2175)$ resonances are in reasonable agreement between Belle and *BABAR* (considering slightly different modelling, for example (in)coherence of contributing amplitudes). In particular, for the mass and the width of the $Y(2175)$, Belle finds, respectively, $m_Y = (2.079 \pm 0.013^{+0.079}_{-0.028})$ GeV/c^2 and $\Gamma_Y = (192 \pm 23^{+25}_{-61})$ MeV, while *BABAR* finds a higher mass, $m_Y = (2.180 \pm 0.008 \pm 0.008)$ GeV/c^2, and a smaller width, $\Gamma_Y = (77 \pm 15 \pm 10)$ MeV.
Figure 21.3.16. The fit to the $e^+e^- \to \phi\pi^+\pi^-$ cross section measured by *BABAR* (Lees, 2012d) in the two-resonance model described in the text (solid curve). The contribution of the first resonance ($\phi(1680)$) is shown by the dashed line. The dotted line shows the first resonance contribution in the $\phi f_0(980)$ decay mode only.

The nature of the $Y(2175)$ is still uncertain. The similar width (≈ 200 MeV) measured by Belle for the $\phi(1680)$ and the $Y(2175)$, even if with large uncertainties, may suggest that the $Y(2175)$ is a radially excited $s\bar{s}$ vector state. On the other hand, the significantly smaller width reported by *BABAR* and BES, and the different decay modes observed for the $\phi(1680)$ and the $Y(2175)$, do not favor this solution (Napsuciale, Oset, Sasaki, and Vaquera-Araujo, 2007). Several other interpretations have been proposed, such as a $s\bar{s}s\bar{s}$ four-quark state, or a gluon hybrid $s\bar{s}g$. For a review of this and other recently discovered hadrons see (Zhu, 2008) and references therein. The study of the $Y(2175)$ in other decay modes is needed to distinguish between the different possibilities.

21.3.5.4 Summary of studies of J/ψ and $\psi(2S)$ decays.

The clear J/ψ and $\psi(2S)$ signals observed in the cross sections for e^+e^- annihilation to almost all the final states presented in the previous sections allowed a systematic study of the decays of the two charmonium states to light hadrons with the *BABAR* detector.

The Born cross section for the production via ISR of a narrow resonance such as a ψ, and its subsequent decay to the final state X, is given by

$$\sigma_\psi = \frac{12\pi^2 \Gamma(\psi \to e^+e^-)\mathcal{B}(\psi \to X)}{sm_\psi} W_0(s, x_\psi, \theta_0),$$

(21.3.14)

where m_ψ, $\Gamma(\psi \to e^+e^-)$, and $\mathcal{B}(\psi \to X)$ are the mass of the ψ, its partial width to electrons, and its branching fraction to the final state X respectively. The radiator function W_0 has been introduced in Section 21.2.1,

and $x_\psi = 1 - m_\psi^2/s$ is the fraction of the CM energy carried by the photon in the case of radiative return to the ψ mass. Therefore, for a given final state X, the product of the electronic width and the branching fraction $\Gamma(\psi \to e^+e^-)\mathcal{B}(\psi \to X)$ can be obtained by measuring the number of ψ decays in the $e^+e^- \to X$ mass spectrum.

The samples of J/ψ and $\psi(2S)$ available for these studies are significantly smaller than those collected at other facilities. The total cross section for $e^+e^- \to \gamma_{\mathrm{ISR}} J/\psi$ with a tagged ISR photon is about 3.4 pb, corresponding to 1.7 million J/ψ's for an integrated luminosity of ~ 500 fb^{-1}; about 60 million J/ψ's have been produced in the BES II experiment at the BEPC e^+e^- collider. However, systematic uncertainties are significantly smaller at *BABAR* (typically 3–5%, compared to 10–15% at BES II), due in particular to superior particle identification.[161] As a result *BABAR* measurements are competitive and in many cases more accurate than previous data for all decays with branching fractions $O(10^{-3})$ and higher, and many decays to final states containing charged kaons have been studied for the first time. In summary, using the ISR method, the *BABAR* experiment has improved the precision on the measurement of a few tens of J/ψ and $\psi(2S)$ branching fractions, and has observed about 20 new decay modes. A complete list of these results is found in the Review of Particle Physics (Beringer et al., 2012).

21.3.6 Search for $f_J(2220)$

Evidence for the $f_J(2220)$, a narrow resonance with a mass around 2.2 GeV/c^2 also known as $\xi(2230)$, was first presented by the Mark III Collaboration (Baltrusaitis et al., 1986). The $f_J(2220)$ was seen as a narrow signal above a broad enhancement in both $J/\psi \to \gamma f_J(2220)$, $f_J(2220) \to K^+K^-$ and $f_J(2220) \to K_S^0 K_S^0$ decays with significance of 3.6 and 4.7 standard deviations, respectively. The BES Collaboration has also subsequently reported evidence in radiative J/ψ decays at a comparable level of significance (Bai et al., 1996b), while searches for direct formation in $p\bar{p}$ collisions or two-photon processes were inconclusive (see for example Crede and Meyer, 2009, for an experimental review).

The unexpectedly narrow width of the $f_J(2220)$, approximately 20 MeV, triggered many conjectures about its nature (see for example Blundell and Godfrey, 1996). The possibility of a glueball (Ward, 1985), a bound state of gluons, is particularly attractive as several lattice QCD calculations predict a mass for the ground state 2^{++} glueball close to 2.2 GeV/c^2 (Chen and Su, 2004; Morningstar and Peardon, 1997). No glueball candidate has been unambiguously observed to date.

Based on a sample of 16 million J/ψ mesons produced in ISR events, *BABAR* performed a search for $f_J(2220)$ production in radiative $J/\psi \to \gamma f_J(2220)$ decays (del Amo San-

---

[161] In 2009, the upgraded BESIII experiment at BEPCII has collected 225 million J/ψ and 106 million $\psi(2S)$ events. The systematic error is significantly improved over BESII experiment (Ablikim et al., 2012b).

chez, 2010o). The $f_J(2220)$ is identified through its subsequent decay into a K^+K^- or $K^0_S K^0_S$ pair. The ISR photon is not required to be detected.

Requirements on particle identification, secondary vertex reconstruction, decay angles and global event information are used to improve the signal purity. The J/ψ candidates are then fitted, constraining their mass and decay products to a common vertex. The fitted K^+K^- and $K^0_S K^0_S$ mass spectra are shown in Fig. 21.3.17, together with the expected contributions of the inclusive $e^+e^- \to q\bar{q}(\gamma)$ $(q = u, d, s, c)$ background as well as $J/\psi \to \gamma f'_2(1525)$ and $\gamma f_0(1710)$ channels. A possible contribution from $J/\psi \to K^{*\pm}K^{\mp}$ decays was found to be negligible. Sideband data from the unconstrained J/ψ mass distributions are used to model the non-resonant background. The sum of these components reproduces the data well at a global level. Remaining events are due mainly to generic J/ψ decays producing additional undetected particles, mostly with pions misidentified as kaons in the charged mode.

The number of signal events is determined using an unbinned maximum likelihood fit in the range $1.9\,\mathrm{GeV}/c^2 < m_{KK} < 2.6\,\mathrm{GeV}/c^2$, fixing the mass and width of the $f_J(2220)$ to $2.231\,\mathrm{GeV}/c^2$ and $23\,\mathrm{MeV}$, respectively. No evidence of a $f_J(2220)$ signal is observed. Upper limits on the $J/\psi \to \gamma f_J(2220)$, $f_J(2220) \to K^+K^-$ and $K^0_S K^0_S$ product branching fractions are derived at the 90% confidence level as a function of the spin and helicity assumed for the $f_J(2220)$. For all hypotheses of spin and helicity, these limits are below the central values reported by Mark III. Only one hypothesis (spin $J = 2$ and helicity $h = 0$) is compatible with the BES results for both final states, while all other possibilities are excluded.

21.3.7 Measurement of time-like baryon form factors

Electromagnetic form factors (FFs) describe the modifications of pointlike photon-hadron vertices due to the structure of hadrons. The e^+e^- annihilation in two hadrons or the electron scattering off a nucleon are described in QED by a product of an electronic and a hadronic electromagnetic currents. While the coupling of the photon with the electron is exactly calculable in QED, the coupling with the hadron is not. The dynamical content of the hadronic vertex can be however described with a set of form factors, and can be directly extracted from data.

21.3.7.1 Nucleon Form Factors

The elastic scattering of an electron by a nucleon $e^-N \to e^-N$ is represented, in the Born approximation, by Fig. 21.3.18, with time flowing from the bottom to the top of the diagram. In this kinematic region the 4-momentum of the virtual photon is space-like and hence its squared value is negative: $q^2 = -2\omega_1\omega_2(1-\cos\theta_e) \leq 0$, where $\omega_{1(2)}$ is the energy of the incoming (outgoing) electron and θ_e is the scattering angle. The same diagram, but with time flowing left to right (right to left), represents the
Figure 21.3.17. The K^+K^- (top) and $K^0_S K^0_S$ (bottom) mass spectra obtained by BABAR in selected $J/\psi \to \gamma K^+K^-$ and $J/\psi \to \gamma K^0_S K^0_S$ decays, together with the expected contributions of the non-resonant background, $J/\psi \to \gamma f'_2(1525)$ and $J/\psi \to \gamma f_0(1710)$ reactions. The results of the fit to the data are shown in the inset (del Amo Sanchez, 2010o).
Figure 21.3.18. One-photon exchange Feynman diagram for scattering $e^-N \to e^-N$ and annihilation $e^+e^- \to N\bar{N}$.

annihilation $e^+e^- \to N\bar{N}$ $(N\bar{N} \to e^+e^-)$. For these processes the 4-momentum q is time-like: $q^2 = (2\omega)^2 \geq 0$, where $\omega \equiv \omega_1 = \omega_2$ is the common value of the lepton energy in the e^+e^- center-of-mass frame.

The Feynman amplitude for the elastic scattering is

$$\mathcal{M} = \frac{1}{q^2} \left[e\, \overline{u}(k_2) \gamma^\mu u(k_1) \right] \left[e\, \overline{U}(p_2) \Gamma_\mu(p_1, p_2) U(p_1) \right],$$
(21.3.15)

where $k_i = (\omega_i, \boldsymbol{k}_i)$ and p_i $(i = 1, 2)$ are the electron and nucleon four-vectors, u and U are the electron and nucleon spinors, and Γ^μ is a non-constant matrix which describes the nucleon vertex. Using gauge and Lorentz invariance the most general form of such a matrix is (Foldy, 1952)

$$\Gamma^\mu = \gamma^\mu F_1(q^2) + \frac{i\sigma^{\mu\nu} q_\nu}{2m} F_2(q^2),$$
(21.3.16)

where m is the nucleon mass. Γ^μ depends on two Lorentz scalar functions of q^2, the Dirac ($F_1(q^2)$) and Pauli FFs ($F_2(q^2)$), that describe the helicity-conserving and the helicity-reversing parts of the hadronic current, respectively. Normalizations at $q^2 = 0$ follow from total charge and magnetic moment of the nucleon: $F_1(0) = Q_N$ and $F_2(0) = a_N$ respectively, where Q_N is the electric charge (in units of e) and a_N the anomalous magnetic moment of the nucleon N, in units of the nuclear magneton $e\hbar/2m$.[162]

Other pairs of FFs can be defined as combinations of F_1 and F_2: of particular interest are the so-called Sachs FFs G_E and G_M (Hand, 1963), defined as

$$G_E = F_1 + \frac{q^2}{4m^2} F_2,$$
$$G_M = F_1 + F_2.$$
(21.3.17)

These expressions are obtained by considering the hadronic current in the Breit frame: the Fourier transformations of G_E and G_M give the spatial distributions of charge and magnetic moment of the nucleon; the normalizations are

$$G_E(0) = Q_N, \qquad G_M(0) = \mu_N,$$
(21.3.18)

where μ_N is the nucleon magnetic moment in units of the nuclear magneton.[163]

21.3.7.2 Cross sections and data

The differential cross section of the annihilation process $e^+ e^- \to N\overline{N}$, for unpolarized colliding beams, is given in the $e^+ e^-$ CM by (Zichichi, Berman, Cabibbo, and Gatto, 1962)

$$\frac{d\sigma}{d\Omega} = \frac{\alpha^2 \beta C}{4 q^2} \left[(1 + \cos^2 \theta) \left| G_M(q^2) \right|^2 + \frac{1}{\tau} \sin^2 \theta \left| G_E(q^2) \right|^2 \right],$$
(21.3.19)

---

[162] For proton $F_1(0) = 1$, $F_2(0) = 1.7928$, and for neutron $F_1(0) = 0$, $F_2(0) = -1.9130$.
[163] For proton $G_M(0) = 2.7928$ and for neutron $G_M(0) = -1.9130$.

where $\tau = q^2/4m^2$, $\beta = \sqrt{1 - 1/\tau}$ is the velocity of the outgoing nucleon, and C is the so-called Coulomb factor (Sakharov, 1948)

$$C = \begin{cases} \dfrac{\pi\alpha/\beta}{1 - \exp(-\pi\alpha/\beta)} & \text{for } Q_N = 1 \\[2mm] 1 & \text{for } Q_N = 0, \end{cases}$$
(21.3.20)

which accounts for electromagnetic $N\overline{N}$ final state interactions; C corresponds to the squared value of the Coulomb scattering wave function at the origin. Integration of Eq. (21.3.19) over the polar angle gives the total cross section:

$$\sigma(q^2) = \frac{4\pi\alpha^2 \beta C}{3 q^2} \left[\left| G_M(q^2) \right|^2 + \frac{1}{2\tau} \left| G_E(q^2) \right|^2 \right].$$
(21.3.21)

At production threshold $|G_E(4m^2)| = |G_M(4m^2)|$, while at high q^2 the contribution of G_E to the cross section becomes negligible because of the suppression from the $1/2\tau$ term. Experiments usually quote measurements of $|G_M(q^2)|$ under the working hypothesis $|G_E(q^2)| = |G_M(q^2)|$, which is exactly true only at threshold. *BABAR* introduces an effective FF defined as

$$|F(q^2)|^2 = \frac{2\tau |G_M(q^2)|^2 + |G_E(q^2)|^2}{2\tau + 1},$$
(21.3.22)

which can be directly compared to the previous measurements of $|G_M(q^2)|$. The total cross section is thus written as

$$\sigma(q^2) = \frac{4\pi\alpha^2 \beta C}{3 q^2} \left(1 + \frac{1}{2\tau} \right) |F(q^2)|^2.$$
(21.3.23)

Simultaneous extraction of $|G_E|$ and $|G_M|$ requires precise determination of the $|G_E/G_M|$ ratio, which is possible in principle by measuring the angular distributions of the outgoing particles, using Eq. (21.3.19). A $|G_E/G_M|$ measurement for the proton is discussed in Section 21.3.7.4 below.

21.3.7.3 Measurement of $e^+ e^- \to p\overline{p}$

The *BABAR* experiment performed an ISR tagged analysis of $e^+ e^- \to \gamma_{\mathrm{ISR}} p\overline{p}$ based on a sample of $232\,\mathrm{fb}^{-1}$ of data, and selected more than 4000 events, measuring the $e^+ e^- \to p\overline{p}$ cross section with highest accuracy in the range of $p\overline{p}$ invariant mass from threshold up to about $M_{p\overline{p}}^2 = 4.5$ GeV/c^2 (Aubert, 2006d). As for the other ISR processes previously discussed, the reconstructed hadronic mass gives the CM energy of the hadronic process: $M_{p\overline{p}}^2 = q^2$. Figure 21.3.19 shows a comparison of the measured cross section for $M_{p\overline{p}} < 2.9$ GeV/c^2 with previous measurements performed with lower precision by Castellano et al. (1973) and the Fenice experiment (Antonelli et al., 1998) at Adone, by DM1 (Delcourt et al., 1979) and DM2 (Bisello et al., 1990), and more recently by CLEO (Pedlar et al., 2005) and BES (Ablikim et al., 2005a).
Figure 21.3.19. The $e^+e^- \to p\bar{p}$ cross section measured by *BABAR* (Aubert, 2006d) in the energy region from threshold to about 3 GeV. Data from previous experiments are shown for comparison.

Figure 21.3.20. The proton form factor measured by *BABAR* (Aubert, 2006d) compared to data from previous $e^+e^- \to p\bar{p}$ (blue online) and $p\bar{p} \to e^+e^-$ (red online) experiments. The dashed line is the fit to all available data according to the perturbative QCD prediction. The bottom plot shows an expanded view of the energy region below 3 GeV.

One interesting feature, now apparent due to the precision of the data, is that the $p\bar{p}$ cross section is nearly constant at 0.8 nb for energies up to around 200 MeV above the threshold, before falling with increasing energy. The corresponding effective form factor results are presented in Fig. 21.3.20 as a function of $M_{p\bar{p}}$, together with results obtained from the $p\bar{p} \to e^+e^-$ experiments PS170 (Bardin et al., 1994), E760 (Armstrong et al., 1993), and E835 (Ambrogiani et al., 1999; Andreotti et al., 2003). General consistency among all these data is observed: in particular the precise data from *BABAR* and from the PS170 experiment ($p\bar{p}$ annihilation at LEAR) show a similar rise in the form factor when the energy approaches $p\bar{p}$ threshold. Several explanations of this intriguing feature have been proposed, such as that the sharp rise is due to final state interaction of the proton and antiproton (see Dmitriev and Milstein, 2007, and references therein); or that it is due to a contribution from a vector-meson resonance with a mass of about 1.9 GeV/c^2, just below the $p\bar{p}$ production threshold (such a state is observed as a dip in the cross section of the $e^+e^- \to 6\pi$ processes: Aubert, 2006az; Frabetti et al., 2001). The hypothesis of an incorrect evaluation of the Coulomb factor has also been advanced: see for example Ferroli, Pacetti, and Zallo (2012). The dashed line in Fig. 21.3.20 is the result of a fit of the form factor data according to the function $F_{\mathrm{QCD}} = A/(m^4 \log^2(m^2/\Lambda^2))$, which correspond to the perturbative QCD prediction for the asymptotic behavior of the baryon form factors (Chernyak and Zhitnitsky, 1977; Lepage and Brodsky, 1979b). Here, $\Lambda = 0.3$ GeV and A is a free parameter of the fit. It is seen that the asymptotic result provides a reasonable description of the data even at these energies.

21.3.7.4 Measurement of $|G_E^p/G_M^p|$

The distribution of the proton helicity angle in the $p\bar{p}$ rest frame for $e^+e^- \to \gamma_{\mathrm{ISR}}p\bar{p}$ events can be written as a function of the ratio of the electric and magnetic form factors:

$$\frac{dN}{d\cos\theta_p} = A\left(H_M(\cos\theta_p, q^2) + \left|\frac{G_E}{G_M}\right|^2 H_E(\cos\theta_p, q^2)\right).$$
(21.3.24)

The functions H_E and H_M, which are determined using MC simulation, do not strongly differ from the terms $\sin^2\theta_p$ and $1 + \cos^2\theta_p$ that appear in Eq. (21.3.19). The mass region from $p\bar{p}$ threshold up to 3 GeV/c^2 is divided into six intervals. The angular distribution in each interval is then fitted to Eq. (21.3.24), with A and $|G_E/G_M|$ as free parameters. The functions H_E and H_M are modeled with the histograms obtained from MC simulation with the $p\bar{p}$ selection applied. The values of the ratio $|G_E/G_M|$ obtained by Aubert (2005ah) are significantly larger than unity, as shown in Fig. 21.3.21, in disagreement with previous results from PS170 at LEAR (Bardin et al., 1994).
Figure 21.3.21. The proton $|G_E/G_M|$ ratio measured by *BABAR* (Aubert, 2006d; solid points) compared with PS170 data (Bardin et al., 1994; open circles). The curve is a result of a fit to *BABAR* data with the function $(1 + ax/(1 + bx^2))$.

Figure 21.3.22. The $e^+e^- \to \Lambda\overline{\Lambda}$ cross section measured by *BABAR* (Aubert, 2007az) in comparison with the DM2 measurement (Bisello et al., 1990).

We should note that the PS170 data were limited by incomplete angular acceptance ($|\cos\theta_p| < 0.8$) and were affected by strong angular dependence of the detection efficiency: this limitation is not present when a tagged ISR analysis is performed.

21.3.7.5 Measurement of strange baryon form factors.

The *BABAR* Collaboration has also studied the production via ISR of several final states made of strange baryon pairs, namely $e^+e^- \to \Lambda\overline{\Lambda}$, $\Sigma\overline{\Sigma}$, and $\Lambda\overline{\Sigma}^0$ $(\Sigma^0\overline{\Lambda})$ (Aubert, 2007az). Only a single measurement of $\Lambda\overline{\Lambda}$ production at 2.386 GeV, by the DM2 Collaboration, and upper limits on the other process, were previously available. The Λ is reconstructed in the $p\pi^-$ decay, while for the Σ the decay chain $\Sigma \to \Lambda\pi$, $\Lambda \to p\pi^-$ is used. The cross section measured for $e^+e^- \to \Lambda\overline{\Lambda}$, based on about 200 selected events, after background subtraction, is shown in Fig. 21.3.22. The measured cross section is consistent with a behavior similar to that in $p\bar{p}$ production: an almost flat distribution from threshold over a ~ 200 MeV range, and in particular a value different from zero at threshold. This behavior is contrary to expectations, as the Coulomb factor plays no role for neutral final-state particles. However, the large uncertainties due to the limited sample can not exclude a vanishing cross section at threshold.

The study of the angular distribution of produced Λ's allows the measurement of $|G_E/G_M|$: the ratio is consistent with unity within the large statistical uncertainty.

Should the relative phase ϕ between G_E and G_M be different from zero, polarization of the outgoing baryons, perpendicular to the scattering plane of the process $e^+e^- \to \mathfrak{B}\overline{\mathfrak{B}}$, is expected (see Dubnickova, Dubnicka, and Rekalo, 1996, and Czyz, Grzelinska, and Kühn, 2007, for

the specific case of ISR production). While the polarization of the outgoing protons in the $p\bar{p}$ production case cannot be measured in *BABAR*, the Λ polarization ζ can be extracted from the proton angular distribution in the $\Lambda \to p\pi^-$ decay,

$$\frac{dN}{d\cos\theta_{p\zeta}} = A\left(1 + \alpha_\Lambda \zeta \cos\theta_{p\zeta}\right), \qquad (21.3.25)$$

where $\theta_{p\zeta}$ is the angle between the polarization axis and the proton momentum in the Λ rest frame, and $\alpha_\Lambda = 0.642 \pm 0.013$ (Yao et al., 2006) the decays asymmetry parameter, with $\alpha_{\overline{\Lambda}} = -\alpha_\Lambda$. For unpolarized events in the MC simulation, the distribution is consistent with being isotropic (flat in $\cos\theta_{p\zeta}$), as expected.

The fit to the background subtracted data distribution returns a slope of 0.020 ± 0.097. Under the assumption of $|G_E| = |G_M|$ this measurement can be converted into a 90% C.L. interval for the relative phase of the two form factors: $-0.76 < \sin\phi < 0.98$. The obtained limits are very weak, but the method has been proven to work and could give interesting results when significantly larger samples become available.

Fig. 21.3.23 shows the strange-baryon effective form factors measured by *BABAR*. About 20 candidate events have been selected for both $e^+e^- \to \Sigma\overline{\Sigma}$ and $e^+e^- \to \Sigma^0\overline{\Lambda}$. It is seen that the Λ, Σ^0, and $\Sigma^0\Lambda$ form factors are of the same order. For comparison, the proton FF measured by *BABAR* is also shown: the energy-dependence of the Λ and proton FFs differ. A fit to the Λ FF with the power-law function $F(Q^2) \sim Q^{-n}$ returns $n \simeq 9$, showing that the asymptotic regime ($n = 4$) predicted by perturbative-QCD is not reached in the measured energy range below 3 GeV.
Figure 21.3.23. The baryon form factors measured by BABAR versus the dibaryon invariant mass. Data taken from Aubert (2005ah, 2007az).

21.4 Open charm production

Due to intriguing discoveries of exotic charmonium like states (see Secs. 21.5 and 18.3) with masses at which conventional charmonium states are expected to decay predominantly into pairs of open charm mesons it is of great interest to explore the ISR production of these final states.

Exclusive production of open charm has been studied in two different regimes at the B Factories: far from threshold, in e^+e^- annihilation at the CM energy of the collider (Section 21.4.1), and from threshold up to 5–6 GeV, depending on the final state, using the ISR technique (Sections 21.4.2–21.4.6). There is no general approach to these measurements: the method that yields maximum significance needs to be determined case-by-case. The measurement of $e^+e^- \rightarrow D^{(*)+}D^{(*)-}$ production at the CM energy (Section 21.4.1) introduced a partial reconstruction method that exploits the special properties of the D^* decay. Here $D^{(*)}$ denotes a D or D^* meson. Measurement of $D\bar{D}$ production in ISR events, on the other hand, was performed by full reconstruction of both charmed mesons (Section 21.4.2). Analyses of $D^{(*)+}D^{*-}$ (Section 21.4.3), charmed-strange (Section 21.4.4), and three-body charmed meson cross sections (Section 21.4.5), and a study of charmed baryon production (Section 21.4.6), use variants of these techniques.

In ISR events of this type, the continuous spectrum of photons emitted from the initial state provides access to a range of energies above open charm threshold. This allows the measurement of cross sections without the additional systematic uncertainties due to variation of the detector and machine conditions from one energy point to another during the relatively long time of the data collection. However, the electromagnetic suppression of ISR processes and the reduced reconstruction efficiency due to the event topology present considerable challenges. Re-

construction of exclusive production at the CM energy does not face these problems, but in this regime the cross section itself is low. Together with the very high luminosities available at the B Factories, careful choice of analysis methods has allowed many exclusive charmed hadron cross sections to be measured over a wide energy range, with good accuracy.

21.4.1 Measurement of exclusive $D^{(*)+}D^{(*)-}$ production far from threshold

Knowledge of exclusive charmed meson production in e^+e^- annihilation is rather poor. The only exception is the near-threshold region, where the small phase space limits the number of particles in the final state. Heavy quark effective theory (HQET), based on heavy-quark spin symmetry, provides a description of these processes in terms of a universal form factor called the Isgur-Wise function. For large q^2, however, the leading-twist contribution, violating this symmetry, becomes dominant. In the intermediate-q^2 region the contribution of the symmetry-violating terms remains significant. A calculation that takes this effect into account (Grozin and Neubert, 1997) predicts cross sections of about $2.5 \, \text{pb}^{-1}$ for the $e^+e^- \rightarrow D_T^* \bar{D}_L^*$ and $e^+e^- \rightarrow D\bar{D}^*$ processes, where the subscripts T and L indicate transverse and longitudinal polarization of the D^*, respectively. The cross section of the $e^+e^- \rightarrow D\bar{D}$ process is estimated to be at least 1000 times smaller.

Exclusive meson production in e^+e^- annihilation is difficult to study experimentally due to its extremely low cross-section and reconstruction efficiency. A partial reconstruction method is therefore used: one $D^{(*)}$ meson is fully reconstructed while the other remains unreconstructed. For definiteness, suppose the $D^{(*)+}$ is the fully reconstructed meson. The distribution of recoil mass M_{recoil}, where

$$M^2_{\text{recoil}}(D^{(*)+}) = (E_{\text{CM}} - E(D^{(*)+}))^2 - p^2(D^{(*)+}),$$
$$(21.4.1)$$

can be used for identification of the process. Signal events are expected to cluster around the mass of the unreconstructed $D^{(*)-}$ meson. This method provides better reconstruction efficiency than the exclusive reconstruction of the event, but the background level is also much higher. If the unreconstructed meson is a D^*, one can reconstruct one of its decay products—usually the pion, π^-_{slow}, in $D^{*-} \rightarrow \bar{D}^0 \pi^-_{slow}$—and construct the recoil mass difference

$$\Delta M_{\text{recoil}} = M_{\text{recoil}}(D^{(*)+}) - M_{\text{recoil}}(D^{(*)+}\pi^-_{slow}).$$
$$(21.4.2)$$

Since most of the uncertainties cancel in the difference, the peak at the nominal mass difference $m_{D^*} - m_D$ in the ΔM_{recoil} distribution remains narrow ($\sim 1 \, \text{MeV}/c^2$). The width is determined mostly by the slow pion reconstruction accuracy. The use of the recoil mass difference as a discriminating or a signal variable is a powerful tool for background suppression. It was used by the Belle collaboration in ISR analyses (see Section 21.4.3) and in the

study of D-meson semileptonic decays (Widhalm, 2006; see Section 19.1.5).

Exclusive $e^+e^- \rightarrow D^{(*)+}D^{(*)-}$ processes have been studied by the Belle collaboration using $89\,\mathrm{fb}^{-1}$ of data (Uglov, 2004). Recoil mass spectra for events with recoil mass difference lying within $2\,\mathrm{MeV}/c^2$ of the nominal value are shown in Fig. 21.4.1(a) and (b) for $D^{*+}D^{*-}$ and D^+D^{*-} final states. The recoil mass spectrum for the $e^+e^- \rightarrow D^+D^-$ process is shown in Fig. 21.4.1(c). The spectra are fitted with a sum of signal and background functions. ISR photon emission produces a tail in M_{recoil}, which must be taken into account. The approach used is to divide events in the Monte Carlo into those with ($E_{\mathrm{ISR}} > 10\,\mathrm{MeV}$) and without ($E_{\mathrm{ISR}} < 10\,\mathrm{MeV}$) an ISR photon of significant energy, and to determine separate signal shapes for the two categories. The final measurement is of the Born cross-section, which does not depend on the ISR photon cutoff value, although experimental estimation of the ISR fraction does contribute to the systematic uncertainty.

The signal is parameterized as a sum of a signal Gaussian and a Monte Carlo-based shape for events with significant ISR. The background is described by a threshold function $\alpha \cdot (x - m_{D^{*-}} - m_{\pi^0})^\beta$, where α and β are fit parameters. Both signal and background contributions are convolved with the detector resolution. In the $D^{*+}D^{*-}$ and D^+D^{*-} final states, the D^* mesons can have either longitudinal or transverse polarization. To distinguish these cases the angular distributions of the D^* decays are fitted with the sum of the Monte Carlo shapes for all possible polarizations. The fit results and extracted cross sections are summarized in Table 21.4.1.

Systematic uncertainties for $D^{*+}D^{*-}$ and D^+D^{*-} final states, shown in Table 21.4.2, are dominated by the uncertainty in the tracking efficiency, and the estimation of the fraction of events with a hard ISR photon. The main uncertainty in the $e^+e^- \rightarrow D^+D^-$ cross-section is due to the non-resonant $e^+e^- \rightarrow D^+\bar{D}\pi$ process and cannot be reliably estimated.

The measured $e^+e^- \rightarrow D_T^{*+}D_L^{*-}$ and $D^+D_T^{*-}$ cross sections are 3–4 times smaller than predicted in Grozin and Neubert (1997). The upper limits set for the $e^+e^- \rightarrow D_L^{*+}D_L^{*-}$ and $D_T^{*+}D_T^{*-}$ processes are also lower than the HQET prediction; the limit on the $e^+e^- \rightarrow D^+D^-$ process does not contradict the prediction. Unlike the absolute values, the cross-section ratios (on which the theoretical uncertainties are much smaller) are in agreement with the measured values. Calculations in the pQCD framework (Liu, He, Zhang, and Chao, 2010) are in agreement with the measured $e^+e^- \rightarrow D^{*+}D^{*-}$ and D^+D^{*-} cross-sections, although the predicted D^* polarizations are far from the measured values. Another pQCD calculation taking into account the hard part of the meson wave function only (Berezhnoy and Likhoded, 2005) represents the data well, but being a rough estimation, requires a more accurate approach.

Table 21.4.1. Fit results and Born cross-sections for $e^+e^- \rightarrow D^{(*)+}D^{(*)-}$ from Uglov (2004). Upper limits are determined at the 90% confidence level. HQET predictions, which are approximate, are taken from Grozin and Neubert (1997); the $D_L^{*+}D^-$ final state is forbidden within this scheme. The pQCD prediction is from Liu, He, Zhang, and Chao (2010).

final state	signal events	cross-section (pb)	HQET (pb)	pQCD (pb)
$D_T^{*+}D_T^{*-}$	5^{+15}_{-13}	< 0.02	0.05	
$D_T^{*+}D_L^{*-}$	708 ± 36	0.55 ± 0.03	3.0	0.347
$D_L^{*+}D_L^{*-}$	4^{+18}_{-17}	< 0.02	0.1	
$D_T^{*+}D^-$	433 ± 24	0.62 ± 0.03	3.0	0.699
$D_L^{*+}D^-$	-1.5 ± 2.2	< 0.006	–	
D^+D^-	-13 ± 24	< 0.04	0.006	0.098

Table 21.4.2. Systematic uncertainty in the $D^{(*)+}D^{*-}$ cross-sections. From Uglov (2004).

Source	$D^{*+}D^{*-}$	D^+D^{*-}
Tracking efficiency	9%	8%
Estimation of ISR-events fraction	5%	5%
$\mathcal{B}(D^{(*)})$	4%	8%
K/π misidentification	2%	2%
Background estimation	$^{+1}_{-0}\%$	$^{+1}_{-0}\%$
Form-factor energy dependence	0.8%	0.8%
Total	11%	13%

21.4.2 Measurement of the $D\bar{D}$ cross section via full reconstruction

The simplest way to select signal events in the $e^+e^- \rightarrow D\bar{D}\gamma_{\mathrm{ISR}}$ process (where $D = D^0$ or D^+) is a full reconstruction of the final state, i.e. reconstruction of both D and $\bar{D}$ mesons, and the ISR photon. Although this tagged ISR method provides almost complete background suppression due to the specific event topology (the final state contains an energetic photon of $(4-5)\,\mathrm{GeV}$ and a pair of charmed mesons), the efficiency is low as the photon escapes detection in $\sim 90\%$ of events. To increase the efficiency the presence of the ISR photon is inferred using energy-momentum conservation. The γ_{ISR} signature in this case is a peak at zero in the spectrum of the square of the mass recoiling against the reconstructed $D\bar{D}$ system:

$$M_{\mathrm{recoil}}^2(D\bar{D}) = (E_{\mathrm{CM}} - E_{D\bar{D}})^2 - p_{D\bar{D}}^2. \quad (21.4.3)$$

Here $E_{D\bar{D}}$ and $p_{D\bar{D}}$ are the CM energy and momentum of the $D\bar{D}$ combination, respectively. Good momentum resolution of the reconstructed charmed mesons provides a narrow peak in the recoil mass squared distribution, and a low background level. The remaining background contribution from $e^+e^- \rightarrow D\bar{D}(n)\pi\gamma_{\mathrm{ISR}}$ processes can be strongly suppressed by excluding events
Figure 21.4.1. Recoil mass spectra for: a) $e^+e^- \to D^{*+}D^{*-}$ and b) $e^+e^- \to D^+D^{*-}$ processes with a $\Delta M_{\mathrm{recoil}}$ requirement, respectively; c) $e^+e^- \to D^+D^-$. Points with error bars represent the data. The solid curve corresponds to the fit described in the text; the hatched histogram shows the background contribution estimated from the sidebands; the dotted curve stands for the background fraction found by the fit. The dashed curve represents fraction of the events with significant ISR correction. From (Uglov, 2004).

containing additional charged tracks not used in the D or $\overline{D}$ reconstruction. To suppress the tail of the $e^+e^- \to D^{(*)}\overline{D}^{(*)}(n)\pi^0\gamma_{\mathrm{ISR}}$ spectrum, a tight requirement on $|M_{\mathrm{recoil}}^2(D\overline{D})|$ is applied.

Both *BABAR* and Belle collaborations use this method. The *BABAR* analysis is based on a $384\,\mathrm{fb}^{-1}$ data sample (Aubert, 2009n) in which $D\overline{D}$ candidates are reconstructed in seven combinations of D^0 and D^+ decay modes. Aside from π^0's from D^0 decays, it is required that there be no more than one other π^0 candidate in the event. The tracks of each D candidate are geometrically constrained to come from a common vertex. Subsequently, each $D\overline{D}$ pair is refitted to a common vertex with the constraint that they originate from the e^+e^- interaction region.

The distribution of $M_{\mathrm{recoil}}^2(D\overline{D})$, summed over all $D\overline{D}$ channels, is shown in Fig. 21.4.2. The large bump to the right of the signal peak is due to $e^+e^- \to D\overline{D}\pi^0\gamma_{\mathrm{ISR}}$ events. The inset shows the distribution of the $D\overline{D}$ CM

polar angle θ for events with $|M_{\mathrm{recoil}}^2(D\overline{D})| < 1\,\mathrm{GeV}^2/c^4$. The sharp peak at $\cos(\theta_{D\overline{D}}) = -1$ is typical for ISR production and agrees with Monte Carlo simulations.
Figure 21.4.2. From *BABAR* (Aubert, 2009n). Recoil mass squared, summed over all $D\overline{D}$ channels for $e^+e^- \to D\overline{D}\gamma_{\mathrm{ISR}}$ event candidates. The shaded (yellow) histogram corresponds to combinatorial background estimated from the $D\overline{D}$ mass sidebands. The small inset shows the distribution of the center-of-mass polar angle of the $D\overline{D}$ system in the ISR region, $|M_{\mathrm{recoil}}^2(D\overline{D})| < 1\,\mathrm{GeV}^2/c^4$.

The $e^+e^- \to D\overline{D}$ cross sections (Fig. 21.4.3) are extracted from the $D\overline{D}$ mass distributions after background subtraction, using the method described in Section 21.2.2. The combinatorial background contribution is determined using $D\overline{D}$ sideband regions and amounts to 17.5% for $D^0\overline{D}^0$, and 7.1% for D^+D^-, of the signal candidates with $|M_{\mathrm{recoil}}^2(D\overline{D})| < 1\,\mathrm{GeV}^2/c^4$; this is the dominant source of background. Efficiencies and $D\overline{D}$ mass resolution are obtained from Monte Carlo simulation. The mass resolution determined from the difference between generated and reconstructed $D\overline{D}$ mass is found to be similar for all channels, and increases from 1.5 MeV/c^2 at threshold to 5 MeV/c^2 at $M_{D\overline{D}} = 6.0\,\mathrm{GeV}/c^2$.

The Belle analysis of the $e^+e^- \to D\overline{D}\gamma_{\mathrm{ISR}}$ process (Pakhlova, 2008a), based on a $673.8\,\mathrm{fb}^{-1}$ data sample, is similar. Belle defines a signal region by the requirement $|M_{\mathrm{recoil}}^2(D\overline{D})| < 0.7\,\mathrm{GeV}^2/c^4$. In cases when the ISR photon falls within the detector acceptance ($|\cos(\theta_{D\overline{D}})| < 0.9$), its detection is required and the difference between the CM energy and the invariant mass of the $D\overline{D}\gamma_{\mathrm{ISR}}$ combination must be smaller than $0.58\,\mathrm{GeV}/c^2$.

The resulting $e^+e^- \to D^0\overline{D}^0$ and D^+D^- exclusive cross sections, averaged over each bin width, are shown in Fig. 21.4.3 with statistical uncertainties only. The total systematic uncertainties are 10% (*BABAR* obtained 10.9%
Figure 21.4.3. Exclusive cross sections vs. $\sqrt{s}$ for (upper plot) $e^+e^- \to D^0\bar{D}^0$ and (lower plot) $e^+e^- \to D^+D^-$, measured by Belle (solid squares) and BABAR (open circles). The region immediately above the $\psi(3770)$ is shown inset on an expanded scale. Prepared from the Pakhlova (2008a) and Aubert (2009n) data.

for $D^0\bar{D}^0$ and 8.1% for D^+D^-) and comparable with the statistical errors in the cross section around the $\psi(3770)$ peak; elsewhere, statistical errors dominate.

The $e^+e^- \to D\bar{D}$ exclusive cross sections observed by the two collaborations are in a good agreement. Both contain a clear $\psi(3770)$ signal and structures near the $\psi(4040)$ and $\psi(4415)$ masses. A significant peak at $3.9\,\mathrm{GeV}/c^2$, called $G(3900)$, is in qualitative agreement with predictions of the coupled-channel model (Eichten, Gottfried, Kinoshita, Lane, and Yan, 1980).

The cross section ratio $\sigma(e^+e^- \to D^+D^-)/\sigma(e^+e^- \to D^0\bar{D}^0)$ for $M_{D\bar{D}} \approx M_{\psi(3770)}$ is measured by Belle (in the bin $(3.76 - 3.78)\ \mathrm{GeV}/c^2$) and by BABAR $((3.74 - 3.80)\,\mathrm{GeV}/c^2)$ to be $1.39 \pm 0.31 \pm 0.12$ and $1.78 \pm 0.33 \pm 0.24$ respectively. These values are in agreement with the world average value of 1.28 ± 0.14 (Beringer et al., 2012).

21.4.3 Partial reconstruction of $D^{(*)+}D^{*-}$ final states

In the case of $D^{(*)+}D^{*-}$ final states,[164] the full reconstruction method discussed in the previous section turns out to be too inefficient. The main reason for this is the very low reconstruction efficiency of the $D^{*\pm}$ when the ISR photon is emitted at small polar angles, due to the low reconstruction efficiency for slow pions from $D^{*\pm}$ decays. If the photon is emitted along the beam axis and the $D^{(*)+}D^{*-}$ system is close to threshold, the $D^{(*)+}$ and D^{*-} meson transverse momenta are low. Because of the small energy release in $D^{*-} \to \bar{D}\pi^-_{\mathrm{slow}}$ decay, the π^-_{slow} transverse momentum is also very low, and such pions do not reach the instrumented parts of the detector. Therefore, reconstructable $D^{*\pm}$ mesons correspond to the γ_{ISR} emitted at large angles, *i.e.* both the γ_{ISR} and the $D^{(*)+}D^{*-}$ pair possess large transverse momenta. The reconstruction efficiency of such isolated energetic photons is high, and it is worth requiring the γ_{ISR} to be detected.

The signal efficiency can be increased further by selecting events without explicitly reconstructing one of the charm mesons. In particular, full reconstruction of only the $D^{(*)+}$, together with the γ_{ISR}, allows the D^{*-} meson to be identified using the peak around the D^{*-} mass in the spectrum of masses recoiling against the $D^{(*)+}\gamma_{\mathrm{ISR}}$ system:

$$M_{\mathrm{recoil}}(D^{(*)+}\gamma_{\mathrm{ISR}}) = \sqrt{(E_{\mathrm{CM}} - E_{D^{(*)+}\gamma_{\mathrm{ISR}}})^2 - p^2_{D^{(*)+}\gamma_{\mathrm{ISR}}}}. \tag{21.4.4}$$

Here $E_{D^{(*)+}\gamma_{\mathrm{ISR}}}$ and $p_{D^{(*)+}\gamma_{\mathrm{ISR}}}$ are the CM energy and momentum, respectively, of the $D^{(*)+}\gamma_{\mathrm{ISR}}$ combination. This peak is expected to be wide and asymmetric due to the γ_{ISR} energy resolution and higher-order corrections to ISR cross section. The resolution of this peak (estimated to be $\sim 300\,\mathrm{MeV}/c^2$) is not sufficient to separate the $D\bar{D}^*$, $D^*\bar{D}^*$, and $D^{(*)}\bar{D}^*\pi$ final states. To disentangle these various contributions and to suppress combinatorial backgrounds, one can use the slow pion from the unreconstructed D^{*-}. The difference between the masses recoiling against $D^{(*)+}\gamma_{\mathrm{ISR}}$ and $D^{(*)+}\pi^-_{\mathrm{slow}}\gamma_{\mathrm{ISR}}$ (recoil mass difference),

$$\Delta M_{\mathrm{recoil}} = M_{\mathrm{recoil}}(D^{(*)+}\gamma_{\mathrm{ISR}}) - M_{\mathrm{recoil}}(D^{(*)+}\pi^-_{\mathrm{slow}}\gamma_{\mathrm{ISR}}), \tag{21.4.5}$$

has a narrow distribution for signal events ($\sigma \sim 1.4\,\mathrm{MeV}/c^2$) around $m_{D^{*-}} - m_{\bar{D}^0}$, since the uncertainty in the γ_{ISR} momentum partially cancels out.

The efficiency gain using the described partial reconstruction method over the full reconstruction method is $\sim 1/\epsilon_{D^0}$ and $\sim 2/\epsilon_{D^0}$, for D^+D^{*-} and $D^{*+}D^{*-}$ final states respectively, where ϵ_{D^0} is the D^0 reconstruction efficiency.

In the case of full reconstruction, exclusive cross sections are obtained from $D^{(*)+}D^{*-}$ mass spectra. In the partial reconstruction case D^{*-} is not reconstructed and the $D^{(*)+}D^{*-}$ mass can not be calculated directly. However, it is equivalent to $M_{\mathrm{recoil}}(\gamma_{\mathrm{ISR}})$, the mass recoiling

---

[164] The notation represents the sum of D^+D^{*-} and $D^{*+}D^{*-}$ final states.

against the ISR photon (ignoring higher-order QED processes). The problem of poor photon energy resolution (and, thus poor $M_{\mathrm{recoil}}(\gamma_{\mathrm{ISR}})$ resolution) is solved by applying a fit constraining $M_{\mathrm{recoil}}(D^{(*)+}\gamma_{\mathrm{ISR}})$ to the D^{*-} mass. This refit procedure corrects the γ_{ISR} momentum and as a result, the $M_{\mathrm{recoil}}(\gamma_{\mathrm{ISR}}) = M(D^{(*)+}D^{*-})$ resolution is improved by a factor ~ 10: it varies from $\sim 6\,\mathrm{MeV}$ at $D^{(*)+}D^{*-}$ threshold to $\sim 12\,\mathrm{MeV}$ at $M(D^{(*)+}D^{*-}) = 5\,\mathrm{GeV}/c^2$. In addition the resolution of the recoil mass difference after the refit procedure ($\Delta M_{\mathrm{recoil}}^{\mathrm{fit}}$) is improved by a factor ~ 2.

This method, developed by Belle, is applied to the $e^+e^- \to D^{(*)+}D^{*-}$ cross section measurement using a data sample of $673.8\,\mathrm{fb}^{-1}$ (Abe, 2007d). The signal region is defined by the requirement that $M_{\mathrm{recoil}}(D^{*+}\gamma_{\mathrm{ISR}})$ lie within $\pm 0.2\,\mathrm{GeV}/c^2$ of the D^{*-} mass and that $\Delta M_{\mathrm{recoil}}^{\mathrm{fit}}$ be within $\pm 2\,\mathrm{MeV}/c^2$ of $m_{D^{*-}} - m_{\overline{D}^0}$. The $e^+e^- \to D^{(*)+}D^{*-}$ cross sections are extracted from the $M_{\mathrm{recoil}}(\gamma_{\mathrm{ISR}})$ distributions after background subtraction. All background contributions are estimated from the data and the combinatorial background is found to be the dominant source.

The resulting exclusive $e^+e^- \to D^{(*)+}D^{*-}$ cross sections are shown in Figs 21.4.4 and 21.4.5 with statistical uncertainties only. The total systematic uncertainties are 11% for D^+D^{*-} and 10% for $D^{*+}D^{*-}$, comparable to the statistical errors in the cross section.
Figure 21.4.4. The exclusive cross sections for $e^+e^- \to D^+D^{*-}$ measured by Belle (Abe, 2007d; solid squares) and *BABAR* (Aubert, 2009n; open triangles); $e^+e^- \to D^0\overline{D}^{*0}$ measured by *BABAR* (open circles).

The results of the *BABAR* measurements (Aubert, 2009n) based on $384\,\mathrm{fb}^{-1}$ of data are shown in the same plots. Because the full reconstruction method was used, the statistical uncertainties in these measurements are significantly larger than those of Belle. The cross sections for $D^0\overline{D}^{*0}$, D^+D^{*-}, and $D^*\overline{D}^*$ (the latter being the sum of the neutral and charged modes, *i.e.* $D^{*0}\overline{D}^{*0}$ and $D^{*+}D^{*-}$) are presented in Fig. 21.4.4 and Fig. 21.4.5 respectively. The systematic uncertainties in the cross sections are es-
Figure 21.4.5. The exclusive cross sections for $e^+e^- \to D^{*+}D^{*-}$ measured by Belle (Abe, 2007d; solid squares) and $e^+e^- \to D^*\overline{D}^*$ measured by *BABAR* (Aubert, 2009n; open circles).

timated to be 10.9% for $D^0\overline{D}^{*0}$, 9.3% for D^+D^{*-}, and 12.4% for $D^*\overline{D}^*$.

Belle and *BABAR* measurements are in good agreement, and compatible with the $D\overline{D}^*$ and $D^*\overline{D}^*$ exclusive cross sections measured by CLEO-c (Cronin-Hennessy et al., 2009); the CLEO-c measurements are more precise; they include, however, only the narrow energy range from 3.97 to 4.26 GeV. Aside from a prominent excess near the $\psi(4040)$ resonance, the $e^+e^- \to D^+D^{*-}$ cross section is relatively featureless. Integrating the cross sections from threshold to $6\,\mathrm{GeV}/c^2$, *BABAR* obtained

$$\frac{\sigma(D^+D^{*-})}{\sigma(D^0\overline{D}^{*0})} = 0.95 \pm 0.09 \pm 0.10, \qquad (21.4.6)$$

consistent with unity. The shape of the $e^+e^- \to D^{*+}D^{*-}$ cross section is complicated, with several local maxima and minima. Reliable interpretation will require more data.

21.4.4 $e^+e^- \to D_s^{(*)+}D_s^{(*)-}$

Both *BABAR* and Belle use the full reconstruction technique to measure $e^+e^- \to D_s^{(*)+}D_s^{(*)-}$ cross sections. Partial reconstruction of D_s^{*+} decaying to $D_s^+\gamma$ is impractical because of a huge combinatorial background.

BABAR results based on a $525\,\mathrm{fb}^{-1}$ data sample (del Amo Sanchez, 2010d) are presented in Fig. 21.4.6. For each candidate event *BABAR* reconstructs a $D_s^+D_s^-$ pair. While one of the D_s^+ is required to decay to $K^+K^-\pi^+$, the second D_s^- meson is reconstructed in three decay modes: $K^+K^-\pi^-$, $K^+K^-\pi^-\pi^0$, and $K_S^0K^-$. Belle measurements of the exclusive $e^+e^- \to D_s^{(*)+}D_s^{(*)-}$ cross sections (Pakhlova, 2011) based on a $967\,\mathrm{fb}^{-1}$ data sample are shown in Fig. 21.4.7. To increase the sample size Belle reconstructs both D_s^+ (+ c.c.) mesons in six decay modes: $K_S^0K^+$, $K^-K^+\pi^+$, $K^-K^+\pi^+\pi^0$, $K_S^0K^-\pi^+\pi^+$, $\eta\pi^+$ and $\eta'\pi^+$. The presented cross sections are averaged over the bin
Figure 21.4.7. Exclusive cross sections for (a) $e^+e^- \to D_s^+D_s^-$, (b) $e^+e^- \to D_s^+D_s^{*-}$ (and charge conjugate), and (c) $e^+e^- \to D_s^{*+}D_s^{*-}$, from Belle data (Pakhlova, 2011). Error bars show statistical uncertainties only. The dotted lines show the masses of the $\psi(4040)$, $\psi(4160)$ and $\psi(4415)$ states.
Figure 21.4.6. Exclusive cross sections for (a) $e^+e^- \to D_s^+D_s^-$, (b) $e^+e^- \to D_s^+D_s^{*-}$ (and charge conjugate), and (c) $e^+e^- \to D_s^{*+}D_s^{*-}$, from *BABAR* data (del Amo Sanchez, 2010d). The error bars correspond to statistical errors only.

to be 23%(11%) for $D_s^+D_s^-$, 13%(17%) for $D_s^+D_s^{*-}$ and 13%(31%) for $D_s^{*+}D_s^{*-}$.

The identification of relatively narrow ψ states in *BABAR* spectra is complicated by the large bin size of 100 MeV. Nevertheless *BABAR* results are consistent with the more precise Belle measurements (in 40 MeV bins). A clear peak at threshold, around the $\psi(4040)$ mass, is seen in the $e^+e^- \to D_s^+D_s^-$ cross section. In the $e^+e^- \to D_s^+D_s^{*-}$ cross section two peaks are evident, around the $\psi(4160)$ and the $\psi(4415)$ masses. The $e^+e^- \to D_s^{*+}D_s^{*-}$ data sample is small, and there is no clear structure in the cross section. Both the $e^+e^- \to D_s^+D_s^{*-}$ cross section and the sum of the exclusive $e^+e^- \to D_s^{(*)+}D_s^{(*)-}$ cross sections exhibit a dip near the $Y(4260)$ mass (see Section 18.3.5), similar to what is seen in $e^+e^- \to D^{*+}D^{*-}$ and in the total cross section for charm production.

21.4.5 Three-body charm final states
Figure 21.4.8. The exclusive cross section for $e^+e^- \to D^0D^-\pi^+$ measured by Belle (Pakhlova, 2008c). The dotted line corresponds to the mass of the $\psi(4415)$.

width; error bars show statistical uncertainties only. The systematic uncertainties are evaluated by *BABAR* (Belle)

The first measurements of three-body open charm final states in e^+e^- annihilation have been performed using the

full reconstruction method by Belle. The cross section for $e^+e^- \to D^0 D^- \pi^+$ measured using a $673\,\text{fb}^{-1}$ data sample (Pakhlova, 2008c) is shown in Fig. 21.4.8. A prominent $\psi(4415)$ peak is observed. From a study of the resonant structure in $\psi(4415)$ decays (discussed in Section 18.2.2.2) Belle concludes that the $\psi(4415) \to D^0 D^- \pi^+$ process is dominated by $\psi(4415) \to D\bar{D}_2^*(2460)$. It was found that $\mathcal{B}(\psi(4415) \to D^0 D^- \pi^+_{\text{non-res}})/\mathcal{B}(\psi(4415) \to D\bar{D}_2^*(2460) \to D^0 D^- \pi^+) < 0.22$ at the 90% C.L. The peak cross section for the $e^+e^- \to \psi(4415) \to D\bar{D}_2^*(2460)$ process at $E_{\text{CM}} = m_{\psi(4415)}c^2$ is calculated to be $\sigma(e^+e^- \to \psi(4415)) \times \mathcal{B}(\psi(4415) \to D\bar{D}_2^*(2460)) \times \mathcal{B}(\bar{D}_2^*(2460) \to D\pi^+) = (0.74 \pm 0.17 \pm 0.08)\,\text{nb}$.

The $e^+e^- \to D^0 D^{*-} \pi^+$ exclusive cross section, based on a $695\,\text{fb}^{-1}$ data sample (Pakhlova, 2009), is shown in Fig. 21.4.9. The main motivation of this study is the search for $Y(4260) \to D^0 D^{*-} \pi^+$ decays discussed in Section 18.3.5. An estimate of the branching fraction for $\psi(4415) \to D^0 D^{*-} \pi^+$ decay can be found in Section 18.2.2.2.
Figure 21.4.9. The exclusive cross section for $e^+e^- \to D^0 D^{*-} \pi^+$ averaged over the bin width with statistical uncertainties only from Belle data (Pakhlova, 2009). The total systematic uncertainty is 10%. The fit function corresponds to the 90% C.L. upper limit on $\psi(4415)$ taking into account systematic uncertainties. The solid line represents the sum of the signal and threshold contributions. The threshold function is shown by the dashed line.

21.4.6 Charm baryon production in e^+e^- annihilation

The first measurement of the $e^+e^- \to \Lambda_c^+ \Lambda_c^-$ process near threshold has been performed by Belle in ISR events, using $695\,\text{fb}^{-1}$ of data (Pakhlova, 2008b), with the partial reconstruction technique. Full reconstruction of both the Λ_c^+ and Λ_c^- baryons suffers from the low Λ_c reconstruction efficiency, and the small branching fractions for decays to accessible final states; Belle requires reconstruction of only one of the Λ_c baryons (using pK_S^0, $pK\pi$ and $\Lambda\pi$

final states) and the ISR photon. The exclusive $e^+e^- \to \Lambda_c^+ \Lambda_c^-$ cross section is determined from the recoil mass $M_{\text{recoil}}(\gamma_{\text{ISR}})$. A refit constraining $M_{\text{recoil}}(\Lambda_c^+ \gamma_{\text{ISR}})$ to the nominal Λ_c^- mass improves the $M_{\text{recoil}}(\gamma_{\text{ISR}})$ resolution: the final resolution varies from $\sim 3\,\text{MeV}/c^2$ just above threshold to $\sim 8\,\text{MeV}/c^2$ at $M_{\Lambda_c^+ \Lambda_c^-} \sim 5.4\,\text{GeV}/c^2$. Combinatorial background is suppressed by a factor ~ 10 by requiring the presence of at least one $\bar{p}$ in the event from the decay of the unreconstructed Λ_c^-; this requirement reduces the signal efficiency by $\sim 40\%$.

The resulting cross section is shown in Fig. 21.4.10. A significant enhancement, called $X(4630)$ by Belle, is seen at threshold, with a peak cross section $\sigma(e^+e^- \to X(4630)) \times \mathcal{B}(X(4630) \to \Lambda_c^+ \Lambda_c^-) = (0.47^{+0.11+0.05}_{-0.10-0.08} \pm 0.19)\,\text{nb}$. Belle obtains $\Gamma_{ee}/\Gamma_{\text{tot}} \times \mathcal{B}(X(4630) \to \Lambda_c^+ \Lambda_c^-) = (0.68^{+0.16+0.07}_{-0.15-0.11} \pm 0.28) \times 10^{-6}$. The last error is due to the uncertainties of Λ_c branching fractions.
Figure 21.4.10. The exclusive cross section for $e^+e^- \to \Lambda_c^+ \Lambda_c^-$ measured by Belle (Pakhlova, 2008b).

The nature of the observed enhancement remains unclear. More details on its parameters and corresponding discussion can be found in Section 18.3.5.

21.4.7 Sum of exclusive vs inclusive cross section

In conclusion, using the ISR method allows the measurement of nine cross sections for e^+e^- annihilation to open charm final states over a wide energy range, beginning at threshold. For the first time the inclusive cross section to charm hadrons is decomposed into the sum of the exclusive components $e^+e^- \to D\bar{D}$, $D\bar{D}^*$, $D^*\bar{D}^*$, $D\bar{D}\pi$, $D\bar{D}^*\pi$, $D_s^+ D_s^-$, $D_s^+ D_s^{*-}$, $D_s^{*+} D_s^{*-}$, and $\Lambda_c^+ \Lambda_c^-$. This sum, shown in Fig. 21.4.11, almost saturates the inclusive cross section; the $D\bar{D}^*$ and $D^*\bar{D}^*$ final states dominate.

21.5 Search for exotic charmonium

Initial state radiation events provide an ideal environment to study known vector states as well as search for additional such states. Searches for new vector mesons have
Figure 21.4.11. Inclusive measurements of $R - R_{uds}$, where $R = \sigma(e^+e^- \to \text{hadrons})/\sigma(e^+e^- \to \mu^+\mu^-)$ and $R_{uds} = 2.121 \pm 0.023 \pm 0.083$ by BES II (Ablikim et al., 2007; open circles), compared to the sum of exclusive cross sections (solid squares) measured by Belle.

Figure 21.5.1. The scatter plot of $m(\ell^+\ell^-) - m(J/\psi)$ vs. $m(\pi^+\pi^- J/\psi)$ for ISR produced $\pi^+\pi^- J/\psi$ events collected by BABAR in 123 fb^{-1}. (a) low $m(\pi^+\pi^- J/\psi)$ range [3.4, 4.0] GeV/c^2 (log scale): A clean $\psi(2S)$ signal is observed while no evidence of a $X(3872)$ signal is seen. (b) high $m(\pi^+\pi^- J/\psi)$ range [3.8, 7.0] GeV/c^2 (linear scale): An enhancement around 4.3 GeV/c^2 is found. BABAR internal, from (Aubert, 2005y) analysis.

commonly proceeded by looking for their decay to conventional charmonium states plus additional light hadrons. The study of the $\pi^+\pi^- J/\psi$ and $\pi^+\pi^- \psi(2S)$ final states is presented in Sections 21.5.1 and 21.5.2 respectively. Possible vector decays to open charm final states are treated in Section 21.4 above. A general discussion of the new, and possibly exotic vector states is presented elsewhere (Section 18.3.5).

21.5.1 Y family states in ISR $\pi^+\pi^- J/\psi$

An important exotic charmonium candidate, the $Y(4260)$, has been observed in the $\pi^+\pi^- J/\psi$ final state. The discovery and subsequent studies are reported in Sections 21.5.1.1 and 21.5.1.2 respectively. The claimed broad structure $Y(4008)$ is discussed in the latter section.

21.5.1.1 The $Y(4260)$ discovery

The discovery by Belle of the surprisingly narrow $X(3872)$ resonance from the study of $B \to J/\psi \pi^+\pi^- K$ decays (Choi, 2003), discussed in Section 18.3.2, renewed experimental interest in charmonium spectroscopy. In order to understand the $X(3872)$ when its quantum numbers were hardly known in 2004, BABAR searched for $X(3872) \to \pi^+\pi^- J/\psi$ in the ISR process $e^+e^- \to \gamma_{\text{ISR}} \pi^+\pi^- J/\psi$, where J/ψ decays to $\ell^+\ell^-$, using a data sample corresponding to 232 fb^{-1} (Aubert, 2005y). The analysis was performed requiring exclusive reconstruction of the hadronic final state, but not explicit detection of the ISR photon. The large and clean ISR $\psi(2S) \to \pi^+\pi^- J/\psi$ sample provides a good control sample for validation and selection criteria optimization. In a subsample of 123 fb^{-1} of data, as shown in Fig. 21.5.1, no evidence for the $X(3872)$ was found, but an enhancement was seen around 4.3 GeV/c^2.

In order to avoid any possible bias and to firmly establish this observation, the BABAR analysis blinds the enhancement region [4.2, 4.4] GeV/c^2, and optimizes the selection criteria by maximizing the quantity $N/(3/2 + \sqrt{B})$ (Punzi, 2003b), where 3/2 corresponds to the search for a 3σ signal, N is the total number of $\gamma_{\text{ISR}}\psi(2S)$, $\psi(2S) \to \pi^+\pi^- J/\psi$ candidates in the 20 MeV/c^2 $\pi^+\pi^- J/\psi$ mass range that brackets the $\psi(2S)$ nominal mass, and B is the number of (background) events in the $\pi^+\pi^- J/\psi$ mass regions [3.8, 4.2] GeV/c^2 and [4.4, 4.8] GeV/c^2, scaled to the width of the excluded region. The selection criteria are optimized taking advantage of the features of ISR emission, that is, a recoil mass close to zero, and a small transverse component of the visible momentum in the e^+e^- CM, including the ISR photon when it is reconstructed. Exactly four tracks consistent with production at the e^+e^- interaction point are allowed: two oppositely charged tracks identified as pions, and a pair of identified leptons (either e^+e^- or $\mu^+\mu^-$) whose reconstructed invariant mass is within an optimized interval around the J/ψ peak. Additional cuts on kinematic variables of the hadronic system are applied to further reject background sources.

In order to improve the mass resolution, the four tracks are refitted with a constraint to a common vertex, and the lepton pair kinematically constrained to the J/ψ mass. The resulting $\pi^+\pi^- J/\psi$ mass-resolution function is well-described by a Breit-Wigner distribution with a full width at half maximum increasing from 4.2 MeV/c^2 at the $\psi(2S)$
Figure 21.5.2. The $\pi^+\pi^- J/\psi$ invariant mass spectrum in the range $3.8-5.0\,\mathrm{GeV}/c^2$ and (inset) over a wider range that includes the $\psi(2S)$, obtained from *BABAR* with a data sample of $232\,\mathrm{fb}^{-1}$ (Aubert, 2005y). The points with error bars represent the selected data and the shaded histogram represents the scaled data from neighboring J/ψ sidebands. A fit to the mass spectrum with a single Breit-Wigner and a polynomial function, shown as the solid line, clearly identifies the new $Y(4260)$ resonance. The dashed curve represents the background polynomial component.

to $5.3\,\mathrm{MeV}/c^2$ at $4.3\,\mathrm{GeV}/c^2$. The $\pi^+\pi^- J/\psi$ invariant mass spectrum for candidates passing all criteria is shown in Fig. 21.5.2 as points with error bars. A signal of 11802 ± 110 $\psi(2S)$ events is observed, consistent with the expectation. An enhancement near $4.26\,\mathrm{GeV}/c^2$, now known as the $Y(4260)$, is clearly observed; no other structures are evident at the masses of the known $J^{PC} = 1^{--}$ charmonium states (*i.e.* the $\psi(4040)$, $\psi(4160)$, and $\psi(4415)$), or at the $X(3872)$.

An unbinned maximum likelihood fit to the $\pi^+\pi^- J/\psi$ mass spectrum in the range $[3.8, 5.0]$ GeV/c^2 is performed assuming only one broad resonance is present (Fig. 21.5.2). The fitting function consists of a relativistic Breit-Wigner function describing the peak, and a second-order polynomial background, convolved with a Cauchy resolution function. The fit finds (125 ± 23) events in the peak, with a mass of $(4259 \pm 8)\,\mathrm{MeV}/c^2$ and a width of $(88 \pm 23)\,\mathrm{MeV}/c^2$. the significance of the $Y(4260)$ signal is above $8\,\sigma$.

The ISR photon is reconstructed in $(24 \pm 8)\%$ of the $Y(4260)$ events, within the uncertainty the same as 25% observed for ISR $\psi(2S)$ events. Kinematic distributions for a sample of background subtracted data are compared to analogous quantities obtained for simulated ISR events, and found in good agreement, confirming that the ISR-production hypothesis – essential in order to assign the $J^{PC} = 1^{--}$ quantum numbers for the new resonant state – is correct.

21.5.1.2 Subsequent $Y(4260)$ analyses

After the discovery of the $Y(4260)$, CLEO (Coan et al., 2006) performed an energy scan around $\sqrt{s} = 4.26$ GeV,
Figure 21.5.3. (upper) The $\pi^+\pi^- J/\psi$ mass spectrum measured by Belle (Yuan, 2007). Points with errors show selected events in the J/ψ signal region, while the histogram shows the scaled J/ψ sideband distribution. The curves show the best fit (solid line) and the contribution from each component for the two solutions, as described in the text. (lower) The $\pi^+\pi^- J/\psi$ mass spectrum measured by *BABAR* in a $454\,\mathrm{fb}^{-1}$ data sample (Lees, 2012ab). The solid curve shows the result of a simultaneous fit to the data (points with errors) and to the background control sample obtained from the J/ψ sidebands (shaded histogram).

and were able to confirm the process $Y(4260) \to \pi^+\pi^- J/\psi$ and observed also $Y(4260) \to \pi^0\pi^0 J/\psi$. The measured ratio, $\mathcal{B}(Y(4260) \to \pi^0\pi^0 J/\psi)/\mathcal{B}(Y(4260) \to \pi^+\pi^- J/\psi) \approx 0.5$, implies that the $Y(4260)$ has isospin zero. They also found the first evidence for $Y(4260) \to K^+K^- J/\psi$, and set upper limits on many other decay modes. These results are based on measurements at discrete energies, and do not resolve the $Y(4260)$ lineshape; it is assumed that the $Y(4260)$ saturates the $\pi^+\pi^- J/\psi$ and related cross-sections at the peak.

The observation of the $Y(4260) \to \pi^+\pi^- J/\psi$ decay in ISR-untagged studies has been confirmed by CLEO (He et al., 2006), by analysing a data sample of about 13.3 fb^{-1}, and with much more data by Belle (Yuan, 2007) and *BABAR* (Lees, 2012ab). The selection criteria in the Belle and *BABAR* analyses are similar to those in the orig-

inal *BABAR* measurement with some exceptions.[165] The resulting mass spectra shown in Fig. 21.5.3 present a clear peak at ~ 4.26 GeV/c^2, but have differences elsewhere in the analyzed energy region. The analysts of the two Collaborations have adopted different fit models to describe the data.

Table 21.5.1. Results of the best fit to the $\pi^+\pi^- J/\psi$ mass spectrum obtained by the Belle experiment (Yuan, 2007). M, $\Gamma_{\rm tot}$, and $\mathcal{B} \times \Gamma_{e^+e^-}$ are respectively the mass, total width, and product of the branching fraction to $\pi^+\pi^- J/\psi$ and e^+e^- partial width of the two interfering resonances R_1 and R_2, while ϕ is their relative phase. The results for both destructive and constructive interference solutions are reported.

Parameters		Solution I	Solution II
$R_1 : M$	(MeV/c^2)	$4008 \pm 40^{+114}_{-28}$	
$\Gamma_{\rm tot}$	(MeV)	$226 \pm 44 \pm 87$	
$\mathcal{B} \times \Gamma_{e^+e^-}$	(eV)	$5.0 \pm 1.4^{+6.1}_{-0.9}$	$12.4 \pm 2.4^{+14.8}_{-1.1}$
$R_2 : M$	(MeV/c^2)	$4247 \pm 12^{+17}_{-32}$	
$\Gamma_{\rm tot}$	(MeV)	$108 \pm 19 \pm 10$	
$\mathcal{B} \times \Gamma_{e^+e^-}$	(eV)	$6.0 \pm 1.2^{+4.7}_{-0.5}$	$20.6 \pm 2.3^{+9.1}_{-1.7}$
ϕ	(°)	$+12 \pm 29^{+7}_{-98}$	$-111 \pm 7^{+28}_{-31}$

In particular, an accumulation of events at a mass of about 4.01 GeV/c^2 is observed in about 548 fb^{-1} of data analyzed by Belle. An unbinned maximum likelihood fit is performed to the mass spectrum corrected for the mass-dependent efficiency and normalized to the effective ISR luminosity, for masses above 3.8 GeV/c^2, as shown in Fig. 21.5.3 (top). The fit model consists of a coherent sum of two Breit-Wigner resonance functions (see Section 13.2.1), and assumes that there is no continuum production of $e^+e^- \to \pi^+\pi^- J/\psi$. The background is estimated from J/ψ sidebands and fixed in the fit, while contributions from the tail of the $\psi(2S)$ and $\psi(3770)$ are estimated from the world average values of their parameters, added incoherently, and fixed. Two solutions with equally good fit quality are found, corresponding to constructive and destructive interference between the two resonances. They present equal masses and widths for the two resonances, but different partial widths and relative phase. The quality of the fit determined from the binned distribution is $\chi^2/n_{\rm dof} = 81/78$.

The results are summarized in Table 21.5.1. The significance of the resonance at lower mass is larger than 5σ. Although its mass is close to that of the $\psi(4040)$, the fitted width is larger than the world average value (80 ± 10 MeV) of the latter. The fit using two interfering resonances yields a much better description of the observed distribution than a fit with a single resonance. Using the same functional form of the fitted function as in Aubert (2005y) the

parameters of the state at higher mass are consistent with those reported by *BABAR* (see Table 21.5.2).

The *BABAR* update on the study of the ISR-produced $\pi^+\pi^- J/\psi$ final state is based on a data sample corresponding to 454 fb^{-1} (Lees, 2012ab). An unbinned, extended-maximum likelihood fit is performed in the region [3.74, 5.5] GeV/c^2 to the $\pi^+\pi^- J/\psi$ mass distribution from the J/ψ signal region, shown in Fig. 21.5.3(bottom), and simultaneously to the background distribution from the J/ψ sidebands. The shape of the background mass distribution is described by a third order polynomial function. The signal function consists of a coherent sum of a Breit-Wigner function for the $Y(4260)$, and an exponential function, which provides an empirical description of the $\psi(2S)$ tail and possible continuum production of the $\pi^+\pi^- J/\psi$ final state. Also in this case, the signal function accounts for the mass-dependency of the reconstruction efficiency and effective ISR luminosity, and is convolved with a Gaussian resolution function obtained from MC simulation. The parameters of the $Y(4260)$ resulting from the fit are in agreement with the previous measurements, and are reported in Table 21.5.2, which summarizes the ISR $Y(4260) \to \pi^+\pi^- J/\psi$ analyses from various experiments performed under the single-resonance hypothesis. The *BABAR* data do not support the Belle observation of a broad structure at 4.08 GeV/c^2.

The invariant mass distribution of the dipion system for events with a $\pi^+\pi^- J/\psi$ mass close to the $Y(4260)$ is found to deviate significantly from phase space in both *BABAR* and Belle data samples (see Fig. 18.3.10). It shows an accumulation around 0.95 GeV/c^2, followed by an abrupt fall to near zero at ~ 1 GeV/c^2, and then rises again. Such behavior is reproduced by *BABAR* (Lees, 2012ab) with a model assuming a coherent sum of a nonresonant $\pi^+\pi^-$ S-wave amplitude and a resonant amplitude describing the $f_0(980)$. The fit to the data sample assuming this simple model shows that the $f_0(980)$ contribution is produced in a fraction 0.17 ± 0.13 of $Y(4260) \to \pi^+\pi^- J/\psi$ decays, where only the statistical error is quoted.

In another study Belle observes also a significant accumulation of events in the $J/\psi \pi^\pm$ invariant mass of the $Y(4260) \to \pi^+\pi^- J/\psi$ decays (Liu, 2013). The state denoted as $Z(3900)^\pm$, which is clearly not a charmonium state (charge), is observed with a significance larger than 5σ, and is in $Y(4260)$ decays produced with a branching ratio of $\mathcal{B}(Y(4260) \to Z(3900)^\pm \pi^\mp)\mathcal{B}(Z(3900)^\pm \to \pi^\pm J/\psi)/\mathcal{B}(Y(4260) \to \pi^+\pi^- J/\psi) = (29.0 \pm 8.9)\%$, where the uncertainty is statistical only. The properties of the state are consistent with the one observed by BESIII (Ablikim et al., 2013a).

Beside the $J/\psi \pi\pi \gamma_{\rm ISR}$ final state Belle studied also the ISR process with the production of $J/\psi KK$ (Yuan, 2008) and $J/\psi \eta$ (Wang, Han, Yuan, Shen, and Wang, 2013). The former measurement is the first observation of that final state in the ISR process. No evidence for the $Y(4260)$ is found and the upper limit on the product of the two-electron width and the branching fraction is determined to be $\Gamma(Y(4260) \to e^+e^-)\mathcal{B}(Y(4260) \to K^+K^- J/\psi) < 1.2$ eV/ with 90% C.L. In the $J/\psi \eta$ final state clear signals

---

[165] For example, Belle did not use the J/ψ mass constraint and hence the sideband events can be used to estimate the background.

Table 21.5.2. Summary of ISR $\pi^+\pi^- J/\psi$ measurements by various experiments under the single-resonance hypothesis, where Y stands for $Y(4260)$. The first uncertainty is statistical and the second systematic (if only one is given it is the statistical uncertainty only).

Experiments	$\mathcal{L}$ (fb^{-1})	N_Y	mass (MeV/c^2)	Γ_{tot} (MeV)	$\mathcal{B}(Y \to \pi^+\pi^- J/\psi)\Gamma_{Y \to e^+e^-}$ (eV)
CLEO (He et al., 2006)	13.3	37	$4284^{+17}_{-16} \pm 4$	$73^{+39}_{-25} \pm 5$	$8.9^{+3.9}_{-3.1} \pm 1.8$
Belle (Yuan, 2007)	548	324 ± 21	4263 ± 6	126 ± 18	9.7 ± 1.1
BABAR (Lees, 2012ab)	454	344 ± 39	$4244 \pm 5 \pm 4$	$114^{+16}_{-15} \pm 7$	$9.2 \pm 0.8 \pm 0.7$

of $\psi(4040)$ and $\psi(4160)$ are observed, and no signal of $Y(4260)$. For the latter the upper limit is $\Gamma(Y(4260) \to e^+e^-)\mathcal{B}(Y(4260) \to \eta J/\psi) < 14.2$ eV at 90% C.L.

21.5.2 Y family states in ISR $\pi^+\pi^- \psi(2S)$

Since the $Y(4260)$ is above the mass threshold for $\psi(2S)$ plus $\pi^+\pi^-$, it is natural to ask if $Y(4260)$ also decays to $\pi^+\pi^- \psi(2S)$. In order to further clarify the nature of the $Y(4260)$, and search for similar states, *BABAR* (Aubert, 2007m) and Belle (Wang, 2007c) have studied the ISR process $e^+e^- \to \gamma_{\mathrm{ISR}} \pi^+\pi^- \psi(2S)$. The $\psi(2S)$ is reconstructed in the $\pi^+\pi^- J/\psi$ decay mode, with $J/\psi \to \ell^+\ell^-$. The analysis procedure is similar to the case of the $\pi^+\pi^- J/\psi$ final state. An additional background source, produced by different combinations within the same $2(\pi^+\pi^-)J/\psi$ system where at least one of the primary pions is combined with the J/ψ to form a $\pi^+\pi^- J/\psi$ candidate, must be subtracted from the selected sample. The clean sample of selected $\psi(2S)$ decays is used for signal estimation, while the sidebands of the $\psi(2S)$ mass distribution are used for background subtraction.

The *BABAR* analysis (Aubert, 2007m) is based on a sample of 298 fb^{-1}. The $\pi^+\pi^- \psi(2S)$ mass spectrum of 78 events selected within the $\psi(2S)$ mass window is represented by data points in Fig. 21.5.4. The dashed curve shows the result of the fit to the $Y(4260)$ using resonance parameters fixed to those of Aubert (2005y). The χ^2/n_{dof} of 21.3/8 quantifies the inconsistency of the data with the decay of $Y(4260)$ to this final state. However, a clear accumulation of events is seen at a mass of about 4.35 GeV/c^2, and a fit to a single resonance with free mass and width parameters returns $m = (4324 \pm 24)$ MeV/c^2 and $\Gamma = (172 \pm 33)$ MeV, with a much better fit quality: $\chi^2/n_{\mathrm{dof}} = 7.3/7$ (the errors are statistical only). A fit to the known $\psi(4415)$ with fixed parameters is also of poor quality, supporting the hypothesis of a new state.

In a similar analysis, performed using twice the dataset, Belle (Wang, 2007c) confirms the state at about 4.35 GeV/c^2, and observes another structure at higher masses. A fit to the $\pi^+\pi^- \psi(2S)$ invariant-mass spectrum of selected events with two coherent vector resonances returns for the lower-mass resonance $m = (4361 \pm 9 \pm 9)$ MeV/c^2 and $\Gamma = (74 \pm 15 \pm 10)$ MeV, and for the state at higher mass $m = (4664 \pm 11 \pm 5)$ MeV/c^2 and $\Gamma = (48 \pm 15 \pm 3)$ MeV. A small enhancement around 4685 MeV/c^2 in a single 50
Figure 21.5.4. Invariant mass spectrum up to 5.7 GeV/c^2 for selected ISR-produced $2(\pi^+\pi^-)J/\psi$ candidates in 298 fb^{-1} of *BABAR* data (Aubert, 2007m). The shaded histogram represents the background estimated from the sidebands of the $\psi(2S)$ mass spectrum, and the curves represent fits to the data (see the text).

MeV/c^2 bin was visible also in the *BABAR* measurement, but not significant due to the lower integrated luminosity. A recent analysis performed by *BABAR* (Lees, 2012ac) using the whole data set confirms the state, now named $Y(4660)$, with parameters consistent with those measured by Belle.

21.6 Dark force searches

While the astrophysical evidence for dark matter is now overwhelming, its precise nature and origin remain elusive. Recent results from terrestrial and satellite experiments have motivated an interesting proposal in which WIMP-like dark matter particles carry charge of a new yet unknown force (Arkani-Hamed, Finkbeiner, Slatyer, and Weiner, 2009; Fayet, 2007; Pospelov, Ritz, and Voloshin, 2008). The corresponding gauge boson, the so-called dark photon A', couples to the Standard Model photon through mixing between the photon and dark photon fields (kinetic mixing) with mixing strength ϵ.

This opens the possibility of dark matter annihilation into a pair of dark photons which subsequently decay to SM particles. The mass of the dark photon is constrained to be at most a few GeV, to be compatible with the electron/positron excess observed by PAMELA (Adriani
Figure 21.5.5. The $\pi^+\pi^-\psi(2S)$ invariant mass distribution for events that pass the $\psi(2S)$ selection in Belle 673 fb^{-1} data (Wang, 2007c). The open histogram is the data while the shaded histogram is the normalized $\psi(2S)$ sidebands. The solid curve shows the result of the the best fit with two coherent P-wave resonances together with a constant incoherent background term. The two dashed curves at each peak show the two solutions for constructive and destructive interference.

et al., 2010, 2009) and FERMI (Abdo et al., 2009; Ackermann et al., 2012), without a comparable anti-proton signal. Dark photons decay almost exclusively to lepton-pairs if their mass is below ~ 500 MeV, while the contribution of pion pairs is significant between ~ 500 MeV and ~ 1 GeV, and multi-hadron channels become dominant at higher masses. The dark boson masses are usually generated via the Higgs mechanism, adding one or more dark Higgs bosons (h') to the theory.

21.6.1 Searches for a dark photon

A dark photon can be readily produced in the reaction $e^+e^- \to \gamma A'$, $A' \to \ell^+\ell^-$. The signature is similar to that of a light CP-odd Higgs boson, A^0, in $\Upsilon(2S, 3S) \to \gamma A^0$, $A^0 \to \ell^+\ell^-$ (Aubert, 2009an). The $\Upsilon(2S, 3S)$ candidates are reconstructed by combining two oppositely-charged tracks with a photon. At least one track must be identified as a muon and the energy of the photon in the CM frame is required to be larger than 0.5 GeV. No additional tracks or photons must be detected in the event. The signal yield is extracted as a function of the A^0 mass by a series of unbinned extended maximum likelihood fits to the distribution of the dimuon mass. No significant signal is observed, and upper limits on the branching fraction $\Upsilon(2S, 3S) \to \gamma A^0$, $A^0 \to \ell^+\ell^-$ are derived. These results have been reinterpreted (Bjorken, Essig, Schuster, and Toro, 2009) as limits on the mixing strength ϵ at the level $10^{-3} - 10^{-2}$ (Fig. 21.6.1).

Additional searches have been performed which may be reinterpreted as limits on dark photon production, such as $e^+e^- \to \gamma$ invisible (Aubert, 2008at), $e^+e^- \to \gamma$ hadrons (Lees, 2011j), or $e^+e^- \to \gamma\tau^+\tau^-$ (see Section 18.4.7.1, and Aubert, 2009ai).
Figure 21.6.1. Adopted from (Bjorken, Essig, Schuster, and Toro, 2009). Constraints on the mixing strength, ϵ, as a function of the dark photon mass. The red line shows the value of the coupling required to explain the discrepancy between the calculated and measured anomalous magnetic moment of the muon (Pospelov, 2009). The excluded regions obtained by reinterpreting the upper limits on the $Y(2S, 3S) \to A^0\gamma$, $A^0 \to \ell^+\ell^-$ (Aubert, 2009an) branching fractions are shown as a yellow band.

21.6.2 A search for dark gauge bosons

Non-Abelian extensions of dark sectors introduce additional dark gauge bosons, generically denoted $W', W'', ...$. The detailed phenomenology depends on the structure of the model, but heavy dark bosons decay to lighter states if kinematically accessible, while the lightest bosons are metastable and decay to SM fermions via their mixing with the dark photon (Baumgart, Cheung, Ruderman, Wang, and Yavin, 2009; Essig, Schuster, and Toro, 2009).

BABAR has performed a search for di-boson production in the four lepton final state, $e^+e^- \to A'^* \to W'W''$, $W' \to \ell^+\ell^-$, $W'' \to \ell'^+\ell'^-$ with $\ell, \ell' = e, \mu$ (Aubert, 2009aj). The study, based on 513 fb^{-1} of data collected mostly at the $\Upsilon(4S)$ resonance, has been performed in the context of inelastic dark matter models (Tucker-Smith and Weiner, 2001), searching for two bosons with similar masses. Events containing four leptons originating from the interaction point with a total invariant mass greater than 10 GeV are selected. Additional selection criteria on the boson decay angles and the angle between the decay planes of the two bosons are applied to further reject the background.

The signal is extracted as a function of the average dileptonic mass in the range $0.24 - 5.3$ GeV in 10 MeV steps. No significant signal is observed and 90% C.L. upper limits on the mixing strength at the 10^{-3} level have been set, assuming a dark sector coupling constant $\alpha_D =$

$g_D/4\pi = \mathcal{O}(10^{-2})$, and equal branching fractions of a dark gauge boson to e^+e^- and $\mu^+\mu^-$.

21.6.3 A search for dark Higgs bosons

The Higgsstrahlung process, $e^+e^- \to A'h'$, $h' \to A'A'$, offers another gateway to dark sectors, as this process is one of the few suppressed by only a single power of the mixing strength, and the background is expected to be almost negligible (Batell, Pospelov, and Ritz, 2009). A search for dark Higgs boson production has been performed in the range $0.8 < m_{h'} < 10.0\,\mathrm{GeV}$ and $0.25 < m_{A'} < 3.0\,\mathrm{GeV}$ with the constraint $m_{h'} > 2m_{A'}$ (Lees, 2012s). The signal events are either fully reconstructed using $A' \to \ell^+\ell^-$ and $A' \to \pi^+\pi^-$ decays (exclusive mode), or partially reconstructed (inclusive mode). In the latter case, only two of the three dark photons are identified as dilepton resonances, with the four-momentum of the remaining dark photon identified with that of the recoiling system. The exclusive modes contain six tracks having an invariant mass close to $\sqrt{s}$, forming three dark photon candidates of similar mass. The six pion final state has a significantly larger background than the other channels and is excluded from the search. Inclusive modes are first identified by selecting two dileptonic resonances with similar mass, and requiring the mass of the recoiling system to be compatible with the dark photon hypothesis.

No significant signal is observed, and 90% C.L. upper limits on the product of the dark sector coupling constant and the mixing strength, $\alpha_D\epsilon^2$, are derived. The results are displayed in Fig. 21.6.2 as a function of the dark photon mass for selected values of the dark Higgs boson masses. Values as low as $10^{-10} - 10^{-8}$ are excluded for a large range of dark photon and dark Higgs masses. Assuming $\alpha_D = \alpha_{\mathrm{EM}}$, these measurements translate into limits on the mixing strength in the range $10^{-4} - 10^{-3}$.
Figure 21.6.2. Upper limit at 90% C.L. set by BABAR (Lees, 2012s) on the product $\alpha_D\epsilon^2$ as a function of the dark photon mass for selected values of dark Higgs boson masses. The peaking structure arising near $m_{A'} \sim 0.8\,\mathrm{GeV}$ and $m_{A'} \sim 1.0\,\mathrm{GeV}$ reflects the presence of the ω and ϕ resonances. At these masses, dark photons decay predominantly to $3(\pi^+\pi^-\pi^0)$ and $3(K^+K^-)$ final states, not included in the search.

22.1 Descriptions of two-photon topics to be covered

22.1.1 Introduction for two-photon physics

An electron-positron collider is also a photon-photon collider. Since the photon couples directly to the electric charge of quarks, we can study hadron structures and QCD physics, effectively, in hadron production induced by two-photon collisions. The even C-parity of the two-photon system is complementary with the odd C-parity in e^+e^- collisions. In an e^+e^- collider, a virtual photon is emitted from each lepton; a collision of these photons produces final-state particles as shown in Figure 22.1.1. The two-photon center-of-mass (CM) energy, W, which is the same as the invariant mass of the final-state system, is continuously distributed between zero and just below the e^+e^- CM energy. For practical purposes, the usable range is between a few 100 MeV and ~ 4.5 GeV. The lower side is limited by experimental trigger conditions and the upper by the luminosity and backgrounds from e^+e^- annihilation events.
Figure 22.1.1. A Feynman diagram illustrating hadron production in two-photon collisions $e^+e^- \to e^+e^- X$.

The study of hadron production in two-photon processes at the B Factories has contributed to better understanding of non-perturbative QCD and light-quark meson spectroscopy at low and intermediate energies. It also contributes to searches and measurements of charmonium(-like) states as well as a test of perturbative-QCD models for exclusive meson production at high energies (Brodsky and Lepage, 1981; Chernyak and Zhitnitsky, 1984).

22.1.2 Cross section for $\gamma\gamma$ collisions (zero-tag)

In hadron production via two-photon collisions,

$$e^+e^- \to e^+e^- X, \qquad (22.1.1)$$

the cross sections of the processes are given as a function of W and the Q^2 value of each incident photon, where Q^2 is the negative of the mass squared of the virtual photon and is the same as the absolute value of four-momentum transfer squared between the incident ($p_{e,\text{ini}}$) and recoiled electron or positron ($p_{e,\text{rec}}$), $Q^2 = -(p_{e,\text{rec}} - p_{e,\text{ini}})^2$. Hereafter we refer to both electrons and positrons as electrons for brevity.

Roughly speaking for the B Factory energies, the size of the cross section is a comparable order of magnitude with that for e^+e^- annihilation. The cross section is largest in the kinematic regions where the Q^2 value is very close to zero and W is small when compared with the beam energy. In contrast, in regions where either W or Q^2 is much larger than the typical QCD energy scale (~ 1 GeV), the cross section decreases rapidly so that statistical uncertainty dominates the measurement errors at the B Factories.

We discuss here the zero-tag method used to measure and derive the cross section corresponding to real two-photon collisions, where neither of the recoiling electrons are detected. The Q^2 of the emitted virtual photons has a continuous distribution and peaks very close to zero (*i.e.* smaller than the electron mass squared). Most events have Q^2 much smaller than the QCD scale or any hadron-mass squared, say $(100 \text{ MeV})^2$, so the measured cross section approximates that of the collisions of real photons.

We approximate a real photon in $\gamma\gamma$ cross-section measurements with a virtual photon having a small Q^2 and extrapolate the cross section measured with finite Q^2 photons to the $Q^2 = 0$ limit, using an appropriate Q^2 dependence of the cross section that is interpreted as a photon-hadron form factor effect. In addition, when we adopt an equivalent-photon approximation (EPA), the effect from each photon is separated and factorized; also, the real two-photon cross section is decoupled from the photon-emission part (Berger and Wagner, 1987; Budnev, Ginzburg, Meledin, and Serbo, 1975). With these approximations, we can define and calculate a universal two-photon luminosity function $L_{\gamma\gamma}$ as a function of W:

$$L_{\gamma\gamma}(W) = \frac{d}{dW}\left(\int N(k_1, E_b)N(k_2, E_b)\frac{1}{Q_1^2}\frac{1}{Q_2^2} \right.$$
$$\left. F(Q_1^2, W)F(Q_2^2, W)dk_1 dk_2 dQ_1^2 dQ_2^2 \right),$$

$$(22.1.2)$$

where $N(k_i, E_b)$ is the probability density function (obtained from QED) for the virtual photon with index $i = 1, 2$ and energy k_i emitted from the incident lepton with energy E_b, and $F(Q_i^2, W)$ is the factorized form factor effect for this photon (normalized to the real photon $F(0, W) = 1$). The two-photon luminosity function is used

to translate the e^+e^--based cross section σ_{ee} at given W to the corresponding $\gamma\gamma$ cross section $\sigma_{\gamma\gamma}(W)$ by the relation

$$\sigma_{\gamma\gamma}(W) = \frac{1}{L_{\gamma\gamma}(W)} \frac{d\sigma_{ee}}{dW}. \quad (22.1.3)$$

We also use several differential cross sections in the measurement of the angular and momentum distributions of the final-state particles, accounting for the efficiencies as a function of the measured variables. For example, the differential cross section for a process with a two-body final state is given by the following formula:

$$\frac{d\sigma_{\gamma\gamma}}{d|\cos\theta^*|} = \frac{\Delta N}{\Delta W \Delta |\cos\theta^*| \, \epsilon \, L_{\gamma\gamma}(W) \int \mathcal{L}dt}, \quad (22.1.4)$$

where θ^* is the scattering angle of a final-state particle in the two-photon CM frame, ΔN is the number of signal events in a two-dimensional bin with a bin size of $\Delta W \times \Delta |\cos\theta^*|$, ϵ is the efficiency for the bin and $\int \mathcal{L}dt$ is the integrated luminosity for e^+e^- incident beams.

22.1.3 Resonance production

The single meson formation process $\gamma\gamma \to R$, in which only one meson R is produced from the two-photon collision, is one of the most important processes in two-photon physics. The quantum numbers of the meson R are limited: it must be electrically neutral and have even C-parity; the spin-parity of $J = 1^{\pm}$ or $J^P =(\text{odd})^-$ are prohibited in collisions of real photons. There are other restrictions for the helicity for the produced meson R.

This process allows us to measure the two-photon partial width of the final-state meson R. The cross section can be written as:

$$\sigma(W) = 8\pi(2J+1)\frac{\Gamma_{\gamma\gamma}\Gamma\mathcal{B}(R \to \text{final state})}{(W^2 - M_R^2)^2 + M_R^2\Gamma^2}, \quad (22.1.5)$$

where M_R, $\Gamma_{\gamma\gamma}$ and Γ are the mass, two-photon decay width, and total width of the meson resonance R, respectively. $\mathcal{B}(R \to \text{final state})$ is the branching fraction for the decay of the meson R. Here we assume that the resonance shape is represented by a conventional relativistic Breit-Wigner function (see Chapter 13). If we know the branching fraction of the meson's decay mode used in the measurement, then we can extract the two-photon decay width; otherwise, we measure the product of the two-photon decay width and the branching fraction. The two-photon partial decay width is a fundamental and direct observable to explore the $q\bar{q}$ or exotic nature of the neutral meson. Even for a non-exotic meson, the two-photon decay width is useful to study the quarks' quantum state inside the meson and to test QCD models (Munz, 1996).

In a zero-tag measurement, we can make the signal events almost free from other processes by applying a rather stringent transverse-momentum balance. This is a great advantage in searches for new resonances as well as new decay modes of known hadrons. The requirement for the transverse-momentum balance also restricts the Q^2 of

the incident photon and ensures the processes originates from real photon collisions. Similar requirements are also useful in the single-tag cases described below to ensure a small Q^2 for the untagged photon.

22.1.4 Single-tag measurements

When one of the scattered electrons is detected, we refer to these two-photon processes as single-tag modes. In the single-tag process, we can probe the structure of the real photon or a hadron with a high-Q^2 photon; this process is very useful for studies of hadron and QCD physics such as meson transition form factors (Brodsky and Lepage, 1981). The Q^2 of the virtual photon is determined by measuring the scattering angle and energy of the recoil electron with the following Lorentz-invariant formula:

$$Q^2 = 4E_b E' \sin^2\frac{\theta}{2}, \quad (22.1.6)$$

where E_b and E' are the energies of the incident and recoiling (tagged) electrons and θ is the scattering angle of the tagged electron.

The formation of a resonance in the single-tag process is a fertile field of study at the B Factories, especially in the high-Q^2 region where the production cross section is highly suppressed. We impose a kinematic requirement on the single-tag mode that all the final state particles be observed except for the non-tagged incident electron (which can be inferred from a missing-mass constraint). In the B Factory experiments, the pseudoscalar transition form factors have been measured in single-tag modes, and are discussed in section 22.7. It is also possible to produce spin-1 (axial-vector) mesons in the single-tag process, although such measurements have not been reported from the B Factories.

22.1.5 Monte-Carlo Techniques

No general-purpose Monte-Carlo (MC) generator for two-photon processes was available during the running of the B Factories. For exclusive two-photon processes, we can explicitly specify the combination of the final-state particles exclusively as well as the W distribution used in the event generation. In addition, angular distributions must be specified in the event generation.

For these purposes, several MC generators to simulate a resonance or an exclusive final-state system from two-photon collisions, such as `TREPS` (Uehara, 1996), `GGRESRC` (Druzhinin, Kardapoltsev, and Tayursky, 2010), `Gamgam` (Aubert, 2010g) etc., are prepared and are used in the analysis. In these generators, one can specify functional shapes of distributions for W, Q^2 and angles of final-state particles, or they can be generated by built-in default functions. Usually, an equivalent-photon approximation is adopted for zero-tag event generation while a Q^2 distribution not based on EPA is sometimes used for the single-tag cases. Even for the non-EPA cases, we can

obtain the conversion factor to obtain the $\gamma\gamma^*$ physics variable, such as the square of a transition form factor, from the e^+e^--based cross section through the MC calculations.

The Q^2 dependence or its maximum limit affects values or definitions of the luminosity function, the cross section on the e^+e^--incident basis and the efficiency in the measurements of the zero-tag mode; hence consistency among these quantities must be considered in the analysis.

Background processes are modeled using generators which take into account the higher-order QED processes, parton-distribution functions and/or soft hadrons, such as `Pythia` (Sjöstrand, Mrenna, and Skands, 2006).

22.2 Pseudoscalar meson-pair production

The energy region of meson-pair production through two-photon processes can be naturally divided into a low energy region, where resonance production is dominant, and a high energy region, where cross sections tend to show asymptotic behavior and can be compared to QCD predictions.

In this section, we restrict ourselves to the pair production of pseudoscalar mesons (denoted as P_1 and P_2). Belle has made extensive studies of these processes for both charged-meson pairs,

(1) $\gamma\gamma \to \pi^+\pi^-$ (Mori, 2007a,b; Nakazawa, 2005),
(2) $\gamma\gamma \to K^+K^-$ (Abe, 2003d; Nakazawa, 2005),

and neutral-meson pairs,

(3) $\gamma\gamma \to K_S^0 K_S^0$ (Chen, 2007c; Uehara, 2013),
(4) $\gamma\gamma \to \pi^0\pi^0$ (Uehara, 2008a, 2009b),
(5) $\gamma\gamma \to \eta\pi^0$ (Uehara, 2009a),
(6) $\gamma\gamma \to \eta\eta$ (Uehara, 2010a).

The polar angle (θ^*) coverage is typically restricted to $|\cos\theta^*| < 0.6$; for neutral pairs decaying into photons this range is extended to $|\cos\theta^*| < 0.8$ or $|\cos\theta^*| < 1.0$, because small angle photons can be detected by the endcap calorimeters. The wider coverage provides better separation of the partial waves as discussed in Section 22.2.1.1.

As an example of the high statistics in raw data that have been recorded at the B Factories, we show the W dependence of the experimental yields for the $\gamma\gamma \to \pi^+\pi^-$ and $\gamma\gamma \to \eta\pi^0$ candidate events in Fig. 22.2.1 (a) and (b), respectively.

22.2.1 Light-quark meson resonances

A measurement of a meson resonance (denoted as R) decaying into two pseudoscalar mesons through two-photon production allows the determination of its parameters such as the mass, total width and, in particular, the product of the two-photon width and the branching fraction to the meson pair, $\Gamma_{\gamma\gamma}\mathcal{B}(R \to P_1 P_2)$. If $\mathcal{B}(R \to P_1 P_2)$ is known, a two-photon width is derived, which is otherwise difficult to obtain. The two-photon width of a meson is intimately related to its charge structure, giving in turn valuable information on its quark content and structure.
Figure 22.2.1. Invariant mass, W, distribution for (a) $\gamma\gamma \to \pi^+\pi^-$ and (b) $\gamma\gamma \to \eta\pi^0$ candidate events. The distribution in (a) includes the $\gamma\gamma \to \mu^+\mu^-$ background. In (b), the solid curve shows the background from other processes; that is determined experimentally from the transverse-momentum-balance distribution. Taken from (Mori, 2007a; Uehara, 2009a).

One of the longstanding puzzles of QCD is the low mass scalar nonet: $f_0(500)$, $K_0^*(800)$, $f_0(980)$ and $a_0(980)$, whose masses must be higher than 1.2 GeV/c^2 if they are ordinary $q\bar{q}$ bound states (Close and Tornqvist, 2002; 't Hooft, Isidori, Maiani, Polosa, and Riquer, 2008). One possible explanation exploits the attractive force between a quark pair (di-quark) in the color anti-triplet state. In this picture, a di-quark anti-di-quark pair forms a nonet with lower masses for the scalar states. In such a state, its two-photon width is expected to be an order of magnitude smaller compared to that of the $q\bar{q}$ state (Amsler and Tornqvist, 2004). [166]

---

[166] The typical size of the two-photon width for the usual $q\bar{q}$ state is given, for example, for $f_2(1270)$ meson; that is $\Gamma_{\gamma\gamma}(f_2(1270)) = 3.03 \pm 0.35$ keV (Beringer et al., 2012).

22.2.1.1 Differential cross sections and partial wave analysis

In this subsection, we present the formalism of the differential cross section for two-photon production of a meson pair in terms of partial waves and then discuss a possible method to extract the resonance parameters.

In the energy region $W \leq 3$ GeV, the partial waves with spin $J > 4$ may be neglected so that only S-, D- and G- waves need be considered. The differential cross section can be expressed as:

$$\frac{d\sigma}{d\Omega}(\gamma\gamma \to P_1 P_2) = \tag{22.2.1}$$
$$\left| S\, Y_0^0 + D_0\, Y_2^0 + G_0\, Y_4^0 \right|^2 + \left| D_2\, Y_2^2 + G_2\, Y_4^2 \right|^2,$$

where D_0 and G_0 (D_2 and G_2) denote the helicity 0 (2) components of the D- and G- wave, respectively,[167] and Y_J^λ are the spherical harmonics in which the helicity λ is quantized for the $\gamma\gamma$ axis. The angular dependence of the cross section is governed by the spherical harmonics, while the energy dependence is determined by the partial waves. Since the absolute value of harmonics $|Y_J^\lambda|$ are not independent, the partial waves cannot be separated from the information on the differential cross sections alone.

We write Eq. (22.2.1) as

$$\frac{d\sigma}{4\pi d|\cos\theta^*|}(\gamma\gamma \to P_1 P_2) = \tag{22.2.2}$$
$$\widehat{S}^2\, |Y_0^0|^2 + \widehat{D}_0^2\, |Y_2^0|^2 + \widehat{D}_2^2\, |Y_2^2|^2$$
$$+ \widehat{G}_0^2\, |Y_4^0|^2 + \widehat{G}_2^2\, |Y_4^2|^2.$$

The amplitudes $\widehat{S}^2$, $\widehat{D}_0^2$, $\widehat{D}_2^2$, $\widehat{G}_0^2$ and $\widehat{G}_2^2$ can be expressed in terms of S, D_0, D_2, G_0 and G_2 (Uehara, 2008a). Since the squares of the spherical harmonics are orthogonal, we can fit differential cross sections to obtain $\widehat{S}^2$, $\widehat{D}_0^2$, $\widehat{D}_2^2$, $\widehat{G}_0^2$ and $\widehat{G}_2^2$ for each W bin. Two types of fit are used: the "SD" fit and "SDG" fit; G-waves are neglected in the SD fit.

As an example of the analysis, we discuss the Belle results for $\gamma\gamma \to \eta\pi^0$ (Uehara, 2009a). The spectra of $\widehat{S}^2$, $\widehat{D}_0^2$ and $\widehat{D}_2^2$ obtained by the SD fit for this process are shown in Fig. 22.2.2. The spectrum for $\widehat{S}^2$ shows a clear peak of the spin zero $a_0(980)$ with a shoulder that may be due to the $a_0(1450)$ while the spectrum for $\widehat{D}_2^2$ is dominated by the spin two $a_2(1320)$ with a hint of the $a_2(1700)$. There is no clear structure for the $\widehat{D}_0^2$ component. The SDG fit reveals that G-waves are negligible in this energy region.

22.2.1.2 Resonance parameter extraction by partial wave analysis

Here, we describe a method to derive information from resonances by parameterizing partial wave amplitudes and then fitting differential cross sections. Note that we do not

Figure 22.2.2. Spectra of (top) $\widehat{S}^2$, (middle) $\widehat{D}_0^2$ and (bottom) $\widehat{D}_2^2$ for $\gamma\gamma \to \eta\pi^0$. The solid lines are the results of the partial-wave analysis discussed in Section 22.2.1.2. The error bars show the diagonal components of error matrix for the fit parameters. From (Uehara, 2009a).

fit the obtained $\widehat{S}^2$, $\widehat{D}_0^2$ and $\widehat{D}_2^2$ spectra; instead, we fit the differential cross sections directly, but the results are shown in the $\widehat{S}^2$, $\widehat{D}_0^2$, $\widehat{D}_2^2$ spectra. Two to three orders of magnitude higher statistics are available at B Factories compared to pre-B Factory experiments which permits such a luxury.[168]

Once the functional forms of the amplitudes are prepared, we use Eq. (22.2.1) to fit the differential cross sections. The fundamental difficulty is the presence of interference among resonances and non-resonant amplitudes that are basically unknown. A fit with many free parameters often results in multiple solutions corresponding to constructive and destructive interference. Thus, one has to minimize the number of parameters to obtain a stable and unique solution. The effects of parameterization dependence are incorporated in the systematic uncertainties, which are typically obtained by changing the parameterization.

In the partial wave analysis for the low energy region $W < 1.5$ GeV where the $J > 2$ waves can be neglected safely, the $a_2(1320)$ contribution is assumed only in the

---

[167] In this chapter we denote individual partial waves by Roman style and parameterized waves by italics.

[168] See Whalley (2001) for a compilation for pre-B Factory experiments.

D_2 wave, since $\widehat{D}_2^2$ is dominated by the $a_2(1320)$ resonance and the $\widehat{D}_0^2$ component is small. For the S-wave, the shoulder in the $\widehat{S}^2$ spectrum above the $a_0(980)$ peak may be understood due to the $a_0(1450)$. However, in the fit Belle introduces a new resonance $a_0(Y)$, since the resonance parameters are found to be quite different from those of the $a_0(1450)$.

As a result, Belle uses the following parameterization for the S-, D_0 and D_2 waves:

$$S = A_{a_0(980)}e^{i\phi_{s0}} + A_{a_0(Y)}e^{i\phi_{s1}} + B_S \ ,$$
$$D_0 = B_{D0} \ ,$$
$$D_2 = A_{a_2(1320)}e^{i\phi_{d2}} + B_{D2} \ , \qquad (22.2.3)$$

where $A_{a_0(980)}$, $A_{a_0(Y)}$ and $A_{a_2(1320)}$ are the amplitudes of the $a_0(980)$, $a_0(Y)$ and $a_2(1320)$, respectively; B_S, B_{D0} and B_{D2} are non-resonant (hereafter called "background") amplitudes for S-, D_0 and D_2 waves; and ϕ_{s0}, ϕ_{s1}, and ϕ_{d2} are the phases of resonances relative to background amplitudes. The goal of the analysis is to obtain parameters of the $a_0(980)$ and $a_0(Y)$ and to check the consistency of the $a_2(1320)$ parameters that have been measured well in the past.

The background amplitudes are parameterized as second order polynomials in W for both the real and imaginary parts of all waves. The arbitrary phases are fixed by choosing $\phi_{s0} = \phi_{d2} = 0$. for S- and D- waves. We constrain all the background amplitudes to be zero at the threshold in accordance with the expectation that the cross section vanishes in the Thomson limit which was originally discussed in the context of low-energy Compton scattering. The relativistic Breit-Wigner resonance amplitude (see Chapter 13) is used for a resonance.

The data are fit using the minimizer `Minuit` (James and Roos, 1975). Many fits are done using different, randomly chosen starting parameters. In this way, Belle search for a global minimum and locate ambiguous solutions.

The resulting best fit obtained is displayed in Fig. 22.2.2. The measured spectra, $\widehat{S}^2$, $\widehat{D}_0^2$ and $\widehat{D}_2^2$, are reproduced fairly well by the fit.

Table 22.2.1 summarizes the fit results for $\gamma\gamma \to \eta\pi^0$ as well as the other processes measured by Belle: $\gamma\gamma \to \pi^+\pi^-$, $\gamma\gamma \to K^+K^-$, $\gamma\gamma \to K_S^0 K_S^0$, $\gamma\gamma \to \pi^0\pi^0$ and $\gamma\gamma \to \eta\eta$.

The main results in this table are as follows. Belle measures the two-photon widths for the scalar resonances $f_0(980)$ and $a_0(980)$ for the first time with significant statistics; the $f_0(980)$ is observed as a clear peak both in the $\pi^+\pi^-$ and $\pi^0\pi^0$ modes; the $a_0(980)$ is measured clearly in the $\eta\pi^0$ mode. The measured two-photon widths are small compared to those of the $f_2(1270)$ and $a_2(1320)$. This supports the di-quark anti-di-quark hypothesis for these mesons. In addition, Belle finds several resonance states in the range 1.3–2.4 GeV with substantial coupling to two photons. Belle perform a generic partial wave analysis including possible interferences with non-resonant terms. Systematic errors for some resonance parameters are large, resulting from a preference for destructive interference between the resonance and other components.

For example see S and D_2 in Eq. 22.2.3, which tends to enhance variations of parameters. In addition, this generic analysis results in multiple solutions in some cases.

The Belle results provide good-quality unfolded data on the differential cross sections for six pseudoscalar modes, $\gamma\gamma \to \pi^+\pi^-$, K^+K^-, $\pi^0\pi^0$, $K_S^0 K_S^0$, $\eta\pi^0$ and $\eta\eta$. These high-statistics data can be used to update partial wave analyses that employ low energy constraints and incorporate all available hadron data (Pennington, Mori, Uehara, and Watanabe, 2008). We expect that these high-statistics data will be used to derive more accurate resonance parameters.

22.2.2 Comparison with QCD predictions at high energy

Two-photon production of exclusive hadronic final states provides useful information about resonances, perturbative QCD, and non-perturbative QCD. From the theoretical point of view, a two-photon process is attractive because of the absence of strong interactions in the initial state.

Brodsky and Lepage (1981) (BL) numerically calculated the amplitude for the hard exclusive $\gamma\gamma \to M_1 \overline{M}_2$ processes within the context of the perturbative-QCD (pQCD) for the first time. A similar formula is also discussed by Chernyak and Zhitnitsky (1984). In this pQCD framework, the amplitude for $\gamma\gamma \to M_1 \overline{M}_2$ can be described in a factorized form:

$$\mathcal{M}_{\lambda_1\lambda_2}(s,\theta^*) = \qquad\qquad (22.2.4)$$
$$\int_0^1 \int_0^1 dxdy\phi_M(x,Q_x)\phi_{\overline{M}}(y,Q_y)T_{\lambda_1\lambda_2}(x,y,\theta^*),$$

where s is the squared invariant mass of the di-meson system, $\phi_M(x,Q_x)$ is a single-meson distribution amplitude for a meson M. The squared amplitude $|\phi_M(x,Q_x)|^2$ is proportional to a probability for finding a valence quark and antiquark in the meson, carrying a fraction x and $1-x$, respectively, of the meson's momentum. Q_x is the typical momentum scale in the process, $\sim \min(x, 1-x)\sqrt{s}\sin\theta^*$. The term $T_{\lambda_1\lambda_2}$ is a hard scattering amplitude for $\gamma_{\lambda_1}\gamma_{\lambda_2} \to q\bar{q}q\bar{q}$ with photon helicities λ_1 and λ_2. From the sum rule, the overall normalization is fixed as

$$\int_0^1 dx\phi_M(x,0) = f_M/2\sqrt{3}, \qquad (22.2.5)$$

where f_M is the decay constant for meson M.

For mesons with helicity zero the leading-term calculation gives the following dependence on s and scattering angle θ^*:

$$\frac{d\sigma}{d|\cos\theta^*|} = 16\pi\alpha^2 \frac{|F_M(s)|^2}{s} \left\{ \frac{[(e_1-e_2)^2]^2}{(1-\cos^2\theta^*)^2} \right.$$
$$\left. + \frac{2(e_1e_2)[(e_1-e_2)^2]}{1-\cos^2\theta^*}g(\theta^*) \right.$$

Table 22.2.1. Summary of partial wave analyses in the energy region below 2.4 GeV. If two values are given for the two-photon partial decay width $\Gamma_{\gamma\gamma}$, the upper value is the one for the spin-helicity assignment $(J, \lambda) = (2, 2)$ and the lower one for $(0, 0)$. $\mathcal{B}$ is the branching fraction of the resonance to the corresponding decay mode otherwise explicitly noted. For the $\pi^0\pi^0$ mode, we provide the value $\mathcal{B}(f_2 \to \gamma\gamma)$ instead of $\Gamma_{\gamma\gamma}$ since the total width is known for $f_2(1270)$. The resonances $f_0(Y)$, $a_0(X)$ and $f_2(X)$ correspond to signals of new or unidentified resonances found. In the K^+K^- mode, $f_J/f_0/a_2$ and f_J/f_2 mean that there are ambiguities in the signal assignment. Quoted upper limits are at 90% confidence level.

$$+2(e_1 e_2)^2 g^2(\theta^*) \Bigg\}, \qquad (22.2.6)$$

where e_1 and e_2 are the quark charges and F_M is the meson's electromagnetic form factor. Finally, $g(\theta^*)$ is a function of order one expressing the additional θ^* dependence.

[169] In principle, both F_M and $g(\theta^*)$ can be obtained from the meson wave function $\phi_M(x, Q_x)$. However, at present they are unknown since the function $\phi_M(x, Q_x)$ is a non-perturbative quantity with an unknown x dependence.

---

[169] See the original paper (Brodsky and Lepage, 1981) for the explicit formula.

Under the assumption that ϕ_K and ϕ_π are similar in shape, the differential cross section ratio for production of K^+K^- and $\pi^+\pi^-$ depends only on the meson decay constants f_K^4/f_π^4. Benayoun and Chernyak (1990) (BC) employ different wave functions for $\phi_\pi(x)$ and $\phi_K(x)$, taking into account $SU(3)$ symmetry breaking effects. The next-to-leading order calculation is done by Duplancic and Nizic (2006).

As an alternative model for the meson-pair production in the two-photon processes, Diehl, Kroll, and Vogt (2002) (DKV) proposed a "handbag model". In the handbag model, the differential cross section for the process is given by

$$\frac{d\sigma}{d|\cos\theta^*|}(\gamma\gamma \to M\overline{M}) = \frac{8\pi\alpha^2}{s}\frac{1}{\sin^4\theta^*}|R_{M\overline{M}}(s)|^2,$$

$$(22.2.7)$$

where the transition amplitude is expressed as a hard scattering $\gamma\gamma \to q\bar{q}$ times a form factor $R_{M\overline{M}}(s)$ describing the soft transition $q\bar{q} \to M\overline{M}$. The main dynamical assumption of this model is that, at present energies $W \leq 4\,\text{GeV}$, all amplitudes for $\gamma\gamma \to M\overline{M}$ are still dominated by "soft" components. In this model, the angular distribution is proportional to $1/\sin^4\theta^*$ for both charged and neutral meson pairs.

22.2.2.1 Angular Dependence of Differential Cross Section

As can be seen from Eq. (22.2.6), there is distinct difference for charged and neutral meson pair production in pQCD. For charged meson pairs, the angular distribution is given by $1/\sin^4\theta^*$, since the first (leading) term dominates. This angular dependence is expected to be realized in a certain large $|t|$ region of the Mandelstam variable. Meanwhile, for neutral meson pairs, the first and the second terms are zero since the quark charges are the same ($e_1 = e_2$), so the angular dependence is given by the third (non-leading) term $\propto g^2(\theta^*)$. As a result, a complicated angular distribution depending on the meson wave amplitude is expected for the neutral meson pairs. On the other hand, the handbag model predicts a $1/\sin^4\theta^*$ dependence for large W for both charged and neutral meson pairs.

The measured results from Belle are summarized in Table 22.2.2. For the charged meson pairs, $\gamma\gamma \to \pi^+\pi^-$, K^+K^-, the angular distributions are described by the $1/\sin^4\theta^*$ form quite well. On the other hand, for the neutral meson pairs, $\gamma\gamma \to \pi^0\pi^0$, $K_S^0K_S^0$, $\eta\pi^0$ and $\eta\eta$, the angular distributions show more complicated behavior. [170]

22.2.2.2 Energy Dependence of Cross Section and ratio of Cross Sections

Other important predictions for the hard exclusive processes in QCD are the power-law dependence of the cross

---

[170] An update analysis for $\gamma\gamma \to K_S^0K_S^0$ using full Belle data shows clearly that the angular distribution for this mode can not be described by a $1/\sin^4\theta^*$ form. See Uehara (2013).

section, $\sigma_0 \sim W^{-n}$, and the ratio of the cross sections for the different processes. These results are summarized in Table 22.2.3.

For the W dependence, pQCD predicts $n = 6$ for the charged meson pairs, and $n = 10$ for the neutral meson pairs in the energy region accessible in the B Factory experiments (Benayoun and Chernyak, 1990). The data for $\gamma\gamma \to \pi^+\pi^-$, K^+K^- show slightly higher n than the predicted value of $n = 6$ but within the systematic errors as shown in Figs 22.2.3(a) and (b).

On the other hand, for the neutral meson pairs, the processes $\gamma\gamma \to K_S^0K_S^0$ shows a steeper W dependence than that for the charged meson pairs as can be seen in Fig. 22.2.3(d). The measured value of the slope $n = 11.0 \pm 0.4 \pm 0.4$ (Uehara, 2013) shows a good agreement with the pQCD prediction by Chernyak (Chernyak, 2006, 2012).

For the ratio of the cross sections, pQCD predicts a large suppression for the neutral mesons compared to the charged mesons. In contrast, in the handbag model, the ratio is determined by soft dynamics such as the iso-spin, $SU(3)$ relation. As can be seen in Fig. 22.2.3(e), the data show a large suppression for the ratio

$$\frac{\sigma(\gamma\gamma \to K_S^0K_S^0)}{\sigma(\gamma\gamma \to K^+K^-)}.$$

$$(22.2.8)$$

This is consistent with the pQCD expectation, but does not agree with the handbag model. In addition, the ratio $\sigma(\gamma\gamma \to K^+K^-)$ over $\sigma(\gamma\gamma \to \pi^+\pi^-)$ is consistent with pQCD prediction by Benayoun and Chernyak (1990) [BC], where the difference of wave functions for pion and kaon is taken into account (see Fig. 22.2.3(c)).

One exception is the ratio

$$\frac{\sigma(\gamma\gamma \to \pi^0\pi^0)}{\sigma(\gamma\gamma \to \pi^+\pi^-)}.$$

$$(22.2.9)$$

This neutral to charged ratio is rather large as shown in Table 22.2.3. This result is inconsistent with the pQCD predictions where the neutral modes are expected to be suppressed. The result, however, can be explained by the handbag model (Diehl and Kroll, 2010) quite well.

Further study of the differential cross section data is needed to clarify these unresolved problems.

22.3 Vector meson-pair production

A clear signal for the production of a new state via the $\gamma\gamma$ process, $X(3915) \to \omega J/\psi$ (Uehara, 2010b),(Lees, 2012ad), and evidence for another state $X(4350) \to \phi J/\psi$ (Shen, 2010a) have been reported, thereby introducing new puzzles in charmonium(-like) spectroscopy (see also Sections 18.2 and 18.3). It is natural to extend the above theoretical picture to similar states coupling to $\omega\phi$, $\omega\omega$ or $\phi\phi$.

Measurements of the cross sections for $\gamma\gamma \to VV$ (Liu, 2012), where V is a vector particle, in particular $VV = \omega\phi$, $\phi\phi$ and $\omega\omega$, are based on an analysis of the 870 fb^{-1}

Table 22.2.2. Angular dependence of differential cross sections in comparison with $1/\sin^4\theta^*$ dependence.

mode	$1/\sin^4\theta^*$	energy range	$\|\cos\theta^*\|$ range	reference

\#\# From Uehara (2013).

data sample taken at or near the $\Upsilon(nS)$ ($n = 1, ..., 5$) resonances with the Belle detector.

After event selections, clear ω and ϕ signals are observed. We obtain the number of VV events in each VV invariant mass bin by fitting the $|\sum \boldsymbol{P}_t^*|$ distribution between zero and 0.9 GeV/c, where $|\sum \boldsymbol{P}_t^*|$ is the magnitude of the vector sum of the final transverse momenta of the particle in the e^+e^- CM frame. The resulting VV invariant mass distributions are shown in Fig. 22.3.1; some obvious structures are observed in the low VV invariant mass region.

Two-dimensional (2D) angular distributions are investigated to obtain the J^P quantum numbers of the structures. In the process $\gamma\gamma \to VV$, five angular variables are kinematically independent: z, z^*, z^{**}, ϕ^*, and ϕ^{**}. Using $\omega\phi$ as an example, z is the cosine of the scattering polar angle of the ϕ meson in the $\gamma\gamma$ CM system; z^* and ϕ^* are the cosine of the helicity angle of K^+ in the ϕ decay

and the azimuthal angle defined in the ϕ rest frame with respect to the $\gamma\gamma \to \omega\phi$ scattering plane; z^{**} and ϕ^{**} are the cosine of the helicity angle of normal direction to the decay plane of the $\omega \to \pi^+\pi^-\pi^0$ and the azimuthal angle defined in the ω rest frame. We use the transversity angle (ϕ_T) and polar-angle product (Π_θ) to analyze the angular distributions. They are defined as $\phi_T = |\phi^* + \phi^{**}|/2\pi$, $\Pi_\theta = [1 - (z^*)^2][1 - (z^{**})^2]$.

The number of signal events is obtained by fitting the $|\sum \boldsymbol{P}_t^*|$ distribution in each ϕ_T and Π_θ bin in the 2D space. The 2D space is divided into 4×4, 5×5, and 10×10 bins for $\omega\phi$, $\phi\phi$, and $\omega\omega$, respectively, in several wide VV mass bins as shown in Fig. 22.3.2. The resulting 2D angular distributions are fitted with the signal shapes from MC-simulated samples with different J^P assumptions (0^+, 0^-, 2^+, 2^-). The following features are found: (1) for $\omega\phi$: 0^+ (S-wave) or 2^+ (S-wave) can describe the data with $\chi^2/ndf = 1.1$ or 1.2, while a mixture of 0^+ (S-wave) and
Figure 22.2.3. Cross section for the processes (a) $\gamma\gamma \to \pi^+\pi^-$, (b) $\gamma\gamma \to K^+K^-$ and (d) $\gamma\gamma \to K_S^0 K_S^0$, integrated over $|\cos(\theta^*)| < 0.6$, as a function of W. The solid line in (a) and (b) is the prediction $n = 6$, while that in (d) is the best fit. The figures (c) and (e) show the ratio of the cross section among these processes. The solid line in (c) is a fit with a constant. The horizontal lines in (e) show various theoretical predictions. From (Chen, 2007c; Nakazawa, 2005).

Figure 22.3.1. The (a) $\omega\phi$, (b) $\phi\phi$ and (c) $\omega\omega$ invariant mass distributions. The shaded histograms are from the corresponding normalized sidebands. From (Liu, 2012).

2^+ (S-wave) describes the data with $\chi^2/ndf = 0.9$ (ndf being the number of degrees of freedom); (2) for $\phi\phi$: a mixture of 0^+ (S-wave) and 2^- (P-wave) describes the data with $\chi^2/ndf = 1.3$; and (3) for $\omega\omega$: a mixture of 0^+ (S-wave) and 2^+ (S-wave) describes the data with $\chi^2/ndf = 1.3$.

The $\gamma\gamma \to VV$ cross sections are shown in Fig. 22.3.2. The cross sections for different J^P values as a function of $M(VV)$ are also shown in this figure. While there are substantial spin-zero components in all three modes, there are also significant spin-two components, certainly in the $\phi\phi$ and $\omega\omega$ modes.

The cross sections for $\gamma\gamma \to \omega\phi$ are much lower than the prediction of the $q^2\bar{q}^2$ tetraquark model (Achasov and Shestakov, 1991) of 1 nb. The resonant structure in the $\gamma\gamma \to \phi\phi$ mode is found nearly at the predicted mass from the model. However, the $\phi\phi$ cross section is an order of magnitude lower than the expectation. On the other hand, the t-channel factorization model (Alexander, Levy, and Maor, 1986) predicts that the $\phi\phi$ cross sections vary

between 0.001 nb and 0.05 nb in the mass region of 2.0 GeV/c^2 to 5.0 GeV/c^2, which are much lower than the experimental data. For $\gamma\gamma \to \omega\omega$, the t-channel factorization model predicts a broad structure between 1.8 GeV/c^2 and 3.0 GeV/c^2 with a peak cross section of 10-30 nb near 2.2 GeV/c^2, while the one-pion-exchange model (Achasov, Karnakov, and Shestakov, 1987) predicts an enhancement near threshold around 1.6 GeV/c^2 with a peak cross section of 13 nb using their preferred value of the slope parameter. Both the peak position and the peak height predictions from these models disagree with the Belle measurements. Therefore none of the models discussed here can explain the data (Chernyak, 2012).
Figure 22.3.2. The cross sections of $\gamma\gamma \to \omega\phi$ (a), $\phi\phi$ (b), and $\omega\omega$ (c) are shown as points with error bars. The cross sections for different J^P values as a function of $M(VV)$ are shown as the triangles and squares with error bars. The inset also shows the cross section on a semi-logarithmic scale. In the high energy region, the solid curve shows a fit to a $W_{\gamma\gamma}^{-n}$ dependence for the cross section after the significant charmonium contributions (η_c, χ_{c0} and χ_{c2}) were excluded. From (Liu, 2012).

As shown Belle fits the W dependence of the cross section with a form $W_{\gamma\gamma}^{-n}$. The results are shown, in the

inset of Fig. 22.3.2 with solid curves. The fit gives $n = 7.2 \pm 0.6$, 8.4 ± 1.1, and 9.1 ± 0.6 for the $\omega\phi$, $\omega\omega$, and $\phi\phi$ modes, respectively. These results are consistent with the predictions from pQCD (Chernyak, 2010).

22.4 $\eta'\pi^+\pi^-$ production

The invariant mass spectrum of the $\eta'\pi^+\pi^-$ final state produced in two-photon collisions is obtained using a 673 fb^{-1} data sample by the Belle experiment. In addition to the prominent η_c signal, an enhanced shoulder is evident in the mass region below 2 GeV/c^2 in the background-subtracted distribution of Fig. 22.4.1 (Zhang, 2012).
Figure 22.4.1. Background subtracted invariant mass distribution for the $\eta'\pi^+\pi^-$ candidates from (Zhang, 2012). The points with error bars are the $\eta'\pi^+\pi^-$ yields extracted from fitting the $|\sum \boldsymbol{p}_t^*|$ distribution in each sliced mass bin. Here, $|\sum \boldsymbol{p}_t^*|$ is determined by taking the absolute value of the vector sum of the transverse momenta of η' and the $\pi^+\pi^-$ tracks in the e^+e^- CM system.

The first evidence for decays of $\eta(1760)$ to $\eta'\pi^+\pi^-$ is reported, showing two solutions for its parameters, depending on the inclusion or not of the $X(1835)$ (Ablikim et al., 2005b, 2011), whose existence is marginal in our fits. The decay $\eta(1760) \to \eta'\pi^+\pi^-$ is found with a significance of 4.7σ, with the assumption that the $X(1835)$ is not produced; the $\eta(1760)$ mass and width are determined to be $M = (1768^{+24}_{-25} \pm 10)$ MeV/c^2 and $\Gamma = (224^{+62}_{-56} \pm 25)$ MeV/c^2. The fitted $\eta(1760)$ mass is consistent with the existing measurements (Ablikim et al., 2006; Bai et al., 1999; Bisello et al., 1987, 1989). The product of the two-photon decay width and the branching fraction for the $\eta(1760)$ decay to $\eta'\pi^+\pi^-$ is determined to be $\Gamma_{\gamma\gamma}\mathcal{B}(\eta(1760) \to \eta'\pi^+\pi^-) = (28.2^{+7.9}_{-7.5}\pm3.7)$ eV/c^2. When the mass spectrum is fitted with two coherent resonances, the $\eta(1760)$ and $X(1835)$, the $\eta(1760)$ mass and width are found to be $M = (1703^{+12}_{-11} \pm 1.8)$ MeV/c^2 and $\Gamma = (42^{+36}_{-22}\pm15)$ MeV/c^2. The signal significances including the

systematic error are estimated to be 4.1σ for the $\eta(1760)$ and 2.8σ for the $X(1835)$. Upper limits on the product $\Gamma_{\gamma\gamma}\mathcal{B}$ for the $X(1835)$ decay to $\eta'\pi^+\pi^-$ at the 90% confidence level for the two fit solutions are $\Gamma_{\gamma\gamma}\mathcal{B}(X(1835) \rightarrow \eta'\pi^+\pi^-) < 35.6$ eV/c^2 with $\phi = (287^{+42}_{-51})°$ for constructive interference and $\Gamma_{\gamma\gamma}\mathcal{B}(X(1835) \rightarrow \eta'\pi^+\pi^-) < 83$ eV/c^2 with $\phi = (139^{+19}_{-9})°$ for destructive interference. Here ϕ is the relative phase between $X(1835)$ and $\eta(1760)$. The fit results provide a marginal preference for the interpretation of the $X(1835)$ as a radial excitation of the η' (Huang and Zhu, 2006; Klempt and Zaitsev, 2007).

22.5 Baryon-pair production

Two-photon collisions provide a clean environment for baryon pair production, which is a useful laboratory to study baryon production mechanisms and the perturbative QCD prediction. A measurement of the simplest process, $\gamma\gamma \rightarrow p\bar{p}$, has been reported by the Belle experiment (Kuo, 2005).

General theories of hard exclusive processes in QCD predict the dimensional counting rule (Sivers, Brodsky, and Blankenbecler, 1976) in the two-photon production processes of both meson and baryon pairs:

$$\frac{d\sigma}{dt} = s^{2-n_c} f(\theta^*) \qquad (22.5.1)$$

at sufficiently high energy. Where s is the invariant-mass square of the $\gamma\gamma$ system and t is the Mandelstam variable between incident γ and p in the final state; θ^* is the meson scattering angle in the two-photon CM system as defined previously. The coefficient n_c is the number of elementary constituents participating in the hard interaction. For the two-photonic baryon-pair production, n_c is $n_c = 8$, which leads[171] to $\sigma \sim W^{-10}$ (for meson-pair production, $n_c = 6$ leads to $\sigma \sim W^{-6}$). The cross section is predicted to fall rapidly at high energies, and thus, its measurement is useful to test this behavior.

As another approach, the handbag model (Diehl, Kroll, and Vogt, 2003) — discussed earlier for meson-pair production — also provides a prediction for the baryon production process. Thus, we can apply the same models for both meson and baryon production phenomena from the vacuum. Quasi-elementary diquark (qq) models might have the potential to modify these predictions.

In Belle analysis, careful calibration of the trigger efficiency for both track and energy triggers and a base adjustment for time-of-flight measurement is needed in order to cope with the particular experimental conditions for an exclusive final state of a proton and an antiproton.

The cross section integrated over the CM angle in the range $|\cos\theta^*| < 0.6$ has been obtained. The fit, according to the power low ($\sigma \sim W^{-n}$), provides $n = 15.1^{+0.8}_{-1.1}$ and $n = 12.4^{+2.4}_{-2.3}$ in the range of $W = 2.5 - 2.9$ GeV and $3.2 - 4.0$ GeV, respectively, as shown in Fig. 22.5.1. These

---

[171] Note that integration over t results in an additional factor of W^2.

numbers are significantly larger than the meson-pair production case, and support the dimensional counting rule. The result for the higher energy region is consistent with the prediction with $n = 10$. While the measured cross section is more compatible with the calculation based on the diquark model with only helicity conserved amplitudes (Berger and Schweiger, 2003). Since precise data are available for baryon-pair production in two-photon processes at high energy, improved theoretical understanding is needed.

As for the angular dependence of the differential cross section, existing models can reproduce the general tendency, which shows a large-angle enhancement near the threshold (below 2.4 GeV) and a small-angle enhancement at the high energies (above 2.7 GeV). However, at the intermediate and the available highest energies, agreement between the model predictions and the results remains unsatisfactory.
Figure 22.5.1. Cross section for $\gamma\gamma \rightarrow p\bar{p}$. The solid and dotted lines show the results of separate fits with $\sigma \propto W^{-n}$ to the data in the range of $W = 2.5 - 2.9$ GeV and $3.2 - 4.0$ GeV, respectively. The error bars include statistical and systematic errors. The χ^2/ndf values for each fit are indicated in the figure. From (Kuo, 2005).

22.6 Charmonium formation

In this section, we discuss only the two-photon decay width ($\Gamma_{\gamma\gamma}$) measurements of the charmonium(-like) states produced by photon-photon formation. Related studies of new Charmonia or exotic charmonium-like particles and the

other properties of known or newly discovered states are discussed in other sections (18.2, 18.3).

The two-photon width of a charmonium(-like) particle probes the internal structure of the resonance because it is sensitive to electric charge of the constituents and the wave function near the central point. As a result, such measurements test QCD models that describe heavy quarkonia and help to identify possible exotic particles. Measurements of production from two-photon collisions give a direct way to measure this quantity in the presence of relatively small backgrounds.

The cross section for a single-resonance formation is proportional to the product of the two-photon decay width and the branching fraction to the final state(s) where the charmonium is identified, $\Gamma_{\gamma\gamma}(R)\mathcal{B}(R \to \text{final state})$ (see Eq. (22.1.5)). This is the direct observable from such measurements. Then, knowledge of either $\Gamma_{\gamma\gamma}(R)$ or $\mathcal{B}(R \to \text{final state})$ with a reasonable accuracy from independent measurements permits us to extract the other property.

We summarize the measurements from the zero-tag modes in Tables 22.6.1 and 22.6.2. The three well known Charmonia, η_c, χ_{c0} and χ_{c2}, have been measured extensively in various decay modes. According to Beringer et al. (2012), the two-photon decay widths of these states, fitted to these measurements as well as branching fraction measurements in other processes, are more or less established and are dominated by the contributions from the B Factory two-photon measurements. Inconsistencies among different kinds of measurement remain in some decay modes of the η_c. In addition, several new decay modes have been measured for the first time. For example, a new decay mode of $\eta_c(2S)$ to $K^+K^-\pi^+\pi^-\pi^0$ was reported by *BABAR* in the production process $\gamma\gamma \to \eta_c(2S)$ (Lees, 2010b).

The new states $\chi_{c2}(2P)$, also denoted by $Z(3930)$ (Uehara, 2006; Aubert, 2010g), $X(3915)$ (Uehara, 2010b),(Lees, 2012ad); and $X(4350)$ (Shen, 2010a) were found in the two-photon process and thus proved that this test bed is useful in searching for new states. Table 22.6.2 shows an upper limit for the $Y(4140)$ production (Shen, 2010a), which was observed in B decays by CDF (Aaltonen et al., 2009a). It also shows the first-ever measurement reported by CLEO for the $\eta_c(2S)$ state (Asner et al., 2004a).

The measured size of $\Gamma_{\gamma\gamma}\mathcal{B}$ for $\chi_{c2}(2P) \to D\bar{D}$ is consistent with the theoretical prediction (Uehara, 2006), (Aubert, 2010g). The measured $\Gamma_{\gamma\gamma}\mathcal{B}$ values for the $\chi_{c2}(2P)$ and $\eta_c(2S)$ have been cited as evidence of their identification as radially excited states of the sequential Charmonia. In contrast, the large value of $\Gamma_{\gamma\gamma}\mathcal{B}$ for $X(3915) \to \omega J/\psi$ (Uehara, 2010b),(Lees, 2012ad) has attracted interest in exploring the true nature of this state.

22.7 Form factor measurements with single-tag processes

Two-photon production of the pseudoscalar mesons π^0 (Aubert, 2009y), η (del Amo Sanchez, 2011f), η' (del Amo Sanchez, 2011f), and η_c (Lees, 2010b) in the single-tag mode has been studied by *BABAR*. Following these publications,

[†] del Amo Sanchez (2011h)

[*] derived from Asner et al. (2004a)

Belle reported their measurement of the π^0 production (Uehara, 2012). The amplitude of two-photon production of a pseudoscalar meson is written as follows

$$A = e^2 \varepsilon_{\mu\nu\alpha\beta} e_1^\mu e_2^\nu q_1^\alpha q_2^\beta F(q_1^2, q_2^2), \qquad (22.7.1)$$

where $\varepsilon_{\mu\nu\alpha\beta}$ is a Levi-Civita antisymmetric tensor and e_i and q_i are the polarization four-vectors and four-momenta of the photons. The effect of strong interactions in this process is described by the photon-meson transition form factor $F(q_1^2, q_2^2)$, which depends on the photon virtualities q_1^2 and q_2^2. In the single-tag mode, one of the photons is quasi-real, $q_2^2 \approx 0$. The form factor is measured as a function of the squared momentum transfer to the tagged (detected) electron $Q^2 = -q_1^2$.

In theory, the transition form factor $F(Q^2) \equiv F(-Q^2, 0)$ for the π^0 is calculated from first principles only in two extreme cases: at $Q^2 = 0$ from the axial anomaly in the chiral limit of QCD, $F(0) = \sqrt{2}/(4\pi^2 f_\pi)$ (Adler, 1969; Bell and Jackiw, 1969), and at $Q^2 \to \infty$ from perturbative QCD (pQCD), $Q^2 F(Q^2) = \sqrt{2} f_\pi$ (Lepage and Brodsky, 1980), where $f_\pi \approx 0.131$ GeV is the pion decay constant. At large Q^2 ($Q^2 \gg \Lambda_{\rm QCD}^2$) in the frame-

work of pQCD, the transition form factor can be represented as the convolution of a calculable amplitude for $\gamma\gamma^* \to q\overline{q}$ with a non-perturbative meson distribution amplitude (DA) $\phi_\pi(x, Q^2)$ (Lepage and Brodsky, 1980). The latter describes the transition of the meson with momentum P into two quarks with momenta Px and $P(1-x)$. In lowest order pQCD, the photon-pion transition form factor is given by

$$Q^2 F(Q^2) = \frac{\sqrt{2} f_\pi}{3} \int_0^1 \frac{dx}{x} \phi_\pi(x, Q^2) + O(\alpha_s) + O\left(\frac{\Lambda_{\rm QCD}^2}{Q^2}\right), \qquad (22.7.2)$$

where $\Lambda_{\rm QCD}$ is the QCD scale parameter.

The meson DA plays an important role in theoretical descriptions of many QCD processes ($\gamma^* \to \pi^+\pi^-$, $\gamma\gamma \to \pi^+\pi^-$, and $B \to \pi l \nu_l$, for example). The shape of DA (i.e., the x dependence) is unknown, but its evolution with Q^2 is predicted by pQCD. The models for DA's can be tested using data on the photon meson transition form-factors.

It is instructive to estimate the sizes of the NLO pQCD and power corrections for Eq. (22.7.2). For this, we use results of the form-factor calculation with the asymptotic DA $\phi_{\rm ASY}(x) = 6x(1-x)$ (Lepage and Brodsky, 1979a) from Bakulev, Mikhailov, and Stefanis (2003, 2004). The NLO contribution (Braaten, 1983; del Aguila and Chase, 1981) varies from 15% to 10% in the Q^2 range of 4 to 50 GeV^2 in the *BABAR* measurements. The power correction, estimated using the light-cone sum rule method (Khodjamirian, 1999; Schmedding and Yakovlev, 2000) (where the twist-4 contribution is also taken into account), is about 15% at 4 GeV^2 and falls to about 2% at $Q^2 = 20$ GeV^2. The calculation of the power correction is model-dependent. It is difficult to estimate the corresponding model uncertainty so it is important to perform form-factor measurements at the largest possible values of Q^2. At the center-of-mass energy $\sqrt{s} = 10.6$ GeV, the $e^+e^- \to e^+e^-\pi^0$ differential cross section $d\sigma/dQ^2$ is about 10 fb/GeV^2 at $Q^2 = 10$ GeV^2. It falls with increasing Q^2 as Q^{-6}. The most precise measurement of the form factors prior to *BABAR* was made by CLEO using data collected at $\Upsilon(4S)$ with an integrated luminosity of 3 fb^{-1}. The $\gamma\gamma^*\pi^0$ form factor was measured for Q^2 up to 8 GeV^2. The B Factory measurements have extended the Q^2 region up to 40 GeV^2. These measurements are described in the following section.

22.7.1 The $\gamma\gamma^*\pi^0$ transition form factor

The process $e^+e^- \to e^+e^-\pi^0$ in the single-tag mode has specific features that complicate its experimental study. The event contains only three detectable particles: two photons from π^0 decay and an electron. Such events, with only one charged track and low multiplicity, are rejected by the standard *BABAR* trigger and offline filters. Fortunately, a special trigger line was designed at *BABAR* to select so-called virtual Compton scattering (VCS) events for electromagnetic-calorimeter calibration. VCS is the

$e^+e^- \rightarrow e^+e^-\gamma$ process in the specific kinematical configuration in which one of the final electrons moves along the collision axis while the other electron and photon are emitted at large angles. The VCS trigger selects events in which the detected electron plus photon system has a small transverse momentum and the recoil mass close to zero. For most of $e^+e^- \rightarrow e^+e^-\pi^0$ events, the close photons from π^0 decay cannot be separated by the trigger cluster algorithm and are identified as a single photon. Therefore, the VCS trigger has relatively large efficiency for events of the process under study (50–80%, depending on the π^0 energy).

The second feature is the large QED background. The main background source is VCS. There is also a sizable background from the $e^+e^- \rightarrow e^+e^-\gamma\gamma$ process in which one of the final electrons is soft and one of the photons is emitted along the beam axis. The photon from the QED process, together with a soft photon (from beam background, for example) may give the invariant mass close to the π^0 mass. Special selection criteria described in detail in Aubert (2009y) are applied to suppress QED background.

After QED background suppression, the signal events are selected by the requirements that there are electron and π^0 candidates in an event with energies above 2.0 and 1.5 GeV, respectively, and that the electron plus π^0 system has a small transverse momentum and a recoil mass close to zero. To avoid systematic uncertainty due to possible data-simulation differences in detector response near the detector edges, the $e^+e^- \rightarrow e^+e^-\pi^0$ cross section is measured in the region $Q^2 > 4$ GeV^2, where the detection efficiency for signal events is greater than 5%. The Q^2 region from 4 to 40 GeV^2 is divided into 17 intervals. For each interval, the number of signal events is determined from the fit to the two-photon invariant mass spectrum with a sum of a π^0 resolution function and a polynomial background distribution. For $Q^2 > 40$ GeV^2, no evidence of a signal over background is found in the two-photon invariant mass distribution. The total number of events with a π^0 in the Q^2 range 4–40 GeV^2 is about 14000.

Some events containing a π^0 may arise from background processes such as e^+e^- annihilation, vector-meson bremsstrahlung $e^+e^- \rightarrow e^+e^-V$, and two-photon processes with higher multiplicity final states such as $e^+e^- \rightarrow e^+e^-\pi^0\pi^0$.

The e^+e^- annihilation background is estimated using the difference in the distributions of the $e^\pm\pi^0$ momentum z-component for signal and background. In two-photon events with a tagged positron (electron), the momentum z-component is negative (positive), while annihilation events are produced symmetrically. The annihilation background is assumed to be equal to the number events with the wrong sign of the $e^\pm\pi^0$ momentum z-component and is found to be negligible.

The largest bremsstrahlung background is expected to arise from the process $e^+e^- \rightarrow e^+e^-\omega$ with ω decaying to $\pi^0\gamma$. The background is estimated from the number of data events with an extra photon, in which the invariant mass of the $\pi^0\gamma$ system is close to the ω mass. This background is also found to be negligible.

The main source of the peaking background is the process $e^+e^- \rightarrow e^+e^-\pi^0\pi^0$. To estimate this background, events with an extra π^0 are selected in data. The number of selected $e^+e^- \rightarrow e^+e^-\pi^0\pi^0$ data events is then scaled to the standard selection using a scale factor determined from MC simulation for the $e^+e^- \rightarrow e^+e^-\pi^0\pi^0$ process. The fraction of two-photon background events in the $e\pi^0$ data sample is found to be about 13% for $Q^2 < 10$ GeV^2 and decreases to 6–7% for $Q^2 > 10$ GeV^2.

The Q^2 dependence of the detection efficiency is determined from MC simulation. The MC efficiency is corrected for a possible data-MC simulation difference in electron identification, trigger inefficiency, π^0 detection efficiency, recoil-mass and transverse-momentum distributions. The identification and trigger corrections are determined from the control sample of VCS events. The π^0 efficiency is studied by using events of the process $e^+e^- \rightarrow \omega\gamma$, $\omega \rightarrow \pi^+\pi^-\pi^0$, which are selected and reconstructed using measured parameters of only the two charged tracks and the photon. A total efficiency correction is found to be about 7% and depends weakly on Q^2. The systematic uncertainty associated with the efficiency correction is about 2.5%.

The transition form factor $F(Q^2)$ is extracted by comparing the measured and calculated values of the differential cross section $d\sigma/dQ^2$. The cross-section measurement is performed at small (less than 0.18 GeV^2) but non-zero values of the momentum transfer to the untagged electron, $|q_2^2|$. This leads to a model uncertainty in the $F(Q^2)$ values extracted from the experiment due to the unknown dependence of the transition form factor on q_2^2. This model uncertainty is estimated from comparison of the $F(Q^2)$ values obtained with two different models for the q_2^2 dependence: the QCD-inspired model $F(q_1^2, q_2^2) \propto 1/(q_1^2 + q_2^2) \approx 1/q_1^2$ with the form factor practically independent of q_2^2, and the vector dominance model $F(q_2^2) \propto 1/(1 - q_2^2/m_\rho^2)$, where m_ρ is the ρ meson mass. The model uncertainty in the form factor is estimated to be 1.8%.

The Q^2 dependence of the scaled $\gamma\gamma^*\pi^0$ transition form factor $Q^2F(Q^2)$ obtained in the *BABAR* experiment, together with the CLEO (Gronberg et al., 1998) and CELLO (Behrend et al., 1991) results, is shown in Fig. 22.7.1.

The errors shown are statistical and Q^2-dependent systematic uncertainties combined in quadrature. The Q^2-dependent systematic uncertainty, which is of the same order of magnitude as the statistical one, is dominated by the uncertainties from the fitting procedure and background subtraction. The Q^2-independent systematic uncertainty, not shown in Fig. 22.7.1, is equal to 2.3% and includes uncertainties in the efficiency correction, radiative correction, integrated luminosity, and the model uncertainty discussed above. In the Q^2 region 4-9 GeV^2 the *BABAR* results are in reasonable agreement with the CLEO measurements (Gronberg et al., 1998), but have significantly better precision.

At $Q^2 > 10$ GeV^2, the measured form factor exceeds the asymptotic limit predicted by pQCD (Lepage and Brodsky, 1980), which is indicated in Fig. 22.7.1 by the horizontal line. Such behavior is specific for a "wide" pion
Figure 22.7.1. The scaled $\gamma\gamma^*\pi^0$ transition form factor. The dashed line indicates the asymptotic limit. The solid line, dotted line, and shaded band represent the predictions for the form factor (Bakulev, Mikhailov, and Stefanis, 2003, 2004) for the Chernyak and Zhitnitsky (1982) [CZ], asymptotic (Lepage and Brodsky, 1979a) [ASY], and Bakulev, Mikhailov, and Stefanis (2001) [BMS] models for the pion distribution amplitude, respectively.

Figure 22.7.2. The pion distribution amplitudes at $Q^2 = 5.76\ \mathrm{GeV}^2$ for three models: asymptotic (Lepage and Brodsky, 1979a) [solid line], Chernyak and Zhitnitsky (1982) [dashed line], and Bakulev, Mikhailov, and Stefanis (2001) [dotted line].

DA. The shapes of three selected DA's [asymptotic (Lepage and Brodsky, 1979a); Chernyak and Zhitnitsky (1982); and Bakulev, Mikhailov, and Stefanis (2001)] with different widths are shown in Fig. 22.7.2 for $Q^2 = 5.76$ GeV^2. The values of the Gegenbauer coefficients a_2 and a_4 used for calculation of the DA's are taken from Bakulev, Mikhailov, and Stefanis (2003, 2004). The form factors corresponding to these DA's (Bakulev, Mikhailov, and Stefanis, 2003, 2004) are presented in Fig. 22.7.1. None of these models describe the data satisfactorily in the full Q^2 range of the *BABAR* measurement. From the three models only one — with the widest Chernyak-Zhitnitsky DA — gives the form factor exceeding the asymptotic limit. The prediction of this model is not inconsistent with the *BABAR* data in the region $Q^2 > 15$ GeV^2, where power corrections are expected to be small.

Many theoretical papers devoted to the $\gamma\gamma^*\pi^0$ transition form factor appeared after the *BABAR* publication. There is no consensus on the theoretical description of the *BABAR* data at the time of writing. Some publications — for example, Bakulev, Mikhailov, Pimikov, and Stefanis (2011); Roberts, Roberts, Bashir, Gutierrez-Guerrero, and Tandy (2010)—argue that the form-factor data cannot be described by theory in the full Q^2 region covered by the CLEO and *BABAR* experiments, and that the *BABAR* data are likely to be incorrect for $Q^2 > 9$ GeV^2. Other authors obtain reasonable descriptions of the data using relatively wide DA's: see, for example, Agaev, Braun, Offen, and Porkert (2011); Kroll (2011). Note that Bakulev, Mikhailov, Pimikov, and Stefanis (2011) and Agaev, Braun, Offen, and Porkert (2011) use the same light-cone sum rule method to estimate power cor-

rections but draw completely different conclusions. The third group of theoretical evaluations, Dorokhov (2010); Polyakov (2009); Radyushkin (2009), suggests the use of an unconventional pion DA, which is non-zero at the end points $x = 0, 1$. The transition form factor obtained with such DA increases logarithmically with increasing Q^2 and describes data well.

The *BABAR* measurement (Aubert, 2009y) covers the Q^2 region above 10 GeV^2 for the first time and, in this region, the form factor goes above the prediction of the asymptotic QCD value with a rather steep increase. This result has attracted the interest of many theoretical physicists as described above. An independent measurement of the pion form factor was much desired and was provided by Belle (Uehara, 2012) using data corresponding to an integrated luminosity of 759 fb^{-1}. The selection of the signal events, the background reduction, and the analysis were made using methods similar to those used in the *BABAR* analysis.

In this Belle analysis, event triggers to collect the signal events are provided by the electromagnetic calorimeter system. The main trigger, the total energy trigger with a high-energy threshold (high-energy trigger), is vetoed by the Bhabha trigger logic (the Bhabha trigger, to detect Bhabha events) to avoid polluting the high-energy trigger with Bhabha events. This mechanism brings a significant loss of the efficiency for the signal process $e^+e^- \to e(e)\pi^0$ and has the side effect of reducing a fraction of the acceptance. Here the symbol (e) indicates the electron scattered in the forward direction and then is not detected. This condition in Belle is in contrast to the *BABAR* measurement, where a special salvaging mechanism for such events was used. Due to this situation in Belle, a complicated selection condition for the polar-angle combinations of the electron and the two-photon system were imposed

to reduce the uncertainty of the trigger inefficiency caused by the Bhabha veto.

Radiative-Bhabha events with a VCS configuration were used for the calibration of the trigger system. Combining event samples collected by the high-energy trigger and by the Bhabha trigger (the latter taken with a prescale factor 50) and compensating for the effect from the Bhabha veto statistically, the trigger efficiency was determined as a function of the energy deposit. The MC events, generated by the Rabhat program (Tobimatsu and Shimizu, 1989) for the radiative-Bhabha process, are fed to the trigger simulator code. The thresholds of the Bhabha trigger have thus been tuned to reproduce the experimentally determined efficiencies. The cross section from the Rabhat program has also enabled a comparison of the absolute experimental yields with those of the MC sample after the tuning of the trigger simulation to verify the efficiency determination. This study validates the trigger efficiency at the 10% level.

In the Belle analysis, background contributions from both $e^+e^- \to e(e)\pi^0\pi^0$ and $e^+e^- \to e(e)\pi^0\gamma$ production processes are anticipated by studies. Belle actively collect these backgrounds and measures the yield of these processes by requiring the detection of an additional pion or photon. The observed yields are introduced into a MC generator for the background processes, and the contamination in the signal sample is estimated. The result is about 2% for the $e^+e^- \to e(e)\pi^0\pi^0$, and is 0.8% – 3% depending on Q^2 for $e^+e^- \to e(e)\pi^0\gamma$. These contributions are subtracted from the measured signal yield.

Among systematic uncertainties from different sources that are assigned to the cross section, the biggest contributions come from the extraction of the π^0 yield with the fit and the uncertainty of the trigger efficiency; they depend largely on the Q^2 regions. The total systematic uncertainty for the combined cross section is between 8% and 14% (and between 4% and 7% for the form factor), depending on the Q^2 region.

The Belle result for the transition form factor is shown in Fig. 22.7.3 together the results of the previous measurements. It is compared with the asymptotic QCD prediction shown by the dashed line. Belle has applied a fit to a parameterization with an asymptotic limit, $Q^2|F(Q^2)| = BQ^2/(Q^2 + C)$. The obtained result for the asymptotic value, $B = 0.209 \pm 0.016$ GeV, is slightly larger than the QCD prediction but still consistent with it. The fit curve is shown in the figure.

The values of $Q^2|F(Q^2)|$ measured by Belle agree with the previous measurements (Aubert (2009y), Behrend et al. (1991); Gronberg et al. (1998)), for $Q^2 \lesssim 9$ GeV^2. The apparent systematic shift between Belle and *BABAR* corresponds to a 2.3σ difference in the Q^2 region between 9 GeV^2 and 20 GeV^2, taking into account both statistical and systematic uncertainties in the two measurements. The Belle result does not show a rapid growth of the form factor beyond the asymptotic prediction of QCD, in contrast to the *BABAR* result, and is closer to the theoretical predictions.
Figure 22.7.3. Comparison of the results for the product $Q^2|F(Q^2)|$ for the π^0 from different experiments. The curves are from the fits (A) to $\sim (Q^2/10\,\mathrm{GeV}^2)^\beta$ and (B) to $\sim Q^2/(Q^2 + C)$. The dashed line shows the asymptotic prediction from pQCD (~ 0.185 GeV).

22.7.2 The $\gamma\gamma^*\eta$ and $\gamma\gamma^*\eta'$ transition form factors

The meson-photon transition form factors for η and η' have been measured by *BABAR* in the $e^+e^- \to e^+e^-\eta^{(\prime)}$ (del Amo Sanchez, 2011f) and $e^+e^- \to \eta^{(\prime)}\gamma$ (Aubert, 2006w) reactions. The decay modes $\eta' \to \pi^+\pi^-\eta$, $\eta \to \gamma\gamma$ and $\eta \to \pi^+\pi^+\pi^0$ are used to reconstruct η' and η mesons, respectively. For single-tag $e^+e^- \to e^+e^-\eta$ events, $\eta \to \pi^+\pi^-\pi^0$ is the only decay mode available for analysis. The events with neutral η decays, to 2γ and to $3\pi^0$, do not pass the *BABAR* trigger and background filters.

In contrast to the $e^+e^- \to e^+e^-\pi^0$ process, the QED background for the processes $e^+e^- \to e^+e^-\eta^{(\prime)}$ is almost fully rejected by the requirement that charged-pion candidates be identified as pions. The hadron background from e^+e^- annihilation is suppressed by the requirement of electron identification. As a result, after applying the transverse-momentum and recoil-mass conditions $e^+e^- \to e^+e^-\eta^{(\prime)}$ events are selected with low non-peaking background. The numbers of events containing true η and η' are determined from the fit to the $\pi^+\pi^+\pi^0$ and $\pi^+\pi^-\eta$ mass distributions with a sum of an $\eta^{(\prime)}$ resolution function and a linear non-peaking background distribution. The fit is performed in 11 Q^2 intervals from the Q^2 range 4–40 GeV^2. Above 40 GeV^2 all observed $\eta^{(\prime)}$ candidates are expected to originate from background. The fitted number of η and η' events in the Q^2 range 4–40 GeV^2 is about 3000 and 5000, respectively.

For η' events the only observed source of peaking background is e^+e^- annihilation. The contribution of e^+e^- annihilation is estimated using events with the wrong sign of the $e^\pm\eta'$ momentum z-component, and subtracted. This background is important only in the two highest-Q^2 intervals ($Q^2 > 25$ GeV^2), where it reaches about 10%.

For η events, three sources of peaking background are studied and subtracted. These are the e^+e^- annihilation

and the two-photon processes $e^+e^- \to e^+e^-\eta\pi^0$ and $e^+e^- \to e^+e^-\eta'$ with η' decaying to $\pi^0\pi^0\eta$. The contributions of the e^+e^- annihilation and the $e^+e^- \to e^+e^-\eta\pi^0$ background are estimated using the difference between signal and background events in the distribution of the $e^\pm\eta$ recoil mass and are found to be about 15% of signal events.

The measured scaled $\gamma\gamma^*\eta$ and $\gamma\gamma^*\eta'$ transition form factors are shown in Fig. 22.7.4 as functions of Q^2. The
Figure 22.7.4. Scaled (a) $\gamma\gamma^*\eta$ and (b) $\gamma\gamma^*\eta'$ transition form factors. The dashed lines indicate the asymptotic limits for the form factors. From (del Amo Sanchez, 2011f) and (Aubert, 2006w).

quoted errors are statistical and Q^2-dependent systematic uncertainty combined in quadrature. The latter include the systematic uncertainty in the number of signal events due to the fitting procedure and background subtraction as well as the statistical errors on the efficiency correction and MC simulation, and do not exceed 50% of the statistical error. The Q^2-independent systematic error

is about 3% and includes uncertainties in the efficiency correction, radiative correction, integrated luminosity, $\eta^{(\prime)}$ decay branching fractions, and the model uncertainty due to the unknown dependence of the transition form factor on the momentum transfer to the untagged electron. Figure 22.7.4 shows also results of the CLEO measurement (Gronberg et al., 1998). *BABAR* has improved significantly the precision and has extended the Q^2 region for form factor measurements relative to CLEO. For η', the *BABAR* and CLEO data are in good agreement. For η, the agreement is worse. The CLEO point at 7 GeV^2 lies higher than the *BABAR* data by about 3σ.

The $e^+e^- \to \eta^{(\prime)}\gamma$ reactions can also be used to determine the transition form factors in the time-like region ($q^2 > 0$). The form factors at $Q^2 = 14.2$ GeV^2 are obtained from the values of the $e^+e^- \to \eta^{(\prime)}\gamma$ cross sections measured by CLEO (Pedlar et al., 2009) near the maximum of the $\psi(3770)$ resonance. The assumption is used that the contributions of the $\psi(3770) \to \eta^{(\prime)}\gamma$ decays to the cross sections are negligible. The CLEO form factors in both the time-like and space-like q^2 regions are compared in Fig. 22.7.4; they are expected to be close to each other at high Q^2. The CLEO measurements support this hypothesis. Therefore, the *BABAR* measurements of the $e^+e^- \to \eta^{(\prime)}\gamma$ cross sections (Aubert, 2006w) near the maximum of the $\Upsilon(4S)$ resonance can be used to extend the Q^2 region for the η and η' form-factor measurements up to 112 GeV^2. The time-like form-factor values at 112 GeV^2 are shown in Fig. 22.7.4.

Theoretical interpretation of the results on the η and η' form factors takes into account the $\eta - \eta'$ mixing and an admixture of the gluon component in the $SU(3)$-singlet state. The dashed lines in Fig. 22.7.4 indicate the asymptotic limits for the scaled η and η' form factors. They are calculated using mixing parameters from Kroll (2011). It is seen that Q^2 dependencies of the form factors for η and η' differ from those for π^0. On the other hand, there is an indication that the η form factor exceeds the asymptotic limit at large Q^2. The theoretical analyses (see, for example, Agaev (2010); Brodsky, Cao, and de Teramond (2011); Kroll (2011); Noguera and Scopetta (2012)) show that the η and η' form-factor data are reasonably well reproduced by models with DA's not very different from the asymptotic one. The *BABAR* results on the meson-photon transition form factors for light pseudoscalars indicate that the pion DA is significantly wider than the DA's of η and η' mesons. However, Belle results do not exhibit such rapid growth in the higher Q^2 region seen in the *BABAR*. So further investigations are very important for understanding of the pion DA.

22.7.3 The $\gamma\gamma^*\eta_c$ transition form factor

The meson-photon transition form factor for η_c has been measured by *BABAR* (Lees, 2010b) using single-tag events of the $e^+e^- \to e^+e^-\eta_c$ process. The η_c is reconstructed via its decay to $K_SK^-\pi^+$. Since the branching fraction for $\eta_c \to K_SK^-\pi^+$ is known with low accuracy, it is impossible to perform an absolute measurement of the

form factor. Therefore, the Q^2 distribution for selected η_c events is divided by the number of no-tag two-photon $\eta_c \to K_S K^- \pi^+$ events, and the normalized form factor $F(Q^2)/F(0)$ is measured.

The number of single-tag events containing η_c meson is determined from the fit to the $K_S K^- \pi^+$ invariant mass distributions with a sum of an η_c resolution function, a J/ψ resolution function, and a quadratic background distribution. The J/ψ's are produced in the process $e^+ e^- \to e^+ e^- J/\psi$. The fitted number of η_c events in the Q^2 region from 2 to 50 GeV^2 is about 500. To obtain the Q^2 distribution this region is divided into 11 intervals.

The process $e^+ e^- \to e^+ e^- J/\psi$ with J/ψ decaying to $\eta_c \gamma$ is the dominant source of background peaking at η_c mass. The background is estimated from the Q^2 distribution for $e^+ e^- \to e^+ e^- J/\psi$ events with $J/\psi \to K_S K^- \pi^+$. Its fraction changes from about 1.0% for $Q^2 < 10$ GeV^2 to about 5% at $Q^2 \sim 30$ GeV^2.
Figure 22.7.5. The normalized $\gamma\gamma^*\eta_c$ transition form factor measured by *BABAR*. The curve shows the fit with a monopole function. From (Lees, 2010b).

The normalized η_c transition form factor is shown in Fig. 22.7.5. The errors shown are combined statistical and Q^2-dependent systematic uncertainty. There is also a Q^2-independent error equal to 4.3%. The main source of the systematic error is an uncertainty on the detection efficiency.

For the η_c meson, the leading order formula for the light-meson transition form factor is modified to take into account the large mass of the c-quark. The term $1/x$ in Eq. (22.7.2) should be replaced with $Q^2/[xQ^2 + m_c^2(1 + 4x\bar{x})]$, where $\bar{x} = 1 - x$, and m_c is the c-quark mass. As a consequence, the $\gamma\gamma^*\eta_c$ transition form factor can be predicted by pQCD starting from $Q^2 = 0$. However, the Q^2 dependence of the form factor becomes rather insensitive to the shape of the η_c DA, and is described by a monopole function with a pole parameter $\Lambda \sim 10$ GeV^2 (Feldmann

and Kroll, 1997). This value is close to the vector-meson dominance model (VDM) prediction $\Lambda = m_{J/\psi}^2 = 9.6$ GeV^2.

The result of the fit to the *BABAR* data on the normalized η_c form factor with a monopole function is shown in Fig. 22.7.5. The extracted pole parameter $\Lambda = 8.5 \pm 0.6 \pm 0.7$ GeV^2 is in agreement with both VDM and QCD (Feldmann and Kroll, 1997) predictions, and with the result of the lattice QCD calculation $\Lambda = 8.4 \pm 0.4$ GeV^2 (Dudek and Edwards, 2006).

22.7.4 Summary

Two-photon physics has entered a completely new level of maturity as a result of the B Factory experiments. Prior to the B Factories, two-photon couplings of resonances have been measured for a limited number of mesons only, and many of those were only known approximately. The B Factory experiments have provided precise measurements and opened a path to the systematic study of spectroscopy including classification of mesons and exploration of exotic and new states.

In addition, the measurements of exclusive processes of hadron-pair production and of two-photon meson transition form factors have become practical tests of QCD using data from the the B Factory experiments.

While many phenomena have been investigated, some subjects are still left to be clarified because of systematic uncertainties in experiments or yet-to-be developed theoretical frameworks. In some other subjects, insufficient statistics prevent us from obtaining a clear view. It is expected that future projects will be able to significantly advance our understanding in this area.

Chapter 23
B_s^0 physics at the $\Upsilon(5S)$

23.1 Introduction

In this section we discuss the results of B_s^0 meson studies using *BABAR* and Belle data collected with a center-of-mass (CM) energy in the region of the $\Upsilon(5S)$ resonance.[172] The experimental exploration of this region was started in 1985 by the CUSB Collaboration (Lovelock et al., 1985) and since then much has been learned about B_s^0 decays using data from the $\Upsilon(5S)$. Future super flavor factories include B_s^0 studies in their physics proposals as an important part of their research program.

Experimental determination of the B_s^0 meson began circa 1990 at CUSB II (Lee-Franzini et al., 1990). Subsequently B_s^0 mesons were studied by the LEP experiments in e^+e^- collisions at the CM energy of the Z^0 boson mass, however the statistical significance of those results is limited. Later, B_s^0 physics was explored with improved accuracy at the Tevatron experiments using $p\bar{p}$ collision data with a 1.8 TeV CM energy taken during the first run period, 1990–1995, and later with higher statistics during the run II period at 1.96 TeV. The Tevatron experiments CDF and DØ measure several B_s^0 decay branching fractions, determined for the first time the mixing parameter Δm_s, as opposed to placing lower bounds on this frequency, and obtained many other interesting results in this area.

Historically, e^+e^- colliders near open beauty threshold were designed to run at the $\Upsilon(4S)$ resonance and focused on studies of B_d^0 and B^+ mesons. In particular, Belle and *BABAR* were designed to take data with asymmetric energy e^+e^- beam collisions at a CM energy of 10.58 GeV. However, the new territory of B_s^0 physics could also be explored at the B Factories. The $B_s^0 \overline{B}_s^0$ production threshold lies only about 150 MeV higher than the $\Upsilon(4S)$ production energy, and therefore, is reachable by B Factories without significant modification. Fig. 23.1.1 shows the ratio of hadronic to $e^+e^- \to \mu^+\mu^-$ cross-sections as a function of the CM energy in the region just above the $\Upsilon(4S)$, where two further resonances are clearly seen. These are usually called the $\Upsilon(5S)$ and $\Upsilon(6S)$. As the $\Upsilon(5S)$ has a $b\bar{b}$ quark content, e^+e^- collisions at the $\Upsilon(5S)$ CM energy are expected to be an effective source of the B_s^0 meson production. However a very high luminosity must be delivered by the B Factories to provide a sufficient number of B_s^0 mesons, for statistically significant measurements. The

---

[172] The $\Upsilon(5S)$ resonance is also referred to as the $\Upsilon(10860)$ in the literature.
Figure 23.1.1. Measured ratio of hadronic to $e^+e^- \to \mu^+\mu^-$ cross-sections, R_b, as a function of the CM energy, from an energy scan performed by the *BABAR* collaboration (Aubert, 2009x). The result of a fit to a function including background and $\Upsilon(5S)$ and $\Upsilon(6S)$ resonances is shown by the curve. The error bars represent the statistical and the uncorrelated systematic uncertainties added in quadrature.

cross section for B_s^0 production at the $\Upsilon(5S)$ is measured to be (0.340 ± 0.016) nb (see Section 23.2.4).

The opportunity to perform detailed studies of the B and B_s^0 mesons using data collected at the $\Upsilon(5S)$ was discussed by theorists many years ago (Atwood and Soni, 2002; Falk and Petrov, 2000; Lee-Franzini, Ono, Sanda, and Tornqvist, 1985; Lellouch, Randall, and Sather, 1993). These ideas were explored experimentally from the outset, however the first significant tests were made in 2003 when the CLEO collaboration collected a small $\Upsilon(5S)$ data sample of 0.42 fb^{-1}. Using these data, CLEO found evidence of B_s^0 production at the $\Upsilon(5S)$ (Artuso et al., 2005a; Bonvicini et al., 2006; Huang et al., 2007). In 2005 the Belle collaboration collected 1.86 fb^{-1} of data at the $\Upsilon(5S)$ and obtained statistically significant estimates of the B_s^0 production parameters (Drutskoy, 2007a,b) that established the feasibility of physics studies of B_s^0 mesons at Belle. Motivated by these results Belle started to accumulate data at the $\Upsilon(5S)$, collecting ~ 22 fb^{-1} in 2006, ~ 27 fb^{-1} in 2008 and ~ 71 fb^{-1} in 2009. In the last periods of running both Belle and *BABAR* performed energy scans in the region of the $\Upsilon(5S)$ and $\Upsilon(6S)$ resonances. Details of data taking for these experiments are found in Chapter 3, and the energy scan results are discussed in Section 18.4.3.

There are many reasons to develop a comprehensive physics program for the study of B_s^0 mesons at Belle. In 2005 the available information regarding B_s^0 decays was very limited, with only a few decay branching fractions measured. Studies of B_s^0 decays are important to build a more complete picture of B physics: any significant difference between the behavior of B_s^0 decays and the corresponding decays of B^0 and B^+ mesons could indicate additional SM contributions such as annihilation penguins or large W-exchange topologies that play an important role. Formulae relating B_s^0, B^0, and B^+ production or decay parameters are tested and $SU(3)$ symmetry violating effects

are estimated. B_s^0 decays are well suited for precise tests of the Standard Model, in particular there are unique features and processes that can be studied, such as the large lifetime difference between the short-lived and long-lived states and processes described by a penguin annihilation diagram.

In this chapter we discuss measurements of B_s^0 decays at the $\Upsilon(5S)$ that have been performed by the Belle collaboration since 2005. Currently the Belle sample comprises $121\,\mathrm{fb}^{-1}$ of data, which is the world's largest dataset at the $\Upsilon(5S)$. At the time of writing most of the published Belle results were obtained using only $23.6\,\mathrm{fb}^{-1}$ of data. However, it is worth noting that several measurements are in the process of being updated. The *BABAR* collaboration performed an energy scan in the range $10.54\,\mathrm{GeV}$ to $11.20\,\mathrm{GeV}$, however *BABAR* did not take a large data sample of a fixed energy at the $\Upsilon(5S)$ peak. Section 23.3.1 discusses the *BABAR* measurement of the B_s^0 semileptonic branching fraction.

23.2 Basic $\Upsilon(5S)$ properties and beauty hadronization

In this section we give a classification of the basic processes which take place in e^+e^- annihilation with CM energy close to the $\Upsilon(5S)$ mass peak (Section 23.2.1). The choice of the CM energy optimal for B_s^0 studies is then explained (Section 23.2.2). Then the procedures used to calculate the number of B_s^0 mesons in a data sample (Section 23.2.3) and to measure the $b\bar{b}$ cross section (Section 23.2.4) are discussed. We describe the method used to reconstruct B and B_s^0 mesons exclusively in Section 23.2.6. The rates determined for specific $\Upsilon(5S)$ decay channels with the B and B_s^0 mesons in the final states are summarized in Sections 23.2.5 and 23.2.7.

23.2.1 Event classification

The classification of hadronic events produced at the $\Upsilon(5S)$ is shown in Fig. 23.2.1: for simplicity, non-hadronic processes are not included. Final states with B and B_s^0 mesons (designated as $b\bar{b}$ events) are formed through both resonant $\Upsilon(5S)$ production and $b\bar{b}$ continuum production. As these two event classes have the same final states, an individual event cannot be attributed to a specific class. The existence of two possible sources of B and B_s^0 event production should always be taken into account in theoretical calculations. The $u\bar{u}$, $d\bar{d}$, $s\bar{s}$, and $c\bar{c}$ continuum is usually a significant source of background, when a specific B or B_s^0 decay mode is reconstructed.

Thus $b\bar{b}$ events are divided into three categories: events containing B_s^0 mesons, B mesons, and bottomonium states. A bottomonium state should have allowed quantum numbers and is accompanied by a light particle or a combination of light particles, such as π^0, η, γ, $\pi^+\pi^-$, K^+K^-, and so on. Taking into account the limited phase-space, only three final states with B_s^0 mesons
Figure 23.2.1. Classification of hadronic events produced in e^+e^- collisions at a CM energy close to the $\Upsilon(5S)$ peak position. As noted in the text it is possible to have initial state radiation production of the lower mass states for CM energy collisions in the region of the $\Upsilon(5S)$ resonance, signified by the ISR term circled twice in this schematic.

are possible: $B_s^0\overline{B}_s^0$, $B_s^{*0}\overline{B}_s^0 + B_s^0\overline{B}_s^{*0}$, and $B_s^{*0}\overline{B}_s^{*0}$. Here the $B_s^{*0}\overline{B}_s^0$ and $B_s^0\overline{B}_s^{*0}$ states have the same mass combination and are almost indistinguishable experimentally, and are therefore counted as a single final state. For B final states there is enough energy to produce three two-body final states, three three-body final states, and one four-body final state (see Fig. 23.2.1). Here the neutral B^0 and charged B^+ mesons are treated together as a B. Resonant states decay with $\sim 100\%$ probability via the modes $B_s^{*0} \to B_s^0\gamma$ and $B^{*0} \to B^0\gamma$. Additionally e^+e^- collisions with a center-of-mass energy corresponding to the $\Upsilon(5S)$ resonance undergoing Initial State Radiation (ISR) can result in direct production of B or B_s^0 mesons in association with an ISR photon.

Non-hadronic processes are not included in the above classification. Some of these processes have large cross-sections, in particular $e^+e^- \to e^+e^-$, $\mu^+\mu^-$, $\tau^+\tau^-$, $e^+e^-e^-e^-$, $\gamma\gamma$, and $\gamma\gamma X$. However these processes are strongly suppressed by the Belle trigger and HadronBJ (see Section 3.5.3) event selections, and therefore their residual contributions are negligible in most studies. The proposed classification reflects our best knowledge of possible mechanisms, and does not include some rare processes that have very low probabilities. For example, the strongly suppressed transition $e^+e^- \to s\bar{s} \to B_s^0\overline{B}_s^0$ is due to $s\bar{s}$ continuum production with subsequent $b\bar{b}$ pair creation, however here it is classified as $b\bar{b}$ continuum. The process of $b\bar{b}$ annihilation to lighter quarks also has a very

low probability and is treated as non-$b\bar{b}$ continuum in the following.

23.2.2 Choice of CM energy for data taking at the $\Upsilon(5S)$

To maximize the $b\bar{b}$ and B_s^0 event production an optimal CM energy is chosen for taking data in the region of the $\Upsilon(5S)$. The suitable CM energy region was approximately known from the data collected by CLEO (Besson et al., 1985) and CUSB (Lovelock et al., 1985). However, to optimize the choice of CM energy, an energy scan in the region of the peak position of the $\Upsilon(5S)$ resonance was performed by Belle as a precursor to taking data at the $\Upsilon(5S)$ resonance. For technical reasons both KEKB beam energies were changed simultaneously, keeping the CM boost unchanged with respect to $\Upsilon(4S)$ running.

An integrated luminosity of $\sim 30\,\text{pb}^{-1}$ was collected at five values with an e^+e^- CM energy between 10825 MeV and 10905 MeV. The ratio of the number of hadronic events with second-to-zeroth Fox-Wolfram moment $R_2 < 0.2$ (see Chapter 9 for a definition of R_2) to the number of Bhabha events is measured as a function of the CM energy (Fig. 23.2.2). This ratio is expected to have a shape close to that of a Breit-Wigner function in the region of the $\Upsilon(5S)$ resonance, above a flat background. As a systematic check, the mean value of the mass obtained from the fit, $M = (10868 \pm 6 \pm 14)\,\text{MeV}/c^2$, was found to be in good agreement with the PDG 2006 value $M_{\Upsilon(5S)} = (10865 \pm 8)\,\text{MeV}/c^2$ (Yao et al., 2006). Finally, the energy of 10869 MeV was chosen for subsequent $\Upsilon(5S)$ runs.

The accuracy of the CM energy measurement based on the collider magnet currents is about ± 6 MeV. Three methods are employed in order to measure the CM energy more precisely, all of these have an accuracy of about 1 MeV. The original method applied for data samples of $10\,\text{fb}^{-1}$ or larger measures the energy by reconstructing $e^+e^- \to \Upsilon(1S)\pi^+\pi^-$ and $e^+e^- \to \Upsilon(2S)\pi^+\pi^-$ decays. As the masses of these Υ resonances are known to a precision better that $1\,\text{MeV}/c^2$, these mass constraints are used to significantly improve the CM energy resolution relative to the collider measurement. Subsequent methods that are used include reconstructing specific B and B_s^0 decay modes, and using $e^+e^- \to \mu^+\mu^-$. This last method requires that ISR corrections be determined accurately using Monte Carlo (MC) simulation.

The first two methods are applied post factum to obtain the CM energy; however, to keep the same energy from run to run, we need to know the energy accurately before taking data. Due to the proximity of the B_s^0 production threshold (in particular the $B_s^{*0}\bar{B}_s^{*0}$ channel opens up only ~ 40 MeV below the chosen CM energy) even a few MeV CM energy shift can result in sizable variations of production rates of individual channels. Unfortunately, hysteresis can affect the CM energy setup process based on the magnet currents (taking into account the large uncertainty of the energy definition), even when the set-up
Figure 23.2.2. The ratio of the number of hadronic events ($R_2 < 0.2$) to the number of Bhabha events as a function of the e^+e^- CM energy, from Drutskoy (2007a). Only statistical errors are shown. The curve is the result of the fit to a sum of a Breit-Wigner function and a constant.

procedure used to reach the same CM energy is similar for all data taking periods. To maximize luminosity the CM energy must be chosen at the beginning of a run. The $e^+e^- \to \mu^+\mu^-$ method is expected to provide the most robust and accurate value of the CM energy for future experiments.

23.2.3 Calculation of the number of B_s^0 mesons in a data sample

It is important to determine the number of B_s^0 mesons in a data sample with high precision because the corresponding uncertainty is usually the dominant systematic uncertainty in B_s^0 branching fraction measurements. Taking into account the hadronic event classification discussed above, the following parameters are required in order to obtain the number of B_s^0 mesons in a data sample taken at a given CM energy:

1. The integrated luminosity of the data sample $\mathcal{L}_{\text{int}}$.
2. The $b\bar{b}$ production cross section $\sigma\,(e^+e^- \to b\bar{b})$, also denoted as $\sigma_{b\bar{b}}$.
3. The fraction of $b\bar{b}$ events containing a $B_s^{(*)0}\bar{B}_s^{(*)0}$ pair, usually referred to as f_s.
4. The fractions of events produced through specific production channels over all $B_s^{(*)0}\bar{B}_s^{(*)0}$ events: $f_{B_s^0\bar{B}_s^0}$, $f_{B_s^{*0}\bar{B}_s^0}$, and $f_{B_s^{*0}\bar{B}_s^{*0}}$.

These parameters are measured experimentally. The integrated luminosity of a data sample is precisely determined using the standard Belle procedure briefly discussed in Section 3.2.1. In the following two subsections we discuss the method used for the $\sigma_{b\bar{b}}$ cross section measurement and the experimental technique used to obtain f_s.

Using these parameters the number of B_s^0 mesons in a data sample is calculated:

$$N(B_s^0) = 2 \times \mathcal{L}_{\text{int}} \times \sigma_{b\bar{b}} \times f_s. \qquad (23.2.1)$$

The number of B_s^0 mesons produced through a specific production channel is obtained by multiplying the number of B_s^0 mesons $N(B_s^0)$ by the corresponding channel fractions $f_{B_s^0 \bar{B}_s^0}$, $f_{B_s^{*0} \bar{B}_s^0}$, or $f_{B_s^{*0} \bar{B}_s^{*0}}$.

Similar to the B_s^0 fraction f_s, the fractions of events with B mesons (f_B) and a bottomonium (f_{bot}) over all $b\bar{b}$ events is introduced. The sum of these parameters is fixed to unity: $f_s + f_B + f_{bot} = 1$. Additionally the fractions of charged and neutral B mesons produced per $b\bar{b}$ event, $f(B^+)$ and $f(B^0)$, is defined. As two B mesons are produced per $\Upsilon(5S)$ decay and some channels include both charged and neutral B mesons (such as $B^0 B^- \pi^+$), a factor 2 is included in the definition, resulting in the equality

$$f_B = \frac{f(B^+) + f(B^0)}{2}. \qquad (23.2.2)$$

23.2.4 $b\bar{b}$ cross section at the $\Upsilon(5S)$

The $b\bar{b}$ production cross section at a fixed CM energy is obtained from the formula

$$\sigma_{b\bar{b}} = N_{5S}^{b\bar{b}} / \mathcal{L}_{5S}, \qquad (23.2.3)$$

where $N_{5S}^{b\bar{b}}$ is the number of $b\bar{b}$ events in the $\Upsilon(5S)$ data sample and $\mathcal{L}_{5S}$ is the integrated luminosity of the sample.

To obtain the number of $b\bar{b}$ events in a $\Upsilon(5S)$ data sample the $u\bar{u}$, $d\bar{d}$, $s\bar{s}$, and $c\bar{c}$ continuum are subtracted from the full number of hadronic events. The $u\bar{u} + d\bar{d} + s\bar{s} + c\bar{c}$ continuum contribution is estimated using the data collected at a CM energy 60 MeV below the $\Upsilon(4S)$ resonance (so-called "off-resonance" data). As the continuum cross section decreases with energy as $1/E_{CM}^2$, the corresponding factor has to be applied to correct for the CM energy difference. Belle measured the $b\bar{b}$ cross section (Drutskoy, 2007a) using a data sample of 1.86 fb^{-1} taken at the $\Upsilon(5S)$ energy of ~ 10869 MeV and a data sample of 3.67 fb^{-1} collected at the off-resonance energy 10520 MeV.

The number of $b\bar{b}$ events is obtained from the formula

$$N_{5S}^{b\bar{b}} = \frac{1}{\epsilon_{5S}^{b\bar{b}}} \left(N_{5S}^{had} - N_{off}^{had} \cdot \frac{\mathcal{L}_{5S}}{\mathcal{L}_{off}} \cdot \frac{E_{off}^2}{E_{5S}^2} \cdot \frac{\epsilon_{5S}^{con}}{\epsilon_{off}^{con}} \right), \quad (23.2.4)$$

where N_{5S}^{had} and N_{off}^{had} are the numbers of hadronic events in the $\Upsilon(5S)$ and off-resonance continuum data samples, respectively. Here $\epsilon_{5S}^{b\bar{b}}$ is the efficiency to select a $b\bar{b}$ event in the $\Upsilon(5S)$ data sample, which was estimated from MC simulation and found to be $\epsilon_{5S}^{b\bar{b}} = (99 \pm 1)\%$. The ratio of efficiencies to reconstruct continuum events in the $\Upsilon(5S)$ and off-resonance data samples (each one is around 79 %) was also obtained from MC: $\epsilon_{5S}^{con}/\epsilon_{off}^{con} = 1.007 \pm 0.003$. The CM energy ratio E_{off}/E_{5S} is known with high accuracy, as discussed above. The integrated luminosity ratio $\mathcal{L}_{5S}/\mathcal{L}_{off} = 0.5061 \pm 0.0020$ is calculated using the standard Belle luminosity measurement procedure with Bhabha events (Section 3.2.1).

The number of $b\bar{b}$ events obtained is very sensitive to these ratios of luminosities, energies, and efficiencies. The corresponding uncertainties are 0.4 % for the luminosity ratio, 0.3 % for the efficiency ratio, and less than 0.1 % for the energy ratio. The combined uncertainty is about 0.5 % and it is difficult to reduce this systematic uncertainty further. As the two terms in the subtraction are of the same order and about 10 times larger than the result (since continuum is about 10 times larger than $b\bar{b}$ production), the uncertainty of the $b\bar{b}$ event definition is dominated by the 0.5 % uncertainty multiplied by a factor 10: ~ 5 % in total. An improvement in the determination of the luminosity ratio is required if one is to reduce the total uncertainty of this method.

Potentially a precise luminosity ratio measurement is directly obtained from the ratio of normalized momentum distributions (for these two datasets) of high momentum charged pions, charged kaons, and D^0 mesons (Drutskoy, 2007a), however non-hadronic backgrounds must be accurately subtracted. Here the normalized momentum of a particle h is defined as $x(h) = P(h)/P_{max}(h)$, where $P(h)$ is the measured momentum of the particle, and $P_{max}(h)$ is the expected value of its momentum if it were produced in the process $e^+ e^- \to h\bar{h}$ at the same CM energy.

Using Eqs (23.2.3) and (23.2.4) Belle obtains the $b\bar{b}$ production cross section $\sigma_{b\bar{b}} = (0.302 \pm 0.015)$ nb using 1.86 fb^{-1} $\Upsilon(5S)$ data sample (Drutskoy, 2007a). This number is used in the initial Belle B_s^0 studies based on the 23.6 fb^{-1} data sample. Later with the full data sample of 121.4 fb^{-1} a slightly higher $b\bar{b}$ production cross section was obtained, $\sigma_{b\bar{b}} = (0.340 \pm 0.016)$ nb, and is used in analyses of the full dataset.

23.2.5 Fraction of $b\bar{b}$ events with B_s^0 mesons

A method also used in inclusive particle spectra analyses is adopted to obtain the fraction of $b\bar{b}$ events resulting in final states with B_s^0 mesons in the $\Upsilon(5S)$ data. This method was developed by CLEO and was applied to the analysis of inclusive $D_{(s)}^+$ production (Artuso et al., 2005a), then later for the study of ϕ production (Huang et al., 2007). Belle measures the $D_{(s)}^+$ and D^0 inclusive spectra (Drutskoy, 2007a) and an estimate for f_s is obtained from these studies. The inclusive spectra analysis method is based on the fact that the inclusive production rate of the $D_{(s)}^+$, D^0, and ϕ mesons is very different in B_s^0 and B decays.

The analysis of the $D_{(s)}^+$ inclusive spectra will be discussed below to illustrate the method; the D^0 and ϕ spectra analyses are very similar. As Belle combines results of $D_{(s)}^+$ and D^0 production spectra to reduce the systematic uncertainty obtained for f_s, additional detail is given for the D^0 spectra analysis. The Belle measurement of f_s was made using data samples of 1.86 fb^{-1} taken at the $\Upsilon(5S)$ and 3.67 fb^{-1} at the off-resonance energy of 10520 MeV. To avoid large backgrounds, only the clean decay mode $D_{(s)}^+ \to \phi\pi^+$, where $\phi \to K^+K^-$, is used in this analysis; similarly in order to select D^0, the decay $D^0 \to K^-\pi^+$ is used.
Figure 23.2.3. The D_s^+ normalized momentum $x(D_s^+)$ (a) and the D^0 normalized momentum $x(D^0)$ (b). The points with error bars are the $\Upsilon(5S)$ data, while the histograms show the normalized off-resonance data. Plots are from Drutskoy (2007a).

As the CM energy is different for the $\Upsilon(5S)$ and off-resonance data samples, a momentum scale normalization is applied when comparing the inclusive spectra. The normalized $D_{(s)}^+$ momentum distributions (as defined in the previous subsection) obtained for the $\Upsilon(5S)$ and off-resonance data samples are shown in Fig. 23.2.3(a). To obtain these distributions the $D_{(s)}^+$ signal yields were extracted from a fit in each bin of $x(D_s^+)$. The continuum distribution is normalized to the $\Upsilon(5S)$ distribution using the energy-corrected luminosity ratio. As we can see in Fig. 23.2.3(a) the $\Upsilon(5S)$ and off-resonance distributions agree well in the region $x(D_s^+) > 0.5$, where $b\bar{b}$ events cannot contribute. The excess of events in the region $x(D_s^+) < 0.5$ corresponds to inclusive $D_{(s)}^+$ production in $b\bar{b}$ events. Similar behavior is observed for the D^0 inclusive spectra as shown in Fig. 23.2.3(b).

After continuum subtraction and a bin-by-bin efficiency correction, the sum of events over all bins within the interval $x(D_s^+) < 0.5$ is divided by the $D_{(s)}^+$ and ϕ decay branching fractions and by the number of $b\bar{b}$ events in the $\Upsilon(5S)$ data sample to obtain the inclusive branching frac-

tion:

$$\mathcal{B}(\Upsilon(5S) \to D_s X) =$$

$$\frac{\sum N_{bin}^{b\bar{b}}(D_s)/\epsilon_{bin}}{N_{5S}^{b\bar{b}} \cdot \mathcal{B}(D_s^+ \to \phi\pi^+) \cdot \mathcal{B}(\phi \to K^+K^-)}. \tag{23.2.5}$$

From this formula Belle obtains the value $\mathcal{B}(\Upsilon(5S) \to D_s^+ X)/2 = (23.6 \pm 1.2 \pm 3.6)\%$, which includes a factor of $1/2$ to compare with $B_{(s)}$ branching fractions. This inclusive branching fraction gives the average number of D_s^+ mesons produced in $b\bar{b}$ events at the $\Upsilon(5S)$ energy.

The value of $\mathcal{B}(\Upsilon(5S) \to D_s^+ X)/2$ is significantly larger than the branching fraction for D_s^+ production in B decays, which was calculated in Drutskoy (2007a) as $\mathcal{B}(B \to D_s^+ X) = (8.7 \pm 1.2)\%$. The significant increase of D_s^+ production at the $\Upsilon(5S)$ compared to that at the $\Upsilon(4S)$ indicates a sizable B_s^0 production rate.

The fraction f_s of $B_s^{(*)0}\bar{B}_s^{(*)0}$ events in all $b\bar{b}$ events produced at the $\Upsilon(5S)$ is extracted from the following relation:

$$\mathcal{B}(\Upsilon(5S) \to D_s^+ X)/2 = f_s \cdot \mathcal{B}(B_s^0 \to D_s^+ X) +$$
$$(1 - f_s) \cdot \mathcal{B}(B \to D_s^+ X), \tag{23.2.6}$$

where $\mathcal{B}(B_s^0 \to D_s^+ X)$ and $\mathcal{B}(B \to D_s^+ X)$ are the average fractions of D_s^+ mesons produced in B_s^0 and B decays, respectively. Using the measurement of $\mathcal{B}(\Upsilon(5S) \to D_s^+ X)$, the measured value of $\mathcal{B}(B \to D_s^+ X) = (8.7 \pm 1.2)\%$, and the model-dependent estimate $\mathcal{B}(B_s^0 \to D_s^+ X) = (92 \pm 11)\%$ (Artuso et al., 2005a), Belle determines $f_s = (17.9 \pm 1.4 \pm 4.1)\%$. The systematic uncertainty on f_s is obtained by propagating the systematic uncertainties on the branching fractions included in Eq. (23.2.6), taking into account the correlation induced by $\mathcal{B}(D_{(s)}^+ \to \phi\pi^+)$. Bottomonium production in $\Upsilon(5S)$ decays, which occurs at the few percent level, is neglected in Eq. (23.2.6).

A similar procedure is applied to D^0 inclusive spectra and the inclusive branching fraction

$$\mathcal{B}(\Upsilon(5S) \to D^0 X)/2 = (53.8 \pm 2.0 \pm 3.4)\% \tag{23.2.7}$$

is determined. Using the inclusive D^0 production branching fractions of the $\Upsilon(5S)$, B, and B_s^0 decays and replacing D_s^+ by D^0 in Eq. (23.2.6), the ratio $f_s = (18.1 \pm 3.6 \pm 7.5)\%$ of $B_s^{(*)0}\bar{B}_s^{(*)0}$ events to all $b\bar{b}$ events at the $\Upsilon(5S)$ is obtained. Combining these two f_s measurements and taking into account the anti-correlated systematic uncertainty due to the number of $b\bar{b}$ events, an average value $f_s = (18.0 \pm 1.3 \pm 3.2)\%$ is obtained. This measurement is in good agreement with the CLEO measurement $f_s = (16.0 \pm 2.6 \pm 5.8)\%$ (Artuso et al., 2005a).[173] In the Belle measurements based on 23.6 fb^{-1} of data the value $f_s = (19.5^{+3.0}_{-2.3})\%$ is used, which was the PDG average of all f_s measurements obtained at that time. The Belle analyses

---

[173] Subsequently CLEO used several methods to measure f_s (Huang et al., 2007); however, all of these measurements have large uncertainties.

with the full data sample of $121.4\,\text{fb}^{-1}$ use run-dependent measurements of f_s, which are obtained from $D^+_{(s)}$ inclusive spectra studies.

The uncertainty due to f_s is currently the dominant systematic uncertainty on B^0_s decay branching fraction measurements at the $\Upsilon(5S)$. There are several methods that can be used to potentially reduce this uncertainty to less than $(4$–$5)\%$, however the choice of the most precise method requires further study. For the next generation of B Factories this uncertainty is expected to be reduced to $(2$–$3)\%$, which would result in a total systematic uncertainty of $\approx 5\%$ for B^0_s branching fraction measurements.

23.2.6 Exclusive B^0_s and B decay reconstruction technique

The technique used for exclusive B^0_s and B meson reconstruction at the $\Upsilon(5S)$ is similar to the one used at the $\Upsilon(4S)$. However additional complexity appears at the $\Upsilon(5S)$ due to many new intermediate channels that open up at the increased CM energy. For a given B^0_s or B decay channel the energy and momenta for all final state particles are calculated in the CM system. Usually the low-momentum photons from B^{*0}_s and B^* decays are not reconstructed because of their low reconstruction efficiency. Two kinematic variables are used to reconstruct and identify exclusive B (or B^0_s) signals at the $\Upsilon(5S)$ using a technique similar to that used at the $\Upsilon(4S)$ for isolating $B_{u,d}$ mesons (see Chapter 7). The first is the energy difference ΔE given by

$$\Delta E = E^\star_B - E^\star_{\text{beam}}, \qquad (23.2.8)$$

and the second is the beam-energy-substituted mass

$$m_{\text{ES}} = \sqrt{E^{\star 2}_{\text{beam}} - \boldsymbol{p}^{\star 2}_B}, \qquad (23.2.9)$$

called "M_{bc}" in Belle publications, where $E^\star_B$ and $\boldsymbol{p}^\star_B$ are the energy and momentum of the B^0_s or B candidate in the e^+e^- CM system, and $E^\star_{\text{beam}}$ is the CM beam energy.

Figure 23.2.4 shows the B^0_s and B signal distributions in the m_{ES} and ΔE plane for different intermediate $\Upsilon(5S)$ decay channels. The events shown are obtained from MC simulation of $B^0_s \to D^-_s \pi^+$ and $B^0 \to D^- \pi^+$ decays.

The three ellipsoidal regions on the right side of Figure 23.2.4 correspond to the intermediate $\Upsilon(5S)$ decay channels $B^{*0}_s \overline{B}^{*0}_s$, $B^{*0}_s \overline{B}^0_s + B^0_s \overline{B}^{*0}_s$, and $B^0_s \overline{B}^0_s$. These three B^0_s signal regions are well separated, reflecting changes in kinematics corresponding to the cases where both, only one, or neither of the B^0_s mesons originate from a B^{*0}_s decay. A MC simulation indicates that the correlation between the reconstructed m_{ES} and ΔE variables within the ellipses is small and can usually be neglected. The central point of each ellipse corresponds to the decay parameters $M^{\text{cen}}_{\text{bc}} = M(B^0_s)$ and $\Delta E^{\text{cen}} = 0$ for the channel $B^0_s \overline{B}^0_s$, and $M^{\text{cen}}_{\text{bc}} = M(B^0_s)$ and $\Delta E^{\text{cen}} = -E(\gamma)$ for the channel $B^0_s \overline{B}^{*0}_s$, with the central value for the $B^{*0}_s \overline{B}^0_s + B^0_s \overline{B}^{*0}_s$ channel as the midpoint between the two individual contributions.
Figure 23.2.4. The $M_{\text{bc}} = m_{\text{ES}}$ and ΔE scatter plot obtained from MC simulations of different intermediate $\Upsilon(5S)$ decay channels with $B^0_s \to D^-_s \pi^+$ and $B^0 \to D^- \pi^+$ decays. The ellipses show the signal regions for the intermediate $B^{*0}_s \overline{B}^{*0}_s$ (top, blue), $B^{*0}_s \overline{B}^0_s$ and $B^0_s \overline{B}^{*0}_s$ (middle, green), and $B^0_s \overline{B}^0_s$ (bottom, red) channels. The band region includes (from bottom to top) the signals from $B\overline{B}$ (red), $B^*\overline{B}$ and $B\overline{B}^*$ (green), $B^*\overline{B}^*$ (blue), three-body $B^{(*)}\overline{B}^{(*)}\pi$ (violet), and four-body $B\overline{B}\pi\pi$ (turquoise) channels.

The band in the center of Fig. 23.2.4 corresponds to the intermediate $\Upsilon(5S)$ decay channels with non-strange B mesons. The channels are located inside the band in the following order with increasing m_{ES}: $B\overline{B}$, $B^*\overline{B} + B\overline{B}^*$, $B^*\overline{B}^*$, three-body $B^{(*)}\overline{B}^{(*)}\pi$, and four-body $B\overline{B}\pi\pi$. The two-body channels are well separated from each other in m_{ES} (for B decays with only a few reconstructed photons). In contrast, the m_{ES} distributions of the three three-body channels overlap significantly with each other and partially overlap the distribution for the four-body channel.

The numbers of events inside and outside the elliptical regions is used to estimate the number of B^0_s signal and background events. However, in general an unbinned extended maximum likelihood fit to m_{ES} and ΔE is applied to extract the number of signal events. The probability density functions used for this are adjusted using MC simulation and sideband data.

As for studies of B mesons at the $\Upsilon(4S)$, the B^0_s signal shapes at the $\Upsilon(5S)$ are usually modeled with a single Gaussian for m_{ES} and a double Gaussian with common mean for ΔE. More complicated shapes have to be used to describe an electromagnetic tail, which appears if photons or electrons are present in the reconstructed B^0_s final state of interest. Light quark continuum backgrounds are usually modeled with an ARGUS function (see Chapter 7) for m_{ES} and a polynomial function for ΔE. Potentially it

is possible to simultaneously fit all three B_s^0 signal regions (three intermediate channels, *i.e.* the three types of final state containing B_s^0 mesons introduced in Section 23.2.1). However, as shown below the rate of the channel $B_s^{*0}\overline{B}_s^{*0}$ is about 90% of all B_s^0 channels (if the CM energy is close to the $\Upsilon(5S)$ peak position), and in many cases it is reasonable to only include the region corresponding to this final state in the fit.

23.2.7 Fractions of events with B mesons

Measurements of event fractions containing B_s^0 mesons in the final state produced at the CM energy of the $\Upsilon(5S)$ resonance (see Fig. 23.2.1) provide information about *b*-quark dynamics. Moreover, these fractions have to be precisely known to build a reliable MC model of $\Upsilon(5S)$ decays, which is required in order to make accurate background estimates in $B_{(s)}$ decay studies. Several measurements of the B channel fractions at the $\Upsilon(5S)$ have been performed by Belle (Drutskoy, 2010). The experimental techniques used in these measurements are described below, and finally all results obtained are summarized in Table 23.2.1 and discussed together with the results of B_s^0 branching fraction measurements.

The measurements are based on a 23.6 fb^{-1} data sample. The five decay modes $B^+ \to J/\psi K^+$, $B^0 \to J/\psi K^{*0}$, $B^+ \to \overline{D}^0\pi^+$ (with $\overline{D}^0 \to K^+\pi^-$ and $K^+\pi^+\pi^-\pi^-$), and $B^0 \to D^-\pi^+$ ($D^- \to K^+\pi^-\pi^-$) were used to reconstruct B mesons. These modes were chosen because they have large and precisely measured branching fractions and contain only charged particles in the final state; these characteristics result in small systematic uncertainties.

Belle measures the charged and neutral B production rates normalized to the number of $b\overline{b}$ events. To obtain the sum of all possible channels, the $\Delta E + m_{\rm ES} - m_B$ projections of the two-dimensional scatter plots for all events within the allowed range $5.268\,{\rm GeV}/c^2 < m_{\rm ES} < 5.440\,{\rm GeV}/c^2$ are used. The $\Delta E + m_{\rm ES} - m_B$ projection works as a rotation in the ΔE and $m_{\rm ES}$ plane (see Fig. 23.2.4 for an illustration). Therefore all signal events from the inclined band contribute to the $\Delta E + m_{\rm ES} - m_B$ distribution as a single Gaussian peak. These inclined projections are fit to obtain the integrated B decay event yields with a function including two terms: a Gaussian to describe the signal and a first-order polynomial to describe background.

Using the fit results, the charged and neutral B production rates per $b\overline{b}$ event are obtained from the formula

$$f(B^{+,0}) = \frac{Y_{B\to X}^{\rm fit}}{\left(N_{\rm 5S}^{b\overline{b}} \times \epsilon_{B\to X} \times \mathcal{B}_{B\to X}\right)}, \qquad (23.2.10)$$

where $Y_{B\to X}^{\rm fit}$ is the event yield obtained from the fit for a specific mode $B \to X$, $N_{\rm 5S}^{b\overline{b}}$ is the full number of $b\overline{b}$ events in the dataset, $\epsilon_{B\to X}$ is the reconstruction efficiency including all types of strange B meson branching fractions, and $\mathcal{B}_{B\to X}$ is the corresponding B decay branching fraction taken from the PDG (Beringer et al., 2012). The average production rates obtained for charged and neutral B

Table 23.2.1. The B and B_s^0 channel fractions at the CM energy of the $\Upsilon(5S)$.

Channel	% / $b\overline{b}$ event	% / B_s^0 event
All B_s^0 events	$19.5^{+3.0}_{-2.3}$	
$B_s^{*0}\overline{B}_s^{*0}$		$90.1^{+3.8}_{-4.0} \pm 0.2$
$B_s^{*0}\overline{B}_s^0 + B_s^0\overline{B}_s^{*0}$		$7.3^{+3.3}_{-3.0} \pm 0.1$
$B_s^0\overline{B}_s^0$		$2.6^{+2.6}_{-2.5}$
All B events	$73.7 \pm 3.2 \pm 5.1$	
B^+ mesons	$72.1^{+3.9}_{-3.8} \pm 5.0$	
B^0 mesons	$77.0^{+5.8}_{-5.6} \pm 6.1$	
$B\overline{B}$	$5.5^{+1.0}_{-0.9} \pm 0.4$	
$B\overline{B}^* + B^*\overline{B}$	$13.7 \pm 1.3 \pm 1.1$	
$B^*\overline{B}^*$	$37.5^{+2.1}_{-1.9} \pm 3.0$	
$B\overline{B}\pi$	$0.0 \pm 1.2 \pm 0.3$	
$B\overline{B}^*\pi + B^*\overline{B}\pi$	$7.3^{+2.3}_{-2.1} \pm 0.8$	
$B^*\overline{B}^*\pi$	$1.0^{+1.4}_{-1.3} \pm 0.4$	
ISR to final B	$9.2^{+3.0}_{-2.8} \pm 1.0$	

mesons are shown in Table 23.2.1. The $f(B^+)$ and $f(B^0)$ values are equal within uncertainties, which is consistent with isospin symmetry. The average of the charged and neutral B modes is $(73.7 \pm 3.2 \pm 5.1)\%$.

The two-body channel branching fractions are measured; values are averaged over charged and neutral B mesons. The $m_{\rm ES}$ projections are obtained for events in the signal band (shown in Fig. 23.2.5(a)) and the projections are fit with a function including signal and background terms (Fig. 23.2.5(b)). The shapes of the signal components are taken from MC simulation, and those of combinatorial background are modeled using sideband data. The fit region is restricted to the interval $m_{\rm ES} \in [5.268, 5.348]\,{\rm GeV}/c^2$. The three peaks corresponding to the $B\overline{B}$, $B\overline{B}^* + B^*\overline{B}$ and $B^*\overline{B}^*$ channels (from left to right) are clearly seen in Fig. 23.2.5(b). The matrix elements responsible for three- and four-body decays are not known, and the rates of three- and four-body contributions cannot be obtained in a model-independent way from a fit to these $m_{\rm ES}$ distributions. The fit results are given in Table 23.2.1.

In order to reconstruct the three-body channels, an additional charged pion produced directly via $B^{(*)}\overline{B}^{(*)}\pi^+$ is combined with two $B^{(*)}$ mesons. For each charged pion not included in the reconstructed B candidate, right-sign $B^+\pi^-$, $\overline{B}^0\pi^-$, $B^0\pi^+$, or $B^-\pi^+$ combinations are formed. The reconstructed B candidates are selected from the three-body signal region given by $5.37\,{\rm GeV}/c^2 < m_{\rm ES} < 5.44\,{\rm GeV}/c^2$ and $|\Delta E + m_{\rm ES} - m_B| < 0.03\,{\rm GeV}$. Then a special variable $\Delta X = \Delta E^{\rm mis} + m_{\rm ES}^{\rm mis} - m_B$ was calculated for all selected $B\pi$ candidates, where the variables $m_{\rm ES}^{\rm mis}$ and $\Delta E^{\rm mis}$ are obtained for the missing B meson using the energy and momentum of the reconstructed $B\pi$ combination in the CM frame. The ΔX variable reflects the missing mass in the reconstructed $B\pi$ system.
Figure 23.2.5. (a) The $M_{bc} = m_{ES}$ and ΔE scatter plot for the $B^+ \to J/\psi K^+$ mode (data) from Drutskoy (2010). The band indicates the signal region corresponding to the intervals $5.268\,\text{GeV}/c^2 < m_{ES} < 5.440\,\text{GeV}/c^2$ and $|\Delta E + m_{ES} - m_B| < 0.03\,\text{GeV}$. (b) The m_{ES} distribution in data after background subtraction. The sum of the five significant B decays (points with error bars, see Table 23.2.1) and results of the fit (histogram) used to extract the two-body channel fractions are shown.
Figure 23.2.6. (a) The $\Delta X = \Delta E^{\text{mis}} + m_{ES}^{\text{mis}} - m_B$ distribution normalized to unity for MC simulated $B^+ \to J/\psi K^+$ decays in the (peaks from left to right) $B\bar{B}\pi^+$, $B\bar{B}^*\pi^+ + B^*\bar{B}\pi^+$, $B^*\bar{B}^*\pi^+$, and $B\bar{B}\pi\pi$ channels. (b) The $\Delta X = \Delta E^{\text{mis}} + m_{ES}^{\text{mis}} - m_B$ data distribution for right-sign $B^{-/0}\pi^+$ combinations for the sum of the five studied B modes. Plots are from Drutskoy (2010).

Figure 23.2.6(a) shows the ΔX distributions obtained for MC simulated $B\bar{B}\pi^+$, $B\bar{B}^*\pi^+ + B^*\bar{B}\pi^+$, $B^*\bar{B}^*\pi^+$, and $B\bar{B}\pi\pi$ events where the $B^+ \to J/\psi K^+$ mode is generated. The background due to random charged tracks from the unobserved B meson is also shown. The studied channel contributions are well separated as seen in Fig. 23.2.6(a). The reconstruction efficiency for the four-body channel (the small peak on the rightmost part of Fig. 23.2.6(a)) is small and model dependent.

Finally, the ΔX distribution obtained from the data is shown in Fig. 23.2.6(b). This distribution is fitted with a function including four terms: three Gaussian distributions with fixed shapes in order to describe the $B\bar{B}\pi^+$, $B\bar{B}^*\pi^+ + B^*\bar{B}\pi^+$, and $B^*\bar{B}^*\pi^+$ contributions, and a second-order polynomial to describe the background. The four-body channel contribution is negligible and is not included in the fit. The three-body channel fractions obtained from the fit are given in Table 23.2.1.

All results obtained on B and B_s^0 channel fraction measurements are summarized in Table 23.2.1. The fractions for specific B_s^0 channels for all events with B_s^0 mesons are taken from Louvot (2009). The difference between the number of B events and the sum of all two-body or three-body channels is assumed to be due to ISR producing a system of lower CM energy with subsequent $B\bar{B}$-pair production. The ISR rate obtained using this assumption agrees with theoretical expectations.

The measurement of fractions for specific B_s^0 channels of all events with B_s^0 mesons is discussed in the next section. An unexpected feature of B_s^0 production at the $\Upsilon(5S)$ is the strong dominance of the $B_s^{*0}\bar{B}_s^{*0}$ channel. The observed value is close to 90%, although initial theoretical estimates gives values of about 70%. Taking into account the B event rate of $(73.7 \pm 3.2 \pm 5.1)\%$ and the B_s^0 event rate of $f_s = (19.5^{+3.0}_{-2.2})\%$ at the $\Upsilon(5S)$, there is still room for unobserved transitions to non-$B\bar{B}$ final states with a bottomonium meson. The large fraction for the

three-body $B\bar{B}^*\pi + B^*\bar{B}\pi$ channel was not predicted theoretically and is not yet understood. The channel $B\bar{B}\pi$ was not observed and its production is probably suppressed due to the 0^- quantum numbers of all three final particles produced from the 1^- initial state, which results in two P-wave amplitudes.

23.3 Measurements of B_s^0 decays at $\Upsilon(5S)$

Branching fraction measurements discussed here are ordered in terms of decreasing value and cover semi-leptonic B_s^0 decays (Section 23.3.1); the Cabibbo favored decays $B_s^0 \to D_s^{(*)-}\pi^+(\rho^+)$ and $B_s^0 \to D_s^{(*)+}D_s^{(*)-}$ (Sections 23.3.2 and 23.3.3, respectively); color suppressed decays (Section 23.3.4); charmless two-body decays (Section 23.3.5); and finally loop (or penguin) decays (Section 23.3.6).

23.3.1 B_s^0 semileptonic branching fraction

Although *BABAR* performed no dedicated $\Upsilon(5S)$ running, a scan was performed in 2008 in 5 MeV steps covering the CM energy ($E_{\rm CM}$) range $10.54\,{\rm GeV} \le E_{\rm CM} \le 11.2\,{\rm GeV}$, integrating a total of $4.25\,{\rm fb}^{-1}$ of data. These data are used to study B_s^0 production in this region and to obtain a measurement of the inclusive B_s^0 semileptonic branching fraction $\mathcal{B}(B_s^0 \to \ell\nu X)$. Semileptonic decays of B_d^0 mesons have a large branching fraction to final states including a charm meson. Similarly semileptonic decays of B_s^0 mesons have large transition rates to final states including a D_s meson, which subsequently decays (15.7% of the time (Beringer et al., 2012)) into a ϕ+anything final state. The *BABAR* analysis exploits the existence of the Cabibbo-favored decay chain $B_s \to D_s \to \phi$.

In 15 MeV wide bins of $E_{\rm CM}$, *BABAR* measures the yields of three inclusive processes in the scan data: the yield of multi-hadronic events containing at least three charged tracks and with Fox-Wolfram moment less than or equal to 0.2 (the event yield), the inclusive yield of events containing ϕ mesons (the ϕ yield), and the inclusive yield of events containing a ϕ in coincidence with a well-identified e or μ having a CM momentum exceeding 900 MeV (the ϕ-lepton yield). The ϕ candidates are reconstructed in the decay mode $\phi \to K^+K^-$ from pairs of tracks, with the highest probability to be kaons, that are fitted to a common vertex. Yields are determined by binned maximum likelihood fits to the K^+K^- invariant mass distribution of the selected candidates in events with (ϕ-lepton) and without (ϕ) a track passing the lepton selection. The *p.d.f.* used to fit the distribution consists of a Voigt profile[174] signal peak on top of a background consisting of the product of a threshold function opening at $2m_{K^\pm}$ and a linear factor. Each yield is normalized to the number of events in the $E_{\rm CM}$ bin which pass criteria identifying them as $e^+e^- \to \mu^+\mu^-$ events.

---
[174] The convolution of a Breit-Wigner with a Gaussian resolution function.

In order to remove the contribution from continuum $e^+e^- \to q\bar{q}$ events, where $q = u, d, s, c$, *BABAR* performs the same measurements in a 7.89 fb^{-1} sample of data taken 40 MeV below the $\Upsilon(4S)$ mass and subtracts the off-resonance yields from the yields obtained in each bin. The value to be subtracted is corrected as a function of $E_{\rm CM}$ for the variation of the selection efficiency with energy as deduced from simulation. With continuum contributions to the yields removed, the remaining yield is the sum of contributions from $B\bar{B}$ and $B_s^0\bar{B}_s^0$ events as follows:

$$C_h = R_B \left[f_s \epsilon_h^s + (1 - f_s)\epsilon_h \right] \tag{23.3.1}$$

$$C_\phi = R_B \left[f_s \epsilon_\phi^s P(B_s\bar{B}_s \to \phi X) \right.$$
$$\left. + (1 - f_s)\epsilon_\phi P(B\bar{B} \to \phi X) \right] \tag{23.3.2}$$

$$C_{\phi\ell} = R_B \left[f_s \epsilon_{\phi\ell}^s P(B_s\bar{B}_s \to \phi\ell X) \right.$$
$$\left. + (1 - f_s)\epsilon_{\phi\ell} P(B\bar{B} \to \phi\ell X) \right], \tag{23.3.3}$$

where

$$f_s \equiv \frac{N_{B_s}}{N_{B_u} + N_{B_d} + N_{B_s}} \tag{23.3.4}$$

is the ratio of B_s^0 events to all b hadron events, $R_B = \sigma(e^+e^- \to B_{(s)}\bar{B}_{(s)})/\sigma(e^+e^- \to \mu^+\mu^-)$, and the efficiencies $\epsilon_X^{(s)}$ and probabilities $P(B_{(s)}\bar{B}_{(s)} \to \phi(\ell)X)$ are presented schematically. The values of C_h, C_ϕ and $C_{\phi\ell}$ across the scanned region are shown in Fig. 23.3.1.

The ratio f_s is obtained from the combination of Eqs (23.3.1) and (23.3.2). The probability that a $B\bar{B}$ pair produces a ϕ meson scaled by the corresponding efficiency, $\epsilon_\phi P(B\bar{B} \to \phi X)$, is obtained by direct measurement of the event and ϕ yields in an 18.55 fb^{-1} sample of data taken at the $\Upsilon(4S)$ resonance, followed by the application of Eqs (23.3.1) and (23.3.2) with $f_s = 0$. The corresponding probability in B_s^0 events is estimated from previously measured branching fractions plus small corrections from estimated $B_s \to c\bar{c}\phi$ and $B_s \to DD_sX$ (followed by $D \to \phi$) rates. The result, presented in 45 MeV wide bins, is seen in Fig. 23.3.2. The ratio, above threshold, is observed to peak around the $\Upsilon(5S)$ mass and is small elsewhere.

In order to extract the semileptonic branching fraction, an estimate of $P(B_s^0\bar{B}_s^0 \to \phi\ell X)$ as a function of $\mathcal{B}(B_s \to \ell\nu X)$ is constructed using known branching fractions plus the estimated ones mentioned earlier. This estimate separately treats leptons from events with one B_s^0 semileptonic decay, events with two B_s^0 semileptonic decays, and events in which neither B_s^0 has decayed semileptonically but instead a lepton from a charmed meson has passed the lepton momentum selection. For the latter *BABAR* includes contributions from events with up to two leptons coming from $D^\pm$, D^0, or $D_s^\pm$ decays. Selection efficiencies for each case are determined separately from simulation. Again the $\Upsilon(4S)$ data mentioned earlier are used to obtain $\epsilon_{\phi\ell} P(B\bar{B} \to \phi\ell X)$. With these estimates, *BABAR* constructs a χ^2 from the expected value of $\epsilon_{\phi\ell} P(B_s\bar{B}_s \to \phi\ell X)$, estimated as a function of $\mathcal{B}(B_s \to \ell\nu X)$, and the value obtained by the measured quantities and Eqs (23.3.1) and (23.3.3). Minimization of this
Figure 23.3.1. Relative values of the (a) event, (b) ϕ, and (c) ϕ-lepton yields after continuum subtraction is performed. Corrections for detector efficiency have not been applied. The B_s^0 production threshold is located at the dotted line. From Lees (2012a).
Figure 23.3.2. f_s in 45 MeV wide bins of E_{CM}. The larger blue error bars represent the sum in quadrature of statistical and systematic uncertainties, while the inner ones show the statistical uncertainty alone. The broken line denotes the B_s^0 threshold. From Lees (2012a).

χ^2 with respect to the branching fraction yields $\mathcal{B}(B_s \to \ell\nu X) = (9.5^{+2.5}_{-2.0})\%$.

The dominant contribution to the systematic uncertainty comes from the poor knowledge of the inclusive rate $\mathcal{B}(B_s \to D_s X)$ $\left(^{+8.72}_{-13.58}\right.$ events). Other sources include uncertainties due to biases in the technique found using ensembles of simulated experiments $\left(^{+0.39}_{-10.00}\right.$ events), see Section 11.5.2; the impact of neglecting ISR and two-photon contributions to the event subtraction $\left(^{+1.57}_{-7.14}\right.$ events); estimated branching fractions used (± 3.4 events); uncertainties due to the use of particle identification (± 3.21 events); statistical uncertainties in the quantities determined from $\Upsilon(4S)$ data and daughter branching fractions (± 3.1 events); uncertainties in the selection efficiency obtained by variation of the R_2 and lepton momentum requirements $\left(^{+1.99}_{-2.85}\right.$ events); sensitivity to the background parameterization and possible presence of scalar contributions in the threshold region (± 0.93 events); the uncertainty in other world-average branching fractions used $\left(^{+0.52}_{-0.54}\right.$ events); and fixed parameters used in the fit to the K^+K^- invariant mass distribution $\left(^{+0.49}_{-0.15}\right.$ events).

With systematic uncertainties included, the final result is found to be $\mathcal{B}(B_s \to \ell\nu X) = (9.5^{+2.5+1.1}_{-2.0-1.9})\%$, in good agreement with expectations from spectator processes that would predict a similar branching fraction for the B^0 and the B_s^0. A more complete overview may be found in Lees (2012a).

23.3.2 Cabibbo favored decays $B_s^0 \to D_s^{(*)-}\pi^+(\rho^+)$

The $B_s^0 \to D_s^{(*)-}\pi^+$ and $B_s^0 \to D_s^{(*)-}\rho^+$ decays were the first processes studied by Belle at the $\Upsilon(5S)$. These decays are described by Cabibbo-favored tree diagrams, which have no suppression factors; therefore, relatively large branching fractions are expected for these decays. The decay $B_s^0 \to D_s^-\pi^+$ was previously observed and studied with high statistics at the Tevatron experiments. However to identify the other three modes the neutral particles (γ from D_s^{*-} and π^0 from ρ) have to be reconstructed, which was not possible at other experiments; LHCb was not in operation at that time. These decay modes were the primary goals for observation at Belle.

Although the theoretical models used to describe these decays are relatively simple, any experimental results on these modes are welcome because they test the applicability and accuracy of the basic approaches of B meson theoretical calculations. In particular these decays are well suited to test heavy-quark theories that predict, based on $SU(3)$ symmetry, similarities between the decay parameters of B_s^0 mesons and their corresponding B^0 counterparts. These include the unitarized quark model (Tornqvist, 1984), heavy quark effective theory (HQET; Deandrea, Di Bartolomeo, Gatto, and Nardulli, 1993), and a more recent approach based on chiral symmetry (Bardeen, Eichten, and Hill, 2003).

Moreover, because of their large branching fractions, these decays can be used to measure parameters in $\Upsilon(5S)$ decays, such as the masses of the B_s^0 and B_s^{*0} mesons
Figure 23.3.3. (a) $M_{bc} = m_{ES}$ distribution of the $B_s^0 \rightarrow D_s^- \pi^+$ candidates with ΔE in the $B_s^{*0} \bar{B}_s^{*0}$ signal region $[-80, -17]$ MeV. (b) ΔE distribution of the $B_s^0 \rightarrow D_s^- \pi^+$ candidates with M_{bc} in the $B_s^{*0} \bar{B}_s^{*0}$ signal region $[5.41, 5.43]$ GeV/c^2. The different fitted components are shown with dashed curves for the signal, dotted curves for the $B_s^0 \rightarrow D_s^{*-} \pi^+$ background, and dash-dotted curves for the continuum. The total fit is shown as a solid line. Plots are from Louvot (2009).

and the relative fractions of different $\Upsilon(5S)$ decay channels. Precisely measured branching fractions of these decay modes can also be used as a primary normalization at hadron colliders, where the absolute branching fractions are difficult to measure.

The $B_s^0 \rightarrow D_s^{(*)-} \pi^+$ and $B_s^0 \rightarrow D_s^{(*)-} \rho^+$ decays are observed and studied by Belle using 23.6 fb^{-1} of data collected at the $\Upsilon(5S)$ resonance CM energy region (Louvot, 2009, 2010). Evidence for the $B_s^0 \rightarrow D_s^{(*)\mp} K^\pm$ decay is also found, at the level of 3.5σ, in these studies. The technique used to identify B_s^0 signals is described in Section 23.2 and only final results are discussed here. Details of the analyses are found in the original papers.

Two-dimensional unbinned extended maximum likelihood fits are applied to obtain the $B_s^0 \rightarrow D_s^{(*)-} \pi^+$ and $B_s^0 \rightarrow D_s^{(*)-} \rho^+$ decay branching fractions. The m_{ES} and ΔE projections of the two-dimensional distribution for the decay $B_s^0 \rightarrow D_s^- \pi^+$ are shown in Fig. 23.3.3 together with the fit projections. Five additional parameters were measured using this decay mode: the fractions of the B_s^0 pair production modes at the $\Upsilon(5S)$ energy,
Figure 23.3.4. Left (right): $M_{bc} = m_{ES}$ (ΔE) distributions for $B_s^0 \rightarrow D_s^{*-} \pi^+$ (top) and $B_s^0 \rightarrow D_s^- \rho^+$ (bottom) candidates with ΔE (m_{ES}) restricted to the $\pm 2.5\sigma$ $B_s^{*0} \bar{B}_s^{*0}$ signal region. The blue solid curve is the total fitted p.d.f., while the green (black) dotted curve is the peaking (continuum) background and the red dashed curve is the signal. Plots are from Louvot (2010).
Figure 23.3.5. Distributions for the $B_s^0 \rightarrow D_s^{*-} \rho^+$ candidates. Top: $M_{bc} = m_{ES}$ and ΔE distributions, as in the previous figure. Bottom: distributions of the cosine of the helicity angles of the D_s^{*-} (left) and ρ^+ (right) with m_{ES} and ΔE restricted to the $B_s^{*0} \bar{B}_s^{*0}$ kinematic region. The components of the total p.d.f. (blue solid line) are shown separately: the black-dotted curve is the background and the two red-dashed curves are the signal. The large (small) signal component corresponds to the longitudinal (transverse) signal. Plots are from Louvot (2010).

$f_{B_s^{*0} \bar{B}_s^{*0}} = \left(90.1^{+3.8}_{-4.0} \pm 0.2\right)\%$, $f_{B_s^{*0} \bar{B}_s^0} = \left(7.3^{+3.3}_{-3.0} \pm 0.1\right)\%$, $f_{B_s^0 \bar{B}_s^0} = \left(2.6^{+2.6}_{-2.5}\right)\%$, and the masses $m_{B_s^{*0}} = (5416.4 \pm 0.4 \pm 0.5)$ MeV/c^2 and $m_{B_s^0} = (5364.4 \pm 1.3 \pm 0.7)$ MeV/c^2. The $\Upsilon(5S) \rightarrow B_s^{*0} \bar{B}_s^{*0}$ channel fraction is found to be large and this channel strongly dominates over other channels.

A similar method is used to extract the branching fractions for the other three decay modes. The m_{ES} and ΔE projections of the two-dimensional distributions for the decays $B_s^0 \rightarrow D_s^{*-} \pi^+$ and $B_s^0 \rightarrow D_s^- \rho^+$ are shown in Fig. 23.3.4. The m_{ES} and ΔE projections and helicity dis-

Table 23.3.1. Top: measured branching fractions with statistical, systematic (without f_s), and f_s uncertainties, and HQET predictions from the factorization hypothesis (Deandrea, Di Bartolomeo, Gatto, and Nardulli, 1993). Bottom: branching fraction ratios where several systematic uncertainties cancel out.

Mode	$\mathcal{B}$ (10^{-3})	$\mathcal{B}_{\mathrm{HQET}}$ (10^{-3})
$B_s^0 \to D_s^- \pi^+$	$3.67^{+0.35+0.43}_{-0.33-0.42} \pm 0.49$	2.8
$B_s^0 \to D_s^{*-} \pi^+$	$2.4^{+0.5}_{-0.4} \pm 0.3 \pm 0.4$	2.8
$B_s^0 \to D_s^- \rho^+$	$8.5^{+1.3}_{-1.2} \pm 1.1 \pm 1.3$	7.5
$B_s^0 \to D_s^{*-} \rho^+$	$11.8^{+2.2}_{-2.0} \pm 1.7 \pm 1.8$	8.9
$B_s^0 \to D_s^\mp K^\pm$	$0.24^{+0.12}_{-0.10} \pm 0.03 \pm 0.03$	
Ratios		
$\mathcal{B}(B_s^0 \to D_s^{*-} \pi^+)/\mathcal{B}(B_s^0 \to D_s^- \pi^+) = 0.65^{+0.15}_{-0.13} \pm 0.07$		
$\mathcal{B}(B_s^0 \to D_s^- \rho^+)/\mathcal{B}(B_s^0 \to D_s^- \pi^+) = 2.3 \pm 0.4 \pm 0.2$		
$\mathcal{B}(B_s^0 \to D_s^{*-} \rho^+)/\mathcal{B}(B_s^0 \to D_s^- \pi^+) = 3.2 \pm 0.6 \pm 0.3$		
$\mathcal{B}(B_s^0 \to D_s^{*-} \rho^+)/\mathcal{B}(B_s^0 \to D_s^- \rho^+) = 1.4 \pm 0.3 \pm 0.1$		

tributions for the D_s^{*-} and ρ are shown in Fig. 23.3.5 for the decay $B_s^0 \to D_s^{*-} \rho^+$. As the latter decay is that of a B_s^0 meson decaying into a final state with two vector particles, one can perform an angular analysis of the final state in terms of the helicity angles (and angle between decay planes) of the intermediate vector particles as described in Chapter 12. A simplified angular analysis (integrating over the angle between the two decay planes) of $B_s^0 \to D_s^{*-} \rho^+$ indicates strong dominance of the longitudinal polarization: the obtained fraction of this component is $f_L = 1.05^{+0.08}_{-0.10}(\text{stat})^{+0.03}_{-0.04}(\text{syst})$. This result is compatible with expectations from HQET and naïve factorization computed for some $B_{u,d}$ to two-vector particle final states (see Sections 17.3 and 17.4 for discussions of such states). All branching fractions measured and their ratios are summarized in Table 23.3.1. The results obtained are consistent with theoretical predictions based on HQET (Deandrea, Di Bartolomeo, Gatto, and Nardulli, 1993) and are similar to the corresponding B^0 decay branching fractions.

23.3.3 Cabibbo favored decays $B_s^0 \to D_s^{(*)+} D_s^{(*)-}$

Belle has also used $\Upsilon(5S)$ data to measure $B_s^0 \to D_s^{(*)+} D_s^{(*)-}$ decays. An initial study was done using $23.6\,\mathrm{fb}^{-1}$ of data (Esen, 2010), while a subsequent study uses the full $121.4\,\mathrm{fb}^{-1}$ data set (Esen, 2013). The final states reconstructed consist of $D_{(s)}^+ D_s^-$, $D_s^{*+} D_s^- + D_s^{*-} D_{(s)}^+ (\equiv D_s^{*\pm} D_s^\mp)$, and $D_s^{*+} D_s^{*-}$. These are expected to be mostly CP-even, and their partial widths are expected to dominate the difference in widths between the two B_s^0 CP eigenstates, $\Delta\Gamma_s^{CP}$ (Aleksan, Le Yaouanc, Oliver, Pène, and Raynal, 1993). This parameter is equal to $\Delta\Gamma_s / \cos\phi_{12}$, where $\Delta\Gamma_s$ is the decay width difference between the mass eigenstates, and ϕ_{12} is the CP-

violating phase in B_s^0-$\bar{B}_s^0$ mixing.[175] Thus the branching fraction gives a constraint in the $\Delta\Gamma_s$-ϕ_{12} parameter space. Both parameters can receive contributions from new physics (Buras, Carlucci, Gori, and Isidori, 2010; Lenz and Nierste, 2011; Ligeti, Papucci, Perez, and Zupan, 2010).

The decays $B_s^0 \to D_{(s)}^+ D_s^-$, $D_s^{*\pm} D_s^\mp$, and $D_s^{*+} D_s^{*-}$ are reconstructed via $D_{(s)}^+ \to \phi\pi^+$, $K_S^0 K^+$, $\bar{K}^{*0} K^+$, $\phi\rho^+$, $K_S^0 K^{*+}$, and $\bar{K}^{*0} K^{*+}$; charge-conjugate modes are implicitly included. The daughter mesons are reconstructed via $K_S^0 \to \pi^+\pi^-$, $K^{*0} \to K^+\pi^-$, $K^{*+} \to K_S^0\pi^+$, $\phi \to K^+K^-$, $\rho^+ \to \pi^+\pi^0$, and $\pi^0 \to \gamma\gamma$. For the three vector-pseudoscalar final states, it is required that $|\cos\theta_{\mathrm{hel}}| > 0.20$, where θ_{hel} is the angle between the momentum of the charged daughter of the vector particle and the direction opposite the D_s^+ momentum, evaluated in the rest frame of the vector particle.

Belle combines $D_{(s)}^+$ candidates with photon candidates to reconstruct $D_s^{*+} \to D_{(s)}^+ \gamma$ decays. The mass difference $M_{D_s^+ \gamma} - M_{D_s^+}$ must be within 12.0 MeV/c^2 of the nominal value. Events are required to satisfy $5.25\,\mathrm{GeV}/c^2 < m_{\mathrm{ES}} < 5.45\,\mathrm{GeV}/c^2$ and $-0.15\,\mathrm{GeV} < \Delta E < 0.10$ GeV. Only small contributions from $B_s^0 \bar{B}_s^0$ and $B_s^0 \bar{B}_s^{*0}$ events are expected, and these contributions are fixed relative to $B_s^{*0} \bar{B}_s^{*0}$ according to the Belle measurement of $B_s^0 \to D_s^- \pi^+$ decays (Louvot, 2009). Belle quotes fitted signal yields from $B_s^{*0} \bar{B}_s^{*0}$ only and uses these to determine the branching fractions. Approximately half of the selected events have multiple $B_s^0 \to D_s^{(*)+} D_s^{(*)-}$ candidates. These typically arise from photons produced via $\pi^0 \to \gamma\gamma$ that are wrongly assigned as D_s^{*+} daughters. For these events the candidate that minimizes a χ^2 constructed from the reconstructed D_s^+ and (if present) D_s^{*+} masses is selected.

Background from $e^+e^- \to q\bar{q}$ ($q = u, d, s, c$) is rejected by using a Fisher discriminant based on a set of modified Fox-Wolfram moments (see Section 9.5). The remaining background consists of $\Upsilon(5S) \to B_s^{(*)} \bar{B}_s^{(*)} \to D_s^+ X$, $\Upsilon(5S) \to B\bar{B}X$ ($b\bar{b}$ hadronizes to B^0, $\bar{B}^0$, or $B^\pm$), and $B_s^0 \to D_{sJ}^\pm(2317)D_s^{(*)}$, $D_{sJ}^\pm(2460)D_s^{(*)}$, or $D_s^\pm D_s^\mp \pi^0$. The last three processes peak at negative ΔE, and their yields are estimated to be small using analogous $B_d^0 \to D_{sJ}^\pm D^{(*)}$ branching fractions. They are considered only when evaluating the systematic uncertainty due to backgrounds.

The signal yields are determined via a two-dimensional unbinned maximum-likelihood fit to the m_{ES}-ΔE distributions. The signal $p.d.f.$s have components for correctly reconstructed decays, "wrong combination" decays in which a non-signal track or γ is included, and "cross-feed" decays in which a $D_s^{*\pm} D_s^\mp$ ($D_s^{*+} D_s^{*-}$) is reconstructed as a $D_s^+ D_s^-$ ($D_s^+ D_s^-$ or $D_s^{*\pm} D_s^\mp$), or a $D_s^+ D_s^-$ ($D_s^{*\pm} D_s^\mp$) is reconstructed as a $D_s^{*\pm} D_s^\mp$ or $D_s^{*+} D_s^{*-}$ ($D_s^{*+} D_s^{*-}$). All signal shape parameters are taken from the MC simulation and calibrated using $B_s^0 \to D_s^{(*)-} \pi^+$ and

---

[175] Specifically, $\phi_{12} = \arg(-M_{12}/\Gamma_{12})$, where M_{12} and Γ_{12} are the off-diagonal elements of the B_s^0-$\bar{B}_s^0$ mass and decay matrices. Also see Chapter 10.

Table 23.3.2. The fractions of B_s^0 signal events in % (from MC simulation) reconstructed as correctly reconstructed (CR) and wrong combination (WC) signal, and cross-feed events. Cross-feed up and down are denoted by † and ‡, respectively.

Mode	CR	WC	Cross-feed
$D_s^+ D_s^-$	76.1	6.0	17.1 $(D_s^{*\pm} D_s^{\mp})^{\ddagger}$; 0.8 $(D_s^{*+} D_s^{*-})^{\ddagger}$
$D_s^{*\pm} D_s^{\mp}$	44.4	38.5	8.2 $(D_s^+ D_s^-)^{\dagger}$; 8.9 $(D_s^{*+} D_s^{*-})^{\ddagger}$
$D_s^{*+} D_s^{*-}$	31.8	37.6	2.0 $(D_s^+ D_s^-)^{\dagger}$; 28.6 $(D_s^{*\pm} D_s^{\mp})^{\dagger}$

Table 23.3.3. $B_s^{*0} \bar{B}_s^{*0}$ correctly reconstructed signal yield (Y) and efficiency (ε), including intermediate branching fractions, and resulting branching fraction ($\mathcal{B}$). The first uncertainties listed are statistical; the others are systematic. The last error for the sum is due to external factors ($\Upsilon(5S) \to B_s^{*0} \bar{B}_s^{*0}$ and D_s^+ branching fractions).

Mode	Y (events)	ε ($\times 10^{-4}$)	$\mathcal{B}$ (%)
$D_{(s)}^+ D_s^-$	$33.1^{+6.0}_{-5.4}$	4.72	$0.58^{+0.11}_{-0.09} \pm 0.13$
$D_s^{*\pm} D_s^{\mp}$	$44.5^{+5.8}_{-5.5}$	2.08	$1.76^{+0.23}_{-0.22} \pm 0.40$
$D_s^{*+} D_s^{*-}$	$24.4^{+4.1}_{-3.8}$	1.01	$1.98^{+0.33}_{-0.31}\,{}_{-0.50}$
Sum	$102.0^{+9.3}_{-8.6}$		$4.32^{+0.42}_{-0.39}\,{}^{+0.56}_{-0.54} \pm 0.88$

$B^0 \to D_{(s)}^{(*)+} D^-$ decays. The fractions of wrong combination signal and cross-feed down events are taken from MC (see Table 23.3.2); the fractions of cross-feed up events are floated as they are difficult to simulate accurately (many B_s^0 partial widths are unmeasured).[176] As the cross-feed down fractions are fixed, the separate $D_s^+ D_s^-$, $D_s^{*\pm} D_s^{\mp}$, and $D_s^{*+} D_s^{*-}$ samples are fitted simultaneously.

The projections of the fit are shown in Fig. 23.3.6. The fitted correctly reconstructed signal yields are listed in Table 23.3.3 along with signal efficiencies (including intermediate branching fractions from Nakamura et al., 2010) and the resulting branching fractions. The significance is calculated as $\sqrt{2 \ln(\mathcal{L}_{max}/\mathcal{L}_0)}$, where $\mathcal{L}_{max}$ and $\mathcal{L}_0$ are the likelihood values when the signal yield is floated and when it is set to zero, respectively. Systematic uncertainties on the yield are included in the significance by smearing the likelihood function by a Gaussian distribution with width corresponding to the total additive systematic uncertainty. The significance computed for $D_{(s)}^+ D_s^-$, $D_s^{*\pm} D_s^{\mp}$, and $D_s^{*+} D_s^{*-}$, is 11.5σ, 10.1σ and 7.8σ, respectively.

The systematic uncertainties are dominated by factors external to the analysis, i.e., f_s (18%) and the $D_{(s)}^+$ branching fractions (8.6%). The uncertainty due to the wrong combination and cross-feed fractions, which are taken from the MC simulation, is $\sim 4.6\%$ for $D_s^{*\pm} D_s^{\mp}$ and $\sim 10\%$

---

[176] Cross-feed up/down corresponds to a background event type that is mis-reconstructed so as to move upward/downward in ΔE in order to overlap with signal. For example a $D_s^+ D_s^-$ final state would have to be mis-reconstructed, including an extra photon, in order to be reconstructed under the $D_s^{*+} D_s^-$ peak in ΔE. This is an example of cross-feed up.
Figure 23.3.6. (left) ΔE fit projections for events satisfying $M_{bc} = m_{ES} \in [5.41, 5.43]$ GeV/c^2, and (right) m_{ES} fit projections for events satisfying $\Delta E \in [-0.08, -0.02]$ GeV. The top row shows $B_s^0 \to D_{(s)}^+ D_s^-$; the middle row shows $B_s^0 \to D_s^{*\pm} D_s^{\mp}$; and the bottom row shows $B_s^0 \to D_s^{*+} D_s^{*-}$. The red dashed curves show correctly reconstructed and wrong combination signal; the blue dash-dotted curves show cross-feed; the magenta dotted curves show background; and the black solid curves show the total. Plots are from Esen (2013).

for $D_s^{*+} D_s^{*-}$. The fraction of longitudinal $D_s^{*+} D_s^{*-}$ polarization f_L for this measurement is taken to be the value from the analogous decay $B_d^0 \to D_s^{*+} D^{*-}$: 0.52 ± 0.05 (Beringer et al., 2012). The systematic error is taken to be the change in signal yield when f_L is varied over a wide range: from 2σ higher than 0.52 down to the low central value measured by Belle (see below). This error is less than three events on each of the modes.

In the limits of $m_{b,c} \to \infty$ with $(m_b - 2m_c) \to 0$ and N_c (number of colors)$\to \infty$, the $D_s^{*\pm} D_s^{\mp}$ and $D_s^{*+} D_s^{*-}$ modes are CP-even and (along with $D_s^+ D_s^-$) saturate the width difference $\Delta\Gamma_s^{CP}$ (Aleksan, Le Yaouanc, Oliver, Pène, and Raynal, 1993). Assuming negligible CP violation ($\phi_s \approx 0$), the branching fraction is related to $\Delta\Gamma_s$ via $\Delta\Gamma_s/\Gamma_s =$

$2\mathcal{B}/(1 - \mathcal{B})$. Inserting the total $\mathcal{B}$ from Table 23.3.3 gives $\Delta\Gamma_s/\Gamma_s = 0.090 \pm 0.009(\text{stat}) \pm 0.023(\text{syst})$, which is consistent with the HFAG average (Asner et al., 2011). This result has similar precision to that of recent measurements (Aaij et al., 2012h; Aaltonen et al., 2012b). The central value is consistent with, but lower than, the theoretical prediction (Lenz and Nierste, 2011); the difference may be due to the unknown CP-odd component in $B_s^0 \to D_s^{*+} D_s^{*-}$, and contributions from three-body final states. The former is estimated to be only 6% for analogous $B^0 \to D_s^{*+} D^{*-}$ decays (Rosner, 1990), but the latter are expected to be significant: Chua, Hou, and Shen (2011) calculate $\Delta\Gamma(B_s^0 \to D_s^{(*)} D^{(*)} K^{(*)})/\Gamma_s = 0.064 \pm 0.047$. This calculation predicts $\Delta\Gamma_s/\Gamma_s$ from $D_s^{(*)+} D_s^{(*)-}$ alone to be 0.102 ± 0.030, which agrees well with the Belle result.

In addition to measuring the branching fractions, Belle also measures the longitudinal polarization fraction (f_L) of $B_s^0 \to D_s^{*+} D_s^{*-}$. To measure f_L, Belle performs an unbinned maximum likelihood fit to the cosine of the helicity angles θ_1 and θ_2, where $\theta_{1,2}$ are the angles between the daughter γ momentum and the direction opposite to the B_s^0 momentum in the D_s^{*+} and D_s^{*-} rest frames, respectively. The angular distribution is $\left(|A_+|^2 + |A_-|^2\right)\left(\cos^2\theta_1 + 1\right)\left(\cos^2\theta_2 + 1\right) + |A_0|^2 4\sin^2\theta_1 \sin^2\theta_2$, where A_+, A_-, and A_0 are the three polarization amplitudes in the helicity basis (see Chapter 12). The fraction f_L equals $|A_0|^2/(|A_0|^2 + |A_+|^2 + |A_-|^2)$. To account for resolution and efficiency variation, the signal $p.d.f.$s are taken from MC. The result is

$$f_L = 0.06^{+0.18}_{-0.17} \pm 0.03, \qquad (23.3.5)$$

where the systematic errors are dominated by the fixed wrong combination signal fractions ($+0.013, -0.015$) and the fixed background level (± 0.022). The helicity angle distributions and fit projections are shown in Fig. 23.3.7.
Figure 23.3.7. Helicity angle distributions and projections of the fit result for $B_s^0 \to D_s^{*+} D_s^{*-}$. The red dashed (blue dash-dotted) curves show the transverse (longitudinal) components; the magenta dotted curves show background; and the black solid curves show the total. Plots are from Esen (2013).

23.3.4 Color suppressed decays $B_s^0 \to J/\psi\eta^{(\prime)}$ and $B_s^0 \to J/\psi f_0(980)$

Belle uses $121.4\,\text{fb}^{-1}$ of data accumulated at the $\Upsilon(5S)$ resonance to search for, and observe, exclusive color-suppressed B_s^0 decays with an underlying $b \to c\bar{c}s$ quark transition. Among these, the pure CP-eigenstate final state decays $B_s^0 \to J/\psi f_0(980)$ and $B_s^0 \to J/\psi\eta^{(\prime)}$ are of special interest. These decays, which were not yet observed, could be used in the future to study time-dependent CP asymmetries. In addition the ratio of the $B_s^0 \to J/\psi\eta^\prime$ and $J/\psi\eta$ branching fractions constitutes a test of $\eta - \eta^\prime$ mixing.

The study of the $B_s^0 \to J/\psi f_0(980)$ decay is described in detail in Li (2011). The reconstruction of the decay mode $B_s^0 \to J/\psi f_0(980)$ includes $f_0(980)$ decaying into two charged pions. The main backgrounds are from the inclusive decays B_s^0, B_d^0, and $B^+ \to J/\psi X$, where the contributions from $B_s^0 \to J/\psi\eta^\prime$ and $B^+ \to J/\psi(K^+, \pi^+)$ are modeled exclusively and set to their known branching fractions. Since the $f_0(980)$ resonance is wide, $\sim 60\,\text{MeV}/c^2$, we need to describe the $M_{\pi\pi}$ spectrum using the Flatté formula with a phase-space factor, and the $f_0(1370)$ line-shape is described using a relativistic Breit-Wigner. Both of these line shapes are described in Section 13.2.1. A two-dimensional fit with the variables ΔE and $M_{\pi\pi}$ is performed to extract the signal yield, where the m_{ES} signal region corresponding to the $B_s^{*0}\bar{B}_s^{*0}$ channel was chosen. The data surprisingly also show an enhancement around $M_{\pi\pi} \sim 1400\,\text{MeV}/c^2$, where the ΔE distribution is also strongly peaked (see Fig. 23.3.8). Thus Belle includes the contribution from the $f_0(1370)$ resonance coherently with the $f_0(980)$ resonance in the $M_{\pi\pi}$ signal fit model.

Studies of the decay modes $B_s^0 \to J/\psi\eta$ and $J/\psi\eta^\prime$ are described in (Li, 2012). Five η and $\eta^\prime$ sub-channels are reconstructed, $\eta \to \gamma\gamma$, $\eta \to \pi^+\pi^-\pi^0$, $\eta^\prime \to \eta(\gamma\gamma)\pi^+\pi^-$, $\eta^\prime \to \eta(\pi^+\pi^-\pi^0)\pi^+\pi^-$ and $\eta^\prime \to \rho^0\gamma$. To use as much information as possible, a simultaneous fit to the two-dimensional ΔE - m_{ES} distributions of all five sub-channels is performed in order to extract the branching fraction. The signal includes contributions from all three B_s^0 production channels $\Upsilon(5S) \to B_s^{(*)0}\bar{B}_s^{(*)0}$. The fit results are shown in Fig. 23.3.8.

Belle observes the three decay modes and measures their branching fractions:

$$\mathcal{B}(B_s^0 \to J/\psi f_0(980); f_0(980) \to \pi^+\pi^-)$$
$$= (1.16^{+0.31}_{-0.19}{}^{+0.15}_{-0.17}{}^{+0.26}_{-0.18}) \times 10^{-4},$$
$$\mathcal{B}(B_s^0 \to J/\psi\eta) = (5.10 \pm 0.50 \pm 0.25^{+1.14}_{-0.79}) \times 10^{-4},$$
$$\mathcal{B}(B_s^0 \to J/\psi\eta^\prime) = (3.71 \pm 0.61 \pm 0.18^{+0.83}_{-0.57}) \times 10^{-4}, \qquad (23.3.6)$$

where the three quoted uncertainties are statistical, systematic, and from $N_{B_s^{(*)0}\bar{B}_s^{(*)0}}$. Evidence for the decay with the $f_0(1370)$ is also found and the branching fraction

$$\mathcal{B}(B_s^0 \to J/\psi f_0(1370); f_0(1370) \to \pi^+\pi^-)$$
$$= (0.34^{+0.11}_{-0.14}{}^{+0.03}_{-0.02}{}^{+0.08}_{-0.05}) \times 10^{-4} \qquad (23.3.7)$$
Figure 23.3.8. Data fit projections for $B_s^0 \to J/\psi\,\pi^+\pi^-$ (top two plots), $B_s^0 \to J/\psi\,\eta\,(\eta \to \gamma\gamma)$ and $B_s^0 \to J/\psi\,\eta'\,(\eta' \to \rho\gamma)$ (bottom two plots, respectively). The $J/\psi\,\pi^+\pi^-$ $M_{\pi\pi}$ (ΔE) distributions are for events in the ΔE ($f_0(980)$) signal region. The $J/\psi\,\eta^{(\prime)}$ ΔE distributions are for events in the m_{ES} signal region. The dotted curves show the total background contribution. Plots are from Li (2011, 2012).

is measured, where the significance of the signal is 4.2σ. The quoted uncertainties are statistical, systematic, and from $N_{B_s^{(*)0}\bar{B}_s^{(*)0}}$, respectively. The observed J/ψ helicity distributions corresponding to $f_0(980)$ and $f_0(1370)$ signals are consistent with scalar $\pi\pi$ resonances.

The ratio obtained for the two branching fractions

$$\frac{\mathcal{B}(B_s^0 \to J/\psi\eta')}{\mathcal{B}(B_s^0 \to J/\psi\eta)} = 0.73 \pm 0.14(\text{stat}) \pm 0.02(\text{syst}) \tag{23.3.8}$$

is smaller than the expected value 1.04 ± 0.04 calculated from other $\eta-\eta'$ mixing measurements at the level of 2.1σ. The measured production channel fractions $f_{B_s^{*0}\bar{B}_s^{*0}}$ and $f_{B_s^{*0}\bar{B}_s^0}$ from the $B_s \to J/\psi\eta^{(\prime)}$ study are consistent with averages from other measurements.

23.3.5 Charmless decays $B_s^0 \to hh$, $h = \pi, K$

Belle uses $23.6\,\text{fb}^{-1}$ of data to search for the two-body charmless decays $B_s^0 \to K^+K^-$, $B_s^0 \to K^0\bar{K}^0$, $B_s^0 \to K^-\pi^+$, and $B_s^0 \to \pi^+\pi^-$. The branching fractions for these modes may exhibit direct CP asymmetries, as has been observed for $B_d^0 \to K^\pm\pi^\mp$ decays. In addition, measurement of the K^+K^- and $\pi^+\pi^-$ time-dependent CP asymmetries yields information on the CKM phases ϕ_1 and ϕ_3. While the all-charged final states have also been studied at hadron collider experiments (Aaij et al., 2012d; Aaltonen et al., 2009b; Abulencia et al., 2006c; Morello, 2007), the $K^0\bar{K}^0$ final state is difficult to reconstruct at a hadron collider but is well-suited to an e^+e^- experiment.

Details of the analysis are found in Peng (2010). To select B_s^0 decays, events are required to satisfy $m_{ES} \in [5.35, 5.45]\,\text{GeV}/c^2$ and $\Delta E \in [-0.20, 0.20]\,\text{GeV}$; this region is referred to as the *fitting* region. Within this region a smaller signal region is defined: $m_{ES} \in [5.40, 5.43]\,\text{GeV}/c^2$ and $\Delta E \in [-0.10, 0.00]\,\text{GeV}$. The signal region corresponds to $e^+e^- \to B_s^{*0}\bar{B}_s^{*0}$ production.

To suppress the large backgrounds from $e^+e^- \to q\bar{q}$ continuum production, a Fisher discriminant based on a set of modified Fox-Wolfram moments is used. This discriminant is used to calculate the likelihood that an event is signal ($\mathcal{L}_s$) or background ($\mathcal{L}_{q\bar{q}}$). A requirement is then made on the ratio $\mathcal{L}_s/\mathcal{L}_{q\bar{q}}$. After this requirement, there are 300, 444, 188, and 345 candidates remaining in the fitting regions for K^+K^-, $K^-\pi^+$, $\pi^+\pi^-$, and $K^0\bar{K}^0$ modes, respectively.

The signal yields are obtained from an unbinned extended maximum likelihood fit to the m_{ES} and ΔE distributions. Projections of the fit are shown in Fig. 23.3.9, and the fit results along with corresponding branching fractions or 90% C.L. upper limits are listed in Table 23.3.4.

A significant signal is observed for the K^+K^- final state; the significance is 5.8σ. Systematic uncertainty is included in the significance by convolving the likelihood function with a Gaussian having a width equal to the total systematic uncertainty associated with the fitting procedure. The 90% C.L. upper limits ($\mathcal{B}_{90\%}$) in Table 23.3.4
Figure 23.3.9. Distributions of ΔE (left) and $M_{bc} = m_{ES}$ (right) with fitted distributions superimposed for K^+K^- (a,b), $K^+\pi^-$ (c,d), $\pi^+\pi^-$ (e,f), and $K^0\bar{K}^0$ (g,h) events. The ΔE (m_{ES}) distributions are for events within the signal region for m_{ES} (ΔE). The red dot-dashed curves show the signal component; the grey dashed curves show the $q\bar{q}$ background; the green dotted curves in the $K^-\pi^+$ plots show the K^+K^- cross-feed; and the blue solid curves show the total. Plots are from Peng (2010).

Table 23.3.4. Signal yields, significances (Σ), reconstruction efficiencies (ϵ), and either the branching fraction or 90% C.L. upper limit for charmless two-body B_s^0 decays. The first error listed is statistical, the second error is systematic, and the third error is due to the $B_s^{(*)0}\bar{B}_s^{(*)0}$ fraction f_s.

Mode	Yield	Σ	$\epsilon(\%)$	$\mathcal{B}$ (10^{-5})
K^+K^-	$23.4^{+5.5}_{-6.3}$	5.8	24.5	$3.8^{+1.0}_{-0.9} \pm 0.5 \pm 0.5$
$K^-\pi^+$	$5.4^{+5.1}_{-4.3}$	1.2	21.0	< 2.6
$\pi^+\pi^-$	$-2.0^{+2.3}_{-1.5}$	–	14.4	< 1.2
$K^0\bar{K}^0$	$5.2^{+5.0}_{-4.3}$	1.2	8.0	< 6.6

are obtained by integrating the likelihood function:

$$\int_0^{\mathcal{B}_{90\%}} \mathcal{L}(\mathcal{B})\, d\mathcal{B} = 0.9 \times \int_0^1 \mathcal{L}(\mathcal{B})\, d\mathcal{B}. \qquad (23.3.9)$$

This method assumes a uniform prior distribution for $\mathcal{B}$. The $K^-\pi^+$ and $\pi^+\pi^-$ limits are consistent with, but have less sensitivity than, results from CDF (Aaltonen et al., 2009b; Morello, 2007). At the time of writing, there were no other limits on $B_s^0 \to K^0\bar{K}^0$.

23.3.6 Penguin decays $B_s^0 \to \phi\gamma$, $B_s^0 \to \gamma\gamma$

Belle uses $23.6\,\text{fb}^{-1}$ of data to search for the radiative penguin decay $B_s^0 \to \phi\gamma$ and the penguin annihilation decay $B_s^0 \to \gamma\gamma$. The Standard Model predictions for these processes are $(3-6) \times 10^{-5}$ and $(5-10) \times 10^{-7}$, respectively (Ali, Pecjak, and Greub, 2008; Ball, Jones, and Zwicky, 2007; Bosch and Buchalla, 2002a; Chang, Lin, and Yao, 1997; Reina, Ricciardi, and Soni, 1997). Both decays proceed via internal loop diagrams and thus are sensitive to new physics at high energy scales occurring within the loops. For example, supersymmetric models with broken R parity (Gemintern, Bar-Shalom, and Eilam, 2004) and two-Higgs doublet models (Aliev and Iltan, 1998) can increase the $B_s^0 \to \gamma\gamma$ branching fraction by an order of magnitude over the Standard Model prediction. As discussed in Section 17.2, a branching ratio measurement of $B_s^0 \to \gamma\gamma$ could be used in the determination of $|V_{td}/V_{ts}|$.

Details of these analyses are found in Wicht (2008). Neutral ϕ mesons are reconstructed via $\phi \to K^+K^-$, in which the K^+K^- invariant mass is required to be within $12\,\text{MeV}/c^2$ ($\sim 2.5\sigma$) of the nominal ϕ mass. For the $B_s^0 \to \gamma\gamma$ decay, only photons reconstructed within the barrel region of the ECL ($33° < \theta < 128°$) are used. To select B_s^0 decays, events are required to satisfy $m_{ES} > 5.3\,\text{GeV}/c^2$, $\Delta E < 0.40\,\text{GeV}$, and either $\Delta E > -0.40\,\text{GeV}$ for $B_s^0 \to \phi\gamma$ or $\Delta E > -0.70\,\text{GeV}$ for $B_s^0 \to \gamma\gamma$. To reject large backgrounds from continuum production, especially $e^+e^- \to q\bar{q}\gamma$ in which a high energy γ is produced, a Fisher discriminant based on a set of Fox-Wolfram moments is used.

The signal yields are obtained from an unbinned extended maximum likelihood fit to the m_{ES}, ΔE, and, for $B_s^0 \to \phi\gamma$, $\cos\theta_{hel}$ distributions. The helicity angle θ_{hel} is defined as the angle between the B_s^0 and the K^+ in the ϕ rest frame. Signal events should follow a $1 - \cos^2\theta_{hel}$ distribution, while $q\bar{q}$ continuum background events tend to be distributed flat in $\cos\theta_{hel}$. The fit obtains separate signal yields for $e^+e^- \to B_s^0\bar{B}_s^0$, $B_s^*B_s^0$, and $B_s^*B_s^*$ production, but only the last of these is used to determine the branching fractions. The projections of the fit are shown in Figs 23.3.10 and 23.3.11, and the fit results are listed in Table 23.3.5.

A significant signal is observed for $B_s^0 \to \phi\gamma$. The significance is calculated as $\sqrt{2\ln(\mathcal{L}_{max}/\mathcal{L}_0)}$, where $\mathcal{L}_{max}$ and $\mathcal{L}_0$ are the likelihood values when the signal yield is floated and when it is set to zero, respectively; the result
Figure 23.3.10. $M_{bc} = m_{ES}$, ΔE, and $\cos \theta_{hel}$ projections for $B_s^0 \to \phi\gamma$. The points with error bars show the data; the thin solid curves show the signal contribution; the dashed curves show the continuum contribution; and the thick solid curves show the total. The bottom right figure shows the $(m_{ES}, \Delta E)$ plane; the dashed lines denote the signal region used to calculate the branching fraction. Plots are from Wicht (2008).
Figure 23.3.11. $M_{bc} = m_{ES}$ and ΔE projections for $B_s^0 \to \gamma\gamma$. The points with error bars show the data; the thin solid curves show the signal contribution; the dashed curves show the continuum contribution; and the thick solid curves show the total. In the m_{ES} figure, the signals (negative) from $e^+e^- \to B_s^0\bar{B}_s^0$, $B_s^{*0}\bar{B}_s^0$, and $B_s^{*0}\bar{B}_s^{*0}$ appear from left to right. Plots are from Wicht (2008).

is 5.5σ. Systematic uncertainties are evaluated by varying fixed parameters in the fit by $\pm 1\sigma$, refitting, and taking the resulting change in the branching fraction as the systematic uncertainty associated with that parameter. The systematic uncertainty is included in the significance by calculating the significance using the lowest value of $\mathcal{L}_{max}$ obtained when evaluating individual systematic uncertainties. The resulting 5.5σ significance constitutes the

Table 23.3.5. Fitted signal yields, and either the branching fraction or 90% C.L. upper limit. The first error listed is statistical, and the second is systematic.

Mode	$S_{B_s^0\bar{B}_s^0}$	$S_{B_s^{*0}\bar{B}_s^0}$	$S_{B_s^{*0}\bar{B}_s^{*0}}$	$\mathcal{B}$ (10^{-6})
$\phi\gamma$	$-0.7^{+2.5}_{-1.6}$	$0.5^{+2.9}_{-1.9}$	18^{+6}_{-5}	57^{+18+12}_{-15-11}

observation of a radiative decay of the B_s^0 meson. The measured branching fraction is in agreement with theoretical predictions.

The 90% C.L. upper limit for the $B_s^0 \to \gamma\gamma$ branching fraction ($\mathcal{B}_{90\%}$) is obtained using the same method as for the two-body decays (see Eq. 23.3.9) by integrating the likelihood function assuming a uniform prior in $\mathcal{B}$. Systematic uncertainties are included by convolving the likelihood function with Gaussian distributions corresponding to each systematic error contribution. The resulting upper limit of 8.7×10^{-6} is a significant improvement over previous limits and about one order of magnitude above the SM prediction.

23.4 Conclusion

B_s^0 mesons were studied using data collected in the $\Upsilon(5S)$ energy region with an e^+e^- collider by the B Factories. Many new B_s^0 decays are observed, and branching fractions for several B_s^0 decays are measured with a precision comparable with that of existing results.

B_s^0 measurements at the $\Upsilon(5S)$, when compared with the measurements at hadron-hadron colliders, have the following advantages:

1. Channels with neutral particles, such as photons, π^0's, or η mesons are precisely measured. The benefit is most prominent in the case of reconstruction of low energy photons or several neutral particles in an event.
2. Missing mass methods are used with the partial reconstruction technique, due to the low momenta of the B_s^0 mesons in the $\Upsilon(5S)$ rest frame.
3. The almost 100% trigger efficiency is an advantage of the B Factory experiments. No special procedures have to be used to estimate the trigger efficiencies.
4. The full number of B_s^0 mesons in a data sample is calculated with a small systematic uncertainty. This allows one to measure absolute -rather than relative-branching fractions.

The most important disadvantages of B_s^0 meson studies at the $\Upsilon(5S)$ are the smaller initial number of B_s^0 mesons, the lack of ability to resolve B_s^0 oscillations (hence it is not possible to perform time-dependent CP analyses), and the necessity to choose between data taking at the $\Upsilon(5S)$ and $\Upsilon(4S)$. In general B_s^0 meson studies with e^+e^- colliders at the $\Upsilon(5S)$ and at hadron-hadron machines are complementary and together provide the best coverage of the whole spectrum of the most interesting decay channels.

Table 23.4.1. Measured B_s^0 branching fractions with statistical, systematic (without f_s), and f_s uncertainties are shown. If no significant signal is observed the 90% C.L. upper limit is given. If the third uncertainty is absent, the second uncertainty includes both systematic uncertainties. The corresponding B^0 branching fractions from PDG Beringer et al. (2012) are also shown for comparison.

$B_s^0 \to \gamma \gamma$	$< 8.7 \times 10^{-6}$		

The B_s^0 decay branching fractions measured at the $\Upsilon(5S)$ are summarized in Table 23.4.1. The branching fractions of the corresponding B^0 decays are also shown for comparison.

The results obtained demonstrate that the B_s^0 and B^0 meson branching fractions are consistent within uncertainties. The B_s^0 branching fractions with η and η' mesons in the final state are expected to be about $1/3$ of the corresponding B^0 branching fractions with a K^0, because the $\eta^{(\prime)}$ meson is assumed to be approximately one third $s\bar{s}$. The results indicate that the larger mass of the s-quark, compared with the mass of the d-quark, does not result in significant rearrangement of the intrinsic structure of the B meson, consisting of both heavy and light quarks. It should also be noted that Belle did not find any significant deviations of the experimentally measured B_s^0 branching fractions from the corresponding theoretical predictions.

Chapter 24
QCD-related physics

Although the main objective of the B Factories is the study of flavor physics and weak decays, some additional insights on QCD-related physics have been gained. From the data of both *BABAR* and Belle, the functions for the fragmentation of light quarks into light hadrons and for the fragmentation of the charm quark into charmed mesons and baryons have been extracted with improved precision. Not only the unpolarized, but also the spin-dependent fragmentation functions have been measured, adding a crucial input to studies of transverse quark polarization in the nucleon.

Another QCD-related issue is the search for exotic states. While charmonium-like exotic states are discussed in Section 18.3, searches for exotic states composed of light quarks are described in Section 24.2. Searches for such states have been performed by *BABAR* and Belle, showing no evidence for any of the previously claimed pentaquark states nor for any other member of the pentaquark family.

24.1 Fragmentation

24.1.1 Introduction

A consequence of the confining property of the strong interaction is that energetic quarks and gluons produced in high-energy collisions appear as collimated "jets" of hadrons. The process by which this occurs, called fragmentation, is understood qualitatively, but there are few quantitative theoretical predictions. A better understanding of this process is desirable as a probe of the strong interaction, and an empirical understanding is essential to the interpretation of much current and future high-energy data, in which the observable products of interactions and decays of heavy particles, known and yet to be discovered, appear as hadronic jets. The intrinsic properties of jets are best studied in e^+e^- annihilation, where hadrons originate from primordial quarks and antiquarks, which are produced back-to-back in the CM frame. This kind of process leads to final sates with two jets, in case hard gluons are emitted by the quarks three and more jet events emerge.

Jets can be characterized by their overall structure, *e.g.* shape, energy flow, etc., and by the number, types and momentum spectra of hadrons produced. These properties depend on the energy, mass, charge and spin of the quark or gluon that initiated the jet. The initial quark is contained in a leading hadron that carries its flavor, perhaps its spin, and a fraction of its energy that is higher, on average, for heavier quarks. Additional $q\bar{q}$ pairs are produced from the vacuum to form the other hadrons in the jet, with probabilities that depend strongly on the quark mass, with $s\bar{s}$ pairs being suppressed with respect to $u\bar{u}$ and $d\bar{d}$ pairs by a factor of roughly three, and heavier quarks by much larger factors. In this way, c and b jets generally contain a single D or B hadron with typically more than half the jet energy, along with a few softer hadrons. However, the leading heavy hadron decays into a number of softer particles that influence the jet structure. Lighter flavor jets contain more primary hadrons with a broader range of momentum.

Hadron-production processes in high-energy reactions are also important for investigating properties of quark-hadron matter in heavy-ion collisions and for finding the origin of the nucleon spin in polarized lepton-nucleon and nucleon-nucleon reactions. In describing the hadron-production cross sections in high-energy reactions, fragmentation functions (FFs) are essential quantities. A fragmentation function quantifies the probability of producing a particular hadron h in a jet initiated by a particular parton. They are measured most directly by the hadron productions in electron-positron annihilation, $e^+e^- \to h\,X$, where h is the hadron under investigation and X is the rest of the hadronic final state.

In e^+e^- annihilation the initial partonic state is rather simple and can be described by a quark-antiquark pair at leading order in the strong coupling α_s. In single $\gamma^\star$ exchange (see Fig. 24.1.1), the relative production of quark flavors is given by the charge squared of the quarks. At energy scales below the open bottom threshold the production of $u\bar{u}$ and $c\bar{c}$ pairs amounts to 40% each, and that of $d\bar{d}$ and $s\bar{s}$ pairs to 10% each. The cross section for hadron production $e^+ + e^- \to h + X$ is described by a quark-antiquark pair creation by the reaction $e^+e^- \to q\bar{q}$ and higher-order corrections such as $e^+e^- \to q\bar{q}g$, and then by a fragmentation process to create a hadron h from quark (q), antiquark ($\bar{q}$), or gluon (g). The hadron multiplicity[177] is defined by the hadron-production cross section and the total hadronic cross section (Ellis, Stirling, and Webber, 1996) $\sigma_{tot} = \sigma_{e^+e^- \to q\bar{q}}$:

$$F^h(z, Q^2) = \frac{1}{\sigma_{tot}} \frac{d\sigma(e^+e^- \to hX)}{dz}, \qquad (24.1.1)$$

where the variable Q^2 is the virtual photon momentum squared in $e^+e^- \to \gamma^\star$, and it is given by $Q^2 = s$, with $\sqrt{s}$ being the CM energy. The variable z is the hadron energy E_h scaled to the beam energy $\sqrt{s}/2$:

$$z \equiv \frac{E_h}{\sqrt{s}/2} = \frac{2E_h}{Q}. \qquad (24.1.2)$$

---

[177] The hadron multiplicity is often also called fragmentation function despite being a different object.
Figure 24.1.1. Typical hadron-production process in electron-positron annihilation ($e^+ + e^- \to h + X$).

The total cross section is described by the $q\bar{q}$-pair creation processes, $e^+ e^- \to \gamma^\star \to q\bar{q}$ and higher-order corrections:

$$\sigma_{tot} = \frac{4\pi\alpha^2}{s} \sum_q e_q^2 \left[1 + \frac{\alpha_S(Q^2)}{\pi} + \cdots \right]. \qquad (24.1.3)$$

At CM energies higher than those available at B factories, Z^0 exchange must be taken into account, as it modifies the total cross section and the flavor composition, but not the FF for a given flavor.

The hadron multiplicities are related to the actual fragmentation functions which are defined as parton densities for inclusively detecting a hadron h with fractional energy z from an initial state parton q. Sometimes FFs are also obtained as a differential in the fractional energy and the hadron transverse momentum $P_{h,\perp}$ relative to the initial parton energy and can also depend on the parton and hadron spin orientations, $d^2\sigma/dz dP_{h,\perp}$. The fragmentation process is described by the sum of hadrons produced from primary quarks, antiquarks, and gluons (Ellis, Stirling, and Webber, 1996):

$$F^h(z, Q^2) = \sum_i C_i(z, \alpha_s) \otimes D_i^h(z, Q^2). \qquad (24.1.4)$$

Here, $D_i^h(z, Q^2)$ is a fragmentation function of the hadron h created by a parton i ($= u, d, s, \cdots, g$), and it indicates the probability of producing the hadron h, from the parton i with the energy fraction z at the momentum squared scale Q^2. The convolution integral $\otimes$ is defined by

$$f(z) \otimes g(z) = \int_z^1 \frac{dy}{y} f(y) g\left(\frac{z}{y}\right). \qquad (24.1.5)$$

The simplest FF is this unpolarized FF $D_i^h(z, Q^2)$. Polarized FFs also exist and are discussed in Section 24.1.3. Although the FF has the meaning of the production probability in the leading order (LO) of the running coupling constant α_S, it is a scheme-dependent quantity if higher-order corrections are taken into account. The coefficient function $C_i(z, \alpha_s)$ is trivial at leading order. At next-to-leading order (NLO), quark-gluon splitting appears, the

corresponding coefficient functions are needed, and the gluon FF appears. The NLO results are listed, for example, in Kretzer (2000) and Albino, Kniehl, and Kramer (2005, 2008) for the modified minimal subtraction ($\overline{\text{MS}}$) scheme. The coefficient functions are now known to the NNLO level for the unpolarized case (Mitov, Moch, and Vogt, 2006).

A sum rule exists for the FFs because of energy conservation. As the variable z is the energy fraction for the produced hadron, its sum weighted by the fragmentation functions should be unity:

$$\sum_h \int_0^1 dz\, z\, D_i^h(z, Q^2) \equiv \sum_h M_i^h = 1, \qquad (24.1.6)$$

where M_i^h is the second moment of $D_i^h(z, Q^2)$. The meaning of this result is that the sum of all final state hadrons' fractional energies integrated over the energy fraction has to retain the initial parton's energy. Not all of the hadrons are observed experimentally, so that in practice it is not possible to confirm this sum rule precisely from measurements. However, it is a useful relation in determining the FFs when performing a global analysis by providing a constraint on their magnitude.

As this hadron formation takes place at small masses and low energies it can only be described non-perturbatively. In the parton model, the fragmentation function is defined by (Brock et al., 1995; Collins, 1993)

$$D_i^h(x) = \sum_X \int \frac{dy^-}{24\pi} e^{ik^+ y^-} \text{Tr} \left[\gamma^+ \left\langle 0 \left| \psi_i(0, y^-, 0_\perp) \right| h, X \right\rangle \right.$$
$$\left. \times \left\langle h, X \left| \bar{\psi}_i(0) \right| 0 \right\rangle \right], \qquad (24.1.7)$$

where k is the parent quark momentum, the light-cone notation is defined by $a^\pm = (a^0 \pm a^3)/\sqrt{2}$, the variable z is then given by $z = p_h^+/k^+$ with the hadron momentum p_h, and $\perp$ is the transverse direction to the third coordinate. To be precise, a gauge link needs to be introduced in Eq. (24.1.7) so as to satisfy color gauge invariance. In the parton model, fragmentation functions are generally defined in a similar way as the parton distribution functions, however they cannot be calculated by lattice simulations due to the hadron in the final state.

The Q^2 evolution for the fragmentation functions is calculated by perturbative QCD in the same way as the one for the parton distribution functions. It is given by the time-like DGLAP (Dokshitzer-Gribov-Lipatov-Altarelli-Parisi) evolution equations (Ellis, Stirling, and Webber,

1996; Hirai and Kumano, 2011):

$$\frac{\partial}{\partial \ln Q^2} D_{q_i^+}^h(z, Q^2) = \frac{\alpha_s(Q^2)}{2\pi} \left[\sum_j P_{q_j q_i}(z) \otimes D_{q_j^+}^h(z, Q^2) \right.$$
$$\left. + 2P_{gq}(z) \otimes D_g^h(z, Q^2) \right],$$

$$\frac{\partial}{\partial \ln Q^2} D_g^h(z, Q^2) = \frac{\alpha_s(Q^2)}{2\pi} \left[P_{qg}(z) \otimes \sum_j D_{q_j^+}^h(z, Q^2) \right.$$
$$\left. + P_{gg}(z) \otimes D_g^h(z, Q^2) \right],$$
$$(24.1.8)$$

where $D_{q^+}^h(x, Q^2)$ denotes the fragmentation-function combination $D_q^h(x, Q^2) + D_{\bar{q}}^h(x, Q^2)$. The functions $P_{q_j q_i}(z)$, $P_{gq}(z)$, $P_{qg}(z)$, and $P_{gg}(z)$ are splitting functions, where the off-diagonal elements $P_{gq}(z)$ and $P_{qg}(z)$ are interchanged in the splitting-function matrix from the parton distribution function case (Ellis, Stirling, and Webber, 1996). One should note that the time-like functions are slightly different from the space-like ones in the next-to-leading order (Ellis, Stirling, and Webber, 1996).

There are measurements of the FFs in electron-positron annihilation at various center-of-mass energies. However, they are not accurate enough to determine precise functional forms. Data were taken mainly in the Z-mass region at the SLAC Linear Collider (SLC) and Large Electron-Positron Collider (LEP), which means that the scaling violation has not been determined precisely for the multiplicities. The FFs still have large uncertainties, particularly for the so-called disfavored functions (such as $D_u^{\pi^-}(z, Q^2)$, *i.e.* the function describing a π^- creation from an initial u quark - as opposed to the favored FF $D_u^{\pi^+}(x, Q^2)$), even for the pion, and there are large discrepancies among the obtained FFs from different global analysis groups.

The Belle and *BABAR* data play an important role in the accurate determination of the FFs by extending the kinematical region of z due to high-statistics measurements. The Belle and *BABAR* measurements are performed at CM energies around 10 GeV. Together with the accurate measurements at the Z mass the scaling behavior of FFs can be studied. The knowledge of the energy dependence will improve the physics results of high-energy experiments at LHC and RHIC, and other high-energy facilities.

Generally, fragmentation functions can be defined for any kind of final state hadron as long as it has been produced in strong processes only. Hadrons being produced in weak decays should in principle not be included, but given the difficulty of determining their relative fractions experimentally they are often included. So far, most of the fragmentation functions were obtained from e^+e^- annihilation alone (Albino, Kniehl, and Kramer, 2008; Hirai, Kumano, Nagai, Oka, and Sudoh, 2007) due to their clean initial state. However, as the unpolarized parton distribution functions in the intermediate $x_{Bjorken}$ range, where $x_{Bjorken}$ is the momentum fraction a parton carries relative to the nucleon, are relatively well known, recent ex-

tractions of FFs from the world data also include some semi-inclusive deep inelastic scattering and proton-proton collision data, such as in de Florian, Sassot, and Stratmann (2008). Given its non-perturbative nature and the need for a DGLAP evolution to obtain all components, FFs are generally obtained from a global analysis of the world data where available. In such a global analysis the fragmentation functions are parameterized at an initial scale which is fit to all existing data. While the e^+e^- data is usually quite precise, it is generally limited to the sum of quark and antiquark FFs as it is not known from which side a final state hadron emerged. Also, as mentioned above, the gluon FF only appears in NLO and therefore can only be obtained from e^+e^- data by comparing very different scales via the evolution. Therefore the data from semi-inclusive DIS and proton-proton scattering gives some valuable additions to the global analysis, but also the large lever arm between data obtained close to the Z^0 resonance and the B Factories' data is quite useful.

Belle and *BABAR* have studied the inclusive momentum spectra of a number of light and charmed hadrons in e^+e^- annihilation. They have also studied spin-induced correlations between particles in opposite jets. These are described in the subsections below.

24.1.2 Unpolarized fragmentation functions

The production rate of a particular type of hadron in jets of a particular (set of) flavor(s) can be quantified by the multiplicities $F^h(z, Q^2)$ (see Eq. 24.1.1), which is the average number of hadrons of type h produced per unit z in a jet, and z is a measure of the fraction of the quark's energy carried by the hadron. Apart from the normalized hadron energy z, a number of other definitions x_h related to normalized momenta are in use, and the relevant one is defined below in each case.

FFs cannot be calculated perturbatively in QCD, so there are no firm theoretical predictions. The ansatz of local parton-hadron duality (LPHD) combined with calculations of gluon radiation in the modified leading logarithm approximation (MLLA) (Azimov, Dokshitzer, Khoze, and Troyan, 1985) predicts properties of the distributions of the dimensionless variable $\xi = \ln(\sqrt{s}/2p^*)$ for light hadrons, where p^* is the magnitude of the hadron momentum in the CM system. The parameters depend on the hadron mass and the jet energy. There are several phenomenological models of fragmentation, involving three different hadron production methods. Here we consider representatives of each, the `HERWIG 5.8` (Marchesini et al., 1992), `Jetset 7.4` (Sjöstrand, 1994) and `UCLA 4.1` (Chun and Buchanan, 1998) event generators.

For sufficiently heavy quarks q, the high mass provides a convenient cut-off point in the perturbative regime and the multiplicity $F^q(x_q)$ of the heavy quark before hadronization can be calculated (Braaten, Cheung, Fleming, and Yuan, 1995; Colangelo and Nason, 1992; Collins and Spiller, 1986; Dokshitzer, Khoze, and Troian, 1996;

Mele and Nason, 1991). The observable heavy hadron multiplicity $F^H(x_H)$ is thought to be related by a simple convolution or hadronization model. Several phenomenological models of heavy-quark fragmentation have been proposed (Andersson, Gustafson, Ingelman, and Sjöstrand, 1983; Bowler, 1981; Kartvelishvili, Likhoded, and Petrov, 1978; Peterson, Schlatter, Schmitt, and Zerwas, 1983). Predictions depend on the quark mass, with $F^H(x_p)$ being much harder for b hadrons than c hadrons, and in some cases on the mass and quantum numbers of H. Hadrons containing the same heavy quark type are generally predicted to have similar $F^H(x_H)$, although differences between mesons and baryons have been suggested (Chun and Buchanan, 1998; Kartvelishvili and Likhoded, 1979).

The scaling properties, or $\sqrt{s}$ dependences, of hadron production are of particular interest. Since QCD is only weakly scale dependent, distributions of x_h should be almost independent of $\sqrt{s}$, except for the effects of hadron masses/phase space and the running of α_s. However, the quark flavor composition varies with $\sqrt{s}$ in e^+e^- annihilation, and must be modeled for light hadrons. This provides a nice test of models and MLLA QCD.

So far, Belle and *BABAR* have measured multiplicities for several of the lightest and heaviest particles produced at around 10.5 GeV. These include the light, non-strange mesons $\pi^\pm$ and η, the lightest strange meson $K^\pm$, and the lightest baryon $p/\overline{p}$, which can be used to test MLLA QCD and hadronization models. The five charmed mesons D^0, D^+, D_s^+, D^{*0} and D^{*+}, and three charmed baryons Λ_c^+, Ξ_c^0 and Ω_c^0 can be used to test models and calculations for heavy quarks. In addition, the correlated production of Λ_c^+ and $\overline{\Lambda_c^-}$ has been studied, providing a stringent test of models in an extreme region. These are discussed in the following subsections.

24.1.2.1 Light hadrons $\pi^\pm$, $K^\pm$, $p/\overline{p}$

BABAR and Belle have measured the inclusive production cross sections of charged pions and kaons in $e^+e^- \rightarrow q\overline{q}$ events at the off-resonance CM energies of 10.54 GeV and 10.52 GeV, respectively, while *BABAR* also measured protons and neutral η meson at 10.54 GeV. The data sets used contain integrated luminosities of 0.91 fb^{-1} for *BABAR* and 68.0 fb^{-1} for Belle. Uncertainties of inclusive measurements of fragmentation are dominated by systematic uncertainties even in relatively small samples of data with good running conditions. Hence the data are selected from runs with very stable running conditions.

Inclusive measurements such as these require a clean sample of multihadron events with low bias against particles of any particular type, multiplicity or momentum. All results reported in this Section are displayed as a function of the normalized hadron energy z.

For the charged $\pi/K/p$ analyses, *BABAR* (Muller, 2004) requires: three or more well reconstructed charged tracks that form a good vertex located within 5 mm of the beam axis and within 5 cm of the center of the collision region along the beam axis; a sum of charged plus neutral energy E_{tot} in the range 5–14 GeV; R_2 (see Section 9.3) less than

0.9; the polar angle θ^*_{thrust} of the event thrust axis with respect to the electron beam direction in the CM frame to satisfy[178] $|\cos\theta^*_{\text{thrust}}| < 0.8$; the track with the highest momentum in the laboratory frame p, not to be identified as an electron in events with fewer than six good tracks, and neither of the two highest-p tracks to be identified as an electron in events with only three tracks.

The requirements on E_{tot} and $\cos\theta^*_{\text{thrust}}$ select events well contained within the sensitive volume of the detector with low bias on the momentum spectra. The efficiency of this selection is determined on a simulated sample of events, and corrected for differences between data and simulation. The result is 68% for $u\overline{u}$, $d\overline{d}$ and $s\overline{s}$ events, and 73% for $c\overline{c}$ events. Similarly, they estimate backgrounds of 5.1% and 0.1%, respectively, from τ-pair and radiative Bhabha events, which contribute up to 20% and 8% of the charged tracks at the highest momenta. The background from two-photon processes is below 1%, and backgrounds from μ-pairs, hard initial state radiation (*i.e.* photon energies of more than several 100 MeV), beam-gas and beam-wall interactions are negligible.

High quality charged tracks are selected and identified as pions, kaons or protons using the momentum and ionization energy loss measured in the DCH and the velocity measured via the Cherenkov angle in the DIRC (see Chapter 2). A global likelihood algorithm is used that considers the set of dE/dx values for the reconstructed tracks in each event, along with the set of Cherenkov angles measured from photons detected in the DIRC (Chapter 5). The likelihood is optimized to keep the misidentification rates as low as reasonably possible, while maintaining high identification efficiencies that vary slowly with both momentum and polar angle. It identifies pions and kaons (protons) with efficiencies of over 99% for p below 0.7 (1.0) GeV/c, over 90% for p below 1.5 (4.5) GeV/c, and over 50% for p below 4.0 (6.5) GeV/c. Misidentification rates are below 1%, 6% and 4% in these three regions.

Since the e^+e^- system is boosted in the laboratory frame of reference, the analysis is performed separately for tracks in six different polar angle regions. The tracks in each region span different ranges of p, but each is transformed into the same range of momenta in the CM frame, p^*. This provides a set of powerful cross checks on the detector performance and material interactions, backgrounds, the true polar angle and p^* distributions, and the boost value itself. In each region, the full matrix of hadron identification efficiencies ($\pi^\pm$, $K^\pm$, $p^\pm$) is calibrated from the data as a function of p using a set of control samples (Chapter 5). The corrected efficiency matrices are inverted and used to convert the numbers of identified pions, kaons and protons into differential production cross sections per

---

[178] The event thrust axis is calculated using all particles in the event, or all charged tracks in the case of the *BABAR* light hadron analysis; it approximates the back-to-back direction of the two leading jets typically produced in events from continuum. We note that the thrust defined in Section 9.3, is instead built upon the decay products of the reconstructed B meson, with θ_T the angle between the thrust of the B decay products and the thrust of the rest of the event.

hadronic event per unit momentum in the laboratory frame, $(1/N_{evt})dn_i/dp$, $i = \pi, K, p$. Each corrected cross section is then transformed into the e^+e^- CM frame. Results from the six regions are compared as a cross check, and then combined to give the final measured cross sections, $(1/N_{evt})\,dn_i/dp^*$. There is a small correction for residual lepton contamination, and results are given in two ways, including or excluding the contributions from decays of K_S^0 and weakly decaying strange baryons; here we consider the latter.

The total systematic uncertainty on the pion cross section is at the level of a few percent in the full momentum range. It is dominated at low momenta by tracking efficiencies, by background contamination between 0.75 and about 3 GeV/c, and by particle identification at the highest momenta. The uncertainties on the kaon and proton cross sections have similar patterns, but are significantly larger, in particular for momenta below 0.2 GeV/c and above 4 GeV/c.

The uncertainties all have large point to point correlations. There is an overall normalization uncertainty of 0.9% that does not affect the shape of any cross section. Several uncertainties are fully correlated over the entire p^* range, but vary slowly with p^* and can have broad effects on the shape. The uncertainties from the calibration of the particle ID are correlated over ranges of a few bins, and can lead to apparent structures.

The Belle analysis (Leitgab, 2012, 2013) similarly requires events with at least 3 charged tracks, a visible energy above 7 GeV and either jet mass[179] above 1.8 GeV or the jet mass normalized by the visible energy to be above 0.25. Tracks are selected within the central detector with $-0.511 \le \cos\theta < 0.842$, where the polar angle θ is calculated in the laboratory frame, with a minimum momentum of a track of 500 MeV and at least three hits in the vertex detector. Tracks are also required to originate from within distances of 1.3 cm radially and 4 cm longitudinally from the interaction point. The particles were identified as pions, kaons, protons, electrons or muons via likelihood ratios obtained from the information of the CDC, ACC, TOF, ECL, and KLM (see Chapter 2). The charge separated particle identification efficiencies and fake rates were evaluated using a data driven method by relying on known decays of D^*, Λ and J/ψ's (see Chapter 5). These matrices for π, K, p, μ and e were obtained in a fine 17 $\times$ 9 $(p, \cos\theta)$ binning. Where not completely defined by data, an interpolation between adjacent bins or extrapolation based on MC simulation (`Pythia 6.2` for u, d, s, c production, a dedicated $\tau^+\tau^-$ and electro-magnetic process generators) was used. The extracted matrices were inverted; the uncertainties arising from the limited size of the data control samples were assigned as systematic uncertainties. Another important uncertainty in the Belle analysis arises from momentum smearing which migrates the contents of a certain z-bin over several, mostly adja-

cent bins. Smearing was evaluated using MC and corrected for by inverting the smearing matrix (from generated z bin a to reconstructed z bin). The statistical uncertainties on the matrix elements were converted into systematic uncertainties of the multiplicities. Further corrections include in-flight decays, detector interactions as well as reconstruction efficiencies. Furthermore backgrounds from non-QCD processes were estimated using MC and subtracted. The effects of ISR events were removed by evaluating the fraction of events with center-of-mass energies less than 0.5% below the nominal energy in the MC and removing that fraction from the data sample. As the fraction might depend on how well the MC describes the data various MC parameter settings were considered and the spread obtained was assigned as systematic uncertainty. Acceptance effects were corrected by fitting both, data and MC $\cos\theta$ distributions within the measured range, to estimate the fraction of non-reconstructed tracks.

The *BABAR* analysis of the momentum spectrum of the η meson begins with a similar hadronic event selection. The η mesons are reconstructed in the $\gamma\gamma$ decay mode: high quality neutral clusters with energy above 0.15 GeV are selected, and all pairs of such photon candidates are considered. If any pair has an invariant mass in the range $0.11 < M_{\gamma\gamma} < 0.155$ GeV/c^2, consistent with a π^0 decay, then both photon candidates are rejected. A pair is also rejected if $|\cos\theta_\gamma| > 0.8$, where θ_γ is the angle between either photon momentum and the boost direction of the laboratory system in the η rest frame.

Surviving pairs of photons are binned by the pair momentum in the CM frame p^*, and the invariant mass distribution in each bin is fitted with a sum of signal and background functions over the range $0.35 < M_{\gamma\gamma} < 0.75$ GeV/c^2. The signal function is the sum of a Gaussian distribution and Novosibirsk[180] distribution whose parameters depend on p^* in such a way as to reproduce the line-shape induced by photon energy loss in front of the EMC. The efficiency, defined as the ratio of the yield fitted for the MC sample to the true number of $\eta \to \gamma\gamma$ decays produced, ranges between 24% and 34%. The relative systematic uncertainty includes a component due to normalization of 6.2%, arising from the single photon efficiency, the event selection and the $\eta \to \gamma\gamma$ branching fraction. Additional point-to-point systematic uncertainties arise from the fitting procedure and signal and background shapes. They are 27% at $p^* = 0$, where backgrounds are very high, but then drop rapidly to well below 6% at 1 GeV/c. Relative statistical uncertainty drops from 15% at low p^* to 2% above 1.5 GeV/c.

Results

Both *BABAR* (Lees, 2013f) and Belle (Leitgab, 2013) published results of the light hadron fragmentation recently,

---

[179] The jet mass squared is defined as the square of the sum of all particle four-momenta in one hemisphere: $M^2 = \left(\sum_i p_i\right)^2$ where the hemisphere is defined by the normal to the thrust axis.

[180] The Novosibirsk function is an empirical *p.d.f.* defined as $f(M_{\gamma\gamma}) = \frac{1}{\sqrt{2\pi}\sigma}\exp\left[-0.5\left(\ln^2(1 + \Lambda \cdot (M_{\gamma\gamma} - \mu)/\sigma\tau^2) + \tau^2\right)\right]$, where $\Lambda = \sinh(\tau\sqrt{\ln 4})/\sqrt{\ln 4}$, μ is the peak position, and τ is the tail parameter.
Figure 24.1.2. Comparison of the multiplicities for $\pi^{\pm}$, $K^{\pm}$, $p/\overline{p}$, and η, measured by *BABAR* at $\sqrt{s} = 10.54$ GeV (compiled from Muller, 2004 and Lees, 2013f), Belle at 10.52 GeV (compiled from Leitgab, 2012 and Leitgab, 2013), and ARGUS at 9.98 GeV (Albrecht et al., 1989a, 1990b).

Figure 24.1.3. Comparison of the *BABAR* (Muller, 2004; Lees, 2013f), Belle (Leitgab, 2012, 2013), and ARGUS (Albrecht et al., 1989a, 1990b) $\pi^{\pm}$, $K^{\pm}$, $p/\overline{p}$, and η multiplicities with the predictions of the UCLA (blue), Jetset/Pythia (red), and HERWIG (green) fragmentation models.

in the form of differential particles multiplicities $((1/N_{evt}) dN/dz)$ and in the form of differential cross sections $((1/\sigma_{had}) d\sigma/dz)$, respectively. The results presented in this section are compiled from earlier results leading to these publications. The measured particle spectra normalized to the number N_{evt} of hadronic events are shown as a function of z in Figs 24.1.2 and 24.1.3 with linear and logarithmic vertical scales, respectively. The measured η spectrum covers almost full kinematic range, and the others cover the range of z from around 0.1 for pions and kaons and 0.15 for protons to the kinematic limit, which includes the bulk of the kaon and proton spectra, as well as the peak and high side of the pion spectrum. The only previous measurements at a nearby energy, from the AR-GUS experiment at $\sqrt{s} = 9.98$ GeV (Albrecht et al., 1989a, 1990b), are also shown in Fig. 24.1.2. Only statistical errors are shown for the *BABAR* data, as the correlated 3-6% systematic uncertainties are dominated by normalization. The results from the three experiments are in fair agreement within uncertainties, and the *B* Factory results are far more precise in most ranges and extend the coverage significantly when compared with previous experiments. For pions, the total uncertainties are comparable and are correlated over significant z ranges in the *BABAR* and AR-GUS cases while they are significantly more precise in the Belle case. The ARGUS data extend to lower z values, so that the majority of the spectrum is covered between the three experiments. At low z, *BABAR* and ARGUS data sets differ by up to $(7 \pm 4)\%$, which might indicate the expected small scaling violation.

Figure 24.1.3 compares the *BABAR*, Belle and ARGUS multiplicities with the predictions of the three fragmentation models discussed above. Default parameter values are used, which have been chosen based on previous data, mostly at higher energies. The shape of the bulk of the $\pi^{\pm}$ spectrum is described qualitatively by all three models, but no model describes the spectrum well in detail. Jetset/Pythia and UCLA also describe the $K^{\pm}$ cross section reasonably well, whereas HERWIG peaks at lower z value. Jetset and UCLA also describe the η cross section fairly well, though UCLA's spectrum is slightly too soft and Jetset's spectrum predicts higher multiplicity than the data both around the peak and at very high z values. HERWIG's spectrum shape does not agree with the data. The proton spectrum is quite problematic: Jetset describes the shape qualitatively, but is consistently above the data (*i.e.* predicts higher multiplicity); UCLA describes the shape in the peak region, but then falls much too slowly, rising above the data at high z; HERWIG also describes the shape in the peak region, but is far too high overall and exhibits an experimentally unobserved structure at high z values.

Similar deficiencies in these models have been reported at higher energies (Abe et al., 1999; Abreu et al., 1998; Aihara et al., 1988; Akers et al., 1994a; Braunschweig et al., 1989; Buskulic et al., 1995; Itoh et al., 1995), although earlier MC versions were used and parameter values varied. One should note that the deviations of predictions from the data had the same sign at higher energies, suggesting that the scaling properties might be well simulated.
Figure 24.1.4. $\pi^\pm$, $K^\pm$, $p/\bar{p}$ and η multiplicities measured at three different CM energies, compared with the predictions of the simulations described in the text. *BABAR* data are from Muller (2004).

To test the scaling properties of the models, each was run with its current default parameters at various energies and compared with the available data.

Figure 24.1.4 shows a scaling test of the `Jetset` model using $\pi^\pm$ cross sections from *BABAR*, TASSO (Braunschweig et al., 1989) and SLD (Abe et al., 1999). The latter two experiments provide the best precision and/or high-z coverage at $\sqrt{s}$ near 30 GeV and at the Z^0, respectively. Data from other experiments are consistent and yield the same conclusions. Strong scaling violations are evident, both at low z due to the pion mass and at high z from the running of the strong coupling α_s. `Jetset` provides an excellent description of all three data sets, with differences of only few percent at very low and very high z values. `UCLA` and `HERWIG` also describe the scaling violation well, although they do not reproduce the spectrum as well at any energy.

Figure 24.1.4 also shows a similar test of the `UCLA` model for $K^\pm$ cross sections. `UCLA` describes the *BABAR* and Belle results best, and similar scaling is predicted by the other models. Here, the different flavor composition of the three samples modifies the expected scaling violation. Charged kaons from $b\bar{b}$ events, which are absent from the *BABAR* data, raise the TASSO cross section in the 0.1–0.3 region, but do not contribute at high z. At the Z^0, the relative production of up- and down-type quarks changes dramatically, and the larger $b\bar{b}$ and $s\bar{s}$ event fractions raise the simulated cross section to nearly the same level as at 35 GeV for z above about 0.2. The flavor dependence has been shown (Abe et al., 1999; Abreu et al., 1998) to be modeled at the Z^0 at the level of about 10%. The change

in the measured cross sections is about 15% less than predicted, but this could be due to issues with the flavor dependence.

Similar results are obtained for the η meson from ALEPH and L3 data at 91 GeV (Adriani et al., 1992; Barate et al., 2000), and compared with the `Jetset` predictions. Again, other data and models give the same conclusions. The flavor dependence is smaller, and the discrepancy at the Z^0 is larger than for $K^\pm$, perhaps indicating a failure of the models.

For protons, also shown in Fig. 24.1.4, the `Jetset` model is tested with one parameter value changed, the probability for a given string break to produce a diquark-antidiquark, rather than quark-antiquark, pair, from 0.1 to 0.085, which provides a good description of the higher-energy data. Here, the simulated high-x_p scaling violation between 10.54 and 34 GeV is about the same as for the pions, but that between 34 and 91 GeV is slightly larger since fast protons are expected to be produced predominantly in $u\bar{u}$ and $d\bar{d}$ events. The prediction for 10.54 GeV rises well above the *BABAR* data, exceeding it by as much as a factor of 4.5 at $z = 0.9$. Similar behavior is seen for `Jetset` with default parameters, `HERWIG`, and `UCLA` at high x_p. This indicates that we do not understand the scaling properties of protons, or perhaps of baryons or heavier hadrons in general.

These data can be used to test the predictions of MLLA QCD combined with the ansatz of LPHD (Azimov, Dokshitzer, Khoze, and Troyan, 1985), by transforming to the variable $\xi = \ln(\sqrt{s}/2p^*)$. This representation emphasizes the low momentum region (large ξ). It is predicted that: the ξ distribution would be approximately Gaussian over a range of ~ 1 unit around it's peak position ξ^*; a distorted Gaussian should describe the distribution over a wider range; ξ^* should decrease exponentially with hadron mass at a given CM energy $\sqrt{s}$ and ξ^* should increase logarithmically with $\sqrt{s}$ for a given hadron. Conventionally, ξ^* is found by fitting a Gaussian distribution to the data over sets of points within 0.5–1 units of the approximate peak position. Next, the widest roughly symmetric range about this position is found in which a Gaussian fit gives a good χ^2, and this range is then extended as far as possible in one direction. Results of such fits and the ranges are listed in Table 24.1.1. Acceptable fits were found over ranges at least 1 unit wide, consistent with the prediction.

Table 24.1.1. Results of the Gaussian and distorted Gaussian (where a skewness term and a kurtosis term are added) fits to the ξ distributions. The fit ranges and the peak positions ξ^* are reported (Muller, 2004).

Particle	Gaussian		Distorted Gaussian	
	Fit range	ξ^*	Fit range	ξ^*
$\pi^\pm$	1.7 - 3.0	2.36 ± 0.01	0.0 - 3.2	2.36 ± 0.01
$K^\pm$	1.0 - 2.2	1.64 ± 0.01	0.0 - 3.2	1.64 ± 0.01
η	0.9 - 2.2	1.48 ± 0.02		
$p/\bar{p}$	1.0 - 2.2	1.61 ± 0.01	0.0 - 2.8	1.61 ± 0.01

Table 24.1.2. The fraction of each particle's spectrum covered by the *BABAR* (Muller, 2004) measurement is given in the second column. The total multiplicity per $e^+e^- \to q\bar{q}$ event at 10.54 GeV measured by *BABAR* in the third column are compared with the predictions of fragmentation models and previous results from CLEO (at 10.49 GeV; Behrends et al., 1985) and ARGUS (at 9.98 GeV; Albrecht et al., 1989a). The first error on each *BABAR* result is experimental and the second is from the extrapolation procedure.

Particle	Coverage	*BABAR*	Jetset	UCLA	HERWIG	CLEO	ARGUS
$\pi^{\pm}$	0.878 ± 0.015	$6.405 \pm 0.134 \pm 0.106$	6.22	6.44	6.31	8.3 ± 0.4	6.38 ± 0.12
$K^{\pm}$	0.985 ± 0.006	$0.910 \pm 0.017 \pm 0.006$	0.934	1.010	1.010	1.3 ± 0.2	0.888 ± 0.030
η	1.0	$0.276 \pm 0.017 \pm 0.000$	0.354	0.278	0.233	–	0.19 ± 0.06
$p/\overline{p}$	0.966 ± 0.008	$0.235 \pm 0.011 \pm 0.002$	0.336	0.217	0.46	0.40 ± 0.06	0.271 ± 0.018

Table 24.1.1 reports also the results of the fits performed adding small skewness s and kurtosis κ terms to the Gaussian distribution.

$$G'(\xi) = \frac{N}{\sigma\sqrt{2\pi}} \exp\left(\frac{\kappa}{8} + \frac{s\delta}{2} - \frac{(2+\kappa)\delta^2}{4} + \frac{s\delta^3}{6} + \frac{\kappa\delta^4}{24} \right),$$
(24.1.9)

where $\delta = (\xi - \xi^*)/\sigma$, σ is the square root of the variance. The fitted ranges are significantly larger, consistent with the MLLA QCD prediction. The values of ξ^* measured by *BABAR* and previous experiments at higher energies for the different particles are shown in Fig. 24.1.5. The lines simply connect the precise points at the Z^0 with those from *BABAR*. The other data points are consistent with these lines, and hence with the expected logarithmic energy dependence, but more precise data at other energies are needed to test this prediction. There is a clear difference between the pions and kaons that increases slowly with energy; the values for η (measured only at *BABAR* and at the Z^0), are slightly below those for $K^{\pm}$. However, the proton data are inconsistent with an overall decrease with hadron mass.
Figure 24.1.5. Peak position ξ^* vs e^+e^- CM energy for charged pions, kaons, and protons from various experiments. The lines connect the precise points at the Z^0 with those from *BABAR* (Muller, 2004).

Total multiplicities of each particle type per event are calculated by integrating the differential rates, taking all uncertainties and their correlations into account, and extrapolating into any unmeasured regions. The second step is model dependent: correction factors are evaluated using a combination of the three models and a number of fits to the ξ distributions, and have large uncertainties when substantial fractions of the spectrum are not measured. The η spectrum is measured over the full kinematic range, so this is not an issue. The good coverage for kaons and protons makes their corrections and their uncertainties fairly small. The coverage for pions at low momenta does not extend much below the peak (see Fig. 24.1.2), requiring large correction and giving the dominant uncertainty. The correction factors and the total rates are listed in Table 24.1.2, along with previous results from CLEO (Behrends et al., 1985) and ARGUS (Albrecht et al., 1989a) and the predictions of the three models. *BABAR* and AR-GUS results are in good agreement, while CLEO measures significantly higher rates for all particle types.

Differential production ratios for pairs of particles are sensitive to specific features of the hadronization process, and many of the systematic uncertainties cancel at least partially. It is equivalent and conventional to report the fractions f_π, f_K and f_p of all charged hadrons that are pions, kaons and protons, respectively. Pions dominate the charged hadron production at low z, as is expected from their lower mass and the contributions from many decays of heavier hadrons. As z increases, the pion fraction drops as the kaon and proton fractions rise toward values of about 35% and 8%, respectively. At higher z, the trend reverses due to kinematics, especially for protons which must be produced along with an anti-baryon. The three models describe the general trend of the data, but none describes either the shape or the magnitude at all momenta.

Global analysis for fragmentation functions

Since there were measurements of the multiplicities given by Eq. (24.1.1) at various facilities, global analyses have been made using the available world data. From the analyses, the optimum FFs were determined, and even their uncertainties were estimated.

In the same way as global analyses for the parton distribution functions are determined, the FFs are expressed in terms of a number of parameters at the initial scale Q^2 ($\equiv Q_0^2$). Usually, a simple polynomial form is used:

$$D_i^h(z, Q_0^2) = N_i^h z^{\alpha_i^h} (1 - z)^{\beta_i^h}, \qquad (24.1.10)$$

because the functions should vanish at $z = 1$. Here, N_i^h, α_i^h, and β_i^h are parameters to be determined by a χ^2 minimization of $e^+ + e^- \to h + X$ data. The initial scale Q_0^2 is arbitrary. However, it is, for example, assumed that $Q_0^2 = 1\,\text{GeV}^2$ for light quark and gluon functions, and above the mass thresholds m_c^2 and m_b^2 for charm and bottom functions, where m_c and m_b are charm- and bottom-quark masses, respectively. For light hadrons (h), one typically separates pions ($\pi^+ + \pi^-$), kaons ($K^+ + K^-$), and protons/anti-protons ($p + \bar{p}$). Because the second moments M_i^h should satisfy the sum rule of Eq. (24.1.6), it is useful to take M_i^h as one of the parameters instead of N_i^h. The parameters are related with each other by the relation

$$N_i^h = \frac{M_i^h}{B(\alpha_i^h + 2, \beta_i^h + 1)}, \qquad (24.1.11)$$

where $B(\alpha_i^h + 2, \beta_i^h + 1)$ is the beta function.

In analyzing the light hadrons, a common function is assumed for favored fragmentation functions (see Section 24.1.1) from up and down quarks while different parameters are allowed for a favored FF from a strange quark by considering the mass difference. Also different parameters are assigned for disfavored FFs. A flavor symmetric form is assumed for disfavored FFs from light quarks (up, down, and strange quarks) due to lack of experimental information, although the light antiquark distributions are not flavor symmetric in the unpolarized parton distribution functions (Kumano, 1998).

In Fig. 24.1.6, FFs for $(\pi^+ + \pi^-)/2$ determined by "HKNS" (Hirai, Kumano, Nagai, and Sudoh, 2007a,b) are shown, together with other parameterizations: "KKP" (Kniehl, Kramer, and Potter, 2000), "Kretzer" (Kretzer, 2000), "AKK" (Albino, Kniehl, and Kramer, 2005, 2008), and "DSS" (de Florian, Sassot, and Stratmann, 2007a,b; Epele, Llubaroff, Sassot, and Stratmann, 2012). Since neither BABAR and Belle results have been published at the time of this analysis, they were not yet taken into account. These functions were obtained in the NLO ($\overline{\text{MS}}$) scheme and the uncertainty bands were obtained in the HKNS analysis by using the Hessian method (Pumplin, Stump, and Tung, 2001). The gluon and light-quark functions are shown at $Q^2 = 2\,\text{GeV}^2$, where the uncertainties are generally large. The charm- and bottom-quark functions are shown at the scale of their mass thresholds $Q^2 = m_c^2$ or m_b^2. Disfavored-quark and gluon functions, for example s-quark functions of Kretzer and AKK, are completely different between the analysis groups; however, they agree within the uncertainties. One can notice that the disfavored-quark and gluon FFs have large uncertainties, which should be significantly improved by the recently published Belle and BABAR measurements once
Figure 24.1.6. Determined fragmentation functions for the pion and their comparison with other parameterizations (Hirai, Kumano, Nagai, and Sudoh, 2007a,b). The shaded bands indicate estimated uncertainties of the HKNS.

they are included. There are available codes from the different analysis groups for calculating the FFs at a given kinematical condition of z and Q^2. A summary of the status of the various FFs is given by Albino et al. (2008); an online generator is provided by Arleo and Guillet (2008). Recent works on the analyses of the FFs can be found in Christova and Leader (2009) and Albino and Christova (2010).

The favored and disfavored FFs reflect internal flavor content of a hadron, which leads to an interesting suggestion that exotic hadrons could be found by investigating their FFs (Hirai, Kumano, Oka, and Sudoh, 2008). As an example, internal structure of the controversial $f_0(980)$ meson, which is possibly $q\bar{q}$ or tetra-quark ($qq\bar{q}\bar{q}$), could be determined if accurate data become available. For example, a future super flavor factory with forty times higher luminosity could provide the accurate information needed to distinguish the disfavored functions from the favored ones of the f_0 meson.

24.1.2.2 Charmed hadrons

Belle and BABAR have measured fragmentation functions for several charmed hadrons, the heaviest particles avail-

able for study below the $\Upsilon(4S)$. These are generally expressed in terms of $x_p = p^*/p_{max}$, where $p_{max} = \sqrt{s/4 - m_h^2}$ is the maximum momentum for production via the $e^+e^- \to q\bar{q}$ process. In this variable, all hadrons have the same kinematic range, $0 \le x_p \le 1$. In B Factories where pairs of B mesons decay nearly at rest in the CM system the x_p for hadrons from B decay cannot exceed 0.5 Charmed hadrons must be reconstructed in a particular decay mode. By convention, an analysis is described for a particular hadron and decay mode, but the inclusion of the charge conjugate state and decay mode is always implied.

Belle (Seuster, 2006) have studied several charmed mesons, the ground state D^0, $D^\pm$, $D_s^\pm$ and the excited D^{*0} and $D^{*\pm}$, as well as the lowest-mass charmed baryon $\Lambda_c^\pm$. Events are selected by requiring at least three charged tracks and a calorimeter energy sum between 10% and 80% of the CM energy. There are also requirements on the average cluster energy, the invariant mass of the particles in each thrust hemisphere, and the position of the event vertex. This selection is 87% efficient for $c\bar{c}$ events. Charged tracks are required to be consistent with originating from the event vertex, and are identified as $\pi^\pm$, $K^\pm$ or $p\bar{p}$ using a combination of information from the drift chamber, time-of-flight and Cherenkov systems (see Chapter 5). A loose selection is used, in which identification efficiencies are above 95% (80% for protons) and misidentification rates are at most 26% (7%). Candidate π^0 mesons are formed from pairs of photon candidates with energy above 30 MeV and invariant mass near the π^0 mass.

Candidate $D^0 \to K^-\pi^+$ decays are formed by combining an identified K^- with an identified π^+. Similarly, $D^+ \to K^-\pi^+\pi^+$ and $\Lambda_c^+ \to pK^-\pi^+$ candidates are formed by combining three identified tracks, and $D_s^+ \to K^+K^-\pi^+$ candidates are selected in which the K^+K^- combination has an invariant mass within 7 MeV/c^2 of the nominal ϕ meson mass. Candidates of each type are binned in x_p, and the number of true charmed hadrons in each bin is estimated by fitting their invariant mass distribution in the region near the relevant hadron mass.

Candidate $D^{*+} \to D^0\pi^+$ decays are formed from those D^0 candidates with an invariant mass within 15 MeV/c^2 of the nominal D^0 mass, combined with each slow, positively charged track, assumed to be a π^+. Similarly, $D^{*+} \to D^+\pi^0$ and $D^{*0} \to D^0\pi^0$ candidates are formed from D candidates with a mass within 15 MeV/c^2 of the relevant nominal mass, combined with a soft π^0 candidate. These D^* candidates are binned in x_p, and the number of true D^* mesons in each bin is extracted from a fit to the distribution of the mass difference Δm between the D^* and D candidates. Since the true mass difference is close to threshold, Δm has better resolution than any individual invariant mass. The yields are divided by the reconstruction efficiency and the relevant branching fraction(s) to give differential cross sections as functions of x_p.

BABAR have studied the charmed baryons $\Lambda_c^\pm$ (Aubert, 2007p), Ξ_c^0 (Aubert, 2005z), Ω_c^0 (Aubert, 2007ao), containing zero, one and two strange valence quarks, respectively, in addition to the charm quark. Since charmed

baryons can only be produced in $e^+e^- \to c\bar{c}$ events, there is no event selection other than the requirement of enough tracks in the event to reconstruct the particle in question in its target decay mode.

The $\Lambda_c^\pm$ study uses a sample of 9.5 fb^{-1} of off-resonance data and reconstructs the 3-body decay mode $\Lambda_c^+ \to pK^-\pi^+$. High quality tracks are selected and identified as described in Section 24.1.2.1. Each set of an identified p, K^- and π^+ is considered a Λ_c^+ candidate, and each track's momentum at its point of closest approach to the beam axis is corrected for energy loss using the correct mass. The invariant mass is calculated with a resolution that varies from 3.75 MeV/c^2 at low x_p to 5.75 MeV/c^2 at high x_p.

The reconstruction efficiency varies rapidly near the edges of the detector acceptance, so a tight fiducial requirement is made that the polar angle of the $\Lambda_c^\pm$ candidate θ_Λ in the e^+e^- CM frame satisfies $-0.7 < \cos\theta_\Lambda < 0.2$ This rejects all candidates in regions with efficiency below 5%, including those with momentum below 0.7 GeV/c in the laboratory frame. A feature of the boosted CM system is that soft $\Lambda_c^\pm$ are boosted forward in the laboratory and often have all three decay tracks within the acceptance, giving access to the full range of x_p with good efficiency and resolution. The efficiency for low-(high-)x_p $\Lambda_c^\pm$ averages to 8% (17%).

In order to reduce model dependence, each candidate is given a weight equal to the inverse of its efficiency. The distribution of weighted invariant mass is then fitted in several bins of x_p to extract a signal yield. Comparisons of results for Λ_c^+ and $\overline{\Lambda_c^-}$ and of results from different regions of $\cos\theta_\Lambda$ provide powerful consistency checks and constraints on systematic errors.

The Ξ_c^0 study uses a sample of 10.7 (105.4) fb^{-1} of off-(on-)resonance data and reconstructs the two decay modes $\Xi_c^0 \to \Omega^-K^+$ and $\Xi^-\pi^+$, where $\Omega^- \to \Lambda^0K^-$, $\Xi^- \to \Lambda^0\pi^-$ and $\Lambda^0 \to p\pi^-$. Identified protons are combined with negatively charged tracks, assumed to be pions, to form Λ^0 candidates. Those with an invariant mass within 3σ, where σ is the fitted mass resolution, of the nominal Λ^0 mass, are accepted, and a kinematic fit is performed to each pair of tracks, in which their mass is constrained to the nominal value. Each of these reconstructed Λ^0 objects is then combined with all identified K^- to form Ω^- (Ξ^-) candidates. Again, those with an invariant mass within 3σ of the nominal value are accepted, and subjected to a mass constrained fit (see Section 6.3). They are then combined with identified K^+ to form Ξ_c^0 candidates.

The position of the fitted Ω^- (Ξ^-) decay vertex must be at least 1.5 mm (2.5 mm) from the beamline, and the Ω^- and Λ^0 decay vertices must be separated by at least 3 mm. The Ξ^- vertex must be farther from the beamline than the Λ^0 vertex, and the scalar product of the Λ^0 momentum vector and the displacement vector from its production vertex to its decay vertex must be positive. The surviving Ξ_c^0 candidates are binned in x_p, and signal yields are extracted by counting those with invariant mass in a signal window about the nominal Ξ_c^0 mass and subtracting backgrounds estimated from mass sidebands. The

yields are divided by the simulated efficiency in each bin to give differential cross sections. Measurements are made using the on-resonance data for x_p above 0.46, to remove the contribution of B decays to Ξ_c production. [181] Below the kinematic limit, the off-resonance data must be used, but are statistics limited and consistent with zero.

The Ω_c^0 study uses a sample of 21.6 (208.9) fb^{-1} of off-(on-)resonance data and reconstructs the four decay modes $\Omega_c^0 \to \Omega^- \pi^+$, $\Omega^- \pi^+ \pi^0$, $\Omega^- \pi^+ \pi^- \pi^+$, and $\Xi^- K^- \pi^+ \pi^+$. Candidate Ω^- and Ξ^- hyperons are reconstructed as above, with slightly different selection criteria. Photon clusters with energy above 80 MeV are paired, and those with total energy above 200 MeV and invariant mass in the range 120-150 MeV/c^2 are retained as π^0 candidates. The Ω^- and Ξ^- candidates are then combined with identified $\pi^\pm$, K^- and π^0 candidates to form Ω_c candidates in the four modes.

A likelihood is formed from the simulated signal and background distributions of: the flight distance of the Ω^- or Ξ^- divided by its uncertainty; its momentum in the CM frame; the total momentum recoiling against it in the CM frame; and the π^0 momentum in the laboratory frame. This likelihood must exceed a threshold that depends on momentum. The surviving Ω_c^0 candidates are binned in x_p, and signal yields are extracted and divided by the simulated efficiency. Measurements are made only for on-resonance data, assumed to be free from $B\overline{B}$ events above the kinematic limit of 0.44. The off-resonance data are statistics limited and consistent with zero below this momentum. There is a normalization uncertainty of 6.5%, and the statistical uncertainties are much larger than the remaining systematic uncertainties.

Results

The differential cross sections measured for several charmed hadrons are shown as a function of x_p in Fig. 24.1.7 and are not corrected for branching ratios into the displayed decay channels. Those for the Ξ_c and Ω_c are for on-resonance data, and the low-x_p regions left of the vertical lines are dominated by $B\overline{B}$ decays. D_s^+ mesons were also studied earlier in Aubert (2002d) but due to lack of numerical values for individual x_p bins they were not included in this figure. These are first measurements for the D_s^+, Ξ_c, and Ω_c; the others are consistent with previous measurements, but much more precise, except for similarly precise $D^{(*)0}$ and $D^{(*)+}$ results from CLEO. The Λ_c^+ spectra from Belle and *BABAR* are consistent.

In all cases, the cross section is very low at low x_p, rises steadily toward a broad peak near 0.6, then drops to zero as $x_p \to 1$. The contrast between this shape and those for the $\pi^\pm$, $K^\pm$ and $p/\overline{p}$ seen above is both striking and expected. The position of the peak at rather high x_p is due to the large charm quark mass, and the low values at

low x_p is consistent with leading charmed hadrons from $e^+e^- \to c\overline{c}$ events being dominant.

A few $D^{(*)}$ mesons are observed with x_p very near (and above) unity. These are due to the exclusive processes $e^+e^- \to D^{(*)}\overline{D}^{(*)}$, involving several combinations of ground state and excited D mesons. Such events are interesting in their own right, but are a small minority, and not considered to be from the jet fragmentation process. There is no sign of the exclusive production of a charmed baryon and antibaryon.

The D^{*0} and D^{*+} spectra are consistent with each other, as expected due to the isospin symmetry and due to the fact that the mass difference amounts to only 3 MeV/c^2. They are similar in shape to the D^0 and D^+ spectra, but shifted to higher x_p values by about 0.04 units, as expected since the D^{*0} mesons are 40 MeV/c^2 heavier. The D^0 is produced twice as often as the D^+ and its spectrum peaks at a slightly lower x_p than the D^+ spectrum. This is due to the fact that the D^{*0} is too light to decay into $D^+\pi^-$, so its decays produce more D^0 mesons with a softer spectrum.

The D_s^+ accounts for 10% of the ground state mesons and their spectrum is both more strongly peaked and peaks at higher x_p than any of the D or D^* spectra. This is not expected in current fragmentation models. The Ξ_c and Λ_c spectra have similar shapes, with the Ξ_c spectrum shifted toward higher x_p values, as shown in Fig. 24.1.7. The Ω_c spectrum is consistent with similar behavior, but statistics are low. From the distributions it is also clear that the baryon spectra have different shapes from the meson spectra: they are more sharply peaked, and fall to zero more rapidly at high x_p. Also, the meson and baryon spectra peak in the same region of x_p, even though the baryons are much heavier. Such differences are predicted by some fragmentation models.

The total cross sections for the continuum production $e^+e^- \to X_cY$ are summarized in Table 24.1.3.

Several fragmentation models exist with different assumptions on the functional form in the fractional energy z and the transverse momentum relative to the initial parton.

Belle tested the models by Bowler (1981), Lund (Andersson, Gustafson, Ingelman, and Sjöstrand, 1983), "KLP" (Kartvelishvili, Likhoded, and Petrov, 1978), "CS" (Collins and Spiller, 1985), and Peterson (Peterson, Schlatter, Schmitt, and Zerwas, 1983). The model predictions were tested against both Λ_c^+ and meson spectra, and several model parameters were optimized in order to achieve a better agreement. No model gives a good χ^2 for all of the spectra, but for most mesons, Bowler and Lund give reasonable qualitative descriptions, KLP and CS are somewhat worse, and Peterson is quite poor. Consequently, the Belle data ruled out the Peterson model which was widely used before while KLP and CS are rather disfavored. In both the `Jetset` (Lund) and `UCLA` models, the fitted parameter values differ substantially from the default values which give the best description of lighter hadron data.

---

[181] The maximal momentum of Ξ_c^0 in a B meson decay conserving the baryon number would be achieved in a 2-body $B \to \Xi_c^0 \overline{p}$ decay and would correspond to $x_p = 0.41$ for Ξ_c^0.
Figure 24.1.7. Fragmentation functions times branching ratios for charmed mesons and baryons as a function of the fractional momentum x_p. The Belle measurements (Seuster, 2006) are displayed in blue (triangles), while the *BABAR* measurements (Aubert, 2005z, 2007p,ao) are displayed in red (circles). Some measurements were performed on the $\Upsilon(4S)$ resonance and therefore contain B decays at x_p values below the vertical lines displayed.

The models have also been tested directly against the data in *BABAR* for the Λ_c^+ spectrum (Aubert, 2007p). Eight models are tested within `Jetset` by re-weighting with varying parameter values so as to minimize the χ^2 of a comparison with the data. The `UCLA` model (Chun and Buchanan, 1998) is fitted similarly, whereas `HERWIG` (Marchesini et al., 1992) has no relevant free parameters. In general, the fitted parameters are different between mesons and baryons, and between light and heavy hadrons.

These results indicate the need for different treatment of heavier hadrons and provide new, precise input for the

development and tuning of such models. One has to keep in mind, however, that models contain a relatively large number of parameters which might affect the light and heavy hadron fragmentation descriptions.

$\Lambda_c^+ \bar{\Lambda}_c^- X$ Events

BABAR has studied events containing both a Λ_c^+ and a $\bar{\Lambda}_c^-$ (Aubert, 2010b), following a study by the CLEO collaboration (Bornheim et al., 2001). CLEO found ~4 times

Table 24.1.3. The total production cross-sections from Belle (Seuster, 2006) and BABAR (Aubert, 2002d, 2007p) for $e^+e^- \to X_cY$ (or Λ_c^+X). The uncertainties are statistical, systematic and the uncertainty due to the knowledge of the branching ratios at the time of the measurement. The branching fractions used in Belle and BABAR measurements are listed in second rows of results. Older measurements by CLEO (Artuso et al., 2004; Bortoletto et al., 1988) are also given taking into account the world average of the respective product branching fractions at the time of the Belle publication.

more events than expected from the Jetset model, in which the Λ_c^+ and $\overline{\Lambda}_c^-$ are always accompanied by an antibaryon and baryon in their respective jets (4−baryon events). They interpreted this excess as evidence for a long-range baryon number correlation, but could not exclude either 4-baryon events or few-body processes, such as charmed pentaquark pair production, as a possible production mechanism.

Candidate Λ_c^+ are reconstructed in the $pK^-\pi^+$ (as in the BABAR study of inclusive Λ_c^+ production described above) and pK_S^0 decay modes. Additional decay modes were considered, but did not improve the result. Events with both a Λ_c^+ and $\overline{\Lambda}_c^-$ candidate with invariant mass within 190 MeV/c^2 of the nominal Λ_c^+ mass are selected if the opening angle between their momenta is over 90°.

The invariant mass distributions of the candidates and the two-dimensional distribution of the $\overline{\Lambda}_c^-$ vs. Λ_c^+ candidate masses are shown in Fig. 24.1.8. There are clear vertical and horizontal bands corresponding to single Λ_c^+ and $\overline{\Lambda}_c^-$ production, respectively, and an enhancement where they overlap. The signal region is considered by a circle of 12 MeV/c^2 radius around the two nominal masses, events well outside the two bands are used to characterize the combinatorial background, and events within the bands to characterize the background from events with either a real Λ_c^+ or a real $\overline{\Lambda}_c^-$. Of the 919 entries in the signal circle, 649 ± 31 are estimated to be $\Lambda_c^+\overline{\Lambda}_c^- X$ events.

If the charmed and anticharmed hadrons in a $c\bar{c}$ event are uncorrelated, then roughly 155 signal events would be expected, given the numbers of $c\bar{c}$ events in the sample
Figure 24.1.8. (a) Invariant mass distributions for $\Lambda_c^+ \to pK^-\pi^+$ (gray) and $\Lambda_c^+ \to pK_S^0$ (black) candidates in events with both a Λ_c^+ and a $\overline{\Lambda}_c^-$ candidate. (b) Invariant mass of the $\overline{\Lambda}_c^-$ candidate vs. that of the Λ_c^+ candidate, in 5 MeV/c^2 × 5 MeV/c^2 bins (Aubert, 2010b).

and reconstructed $\Lambda_c^+/\overline{\Lambda}_c^-$. This estimate is independent of the branching fractions and average reconstruction efficiencies, but has ∼30% model dependence in the correlation between the two efficiencies in an event. Fragmentation models predict a 10–15% suppression of such events, due to the combined mass of the four baryons. The observed number of events is well above 155, by a factor of 4.2, consistent with the ratio reported by CLEO.

The additional tracks, not from the Λ_c^+ or $\overline{\Lambda}_c^-$ decay, are studied in order to characterize these events. The distribution of their multiplicity is shown in Fig. 24.1.9(a),
Figure 24.1.9. Background-subtracted distributions for $\Lambda_c^+ \overline{\Lambda}_c^- X$ events of (a) the numbers of additional tracks in the event and those identified as $K^\pm$ or $p\overline{p}$, and (b) the missing mass in the event, with imaginary masses given negative real values. Most events have no identified $K^\pm$ or $p\overline{p}$, and the corresponding zero-multiplicity points are off the vertical scale in (a) (Aubert, 2010b).

along with those of identified $K^\pm$ and $p/\overline{p}$. The distribution of the missing mass per event is shown in Fig. 24.1.9(b), and can accommodate very few events with both a neutron and an antineutron. This, along with the small number of identified protons (anti-protons), leads to the conclusion that 4-baryon events are suppressed much more strongly than in the models, and that the selected sample is dominated by a new type of event containing a charmed baryon, a charmed antibaryon, several mesons, and no other (anti)baryons.

The events containing an identified $p\overline{p}$ are used to estimate and subtract the contribution from 4-baryon events, and the features of the remaining 619 ± 39 events are studied. The broad multiplicity distribution and the distributions of energies, (transverse) momenta and rapidities of both the $\Lambda_c^+/\overline{\Lambda}_c^-$ and the additional tracks are similar to those in all hadronic events, the single-$\Lambda_c^+/\overline{\Lambda}_c^-$ sidebands, and models. Correcting for the decays of known heavier charmed baryons and tracking efficiency, an average of 2.63 ± 0.21 tracks per event is estimated. These tracks are combined, and only very small signals for K_S^0, K^{*0} and ρ mesons are observed. Along with the small number of $K^\pm$ observed, this indicates that fewer strange and vector mesons are produced than in normal fragmentation. Assuming that about half as many π^0 as $\pi^\pm$ are produced, which is consistent with the missing mass and total energy distributions, there is an average of about 4 additional mesons in these events.

It can be concluded that these events are indeed from a fragmenting $c\overline{c}$ system with a long-range baryon number correlation. Such events are not produced by `Jetset` or `HERWIG`. They are produced by `UCLA`, which also predicts an enhanced rate and suppressions of kaons and vector mesons. However, the predicted enhancements and suppressions are all of the wrong size, and the multiplicity distribution has the wrong shape and average value.

24.1.3 Polarized fragmentation functions

A second class of fragmentation functions depends on the spin of the fragmenting parton. In particular, in the case of transverse quark polarization this opens up a powerful tool to use such spin dependent fragmentation functions as an analyzer of transverse quark polarization in the nucleon, transversity. Transversity can be defined as the number density of transversely polarized partons inside a transversely polarized nucleon. It is a chiral odd distribution function, which means that there are mixed left-handed and right-handed quark fields and because of this spin-flip has been hard to access. The integrated transversity distribution provides the tensor charge of the nucleon, a fundamental charge just like the electric or the axial charge. In the non-relativistic case, the axial charge and the tensor charge are identical. Before the advent of spin dependent fragmentation functions the access to the transverse quark polarization of the nucleon was only possible via the Drell Yan process (Ralston and Soper, 1979). The reason is that the chiral-odd transversity parton distribution function needs to couple with another chiral-odd function to become observable as QCD conserves chirality. In the Drell Yan process that could be the antiquark transversity distribution from the second nucleon. In contrast, in the deep inelastic scattering process (DIS), which is the most abundant source for unpolarized and longitudinally polarized distribution functions of the nucleon transversity is not directly accessible. Using chiral-odd, transverse quark spin dependent fragmentation functions, it became possible to access quark transversity in transversely polarized semi-inclusive deep inelastic scattering (SIDIS) processes as well as in transversely polarized proton-proton collisions. In these cases one chiral-odd distribution function and one chiral-odd fragmentation function make the process chiral-even and thus observable. The e^+e^- annihilation process allows one to cleanly study the fragmentation functions, including the transversely polarized fragmentation functions. However, due to the chiral-odd nature of this FF, one needs to couple it with another chiral-odd object, which in this case is a second chiral-odd fragmentation function. One therefore measures the product of two chiral-odd fragmentation functions, one related to the quark side and the other to the antiquark side. This combination of two chiral-odd fragmentation functions can be understood by the requirement that the initial quark-antiquark pair has its spins transverse to their momentum. Since this orientation is not directly observable, one can use the chiral-odd fragmentation function on one side to fix the spin direction via its spin dependence and analyze the other side with the second chiral-odd fragmentation function. The most prominent chiral-odd fragmentation functions are the Collins FF and the interference fragmentation function (IFF) which will be described below in Sections 24.1.3.1 and 24.1.3.2 respectively. Both were only proposed during the 90's and they remained unmeasured until recent transversely polarized DIS measurements (Airapetian et al., 2005, 2008; Alexakhin et al., 2005) and the B Factories' (Abe, 2006a) measurements.

24.1.3.1 Collins fragmentation function

The most prominent transverse spin dependent fragmentation function is the Collins fragmentation function, $H_{1,q}^{\perp}(z, P_{h\perp})$, which Collins (1993) initially suggested as a possible way to explain the surprisingly large single spin asymmetries seen by the E704 experiment (Adams et al., 1991) in transversely polarized pp collisions. The Collins fragmentation function translates the transverse spin of a quark $\mathbf{S}_q$ with momentum $\mathbf{k}$ into the azimuthal yield of final state hadrons with transverse momentum $\mathbf{P}_{h\perp}$ and fractional energy z. According to the Trento conventions (Bacchetta, D'Alesio, Diehl, and Miller, 2004) the overall number density for finding a hadron h (with mass M_h) produced in the process $q^{\uparrow} \to hX$ can be defined as:

$$D_{q^{\uparrow}}^{h}(z, P_{h\perp}^2) = D_{1,q}^{h}(z, P_{h\perp}^2) + H_{1,q}^{\perp h}(z, P_{h\perp}^2) \frac{(\hat{\mathbf{k}} \times \mathbf{P}_{h\perp}) \cdot \mathbf{S}_q}{zM_h},$$

$$(24.1.12)$$

where the first term is the unpolarized fragmentation function described in Section 24.1.2.1 before integration of the transverse momentum. The second term contains the Collins function $H_{1,q}^{\perp h}(z, P_{h\perp}^2)$ and correlates the spin orientation of the quark $\mathbf{S}_q$, its momentum $\hat{k}$ and the transverse momentum of the hadron $\mathbf{P}_{h\perp}$. Upon flipping the quark spin this product changes sign and thus generates a single spin asymmetry proportional to a $\cos\phi$ modulation of the azimuthal angle spanned by the vectors $\hat{k}, \mathbf{P}_{h\perp}$ and $\mathbf{S}_q$. In an unpolarized case the second term vanishes and the conventional, unpolarized fragmentation function definition is recovered. The existence of the spin dependent term was found by the HERMES experiment when single spin asymmetries attributed to a convolution of quark transversity and the Collins function turned out to be nonzero (Airapetian et al., 2005). However, in order to explicitly measure it, e^+e^- annihilation is used. A first study was performed on DELPHI data by Efremov, Smirnova, and Tkachev (1999), before the large amount of data accumulated by the B Factories became available. The method which is used in both B Factory experiments closely follows the prescription given by Boer (2009). The experimental selection requirements are also similar in the measurements Abe (2006a), Seidl (2008), and Garzia (2013). A product of Collins functions is accessed by selecting two charged pions in opposite hemispheres where the hemisphere is defined by the thrust axis (see Chapter 9). Experimentally this corresponds to the process $e^+e^- \to (\pi^{\pm})(\pi^{\pm,\mp})X$ where the brackets indicate the different hemispheres and X is the remainder of the final state. To select two-jet like events a minimum thrust value of 0.8 is required with the thrust axis being well within the barrel acceptance ($\cos\theta_T < 0.75$). Further selection criteria require the charged particles to be in the barrel part of the detector as well (for example, in Seidl, 2008, $-0.6 < \cos(\theta_{\text{lab}}) < 0.9$ is used) with minimum fractional energies $z = 2E_h/\sqrt{s} > 0.2$. The azimuthal asymmetries are observed in a $\cos(\phi_1 + \phi_2)$ modulation in the normalized two-hadron yields, $R = N(\phi_1 + \phi_2)/\langle N_{12}\rangle$, where $\phi_{1,2}$ are the azimuthal angles defined in the CM by
Figure 24.1.10. Azimuthal angles ϕ_1 and ϕ_2 defined for the two hadrons relative to the plane spanned by the lepton and thrust axis.

the two planes of hadrons relative to the plane containing both the e^+e^- pair and the thrust axis as shown in Fig. 24.1.10. $N(\phi_1 + \phi_2)$ is the number of pion pairs with the sum of the azimuthal angles $\phi_1 + \phi_2$, and $\langle N_{12}\rangle$ is the average number of pion pairs over the whole $\phi_1 + \phi_2$ interval. Similar definitions can be obtained where the reference axis is defined by the plane containing the e^+e^- pair and the second hadron in which case only one angle ϕ_0 appears and the modulation becomes a $\cos(2\phi_0)$ modulation (and the corresponding normalized yields are denoted R_0).

Acceptance effects and gluon radiation can also generate fake azimuthal modulations and were found to be substantial in MC (`Pythia 6.2` and `GEANT3`). To isolate the spin dependent fragmentation effect from these background effects, the method of double ratios was applied using ratios of different pion charge combinations. The normalized yields for opposite-sign pion pairs as a function of the azimuthal angle $R^U(\cos(\phi_1 + \phi_2))$ (or $R_0^U(\cos(2\phi_0))$) were divided by the normalized yields of like-sign pairs, $R_{(0)}^U/R_{(0)}^L$ and fitted. Similar ratios between unlike sign pion pairs and any charged pion pairs ($R_{(0)}^U/R_{(0)}^C$) were also extracted. As both background effects are expected to be proportional to the unpolarized fragmentation functions, their contributions to the normalized yields are the same for both charge sign combinations and they cancel when building the double ratio. As the Collins functions are expected to be different for favored and disfavored fragmentation, a net asymmetry related to the Collins functions should remain. The double ratios as a function of the azimuthal angles were then fit with azimuthal modulations $R^U/R^L = A_{12}^{ULL} \cos(\phi_1 + \phi_2) + B$ (or $R_0^U/R_0^L = A_0^{UL} \cos(2\phi_0) + B_0$) of which the $\cos(\phi_1 + \phi_2)$ (or $\cos(2\phi_0)$) part is proportional to the Collins functions. In case of the any charge pion pairs the corresponding amplitudes are denoted $A_{12(0)}^{UC}$. An example of the normalized raw yield, double ratio and its modulation can be seen in Fig. 24.1.11 using the ϕ_0 angle. The normalized raw yields are paremetrized similarly as the double ratios
Figure 24.1.11. From Abe (2006a). Top: Example of uncorrected unlike-sign (open circles) and like-sign (open squares) di-pion normalized rate R_0 vs. $2\phi_0$ in the bin $z_1(z_2) \in [0.5, 0.7]$, $z_2(z_1) \in [0.3, 0.5]$. Bottom: The di-pion double ratio R_0^U/R_0^L vs. $2\phi_0$ in the same z_1, z_2 bin. Resulting parameters of the fit described in the text (full and dashed lines) are also shown.

for like- and unlike-sign pairs. In order to distinguish the parameters the latter are labeled by a, b instead of A, B.

The double ratio method was tested using a sample of generic light quark MC production, where all effects except those by the Collins fragmentation were present and it was found, that the resulting raw asymmetries canceled as expected. Further tests include destroying the correlation between quark and anti-quark side by mixing pions from different events. Those were found to be consistent with zero as expected. Also artificial asymmetries were introduced in the MC to study the reconstruction efficiency. Some underestimation of the reconstructed asymmetries was found to be caused by the resolution smearing of the reconstructed thrust axis and the resulting azimuthal angles. The reason is that experimentally one cannot directly obtain the actual quark-antiquark axis, but has to rely on obtaining an approximate axis via the event shape variable thrust. As this is performed using the thrust algorithm summing over all reconstructed particles this experimental approximation reproduces the actual quark-antiquark axis with a finite accuracy. It is found that even on the generator level there is some discrepancy, which is further enhanced by detector resolutions. In the Belle experiment the average cosine of the angle formed by the reconstructed thrust axis and the generated quark-antiquark pair axis for light quarks is 0.990 with an RMS of 0.015 (Seidl, 2008), as obtained from a `Pythia` (Sjöstrand, 1995) simulated sample of events and `GEANT` (Brun, Bruyant, Maire, McPherson, and Zanarini, 1987) detector simulation. The resulting reduction of the extracted $\cos(\phi_1 + \phi_2)$ asymmetries was corrected for by scaling them with a factor 1.66 ± 0.04 (Seidl, 2008) which was obtained from the weighted MC simulation asymmetry studies.

The contribution to the asymmetries by light quarks and charm quarks (the latter representing background for the light quark fragmentation measurements) were separated using, in addition to the main data sample, a charm enhanced data sample. In the latter candidate π K pairs with the invariant mass in the range of D meson and $D \pi_s$ combinations consistent with a D^* meson were selected. The initial measurement (Abe, 2006a) was performed on 29.1 fb^{-1} of data obtained 60 MeV below the $\Upsilon(4S)$ resonance, while the second publication (Seidl, 2008) utilized 551 fb^{-1} of data including the resonance data. It was found that the thrust selection mentioned above removes most of the B decay events (the remaining pollution of the sample with B meson decays is around 2%). The results of the latter measurement are shown in Fig. 24.1.12.

It can be seen that the asymmetries are of the order of several percent and are rising with increasing fractional energy. The direct interpretation is not straightforward since the asymmetries are differences of products of favored and disfavored Collins and unpolarized fragmentation functions:

$$\frac{R_{12}^U}{R_{12}^C} = 1 + \cos(\phi_1 + \phi_2)A_{12}^{UC},$$

$$A_{12}^{UC} = \frac{\sin^2\theta}{1 + \cos^2\theta}$$

$$\times \left\{ \frac{f\left(H_1^{\perp,\mathrm{fav}}\bar{H}_2^{\perp,\mathrm{fav}} + H_1^{\perp,\mathrm{dis}}\bar{H}_2^{\perp,\mathrm{dis}}\right)}{\left(D_1^{\mathrm{fav}}\bar{D}_2^{\mathrm{fav}} + D_1^{\mathrm{dis}}\bar{D}_2^{\mathrm{dis}}\right)} \right.$$

$$\left. - \frac{f\left((H_1^{\perp,\mathrm{fav}} + H_1^{\perp,\mathrm{dis}})(\bar{H}_2^{\perp,\mathrm{fav}} + \bar{H}_2^{\perp,\mathrm{dis}})\right)}{\left((D_1^{\mathrm{fav}} + D_1^{\mathrm{dis}})(\bar{D}_2^{\mathrm{fav}} + \bar{D}_2^{\mathrm{dis}})\right)} \right\},$$

$$(24.1.13)$$

where a shorthand notation was used for the fragmentation functions of hemispheres 1 and 2, i.e. $H_2^\perp = H_{1,q}^{\perp h}(z_2)$ and similarly for the unpolarized fragmentation functions $D_2 = D_{1,q}^h(z_2)$; also the favored and disfavored FF's are denoted by superscripts fav and dis, respectively. A similar notation holds for the A_{12}^{UL} amplitude. Anselmino et al. (2007) extracted the corresponding favored and disfavored Collins fragmentation functions from the Belle data and found that they are both sizeable and of opposite sign. Using this they were able to extract the quark transversity distribution from the HERMES (Airapetian et al., 2005) and COMPASS (Alexakhin et al., 2005) data for the first time.

In this extraction some improvements in the knowledge of the Collins function are still needed. For example, the intrinsic transverse momentum dependence is not known and was only estimated. Recent results have been shown by *BABAR* (Garzia, 2013), with an analysis similar to that performed by Belle and based on a data sample corresponding to an integrated luminosity of about 468 fb^{-1} collected at the $\Upsilon(4S)$ and 40 MeV below. A general consistency between the *BABAR* and Belle asymmetries measured as a function of the fractional energies is observed. The z-range explored by *BABAR* extends from 0.15 to 0.9. In addition, *BABAR* performed a study of the azimuthal asymmetries as a function of the transverse momentum of the pions with respect to the thrust axis. As an example,
Figure 24.1.12. Azimuthal $\cos(\phi_1 + \phi_2)$ amplitude A_{12} of the normalized yield ratios of unlike-sign pion pairs over like-sign pion pairs A^{UL} (triangles), and of unlike-sign pion pairs over any charged pion pairs A^{UC} (squares) as a function of the fractional energy z_2 for 4 different bins of z_1, from top left to bottom right, as measured by Belle (Seidl, 2008). The error bars represent the statistical errors, while systematic uncertainties are given as bands for each amplitude, the top band for A^{UL}, the bottom band for A^{UC}.
Figure 24.1.13. Preliminary *BABAR* results (Garzia, 2013) on azimuthal asymmetries measured from fits to the R^U/R^L ($A_{12,UL}$), and R^U/R^C ($A_{12,UC}$) ratios, as functions of the transverse momentum p_{t2} for four bins of p_{t1}, from top left to bottom right. Statistical and systematic errors are shown as errors bars and shaded bands respectively.

Fig. 24.1.13 shows the azimuthal asymmetries measured in the thrust reference frame. The energy and transverse mo-

mentum dependence of the Collins asymmetries obtained by *BABAR* can be combined with the Belle data and the results from SIDIS experiments for an improved global analysis as done in Anselmino et al. (2007).

Collins functions for other final state hadrons still need to be extracted to improve the sensitivity for different quark flavors and to match the extracted asymmetries in SIDIS experiments. Also, an important test of the mechanism which creates this transverse spin effect (Collins effect) still needs to be performed. According to a model by Artru and Mekhfi (1990) which follows string fragmentation, the Collins effect for a transversely polarized vector meson should be of different sign as that for pseudoscalar mesons. Results from those studies are not yet available.

24.1.3.2 Interference fragmentation function

The second chiral-odd fragmentation function is the interference fragmentation function (IFF), $H_1^{\triangleleft}(z, m)$, which describes the fragmentation of a transversely polarized quark into a pair of hadrons of different charge with total fractional energy z and an invariant mass m. A nonzero IFF can be created by the interference of two hadrons in a relative S- or P-wave state. For charged pion pairs this could therefore be either a simple S-wave (which might be related to the σ resonance) interfering with the P-wave state related to the ρ meson (which is observed as a di-pion resonance). This potential interference also governs the invariant mass dependence according to theory predictions. Based on pion-pion phase shift analysis of data, Jaffe, Jin, and Tang (1998) suggest a sign change of the two-pion interference fragmentation function is required at the invariant mass of the ρ meson. Radici, Jakob, and Bianconi (2002) suggest no sign change but the maximum of the IFF magnitude at the same mass. The difference between the interference fragmentation function and the Collins fragmentation function is that intrinsic transverse momenta of hadrons created in the fragmentation are integrated over in the former case, which enables the use
Figure 24.1.14. Azimuthal angles ϕ_1 and ϕ_2 defined for the two hadron pairs's planes (denoted by the yellow planes) relative to plane spanned by the lepton and thrust axis (blue).
Figure 24.1.15. Azimuthal $\cos(\phi_1 + \phi_2)$ modulations a_{12} of normalized yield of charged pion pairs as a function of the fractional energy z_2 for 9 different bins of z_1 from top left to bottom right as measured by Belle (Vossen, 2011). The filled areas represent the systematic uncertainties.

of collinear factorization. This in turn leads to the QCD evolution of the interference fragmentation function being known and makes it easily applicable at various energies and in different processes such as in SIDIS or $p\,p$ collisions.

IFF measurements were performed by HERMES (Airapetian et al., 2008), Compass (Adolph et al., 2012; Wollny, 2009), PHENIX (Yang, 2009) and STAR (Vossen, 2012). These measurements determine the product of two unknown quantities: quark transversity and the interference fragmentation functions. Therefore the measurement of the interference fragmentation function alone in e^+e^- annihilation enable the access to quark transversity, independent of the methods using Collins FF. Similar to the Collins analysis, the interference fragmentation function can be reconstructed at B Factories using the combination of two chiral-odd fragmentation functions in each hemisphere (Boer, Jakob, and Radici, 2003). Therefore, one measures inclusively two hadron pairs in opposite hemispheres in e^+e^- annihilation. Again the two hemispheres are defined by the thrust axis and a thrust > 0.8 ensures two-jet like topology (Vossen, 2011). All four hadrons are required to be detected in the central part of the detector and to have a minimal fractional energy of 0.1. In addition, the invariant mass of each pair is required to be in the range of 0.25 to 2 GeV/c^2. To avoid acceptance

effects at the edges of the detector, hadrons were only selected if they originated in a cone around the thrust axis of $\hat{\mathbf{n}} \cdot \mathbf{P}_h > 0.8$ where the thrust axis was again limited to the barrel parts of the detector, identical to the Collins analysis. Two azimuthal angles $\phi_{1,2}$ are calculated, defined by the plane of each hadron pair relative to the plane spanned by the e^+e^- pair and the thrust axis, as displayed in Fig. 24.1.14.

Again the normalized yields as a function of the azimuthal angles are fitted. The $\cos(\phi_1 + \phi_2)$ modulation is proportional to the product of the interference fragmentation functions for the quark and antiquark sides normalized by the corresponding unpolarized fragmentation functions. After the application of the opening angle selection around the thrust axis, nearly vanishing acceptance effects ($< 0.1\%$) were observed in MC simulations of light quark production. Therefore it is possible to directly obtain the IFFs without the need for double ratios. The azimuthal modulation is again fitted by $b_{12} + a_{12}\cos(\phi_1 + \phi_2)$ of which the cosine modulation can be interpreted as

$$a_{12} \propto -\frac{\sin^2\theta}{1+\cos^2\theta}\frac{\sum_q e_q^2 H_1^{\sphericalangle,q}(z_1, m_1) H_1^{\sphericalangle,\bar{q}}(z_2, m_2) + c.c.}{\sum_q e_q^2 D_1^q(z_1, m_1) D_1^{\bar{q}}(z_2, m_2) + c.c.},$$
(24.1.14)
Figure 24.1.16. Azimuthal $\cos(\phi_1 + \phi_2)$ modulations a_{12} of the normalized yield of charged pion pairs as a function of the invariant mass m_2 for 8 different bins of m_1 from top left to bottom right as measured by Belle (Vossen, 2011). The filled areas represent the systematic uncertainties.

where θ is the polar angle between the lepton and the thrust axis. Similar systematic studies as in the Collins analysis were performed, such as mixed-event tests where the two hadron pairs were selected from different events, the zero tests in MC simulations without any spin effects present as well as studies of the bias of the asymmetries for certain opening angle and thrust selections. The stability over various data-taking periods for on- and off-resonance data were also studied and found to be consistent. Again the thrust axis smearing reduces the magnitude of the asymmetries to 92% of the generated value as found in simulations (less than in the case of Collins FF measurement).

Results have been obtained so far by Belle, for charged pion pairs, using 672 fb^{-1} (Vossen, 2011). The asymmetries are displayed, for example, as a function of the two fractional energies of the two pairs in Fig. 24.1.15. It can be seen that the asymmetries are increasing with fractional energy. This can again be explained if more of the quarks' spin information is contained at the highest fractional energies. The overall magnitude of the asymmetries is quite remarkable, reaching more than 10%. Given that the asymmetry parameter a_{12} is proportional to the product of two IFFs (see Eq. 24.1.14) this means that the effect of a single IFF can be as large as 30%.

Figure 24.1.16 shows the asymmetries as a function of the invariant mass of the pion pairs. Here one sees an increase in the magnitude of asymmetries up to and slightly above the ρ mass, where the asymmetries seem to level off. At the highest invariant masses, the fraction of charm events according to MC is largest, such that some effect might originate from charm events. However efforts to separate charm and uds events showed little difference between the extracted uds and all events. The asymmetries also show clearly that no sign change of the interference fragmentation function occurs at the invariant mass of the ρ meson and therefore rules out Jaffe's prediction (Jaffe, Jin, and Tang, 1998). Theoretical efforts to obtain the quark transversity by combining the e^+e^- IFF results with the corresponding SIDIS results performed by Bacchetta, Courtoy, and Radici (2011) and Courtoy, Bacchetta, Radici, and Bianconi (2012) show a quark transversity distribution similar to the one extracted using the Collins fragmentation functions, although uncertainties are currently still rather large. A recent update of that analysis by Courtoy, Bacchetta, and Radici (2012) shows excellent agreement when the recent COMPASS data (Adolph et al., 2012) are included. The similarity of the extracted transversity distributions suggests that the unknown QCD evolution of the Collins func-

tion is not too different from the regular DGLAP evolution, otherwise the magnitudes at as different scales of $Q^2 = 110 \, \mathrm{GeV}^2$ (B Factories) and $2.4 \, \mathrm{GeV}^2$ (HERMES) would also have been rather different.

Future measurements of IFF should include $\pi^0 \pi^\pm$, $\pi^{\pm,0} K$ and KK, as well as combinations of different pairs in different hemispheres to gain additional information on the two hadron equivalents of favored and disfavored fragmentation.

24.1.4 Summary on fragmentation functions

Belle and *BABAR* have extracted high precision unpolarized fragmentation functions for light and charmed mesons and some of the charmed baryons. While light hadrons contain a relatively small energy fraction of the initial partons the same fraction for charmed hadrons amounts to about 60%. The measured light quark fragmentation functions will be used to significantly improve the global QCD fits on fragmentation and will in turn provide further access to the flavor structure of the nucleon in semi-inclusive DIS and pp experiments. Spin dependent Collins and interference fragmentation functions were directly obtained for the first time and found to be sizeable. They give access to the transverse spin structure of the nucleon since they act as quark spin analyzers. They have also been used together with SIDIS world data to obtain the transversity distribution functions of the nucleon.

24.2 Pentaquark searches

Editors:
Jonathon Coleman (BABAR)

Roman Mizuk

Since the early years of the quark model, there has been speculation concerning states with unusual valence quark content: something other than qqq or $q\bar{q}$. Other color-singlet configurations are allowed by $SU(3)$, so the question becomes whether the dynamics of the strong interaction allows such states to form and to be at least metastable. So-called *pentaquark* states, with valence content $qqqq\bar{q}$ (or charge conjugate), are an important example. Theoretical work on pentaquark states is briefly summarized in Section 24.2.1.

The subject became important for the B Factories due to positive claims in 2003, initially from experiments working at the boundary of particle and nuclear physics. The original $\Theta(1540)^+$ evidence was from a search in photoproduction by LEPS (Nakano et al., 2003), and an analysis of kaon interaction data from DIANA (Barmin et al., 2003). Many other positive claims for the $\Theta(1540)^+$ and other pentaquark states followed. These are summarized in Section 24.2.2.

A programme of searches then followed at both Belle and *BABAR*, which may be roughly divided by production mechanism: inclusive production (Section 24.2.3), searches in B decays (Section 24.2.4), and interaction of primary particles in the material of the detector (Section 24.2.5). The latter provide the most direct challenge to the original pentaquark claims. The lessons from B Factory data are summarized in Section 24.2.6.

24.2.1 Theoretical studies on pentaquarks

In the light-quark baryon sector, spin and flavor are combined to yield a flavor-spin $SU(6)$ representation of the spectroscopy. The baryon states are composed of three quarks, each of which is assumed to be a color triplet, with all baryons assumed to be color singlets. The allowed state vectors are thus anti-symmetric in color, and symmetric in space-spin-flavor, and in this way the quark configurations satisfy Fermi statistics. All of the known baryon states up to $\sim 2\,\mathrm{GeV}$, *i.e.* those with at least 3 stars in the Particle Data Group (PDG) evaluation, are accommodated in this scheme, and the non-relativistic three-quark potential model of Isgur and Karl can also explain the occurrence of "missing states" on the basis of their highly inelastic decay characteristics (Koniuk and Isgur, 1980). In fact, in the review article by Hey and Kelly (1983) it is pointed out that the successful description of the known baryon states in terms of confined triplets of spin-half quarks with a hidden color degree of freedom is perhaps the most significant outcome of all the attempts at describing the spectroscopy (and couplings) of the baryonic excitations. However, in the context of QCD, the apparent absence of baryons with composition $qqqq\bar{q}$ or $qqqg$ is not understood.

24.2.1.1 Early partial wave analyses

The most obvious way to prove the existence of $qqqq\bar{q}$ states is to identify resonant structure in the KN system, since an $S = +1$ baryon must at minimum contain five quarks. Since the early days of the quark model, such evidence has been sought in the Partial Wave Analysis (PWA) of KN elastic, charge exchange, and inelastic scattering data. The results of these searches for Z^* states, as they were called, are summarized briefly in Hey and Kelly (1983). Only the P_{01} and P_{13} amplitudes show hints of structure (in the mass region 1.8–1.9 GeV/c^2), but it was then concluded that there is no convincing evidence of resonant behavior. In its 1986 review (Aguilar-Benitez et al., 1986) the PDG drew a line under these studies with the following comment:

> ... the [PWA] results permit no definite conclusion — the same story heard for 15 years. The standards of proof must simply be much more severe here than in a channel in which many resonances are already known to exist. The general prejudice against baryons not made of three quarks and the lack of any experimental activity in this area make it likely that it will be another 15 years before the issue is decided.

The Z^* listings appeared for the last time in that issue, and starting with the following review (Yost et al., 1988), only a reference to the 1986 edition was included. After that, the subject of exotic baryons did not receive much attention except from a few theorists motivated by the old chiral soliton ideas due to Skyrme (1962).

24.2.1.2 The pentaquark revival; prediction of the $\Theta(1540)^+$

A decade later Diakonov, Petrov, and Polyakov (1997) made a remarkable prediction concerning the existence of a positive strangeness baryon state just above KN threshold in mass ($\sim 1.53\,\mathrm{GeV}/c^2$) and of extremely narrow width ($\Gamma < 15\,\mathrm{MeV}$). Such a state would be manifestly exotic since it would have a minimal content of four quarks and an anti-quark ($\bar{s}$). The predictions were based on the generalization of a chiral soliton model (Skyrme, 1962), in which nucleons are viewed as solitons of the pion field. Quantization of the rotations of this field in ordinary and flavor $SU(3)$ space leads to a baryon ground state which is an octet with spin $1/2$, and to a first excited state which is a spin $3/2$ decuplet, just as happens to be the case in nature. In the case of three flavors, the next excitation corresponds to an anti-decuplet with spin $1/2$. The structure of this anti-decuplet is shown in Fig. 24.2.1, with the exotic $S = +1$ state occupying the apex of the triangle. The states at the extreme edges of the base of the triangle are also manifestly exotic with minimal quark content
Figure 24.2.1. The anti-decuplet (annuli) and octet (filled circles) that are generally assumed for the lowest mass pentaquarks. The vertical axis is the strangeness and the horizontal axis is the isospin. The quark content of the anti-decuplet members is shown. (Reproduced from Aubert, 2004aa.)

as shown. As indicated, the mass splitting between the isospin multiplets of different strangeness is linear; in Diakonov, Petrov, and Polyakov (1997), it is estimated to be $\sim 180\,\mathrm{MeV}/c^2$. The overall mass scale was defined by identifying the nucleon member of the anti-decuplet with the $N(1710)$ resonance (Eidelman et al., 2004), and this led to an estimation of the $\Theta(1540)^+$ mass of $\sim 1.53\,\mathrm{GeV}/c^2$. A subsequent calculation of the width of this state led to the estimate that it should be $\sim 15\,\mathrm{MeV}$, which, if correct, should make it amenable to experimental detection provided that the cross section for production is large enough.

On page 312 of Diakonov, Petrov, and Polyakov (1997), there is a comment that the data from the LASS experiment might be used to look for the $\Theta(1540)^+$. This was in fact done in 1997 using data selected for the reaction $K^+p \rightarrow \pi^+K^+n$ at an incident momentum $11\,\mathrm{GeV}/c$, but no signal was observed. The result shown at the 7th International Symposium on Meson-Nucleon Physics and the Structure of the Nucleon in 1997 can be found in Napolitano, Cummings, and Witkowski (2004). Old, but high quality, bubble chamber data selected for the reaction $K^+p \rightarrow \pi^+K^0p$ in the momentum region around $1\,\mathrm{GeV}/c$ (Berthon et al., 1973) also fail to reveal a signal, and suggest cross section values less than $10\,\mu\mathrm{b}$. Representative Dalitz plots in the $\Theta(1540)^+$ region reported in the 2004 PDG review article by George Trilling (Eidelman et al., 2004) are quite clear: there is no evidence of $\Theta(1540)^+$ production.

For more than five years after the publication of the Diakonov et al. paper there was no experimental evidence to support the prediction of the $\Theta(1540)^+$ but the situation changed dramatically in the fall of 2002 when the LEPS Collaboration claimed to have observed photoproduction of a $\Theta(1540)^+$ candidate (Nakano et al., 2003).

Then, during a pentaquark workshop at Jefferson Lab (JLab) in November 2003, K.Kadija, representing the

NA49 Collaboration, presented evidence for the production of a $\Xi_5(1860)^{++}$ pentaquark candidate and a neutral partner in $p-p$ interactions at a CM energy of 17.2 GeV (later published in Alt et al., 2004). If this state is interpreted as belonging to the anti-decuplet of Diakonov et al., the mass ($\sim 1.862\,\mathrm{GeV}/c^2$) and width ($< 18\,\mathrm{MeV}$) values are much smaller than those predicted ($2.07\,\mathrm{GeV}/c^2$ and $> 140\,\mathrm{MeV}$, respectively). In a subsequent paper, Diakonov and Petrov (2004) no longer used the $N(1710)$ to set the absolute mass scale for their predictions, but used the mass values of the $\Theta(1540)^+$ and $\Xi_5(1860)$ to define a new anti-decuplet central mass and mass splitting ($\sim 108\,\mathrm{MeV}/c^2$). The reduction of the splitting from the $180\,\mathrm{MeV}/c^2$ value of Diakonov, Petrov, and Polyakov (1997) could be reproduced by increasing the value of the nucleon sigma term used in the calculation, and arguments were given to indicate that the NA49 width limit was reasonable if the true width of the $\Theta(1540)^+$ was $< 3\,\mathrm{MeV}$, and the two states were members of the same anti-decuplet.

24.2.1.3 Subsequent studies

Stimulated by the flurry of experimental activity on the pentaquark front, other models of the "quark cluster" type soon appeared. The first of these, due to Karliner and Lipkin (2003), divided the pentaquark constituents into a di-quark and a tri-quark cluster with the quarks of identical flavor in different clusters. Each cluster has isospin zero and is a color non-singlet (separating the pairs of identical flavor); one unit of orbital angular momentum then yields $IJ^P = 0\frac{1}{2}^+$ as expected for the lowest anti-decuplet, and the centrifugal barrier keeps the clusters beyond the range of the repulsive color-magnetic force. The individual clusters bind together as a result of color-electric forces. The model yields a $\Theta(1540)^+$ mass estimate of $\sim 1.59\,\mathrm{GeV}/c^2$, and an anti-decuplet mass splitting which is only $\sim 50\,\mathrm{MeV}/c^2$. This is a quark-based model which led to a resonant $S = +1$ baryon state in the vicinity of KN threshold.

A second model of this type is due to Jaffe and Wilczek (2003). The $\Theta(1540)^+$ is described in terms of two ud diquarks and a bachelor $\bar{s}$ quark. The ground state diquark-diquark-antiquark configuration leads to a degenerate octet and anti-decuplet whose symmetry is broken as a result of the strange quark mass, leading to mixing of the two multiplets. Incorporating the $\Theta(1540)^+$ as the $Y = 2$ member of the anti-decuplet leads to a somewhat different spectroscopy than that of Diakonov, Petrov, and Polyakov (1997), and in particular yields a $J^P = 1/2^+$ nucleon state at a mass lower than the $\Theta(1540)^+$ which is associated with the broad Roper resonance.[182] However, the predicted mass of the $\Xi_5(1860)$ state is more than 100 MeV below the mass of the state claimed by the NA49 experiment.

---

[182] A Roper resonance is a broad baryon state with a mass circa $1440\,\mathrm{MeV}$, denoted by $P_{11}(1440)$, see Alvarez-Ruso (2010) and references therein for more details.

Finally, it should be possible to employ Lattice Gauge techniques to investigate the hypothetical existence of an exotic pentaquark resonant state in the vicinity of KN threshold. Holland and Juge (2006) discussed the status of such calculations, and concluded that there was as yet no evidence favoring the existence of any such state. However the paper cautions that "absence of evidence" should not be considered to be "evidence of absence" at the present early stage of these efforts.

Since the claim of evidence for $\Theta(1540)^+$ production, many models generating estimates of production cross section rates in photoproduction and hadroproduction reactions have been presented in the literature. Cross section estimates range from a fraction of a nanobarn to several hundred nb in photoproduction, and from a fraction of a microbarn to several millibarns in hadroproduction, depending on the reaction and details of the model. A sampling of such calculations can be found in Oh, Kim, and Lee (2004a,b), and in some of the references listed in these papers. Some of the calculations yield unacceptable results: *e.g.* for the reaction $K^+p \rightarrow \pi^+\Theta(1540)^+$ the predicted cross section is ~ 1.5 mb at low beam momentum, clearly inconsistent with the published data (Berthon et al., 1973).

24.2.2 Positive claims in 2003–2005

24.2.2.1 $\Theta(1540)^+$

Table 24.2.1 is adapted from Dzierba, Meyer, and Szczepaniak (2005), and summarizes the various claims for the observation of the $\Theta(1540)^+$ pentaquark state. The corresponding collaborations and reactions studied are summarized; also listed are the mass and width estimates, and claimed significance.

The first three rows of the table result from photoproduction of the same exclusive final state, with the signal appearing in the K^+n invariant mass distribution (Nakano et al., 2003; Stepanyan et al., 2003). The next two rows are from photoproduction of different exclusive final states on a proton target, with the signal again appearing in the K^+n invariant mass distribution (Barth et al., 2003; Kubarovsky et al., 2004). The quoted mass and width values appear to be consistent.

The remaining measurements are for the $K_s^0 p$ system. Only for the exclusive final states of Abdel-Bary et al. (2004) and Barmin et al. (2003) is it known with certainty that the K_s^0 is produced as a K^0. These eight measurements are obtained using a variety of incident particles (K^+, p, neutrino, and $e^\pm$) and targets, and six of them are from inclusive production processes. These measurements yield a discrepancy of at least 3σ between the mass values from the K^+n and $K_s^0 p$ systems.

The overall mean value of the mass from these measurements is 1535.3 ± 2.6 MeV/c^2, where the error is estimated from the spread in the individual values, since this is larger than would be expected from the quoted errors on the measurements.

If the $\Theta(1540)^+$ exists, its effects should be seen in K^+d scattering data for incident K^+ laboratory momenta around 440 MeV/c, unless its width is very small. Since the CM energy in this region is below pion production threshold, the cross section reaches the unitarity limit at resonance, and for spin $1/2$ is $\mathcal{B}_i \times \mathcal{B}_f \times 68$ mb, where $\mathcal{B}_i$ and $\mathcal{B}_f$ are the branching fractions to the initial and final states. These branching fractions are equal to 0.5 for the $\Theta(1540)^+$. Integrating over the resonance peak, the net effect results in a contribution $\Gamma \times (\mathcal{B}_i \times \mathcal{B}_f \times 107$ mb$)$, where Γ is the width of the resonance. Several studies of the rather sparse scattering data in this region (Arndt, Strakovsky, and Workman, 2003; Cahn and Trilling, 2004; Haidenbauer and Krein, 2003; Nussinov, 2003, 2004) conclude that Γ must be less than 5 MeV. In addition, in Cahn and Trilling (2004) the Xe bubble chamber data of Barmin et al. (2003), when interpreted in terms of K^+n charge exchange scattering, yield the value $\Gamma = (0.9 \pm 0.3)$ MeV, with no estimate of systematic uncertainty. The conclusion therefore is that if the $\Theta(1540)^+$ exists its width must be < 5 MeV, and may even be as small as ~ 1 MeV. The width estimates in Table 24.2.1 are consistent with such values.

Since the mass distributions of the claimed signals were obtained in many different contexts, it is difficult to believe that the signals might be spurious. However, the fact that the mass value estimates are spread over a range which seems too large for the uncertainties quoted, and the observation that in all of the distributions, the peak signal bin contains only 0–50 events above background, indicate the need to exercise caution. This is especially relevant in light of JLab results (DeVita, 2005) in what is essentially a much higher statistics repetition of the SAPHIR experiment. Cross section estimates for $\Theta(1540)^+$ production are either non-existent, unclear, or unreliable.

The COSY experiment (Abdel-Bary et al., 2004) quotes a cross section of $(0.4 \pm 0.1 \pm 0.1)$ μb but does not indicate clearly whether all branching fraction values and isospin Clebsch-Gordan coefficients have been taken into account. The SAPHIR experiment (Barth et al., 2003) initially quoted a cross section for the reaction $\gamma p \rightarrow \bar{K}^0\Theta(1540)^+$ of 300 nb, but this has since been reduced to 50 nb, and JLab measurements of the same reaction (DeVita, 2005) yield a 95% C.L. upper limit in the range 1–4 nb for the relevant region of photon laboratory energy. As of 2005, when the B Factory studies were being performed, there was no other useful information.

24.2.2.2 $\Xi_5(1860)$

These are the states contributing the base of the anti-decuplet triangle in Fig. 24.2.1. Only one observation has been claimed to date, from the NA49 Collaboration studying the interactions of a 158 GeV/c proton beam in a liquid hydrogen target (Alt et al., 2004). The combined invariant mass distributions for the systems $\Xi^-\pi^-$, $\Xi^-\pi^+$, and their anti-particle counterparts reveal a narrow signal of ~ 68 events over a background of ~ 77 events; the width is consistent with the detector resolution (18 MeV/c^2). The

Table 24.2.1. Results from experiments reporting the observation of the $\Theta(1540)^+$ in a K^+n or K_S^0p invariant mass distribution, expanded from Table 3 of Dzierba, Meyer, and Szczepaniak (2005). Seven of these experiments involve real or virtual photoproduction (denoted by *), and four more involve hadroproduction on a hydrogen or nuclear target. (Xe)′ denotes a recoiling Xe. The second LEPS result (Nakano, 2004) was a conference presentation that did not include a mass and width.

fitted mass value is $(1.862 \pm 0.002)\,\mathrm{GeV}/c^2$. A $\Xi_5(1860)^{++}$ baryon is manifestly exotic; it occupies the lower-left vertex of the anti-decuplet, with the minimal quark composition shown. It is troubling that there have been no other observations of this state to date, but even more troubling that members of the same collaboration have publicly questioned the analysis (Fischer and Wenig, 2004).

24.2.2.3 $\Theta_c(3100)$

Again there was only one experiment claiming evidence for this anti-charm baryon state (Aktas et al., 2004). The signal is observed by the H1 Collaboration at HERA in the $D^{*-}p$ and $D^{*+}\bar{p}$ invariant mass distributions; the fitted mass value is $(3.099 \pm 0.003 \pm 0.005)\,\mathrm{GeV}/c^2$ and the width is consistent with detector resolution ($\sim 12\,\mathrm{MeV}/c^2$). The minimal quark content is $uudd\bar{c}$, so that the state is a manifestly exotic pentaquark candidate. There has been no corroboration of this state to date; in particular, the ZEUS experiment operating under the same conditions at HERA has found no evidence of a signal (Chekanov et al., 2004b). The H1 result was later retracted.

24.2.2.4 Negative searches

The experiments which have searched in vain for evidence of the three pentaquark states are summarized in Dzierba, Meyer, and Szczepaniak (2005). There is a fairly detailed discussion of the various non-observations in the reference, which we do not repeat here.

24.2.3 Inclusive production searches

24.2.3.1 Strange pentaquark candidates

A dedicated search for inclusive production of the $\Theta(1540)^+$ was performed by *BABAR* (Aubert, 2005ac); searches for the doubly-strange states $\Xi_5(1860)^0$ and $\Xi_5(1860)^{++}$, reported by NA49 (Alt et al., 2004) and supposed to be partners of the $\Theta(1540)^+$ within a pentaquark $\overline{10}$ multiplet, were presented in the same paper.

In this analysis, the pK_S^0 system, with $K_S^0 \to \pi^+\pi^-$, was investigated for evidence of $\Theta(1540)^+$ production in e^+e^- collisions at a CM energy of 10.58 GeV, and 0.04 GeV below.

The pK_S^0 invariant mass distribution showed a large ($\sim$100,000 events) signal corresponding to the production of the $\Lambda(2285)^+$ charmed baryon, and this was used to verify that the dependence of mass resolution upon CM momentum p^* was well reproduced in Monte Carlo simulation. The same simulation in the mass region of the $\Theta(1540)^+$ yields mass resolution values in the range 1.7–$2.2\,\mathrm{MeV}/c^2$. The excellent agreement obtained for the $\Lambda(2285)^+$ data demonstrates that these resolution estimates are reliable. No $\Theta(1540)^+$ signal was observed, neither when the pK_S^0 mass distribution was taken as a whole, nor when it was examined as a function of p^*. This remained true for sub-samples of the data for which each event was required to contain an identified K^- (in order to bias the K_S^0 sample toward K^0 rather than $\bar{K}^0$), and/or an anti-proton (in order to bias the sample toward conserved baryon number).

For a fixed $\Theta(1540)^+$ mass value of $1.54\,\mathrm{GeV}/c^2$, and fixed total width values of 1 MeV and 8 MeV, resolution-
Figure 24.2.2. From Aubert (2004aa): Compilation of light (no c or b quarks) baryon production rates in e^+e^- to hadrons from the PDG. Limits from *BABAR* on pentaquark production in $e^+e^- \to$ hadrons are shown, at least an order of magnitude below the expected trend for "normal" baryons.

smeared P-wave Breit-Wigner lineshapes were used to obtain 95% C.L. cross section upper limits for each $0.5\,\text{GeV}/c$ momentum interval in the range 0–$5\,\text{GeV}/c$.

Limits for the integrated cross section values of $80\,\text{fb}$ and $60\,\text{fb}$ were extracted for width values $1\,\text{MeV}$ and $8\,\text{MeV}$, respectively. The values obtained for a mass choice of $1.53\,\text{GeV}/c^2$ were virtually identical to these. These upper limit values are significantly below the cross section values which would be expected for a particle of mass $1.54\,\text{GeV}/c^2$ on the basis of the observed production rates for "ordinary" hadrons (see Fig. 24.2.2). This suggests that, if the $\Theta(1540)^+$ pentaquark state does in fact exist, its production is highly suppressed in e^+e^- interactions at $10.58\,\text{GeV}$ with respect to that of well-established hadrons.

Two CLAS results testing for the possible existence of the $\Theta(1540)^+$ were found to be in disagreement with each other (McKinnon et al., 2006; Stepanyan et al., 2003). The 2003 result claimed observation of a narrow K^+n resonance in the process $\gamma d \to K^+K^-pn$. The 2006 paper is the result of a dedicated high luminosity run by the CLAS collaboration designed specifically to test the validity of former publication in a data sample over 30 times larger than the original one. This subsequent paper found no evidence for a narrow resonance. In 2007 CLAS re-analysed their data using a consistent Bayesian methodology (Ireland et al., 2008) in order to understand if those previous results were compatible with each other or not, and to verify if there was any evidence for a $\Theta(1540)^+$ signal. They conclude that the results are indeed compatible, however

that there is insufficient information in the 2003 data to support the original claim of the existence of a new state.

24.2.3.2 The charmed pentaquark candidate $\Theta_c(3100)$

Searches for the charmed pentaquark candidate $\Theta_c(3100)^0$ were performed in inclusive production by *BABAR* (Aubert, 2006ar), and in B decays by Belle (Abe, 2004e).

In *BABAR*, no evidence for the production of the $\Theta_c(3100)^0$ state in a sample of over $125{,}000$ pD^* combinations was found. Upper limits on the product of the inclusive $\Theta_c(3100)^0$ production cross section times branching fraction to this mode for two assumptions of its natural width, which are valid for any state in the vicinity of $3100\,\text{MeV}/c^2$, were set. It would be interesting to compare these limits with the rate expected for an ordinary charmed baryon of mass $3100\,\text{MeV}/c^2$. However, rates had been measured for only two charmed baryons, the $\Lambda_c^+(2285)$ (Seuster, 2006; see also Eidelman et al., 2004), and $\Sigma_c(2455)$ (Eidelman et al., 2004) at the time of publication, with a precision that does not allow a meaningful estimate of the mass dependence. The mass dependence observed (Eidelman et al., 2004) for non-charmed baryons in e^+e^- annihilations predicts a rate for a $3100\,\text{MeV}/c^2$ baryon about $1{,}000$ times smaller than that of the $\Lambda_c^+(2285)$. Belle limits for a narrow state in both $e^+e^- \to c\bar{c}$ and $\Upsilon(4S)$ events are roughly $1{,}000$ and 500 times below the $\Lambda_c^+(2285)$ and $\Sigma_c(2455)$ rates, respectively.

As a result the existence of an ordinary charmed baryon with this mass and decay mode cannot be excluded.

24.2.4 Searches in B decays

Parasitic searches were performed at the B Factories for the $\Theta(1540)^+$ and a hypothetical partner Θ^{*++} (Wang, 2005; Aubert, 2005p), through analyses of $B \to p\bar{p}K$ decays (Section 17.12). These searches failed to provide any indication of either of these pentaquark candidates. Belle concludes from their data that a quark fragmentation interpretation is supported, while a resonant gluonic state origin is disfavored.

24.2.5 Searches using interactions in the detector material

If they exist, pentaquarks are thought to be produced at low energy, and as a result low energy searches are of paramount importance. To access the low energy domain, Belle performed a detailed investigation using secondary interactions of hadrons in the detector material. The protons and kaons that do not originate from the e^+e^- interaction point were selected and pK pairs that form high-quality vertices with the radial distance $R > 1\,\text{cm}$ were considered. The spatial distribution of the pK_s^0 pairs for the central part of the Belle detector is shown in Fig. 24.2.3 for the two running periods with different configurations
Figure 24.2.3. Distribution of reconstructed secondary pK_S^0 vertices in the Belle detector for both the SVD1 (left) and SVD2 (right) data samples, from Mizuk, Danilov (2006).
Figure 24.2.4. (a) Mass spectra of $pK^{\pm}$ (points with error bars) and pK_S^0 (histogram) of secondary pairs, and (b) secondary pK_S^0 pairs (small dots with error bars) and expected yield of the charge exchange reaction per 2 MeV/c^2 (open dots). The dashed line in (b) corresponds to the result of a fit to a third order polynomial and the $\Theta(1540)^+$ contribution expected from the DIANA result is shown (solid line). Figures are reproduced from Mizuk, Danilov (2006).

of the inner detectors. The beam pipe, the layers of silicon vertex detector (three layers for SVD1 and four layers for SVD2) and inner support of the central drift chamber are clearly seen, which demonstrates that the secondary interactions are the dominant source of the selected pK_S^0 vertices. Similar "detector tomography" pictures were obtained for the pK^- and pK^+ vertices.

Belle performed the search both for inclusive production and for formation of the $\Theta(1540)^+$ (Mizuk, Danilov, 2006). The invariant mass distributions for the secondary pK^- and pK_S^0 vertices are shown in Figure 24.2.4. There is a clear $\Lambda(1520)$ signal in the pK^- distribution while there is no $\Theta(1540)^+$ signal in the K_S^0 distribution. Belle

used the $\Lambda(1520)$ signal as a reference and placed a 90% C.L. upper limit on the ratio

$$\frac{\sigma(KN \to \Theta(1540)^+ X)}{\sigma(KN \to \Lambda(1520)X)} < 2.5\%. \qquad (24.2.1)$$

Belle finds that it is very rarely that there is an additional kaon track from the secondary pK vertex. Therefore the interactions are induced by strange particles, primarily kaons, with the contribution of hyperons estimated to be negligible. Given that the typical projectile kaon momentum is only 1 GeV, this is a unique null result in the low energy domain. The upper limit is much smaller
(a) Comparison with HERMES (Airapetian et al., 2004), using HERMES data above 1.58 GeV/c^2 for normalization.
(b) Comparison with ZEUS (Chekanov et al., 2004a), using ZEUS data below 1.48 GeV/c^2 for normalization.

Figure 24.2.5. From Coleman (2005): BABAR $K_S^0\,p$ mass distributions from electroproduction in Be, compared with results from previous experiments. In each case, the BABAR distribution is normalized to that of the other experiment in the region shown.

than the corresponding values from experiments with positive results, however, its interpretation remains model-dependent.

To obtain a model-independent constraint on the $\Theta(1540)^+$ parameters Belle searched for the formation of the $\Theta(1540)^+$ using the exclusive charge-exchange reaction $K^+ p \to pK_S^0$. The yield of $\Theta(1540)^+$ formed in s-channel transitions is directly related to its width. In this search the projectile K^+ was not reconstructed and its momentum was determined from the energy-momentum of the secondary pK_S^0 pair and from the vertex constraints. The Fermi momentum of the struck neutron was also determined. The procedure was verified and calibrated using $D^{*+} \to \pi^+ D^0(\to \pi^- K^+)$ decays in which the K^+ had interacted in the detector material. To suppress the background from inelastic $K^+ n \to pK_S^0 X$ scattering, Belle applied veto on additional charged tracks from the secondary vertex and required that the Fermi momentum be in the range 50 to 300 MeV. These requirements suppress inelastic reactions by a factor of four. The charge exchange reaction accounts for about 10% of the resulting sample. No $\Theta(1540)^+$ signal is observed and an upper limit on the $\Theta(1540)^+$ width is set $\Gamma(K^+ p \to \Theta(1540)^+ \to pK_s) < 0.64$ MeV at 90% C.L. for a $\Theta(1540)^+$ mass of 1539 MeV. This upper limit is marginally consistent with the measurement by the DIANA experiment (0.9 ± 0.3) MeV (Barmin et al., 2003) and does not support the evidence reported by DIANA.

Likewise, the search for the $\Theta(1540)^+$ was extended to the interactions of secondary hadrons, background tracks of every type, and beam halo electrons and positrons in the material of the inner BABAR detector (Coleman, 2005). It was demonstrated that the candidate (K_s^0, p) vertices reproduce the detector geometry very well, however the inclusive $K_s^0 p$ mass distribution shows no pentaquark signal.

Sub-samples of the candidates with at least one associated charged track, and also those remaining after rejecting (K_s^0, p) vertices with at least one associated baryon were examined. The study has been restricted to the regions which can be interpreted as corresponding to electroproduction in Be (mainly) and Ta, and has been repeated including in addition a small sample of vertices with an associated electron. Again, no $\Theta(1540)^+$ signal has been observed. Since there is no quantitative information on the flux of off-beam electrons and positrons, it is not possible to estimate upper limits for the production cross section as was done in Aubert (2004aa, 2005ac).

The BABAR electroproduction results have been compared to those of the HERMES (Airapetian et al., 2004) and ZEUS (Chekanov et al., 2004a) experiments, the results of which are shown in Fig. 24.2.5. These comparisons seem to indicate a significant loss of acceptance for the HERMES experiment in the $K_s^0 p$ mass region below ~ 1.52 GeV/c^2. There is no evidence for the $\Lambda(1480)$ and $\Theta(1540)^+$ signals of the ZEUS analysis, and this creates serious reservations about the significance of the $\Theta(1540)^+$ observations claimed by HERMES and ZEUS. A subsequent search by H1 for the $\Theta(1540)^+$ also found no evidence for a signal (Aktas et al., 2006).

Finally, the BABAR results on the electroproduction of the $K_s^0 pK$ system have been compared to the SAPHIR (Barth et al., 2003) results on the photoproduction of the $K^+ nK^0$ final state. A crude attempt at normalizing the production of $\Lambda(1520)$ observed in both analyses leads to the conclusion that a $\Theta(1540)^+$ signal as observed by SAPHIR would not be significant in the corresponding BABAR $K_s^0 p$ mass distribution. The BABAR results are in complete accord with those presented by the CLAS Collaboration (DeVita, 2005).

24.2.6 Summary

In summary, the final result of the high statistics searches at the *B* Factories summarized above is that no experiment has yielded any evidence for the production of the $\Theta(1540)^+$ or other members of the pentaquark family. Furthermore, a comparison of the *BABAR* results on electroproduction in Be to those from the HERMES (e^+D) and ZEUS (e^+p) experiments leads to the conclusion that prior claims for the observation of $\Theta(1540)^+$ in electroproduction are not convincing. The inclusive and exclusive K^+p interaction searches from Belle also result in the conclusion that claims for the observation of $\Theta(1540)^+$ are unconvincing. In light of these results it would seem clear that the only way to clarify the issue brought about by the experiments which still claim a signal is for those experiments to collect and analyse significantly more data. However, many of the analyses have been carried out in experiments which are now decommissioned. Nevertheless, for those which can be repeated, there is a clear need for new high statistics data to be collected with well-calibrated, large-acceptance detectors. Proof of principle has been amply provided by the results from CLAS (DeVita, 2005), which so convincingly refute the earlier claim of $\Theta(1540)^+$ observation from SAPHIR (Barth et al., 2003).

The whole saga is succinctly summed up by the 2006 and 2008 PDG reports as given below. The 2006 Review of Particle Physics concluded (Yao et al., 2006):

> *. . . there has not been a high-statistics confirmation of any of the original experiments that claimed to see the $\Theta(1540)^+$; there have been two high-statistics repeats from Jefferson Lab that have clearly shown the original positive claims in those two cases to be wrong; there have been a number of other high-statistics experiments, none of which have found any evidence for the $\Theta(1540)^+$; and all attempts to confirm the two other claimed pentaquark states have led to negative results. The conclusion that pentaquarks in general, and the $\Theta(1540)^+$, in particular, do not exist, appears compelling.*

The 2008 Review of Particle Physics went even further (Amsler et al., 2008):

> *There are two or three recent experiments that find weak evidence for signals near the nominal masses, but there is simply no point in tabulating them in view of the overwhelming evidence that the claimed pentaquarks do not exist. The only advance in particle physics thought worthy of mention in the American Institute of Physics "Physics News in 2003" was a false alarm. The whole story — the discoveries themselves, the tidal wave of papers by theorists and phenomenologists that followed, and the eventual "undiscovery" — is a curious episode in the history of science.*

Despite these null results, LEPS results as of 2009 continue to claim the existence of a narrow state with a mass of $1524 \pm 4 \, \text{MeV}/c^2$, with a statistical significance of 5.1 σ (Nakano et al., 2009).

Chapter 25
Global interpretation

The chapters in this book have described a wide range of measurements that have been made by the B Factories. It is possible to relate a number of these to either expectations from Standard Model (SM) based calculations, or hypothesized scenarios of physics beyond the SM. This chapter describes in detail how key measurements from the B Factories can be combined in order to constrain our understanding of the CKM matrix, and the role of the KM mechanism in the SM (Section 25.1); and how one may be able to go beyond the SM and constrain features and parts of the parameter space for postulated new physics models (Section 25.2).

Prior to the B Factories there had already been a variety of results on flavor physics, which had produced a reference point to be improved upon by the B Factories. The measurement of ϵ_K as well as measurements in the charm sector provided indirect constraints on B decays. In particular, the charm physics performed at CLEO-c, running at the open charm threshold, produced some results that would not be surpassed by *BABAR* or Belle and gave some tight constraints. ARGUS, CLEO, and the LEP experiments investigated bottom hadrons directly and gave a first picture of what to expect in terms of the SM picture of the Unitarity Triangle. However, the question remained: would the SM expectation be borne out experimentally?

There are two requirements for an observable to be of interest for global fits. Firstly the observable must be something that is "theoretically clean", meaning that the theoretical uncertainties in predicting this quantity in the SM are negligible or at least small. If this is not satisfied, then one will have trouble incorporating theoretical uncertainties into the comparison of data with the model. The result may be apparent deviations from the SM that in reality have a more mundane origin, since they are really a manifestation of an approximate calculation in a SM framework. The second requirement is that one can make a significant measurement of the observable of interest. When looking for CP violation in order to test the KM mechanism this translates into finding evidence for a non-zero level of indirect CP violation. While direct CP violation is also of interest, hadronic uncertainties arising from strong phase differences, which are difficult to calculate, limit the constraints that can be placed on the SM using direct CP asymmetries.

In the context of searching for physics beyond the SM the requirement that an observable be theoretically clean is, again, of paramount importance. However, the requirement that one can perform a significant measurement may be relaxed in some circumstances. Broadly speaking there are two extremes that one can focus on. The first is to search for effects of forbidden or rare decays that would otherwise be absent or unobservable within the SM. If a large signal were to be found in such a mode, then that would unequivocally point to new physics. The second type of study requires the measurement of a process that is sensitive to new physics and in addition has a measur-

able SM contribution. Here one aims to compare a precisely measured observable with the SM expectation to see if there is agreement or not. A significant deviation from the SM would indicate new physics, and compatibility with the SM can be used to infer constraints on new physics models or even exclude them. Any deviation from the SM expectation can be used to constrain the ratio of the complex coupling divided by the square of the energy scale of the new physics appearing in the Lagrangian. This approach is complementary to direct searches at the LHC where one constrains the energy scale directly.

In recent years the focus on constraining benchmark new physics scenarios has matured with the realization that individual searches have so far failed to produce an unambiguous discovery. By combining constraints from a number of different modes one can learn about the allowed structure of beyond-SM scenarios — that is, which patterns of new physics predictions are compatible with the data. This aspect of the B Factory program remains a focus for the next generation of experiments.

Experimental guidance is required in order to help theorists understand what possible behavior could be allowed by new physics, while still being compatible with the existing constraints on the SM. For this reason it is important to understand the SM description of CP violation, which is discussed in Section 25.1, and also to explore benchmark new physics models (Section 25.2), until such time as an experimental discovery is made that can be used to guide us toward an improved understanding of nature.

25.1 Global CKM fits

25.1.1 Introduction

The previous sections of this book present a plethora of analyses that provide measurements of various observables, which in turn can be related to fundamental theory parameters. In particular, some observables are connected with the elements of the CKM matrix, which for three quark families is specified by four independent parameters as discussed in detail in Section 16.4. One convenient parameterization of the CKM matrix is the small-angle approximation by Wolfenstein, Eq. (16.4.4). In this approximation, following the Wolfenstein-Buras redefinition, there are four parameters, A, λ, $\bar{\rho}$ and $\bar{\eta}$, that fully determine the CKM matrix, see Eqns (16.4.5), (16.4.6), and (16.4.8).

The parameter A is of order one and is determined by V_{cb}, λ is the expansion parameter and is related to the Cabibbo angle by $\lambda = \sin\theta_c$, and $\bar{\rho}$ and $\bar{\eta}$ represent the apex of the Unitarity Triangle (see Section 16.5). A non-zero value of $\bar{\eta}$ indicates CP violation in the Standard Model. These four parameters are simultaneously determined by combining various experimental results and theory parameters connecting the observables to the CKM formulation in a global CKM fit.

This section gives a brief overview of CP violation in the era of the B Factories (Section 25.1.2) before describing two global fit strategies that were continually updated during that time (Section 25.1.3). Experimental and theoretical inputs required in order to perform a global fit are discussed in Sections 25.1.4 and 25.1.5, respectively. Results of SM-based global fits are given in Section 25.1.6, and concluding remarks can be found in Section 25.1.7.

25.1.2 CP violation in the era of the B Factories

One of the most important results of the B Factory physics program is the observation that CP violation in quark flavor-changing processes is described by the Kobayashi-Maskawa (KM) mechanism. The KM mechanism has been tested to $\sim \mathcal{O}(10\%)$ by current measurements from the B Factories. In the KM mechanism, only one fundamental weak phase (the Kobayashi-Maskawa phase δ in Eq. (16.4.3)) is present and δ is the single source of CP violation in the SM in the quark sector. The consistency of ε_K with the observed CP violation in B_d decays and measurements of sides and angles of the Unitarity Triangle all point to this common origin of CP violation. In addition, both the value of Δm_s and the recent LHCb measurements of the weak phase describing mixing-induced CP violation in B_s decays agree with the KM mechanism within

errors. This agreement between $b \to d$, $b \to s$ and $s \to d$ transitions is nicely illustrated in Fig. 25.1.1. Another important confirmation of the KM mechanism is the observation that a global CKM fit with only CP-conserving observables and one with only CP-violating observables yield the same values of $\bar{\rho}$ and $\bar{\eta}$, as shown in Figs 25.1.2 and 25.1.3.

25.1.3 Methodology

Two main collaborations have performed global CKM fits, periodically releasing new results in concert with updated measurements from the B Factories. Therefore the impact of new measurements from BABAR and Belle were constantly discussed in terms of their constraints on the SM, and of possible tensions that could point toward new physics. The methodologies employed by these two groups, CKMfitter and UTfit, are discussed below. Detailed references to the various global fit analyses performed are given in the sections concerned with the experimental and theoretical inputs later in this chapter. For the purpose of this book, the two groups used a unified set of inputs coming from the book averages of B Factory data in the context of the Standard Model description of quark flavor-changing processes.

A third approach, called the scan method, has been described in a recent paper (Eigen, Dubois-Felsmann, Hitlin, and Porter, 2013). This method makes minimal assumptions as to the distribution of theory errors in fitting for the Unitarity Triangle parameters, instead scanning over a large range of theoretical parameters for fits found to have an acceptable χ^2 value. It also extends the global fit, allowing the determination of correlations in the fit between underlying physical parameters that are related to more than one observable, *e.g.* ϕ_1 and ϕ_2. The statistical procedure used in the scan method follows the approach adopted in the BABAR physics book (Harrison and Quinn, 1998).

25.1.3.1 CKMfitter

The CKMfitter group (Charles et al., 2005), a collaboration of experimental and theoretical physicists, performs phenomenological studies related to flavor physics and CP violation. To quantify the impact of measurements on the SM parameters as well as on some postulated extensions of the SM, they developed a global fit package based on a frequentist statistical approach. They use a specific model for theoretical uncertainties (most often related to the assessment of hadronic quantities) as biases bounded in a range, Rfit (Höcker, Lacker, Laplace, and Le Diberder, 2001).

The CKMfitter group adopted the following framework. They constrain a certain number of parameters in the model such as the Wolfenstein parameters describing the CKM matrix, quark masses, or hadronic quantities in order to compare a set of observations $\boldsymbol{x}_{\mathrm{obs}}$ with their

theoretical predictions in a given model. The unknown parameters entering the theoretical predictions are split into two sets, parameters of interest such as $(\overline{\rho}, \overline{\eta})$ denoted by $\boldsymbol{\mu}$, and those of no interest called nuisance parameters, such as hadronic quantities, which are denoted by $\boldsymbol{\nu}$.

A general approach to constrain the fundamental parameters of interest is a hypothesis test, quantifying the compatibility of the data with the null hypothesis that the true value of a fundamental parameter μ_t is equal to a particular value μ. In order to interpret the distribution of observables under the null hypothesis, a test statistic measuring whether the data are compatible or not is defined. In analogy with the case of simple hypotheses for which all the values of the fundamental parameters are defined, the CKMfitter framework uses the maximum likelihood ratio defined as

$$\Lambda(\boldsymbol{x}, \boldsymbol{\mu}) = \frac{\sup_{\boldsymbol{\nu}} L_{\boldsymbol{x}}(\boldsymbol{\mu}, \boldsymbol{\nu})}{\sup_{\boldsymbol{\mu}, \boldsymbol{\nu}} L_{\boldsymbol{x}}(\boldsymbol{\mu}, \boldsymbol{\nu})}, \qquad \Delta\chi^2 = -2\ln(\Lambda),$$

(25.1.1)

where $L_{\boldsymbol{x}}(\boldsymbol{\mu}, \boldsymbol{\nu})$ denotes the likelihood built from experimental data and theoretical inputs $\boldsymbol{x}$, and sup refers to the supremum, otherwise known as least upper bound. Note that the $\Delta\chi^2$ of the test statistic does not necessarily follow a χ^2 distribution, especially if the distributions of the observables exhibit significant non-Gaussian properties. In the asymptotic regime, however, Wilks' theorem states that the distribution of $\Delta\chi^2$ should converge to a χ^2 distribution depending only on the number of parameters tested (Wilks, 1938).

From this test statistic, a p-value for the observations $\boldsymbol{x}_{\text{obs}}$ is built under the null hypothesis $\mu_t = \mu$ corresponding to the probability that the test statistic is as large as, or larger than, that observed

$$p(\boldsymbol{x}_{\text{obs}}; \boldsymbol{\mu}) = \mathcal{P}[\Delta\chi^2 \geq \Delta\chi^2(\boldsymbol{x}_{\text{obs}}; \mu)].$$

(25.1.2)

Small p-values provide evidence against the null hypothesis. This p-value can be computed using pseudo experiments with Monte Carlo methods, or directly in terms of incomplete Γ functions if one assumes that the asymptotic regime has been reached. After having computed the p-value associated with each value of μ, confidence intervals for a given confidence level can be defined by considering the region where $1 - \text{C.L.} \leq p(\boldsymbol{x}; \boldsymbol{\mu})$.

Practically the fit is performed by scanning $\boldsymbol{\mu}$, minimizing the likelihood $L_{\boldsymbol{x}}$ with respect to the other parameters, and identifying the "best-fit" value. Unless explicitly provided by the experiments, the likelihoods are built assuming the uncertainties in the experimental measurements are Gaussian, whereas the theoretical errors are treated in the Rfit scheme as constrained in a strict range. The p-values are extracted from the scan of the test statistic and are analyzed to provide confidence intervals or confidence regions for the fundamental parameters of interest.

25.1.3.2 UTfit

The UTfit Collaboration is formed of experimental and theoretical physicists performing the Unitarity Triangle

analysis following the method described in Ciuchini et al. (2001) and Bona et al. (2005). This section summarizes the basic ingredients of the UTfit analysis method that is developed in the framework of a Bayesian approach.

In the following sections, several equations are given that relate a constraint c_j (where c_j stands for one of M constraints such as $|V_{ub}/V_{cb}|$, Δm_d, Δm_s, $|\varepsilon_K|$ and etc., for $j = 1, \ldots, M$) to the Unitarity Triangle parameters $\overline{\rho}$ and $\overline{\eta}$, via a set of N ancillary parameters $\boldsymbol{x}$, where $\boldsymbol{x} = \{x_1, x_2, \ldots, x_N\}$ stand for all experimentally determined or theoretically calculated quantities on which the various c_j depend:

$$c_j \equiv c_j(\overline{\rho}, \overline{\eta}; \boldsymbol{x}).$$

(25.1.3)

In the ideal case of exact knowledge of c_j and $\boldsymbol{x}$, each of the constraints provides a curve in the $(\overline{\rho}, \overline{\eta})$ plane. In such a case, there would be no reason to favor any of the points on the curve, unless one has some further information or physical prejudice, which might exclude points outside a determined physical region, or, in general, assign different weights to different points. In reality one suffers from several uncertainties on the quantities c_j and $\boldsymbol{x}$. However, there are values for c_j and $\boldsymbol{x}$ which can be considered as ruled out. For example if one considers the measurement of $\phi_3 = (67 \pm 11)°$, the value of this angle is currently constrained to lie within some *almost certain* range, $45° < \phi_3 < 89°$, and so a value of $\phi_3 \sim 20°$ is excluded. Moreover, it is much more probable that the value of ϕ_3 lies between $56°$ and $78°$ rather than in the rest of the interval, in spite of the fact that the two subintervals have the same widths. This means that, instead of a single curve in the $(\overline{\rho}, \overline{\eta})$ plane, one has a family of curves which depends on the distributions of c_j and $\boldsymbol{x}$. As a result, different points in the $(\overline{\rho}, \overline{\eta})$ plane have different weights (even if they were taken to be equally probable *a priori*) and our confidence on the values of $\overline{\rho}$ and $\overline{\eta}$ clusters in a region of the plane.

The above considerations can be formalized using the Bayesian approach: the uncertainty is described in terms of a probability density function ($p.d.f.$) which quantifies our confidence on the values of a given quantity. The inference of $\overline{\rho}$ and $\overline{\eta}$ becomes a straightforward application of probability theory. In the following, all the $p.d.f.$s are called $f(\ldots)$ assuming a different functional form that depends on the specified arguments.

We can define the $p.d.f.$ $f(\overline{\rho}, \overline{\eta})$ that takes into account the uncertainties on c_j and $\boldsymbol{x}$:

$$f(\overline{\rho}, \overline{\eta}) \propto \int \frac{1}{\sqrt{2\pi}\,\sigma(c_j)} \exp\left[-\frac{(c_j(\overline{\rho}, \overline{\eta}, \boldsymbol{x}) - \widehat{c}_j)^2}{2\,\sigma^2(c_j)}\right] \cdot$$
$$\cdot f(x_1) \cdot f(x_2) \cdots f(x_N)\, \mathrm{d}\boldsymbol{x},$$

(25.1.4)

where $\widehat{c}_j$ is the experimental best estimate of c_j, with uncertainty $\sigma(c_j)$. For simplicity, a Gaussian distribution can be assumed as an individual $p.d.f.$ for each constraint c_j. In principle we should consider a joint $f(c_j, \boldsymbol{x})$, but we split it into the product of the individual $p.d.f.$s, assuming quantities are independent.

Although the above derivation of Eq. (25.1.4) is probably the most intuitive one, UTfit choose to define a global

inference relating $\overline{\rho}$, $\overline{\eta}$, c_j and $\boldsymbol{x}$, which is the usual way of performing Bayesian inference. This method is followed by a second step where marginalization is performed over those quantities which are not of interest. In this case Bayes theorem can be used to give

$$
\begin{aligned}
f(c_j, \overline{\rho}, \overline{\eta}, \boldsymbol{x} \,|\, \widehat{c}_j) &\propto f(\widehat{c}_j \,|\, c_j, \overline{\rho}, \overline{\eta}, \boldsymbol{x}) \cdot f(c_j, \overline{\rho}, \overline{\eta}, \boldsymbol{x}) \\
&\propto f(\widehat{c}_j \,|\, c_j) \cdot f(c_j \,|\, \overline{\rho}, \overline{\eta}, \boldsymbol{x}) \cdot f(\boldsymbol{x}, \overline{\rho}, \overline{\eta}) \\
&\propto f(\widehat{c}_j \,|\, c_j) \cdot \delta(c_j - c_j(\overline{\rho}, \overline{\eta}, \boldsymbol{x})) \cdot \\
&\quad \cdot f(\boldsymbol{x}) \cdot f_\circ(\overline{\rho}, \overline{\eta}),
\end{aligned} \tag{25.1.5}
$$

where $f_\circ(\overline{\rho}, \overline{\eta})$ denotes the *prior* probability distribution. Equation (25.1.4) can be recovered by i) assuming a Gaussian error function for $\widehat{c}_j$ around c_j; ii) considering the various x_i as independent; iii) taking a flat *a priori* distribution for $\overline{\rho}$ and $\overline{\eta}$; and iv) by integrating Eq. (25.1.5) over c_j and $\boldsymbol{x}$.

At this point, the extension of the formalism to several constraints is straightforward. One can rewrite Eq. (25.1.5) as

$$
\begin{aligned}
f(\overline{\rho}, \overline{\eta}, \boldsymbol{x} \,|\, \widehat{c}_1, ..., \widehat{c}_M) &\propto \prod_{j=1,M} f_j(\widehat{c}_j \,|\, \overline{\rho}, \overline{\eta}, \boldsymbol{x}) \times \prod_{i=1,N} f_i(x_i) \times \\
&\quad \times f_\circ(\overline{\rho}, \overline{\eta}),
\end{aligned} \tag{25.1.6}
$$

where the conditioning on f_j from the c_j have been removed, since the c_j act as intermediate variables which are integrated away to obtain a marginal probability distribution.

Integrating Eq. (25.1.6) over $\boldsymbol{x}$, one can rewrite the global inference in the following way:

$$
f(\overline{\rho}, \overline{\eta} \,|\, \widehat{\mathbf{c}}, \mathbf{f}) \propto \mathcal{L}(\widehat{\mathbf{c}} \,|\, \overline{\rho}, \overline{\eta}, \mathbf{f}) \times f_\circ(\overline{\rho}, \overline{\eta}), \tag{25.1.7}
$$

where $\widehat{\mathbf{c}}$ stands for the set of measured constraints, $\mathbf{f}$ indicates the dependence from the set of *p.d.f.*s that can be explicitly written as:

$$
\mathcal{L}(\widehat{\mathbf{c}} \,|\, \overline{\rho}, \overline{\eta}, \mathbf{f}) = \int \prod_{j=1,M} f_j(\widehat{c}_j \,|\, \overline{\rho}, \overline{\eta}, \boldsymbol{x}) \prod_{i=1,N} f_i(x_i) \, \mathrm{d}x_i \tag{25.1.8}
$$

which is the effective overall likelihood taking into account all possible values of x_j, properly weighted. Hence the overall likelihood depends on the best knowledge of all x_i, described by $f(\boldsymbol{x})$.

In conclusion, while *a priori* all values for $\overline{\rho}$ and $\overline{\eta}$ are considered equally likely, *a posteriori* the probability clusters around the point which maximizes the likelihood. The final (unnormalized) *p.d.f.* obtained starting from a flat distribution of $\overline{\rho}$ and $\overline{\eta}$ is

$$
f(\overline{\rho}, \overline{\eta}) \propto \int \prod_{j=1,M} f_j(\widehat{c}_j \,|\, \overline{\rho}, \overline{\eta}, \boldsymbol{x}) \prod_{i=1,N} f_i(x_i) \, \mathrm{d}x_i, \tag{25.1.9}
$$

where the integration can be performed using Monte Carlo methods.

25.1.4 Experimental inputs

The following sections discuss the observables that are used in global fits in order to extract CKM parameters.

The input values used for these observables are taken from the averages performed for this book and they are summarized in Tables 25.1.1 and 25.1.2.

25.1.4.1 $|V_{ud}|$ and $|V_{us}|$

The magnitudes of the CKM elements V_{ud} and V_{us} required in the CKM global fits are extracted from semileptonic $u \to d$ and $u \to s$ transitions that are not measured at the B Factories. These two CKM matrix elements are the most precisely measured parameters. The determination of V_{ud} involves super-allowed $0^+ \to 0^+$ nuclear beta decays and $\pi^+ \to \pi^0 e^+ \nu$ decays. The determination of V_{us} is based on semileptonic kaon decays. Results are provided by the Flavianet working group (Antonelli et al., 2010b). For the extraction of V_{us}, various structure constants are needed, which are calculated using lattice QCD analyses by averaging the latest $N_f = 2 + 1$ calculations by BMW (Durr et al., 2010), MILC'09 (Bazavov et al., 2009) and HPQCD/UKQCD (Follana, Davies, Lepage, and Shigemitsu, 2008). The latest results yield (Beringer et al., 2012)

$$
|V_{ud}| = 0.97425 \pm 0.00022, \tag{25.1.10}
$$
$$
|V_{us}| = 0.2252 \pm 0.0009. \tag{25.1.11}
$$

25.1.4.2 B Factory results

The experimental inputs from the B Factories are:

Unitarity Triangle sides (see Section 16.5):
The sides of the Unitarity Triangle are:

$$
R_u = \frac{|V_{ud}||V_{ub}|}{|V_{cd}||V_{cb}|} = \sqrt{\overline{\rho}^2 + \overline{\eta}^2} \tag{25.1.12}
$$

and

$$
R_t = \frac{|V_{td}||V_{tb}|}{|V_{cd}||V_{cb}|} = \sqrt{(1 - \overline{\rho})^2 + \overline{\eta}^2}. \tag{25.1.13}
$$

Since $|V_{tb}| \simeq 1$ and $|V_{cd}| \sim |V_{us}|$, we just need to focus on measurements of $|V_{cb}|$, $|V_{ub}|$ and $|V_{td}|$.

- $|V_{cb}|$: this CKM matrix element is measured in semileptonic $b \to c$ transitions as described in Section 17.1. The present average over inclusive and exclusive decays yields $|V_{cb}| = [41.67\,(1 \pm 0.009_{\mathrm{exp}} \pm 0.012_{\mathrm{th}})] \times 10^{-3}$.
- $|V_{ub}|$: this is the CKM matrix element measured in semileptonic $b \to u$ transitions as described in Section 17.1. The present average over inclusive and exclusive decays yields $|V_{ub}| = [3.95\,(1 \pm 0.096_{\mathrm{exp}} \pm 0.099_{\mathrm{th}})] \times 10^{-3}$.
- $|V_{td}|$: this CKM matrix element is extracted from the oscillation frequency Δm_d in $B_d^0 \overline{B}_d^0$ mixing as shown in Eq. (17.2.1). The definition of Δm_d from first principles is given in Section 10.1, while its experimental extraction is described in Section 17.5.2. To relate Δm_d to $|V_{td}|$, we need to

know several other quantities: the Inami-Lim function $S_0(x_t)$ (Buras and Fleischer, 1998; Inami and Lim, 1981) with $x_t = m_t^2/M_W^2$, the top mass m_t taken in the $\overline{MS}$ scheme ($\overline{m}_t$, see below), the perturbative QCD short-distance NLO correction η_B, and the non-perturbative QCD parameters f_{B_d} and B_{B_d}. Table 25.1.3 lists the latest lattice QCD calculations for the latter two parameters (see Section 25.1.5), while m_t is listed in Table 25.1.2.

Unitarity Triangle angles:

- ϕ_1: this weak phase is defined in terms of CKM matrix elements in Eq. (16.5.3). The most precise measurements of this quantity are obtained via time-dependent CP analyses of $b \to c\bar{c}s$ processes. The analyses contributing to ϕ_1 measurements are described in detail in Section 17.6 and yield $\sin 2\phi_1 = 0.677 \pm 0.020$. The ambiguities from the $\sin 2\phi_1$ measurements are resolved via measurements of final states that have an asymmetry dependence on $\cos 2\phi_1$ (see Section 17.6.8).

- ϕ_2: this weak phase is defined in terms of CKM matrix elements in Eq. (16.5.4) and is measured in $b \to u\bar{u}d$ processes. The analyses contributing to ϕ_2 measurement are described in detail in Section 17.7. Averaging results from charmless two-body B decays into $\pi\pi$, $\rho\rho$, and $\rho\pi$ final states yields $\phi_2 = (88 \pm 5)°$.

- ϕ_3: this weak phase is defined in terms of CKM matrix elements in Eq. (16.5.5) and is extracted in $B \to D^{(*)}K$ and $B \to DK^*$ decays using various methods. The individual analyses are described in detail in Section 17.8. The present average from the B Factories is $\phi_3 = (67 \pm 11)°$.

Leptonic decays:

- $\mathcal{B}(B \to \tau\nu_\tau)$: this branching fraction is linked to the CKM matrix elements $|V_{ub}|$ and the B decay constant f_{B_d} via Eq. (17.10.4). Including the recent Belle results as discussed in Section 17.10.2.2, the present world average is $(1.15 \pm 0.23) \times 10^{-4}$.

25.1.4.3 Other measurement inputs

A number of other experimental inputs are required in order to perform global fits. The values of these experimental inputs can be found in the review of particle physics compiled by the PDG (Beringer et al., 2012). The most relevant of these other observables are ε_K, Δm_s and the quark masses. They are described in the following:

- ε_K: this parameter represents indirect CP violation in the mixing in the $K^0\overline{K^0}$ system. Defining the ratios of decay amplitudes of K_S and K_L into two pions as

$$\eta_{00} \equiv \frac{\mathcal{A}(K_L \to \pi^0\pi^0)}{\mathcal{A}(K_S \to \pi^0\pi^0)}, \quad \eta_{+-} \equiv \frac{\mathcal{A}(K_L \to \pi^+\pi^-)}{\mathcal{A}(K_S \to \pi^+\pi^-)}, \quad (25.1.14)$$

indirect (in the mixing) and direct (in the amplitudes) CP violation can be parameterized by

$$\varepsilon_K = \frac{\eta_{00} + 2\eta_{+-}}{3}, \quad \varepsilon'_K = \frac{-\eta_{00} + \eta_{+-}}{3}, \quad (25.1.15)$$

respectively.

Using the effective $\Delta S = 2$ Hamiltonian, ε_K is related to CKM parameters by

$$\begin{aligned} |\varepsilon_K| = \frac{G_F^2 m_W^2 m_K f_K^2}{12\sqrt{2}\pi^2 \Delta m_K} \widehat{B}_K \big(&\eta_{cc} S(x_c, x_c) Im[(V_{cs}V_{cd}^*)^2] \\ &+ \eta_{tt} S(x_t, x_t) Im[(V_{ts}V_{td}^*)^2] \\ &+ 2\eta_{tc} S(x_c, x_t) Im[V_{cs}V_{cd}^* V_{ts}V_{td}^*] \big), \quad (25.1.16) \end{aligned}$$

where Δm_K is the $K^0\overline{K^0}$ oscillation frequency, f_K is the kaon decay constant, m_K is the kaon mass, $\widehat{B}_K$ parameterizes the value of the hadronic matrix element (bag parameter), $S(x_q, x_{q'})$ are Inami-Lim functions for top quark and charm quark contributions that introduce QCD correction factors η_{tt}, η_{tc} and η_{cc} and all other parameters are the same as those in Eq. (17.2.1). As for Δm_d, the quantity $x_q = \overline{m}_q(m_q)^2/m_W^2$ where $q = c$, t and the quark masses are determined in the $\overline{MS}$ scheme discussed below.

While ε'_K suffers from theory uncertainties that are too large to provide a useful constraint in the $(\overline{\rho}, \overline{\eta})$ plane, ε_K provides a hyperbolic dependence between $\overline{\rho}$ and $\overline{\eta}$. This can be shown by rearranging the Wolfenstein parameters in Eq. (25.1.16):

$$|\varepsilon_K| \propto \overline{\eta}\big[(1 - \overline{\rho}) + P(A, \lambda)\big] \quad (25.1.17)$$

where P is a function of A and λ and it does not depend on $\overline{\eta}$ or $\overline{\rho}$. A fit to $K \to \pi\pi$ data yields (Beringer et al., 2012)

$$|\varepsilon_K| = (2.228 \pm 0.011) \times 10^{-3}. \quad (25.1.18)$$

- Δm_s: this parameter is the oscillation frequency measured in $B_s^0\overline{B}_s^0$ mixing and it provides a determination of the CKM matrix element $|V_{ts}|$. It is calculated in a similar way to Δm_d, using the $\Delta B = 2$ effective Hamiltonian, yielding

$$\Delta m_s = \frac{G_F^2}{6\pi^2} \eta_B M_W^2 m_{B_s} f_{B_s}^2 \widehat{B}_{B_s} S_0(x_t)|V_{ts}V_{tb}^*|^2, \quad (25.1.19)$$

where m_{B_s} is the B_s^0 mass, f_{B_s} is the B_s-decay constant, $\widehat{B}_{B_s}$ is the bag parameter and all other parameters are the same as those for Δm_d listed in Eq. (17.2.1). The numerical values of the theoretical input parameters are summarized in Table 25.1.3. The ratio $\Delta m_s/\Delta m_d$ provides a more accurate measurement of the Unitarity Triangle side R_t than Δm_d since the ratios of QCD parameters have smaller theory uncertainties than f_{B_s} and B_{Bs} themselves. The CDF experiment was the first to measure Δm_s, obtaining a value (Abulencia et al., 2006b) of:

$$17.77 \pm 0.10 \pm 0.07 \text{ ps}^{-1}. \quad (25.1.20)$$

This result has been subsequently confirmed by LHCb that obtains now an improved precision (Aaij et al., 2013d). Combining these results yields the present world average of $\Delta m_s = 17.719 \pm 0.043$ shown in Table 25.1.2.

Table 25.1.1. Input values for the global fit from B Factory measurements.

Input	Value	Reference
$\sin 2\phi_1$	0.677 ± 0.020	Section 17.6.

ϕ_3 [°]	67 ± 11	Section 17.8
Δm_d [ps^{-1}]	$0.508 \pm 0.003 \pm 0.003$	Section 17.5.2
$|V_{cb}|$ [10^{-3}]	$41.67\,(1 \pm 0.009 \pm 0.012)$	Section 17.1.6.1
$|V_{ub}|$ [10^{-3}]	$3.95\,(1 \pm 0.096 \pm 0.099)$	Section 17.1.6.2
$\mathcal{B}(B \to \tau\nu_\tau)$	$(1.15 \pm 0.23) \times 10^{-4}$	Section 17.10.2.2

– top mass: the mass of the top quark m_t has been measured by the Tevatron and the LHC experiments with a combined precision of about 0.6%, and its current average value is $m_t = (173.18 \pm 0.94)$ GeV/c^2 (Aaltonen et al., 2012a). Whatever the analysis method adopted, the quantity measured in data corresponds to the top quark mass scheme assumed in the Monte Carlo simulation used. As a consequence, there is no immediate connection between this measured value and any other mass scheme, such as the pole or $\overline{MS}$ mass scheme.

In QED the position of the pole in the propagator is the definition of the particle mass, while in QCD the quark propagator has no pole because the quarks are confined. So the problem of the definition of the quark mass can be addressed from two perspectives: the long-distance behavior which corresponds to the pole-mass scheme, and the short-distance behavior, which, for example, can be represented by the $\overline{MS}$ mass scheme. The relation between the pole mass and any other mass scheme $m_t(R, \mu)$ is expressed as a perturbative series in $\alpha_s(m_t)$ and it can be written as $m_t^{pole} = m_t(R, \mu) + \delta m_t(R, \mu)$ (Hoang and Stewart, 2008) where

$$\delta m_t(R, \mu) = R \sum_{n=1}^{\infty} \sum_{k=0}^{n} a_{nk} \left[\frac{\alpha_s(\mu)}{4\pi} \right]^n \ln^k \left(\frac{\mu}{R} \right) \tag{25.1.21}$$

with R being a dimension-one scale intrinsic to the scheme, a_{nk} finite numerical coefficients and μ is the renormalization scale. An example of this conversion can be found in Beringer et al. (2012).

The experimentally measured m_t is considered to be close to the pole mass and in some analyses it is assumed that m_t measured is indeed equal to m_t^{pole} (see for example ALEPH, CDF, D0, DELPHI, L3, OPAL, SLD and the LEP, Tevatron and SLD Electroweak and Heavy Flavour Working Groups, 2010). Conversely, the input value $\overline{m}_t$ used for the global fits is the top running mass calculated in the $\overline{MS}$ renormalization scheme and its value is obtained by pole-to-$\overline{MS}$ matching. At the 3-loop level with five quark flavors the relation is (Broadhurst, Gray, and Schilcher, 1991; Gray, Broadhurst, and Schilcher, 1990; Melnikov and van Ritbergen, 2000)

$$\overline{m}_t(m_t) = m_t \left(1 - \frac{4}{3} \left(\frac{\alpha_s(m_t)}{\pi} \right) - 9.12530 \left(\frac{\alpha_s(m_t)}{\pi} \right)^2 \right.$$

$$\left. -80.4045 \left(\frac{\alpha_s(m_t)}{\pi} \right)^3 \right), \tag{25.1.22}$$

where $\alpha_s(m_t) = 0.1068 \pm 0.0018$. This yields an $\overline{MS}$ mass of $\overline{m}_t(m_t) = 163.3 \pm 0.9$ GeV/c^2. One can compare this result with the top mass obtained using the measured cross section, which has a similar central value, but slightly larger uncertainty $\overline{m}_t(m_t) = 163.3 \pm 2.7$ GeV/c^2, for example see (Moch, 2012).

– $\overline{m}_b(m_b), \overline{m}_c(m_c), \overline{m}_s(m_s)$: these are the running quark masses evaluated in the $\overline{MS}$ scheme and at the scale indicated. The values used are given in Table 25.1.2.

25.1.5 Theoretical inputs: derivation of hadronic observables

Most of the experimental inputs described above for the global fit rely upon knowledge of hadronic matrix elements that parameterize the non-perturbative QCD contributions to weak decays and mixing. These contributions represent the connection between the quark-level fundamental quantities and the hadronic-level experimental observables.

These hadronic matrix elements are obtained from numerical lattice QCD calculations. State-of-the-art lattice computations now regularly include the effects of the sea up, down and strange quarks. They also typically use simulations at pion masses below 300 MeV/c^2, or even below 200 MeV/c^2, in order to control the extrapolation to the physical pion mass. For many hadronic matrix elements of interest, there are now at least two or more reliable lattice calculation results. In order to use the lattice inputs in a global fit, it is necessary to average different results. However as there are potentially significant correlations between various lattice uncertainties, averaging is not straightforward, and correlations must be taken into account. Statistical and systematic errors may be correlated, and one needs to be sufficiently familiar with the lattice computational methods used in order to understand how to treat a given result in the averaging procedure.

A complete review of lattice techniques is beyond the scope of this book. We therefore rely on the averaging work of Laiho, Lunghi, and Van de Water (2010). They average the latest LQCD results for leptonic decay constants, meson mixing parameters, and semileptonic form

Table 25.1.2. Input values for the global fit from other experimental measurements (non-B Factory). The quark masses are the running $\overline{MS}$ quark masses as explained in the text.

Δm_s	17.719 ± 0.043	(Amhis et al., 2012)

factors. Only results from simulations with three dynamical quark flavors are included in the averages if there are associated proceedings or publications that include comprehensive error budgets. When computing averages, they assume that all errors are normally distributed and follow the prescription outlined by Schmelling (1995) to take the correlations into account. Moreover, they assume that any correlated source of error for two lattice calculations is 100% correlated. This assumption is conservative and will lead to an overestimate of the total error of the lattice averages; nevertheless, it is the most systematic treatment possible without knowledge of the correlation matrices, which do not exist, between the various calculations. Finally, they adopt the PDG prescription to combine several measurements whose spread is wider than that expected from the quoted errors: the error on the average is multiplied by the square root of the χ^2 per degree of freedom.

The global fits use four inputs that depend on these hadronic observables: ε_K, Δm_d, Δm_s, and $B(B \to \tau\nu_\tau)$. These are related to two decay constants (f_{B_d}, f_{B_s}) and three hadronic matrix elements (B_K, B_{B_d}, B_{B_s}). The preferred choice of minimally correlated inputs is B_K, f_{B_s}/f_{B_d}, B_{B_s}/B_{B_d}, B_{B_s} and f_{B_s}. In general the quantities related to $B_s^0\overline{B}_s^0$ mixing are preferred as current lattice QCD calculations can simulate directly at the physical s-quark mass, but must extrapolate to the u- and d-quark masses. Therefore the chiral extrapolation error, which is often the dominant systematic, is smaller for B_{B_s} and f_{B_s} than for the lighter B meson parameters. The ratios are chosen in order to benefit from cancellations of uncertainties done on the lattice. A basic description of the hadronic quantities that must be included in the global fits follows:

– B_K is related to the parameter ε_K as defined in Section 25.1.4.3. When strong interactions are considered, $\Delta S = 2$ transitions can no longer be discussed at the quark level. Instead, an effective Hamiltonian must be considered between mesonic initial and final states. Since the strong coupling constant is large at typical hadronic scales, the resulting matrix element cannot be calculated in perturbation theory. However the OPE does factorize long- and short-distance effects.

The dependence on the renormalization scheme and scale μ is canceled by that of the hadronic matrix element $\langle \overline{K}^0 | Q_R^{\Delta S=2}(\mu) | K^0 \rangle$. The latter corresponds to the long-distance effects of the effective Hamiltonian and must be computed non-perturbatively. For historical, as well as technical reasons, it is convenient to express it in terms of the parameter B_K, defined as:

$$B_K(\mu) = \frac{\langle \overline{K}^0 | Q_R^{\Delta S=2}(\mu) | K^0 \rangle}{\frac{8}{3} m_K^2 f_K^2}. \qquad (25.1.23)$$

The four-quark operator $Q^{\Delta S=2}(\mu)$ is renormalized at the scale μ in some regularization scheme, usually taken to be the naïve dimensional regularization. The renormalization group independent parameter $\widehat{B}_K$ is related to $B_K(\mu)$ by a function of the renormalized gauge coupling $(\overline{g}(\mu))$ and perturbative coefficients (β_0, β_1, γ_0, and γ_1):

$$\widehat{B}_K = \left(\frac{\overline{g}(\mu)^2}{4\pi} \right)^{-\frac{\gamma_0}{2\beta_0}} \left[1 + \frac{\overline{g}(\mu)^2}{(4\pi)^2} \left(\frac{\beta_1\gamma_0 - \beta_0\gamma_1}{2\beta_0} \right) \right] B_K(\mu). \qquad (25.1.24)$$

A more detailed discussion can be found in (Colangelo et al., 2011) and references therein.

– for B_s, the parameter of the renormalized operator is defined as

$$B_{B_s}(\mu) = \frac{\langle \overline{B}_s | Q_d^{\Delta B=2}(\mu) | B_s \rangle}{\frac{8}{3} m_{B_s}^2 f_{B_s}^2}, \qquad (25.1.25)$$

where $Q_s^{\Delta B=2} = (\overline{b}\gamma^\mu(1-\gamma_5)s)(\overline{b}\gamma_\mu(1-\gamma_5)s)$ and μ is the renormalization scale. This definition stems from the vacuum saturation approximation in which $B_{B_s} = 1$. One can define B_{B_d} in a similar way.

The renormalization group invariant parameter $\widehat{B}_{B_s}$ of Eq. (25.1.19) is defined as

$$\widehat{B}_{B_s} = \alpha_S(\mu)^{-\frac{\gamma_0}{2\beta_0}} \left(1 + \frac{\alpha_S(\mu)}{4\pi} J \right) B_{B_s}(\mu). \quad (25.1.26)$$

In all schemes $\gamma_0 = 4$, whereas J depends on the scheme used for renormalizing $Q_s^{\Delta B=2}(\mu)$. In the theoretical expressions, the physical amplitudes are always

defined in terms of $\widehat{B}_{B_s}$. The advantage is that this quantity is both renormalization scale and scheme independent.

However, the important quantities are not the B parameters themselves but the combinations $f_x^2 B_x$ (where x can be K or $B_{d,s}$) which are simply related to the physical amplitudes by the factors $8m_x^2/3$. In the case of the kaon system, the decay constant is derived from experiments as one measures the product $|V_{us}|f_K$, while for the $B_{d,s}$ mesons, we rely on lattice QCD determinations.

The hadronic parameters from lattice QCD discussed above and used as inputs for the global fits can be found in Table 25.1.3.

25.1.6 Results from the global fits

Here we report the results for the global fits from the two main collaborations described in Section 25.1.3. Using all the inputs described in the previous sections and the statistical techniques specific to the two fitting groups, it is possible to extract the CKM matrix parameters from global fits to the set of relevant measurements. Particular attention is paid to the least precisely determined parameters $\bar{\rho}$ and $\bar{\eta}$, especially in light of their importance with regard to CP violation in the SM.

Table 25.1.4 shows the numerical results obtained from the two global fits performed using the inputs given in Tables 25.1.1, 25.1.2 and 25.1.3. Fig. 25.1.1 shows the $(\bar{\rho}, \bar{\eta})$ plane illustrating the constraints used along with the results from the two global fits. These results are consistent, indicating that there is sufficient experimental data to draw meaningful conclusions regarding the CKM matrix picture using either frequentist or Bayesian approaches. The combination of all the constraints gives a single preferred area, illustrating the exceptional agreement of measurements with SM predictions.

Table 25.1.4. Results from the global fits.

Parameter	Output Value	
	CKMfitter	UTfit
$\bar{\rho}$	$0.129^{+0.027}_{-0.022}$	0.130 ± 0.020
$\bar{\eta}$	0.345 ± 0.014	0.348 ± 0.013
$\sin 2\phi_1$	0.684 ± 0.019	0.689 ± 0.018
ϕ_2 [°]	$88.8^{+4.2}_{-3.6}$	88.4 ± 2.8
ϕ_3 [°]	$68.9^{+3.5}_{-4.2}$	69.5 ± 3.0

The compatibility of the constraints used can be evaluated in each of the two fit methods by excluding a single given constraint at a time and evaluating the value for that observable from the global fit performed using all the other constraints. The comparison between this inferred (or predicted) value and the value of the excluded constraint can be used to test the agreement of each individual constraint with respect to all the others, assuming

that the SM is an adequate description of the underlying physics. These predictions are shown in Table 25.1.5.

A few small tensions are currently present in the global fits. None of these are statistically significant, however they should be kept in mind in light of future updates. The value of $\sin 2\phi_1$ is now obtained with such a small uncertainty that it is driving the other predictions, thus highlighting some inconsistencies. For example, ε_K is showing some tension through the less precise determination of the $\widehat{B}_K$ parameter. Moreover, the two determinations of $|V_{ub}|$ and $|V_{cb}|$ still present marginal agreement between the inclusive and exclusive values and in particular the inclusive values show more significant discrepancies in the context of the global fit. Future improvements in lattice QCD determinations will be extremely interesting to assess these effects.

Historically there has been tension between the $B \to \tau\nu$ branching fraction and other constraints on the CKM matrix. For a number of years this tension was interpreted by the community as being a possible hint for new physics. At the time of writing, the experimental situation is compatible with the SM, and there is no significant tension evident between the constraints. The results shown in Table 25.1.4 include the branching fraction of $B \to \tau\nu$ as an input, however very similar results are obtained when this input is removed from the global fit. See Section 17.10 for more details regarding the experimental determination of the branching fraction of $B \to \tau\nu$, and the subsequent interpretation of this observable.

As stated at the start of this chapter, it is also possible to illustrate the success of the SM in describing the measurements of the B Factories by comparing the values obtained for $\bar{\rho}$ and $\bar{\eta}$ for CP-conserving and CP-violating quantities. These constraints are shown in Figs 25.1.2 and 25.1.3. The agreement between these determinations of the apex of the Unitarity Triangle is good, and is taken as evidence that the CKM matrix and KM mechanism give the leading order description of quark mixing and CP violation in the SM. The dominant CP-violating constraints come from charmonium decay measurements of $\phi_1 = \beta$ (Section 17.6) and charmless B decay measurements of $\phi_2 = \alpha$ (Section 17.7). Such a coherent picture is of course possible only after more than a decade of precise measurement by experimentalists and the corresponding improvement in theoretical control and understanding.

25.1.7 Conclusions

Data from the B Factories have enabled the KM mechanism to be tested in a comprehensive way using direct measurements of CP-violating observables. The constraints from CP-violating observables alone is sufficient to verify that the KM mechanism is the dominant source of CP violation in the SM. The level of CP violation measured via Unitarity Triangle angles in B decays is consistent with that obtained from other tests of the CKM matrix (sides: V_{ub}, V_{cb}, mixing parameters, and ε_K). The set of non-angle constraints related to the Unitarity Triangle in the

SM provides a complementary test of the CKM mechanism, however those constraints require theoretical input in order to translate measurements into a constraint on the apex of the Unitarity Triangle. Hence the B factories provided an experimentally and theoretically clean set of tests of the Standard Model in the measurements of the angles of the Unitarity Triangle. M. Kobayashi and T. Maskawa shared the 2008 Nobel Prize for their model of CP violation that inspired several generations of experimental exploration. During the lifetime of the B Factories
Figure 25.1.2. The consistency between the fit to *CP*-conserving observables (left) and *CP*-violating observables (right) from the CKMfitter group. The *CP*-conserving observables are the $B^0 - \bar{B}^0$ and $B_s^0 - \bar{B}_s^0$ mass differences, Δm_d and Δm_s, respectively, and the measurement of $|V_{ub}|$ from semileptonic $b \rightarrow dl\nu_l$ decays. The *CP*-violating observables are from K (ε_K) and B (ϕ_1, ϕ_2, ϕ_3) decays.
Figure 25.1.3. The consistency between the fit to *CP*-conserving observables and from K measurements (on the left) and the angles (B Factory-dominated on the right) from the UTfit group. The constraints used in the left plot are the $B^0 - \bar{B}^0$ and $B_s^0 - \bar{B}_s^0$ mass differences, Δm_d and Δm_s, respectively, the measurements of $|V_{ub}|$ and $|V_{cb}|$ from semileptonic B decays, and the *CP*-violation parameter ε_K. The constraints used in the right plot are the "angles" observables, *i.e.* measurements of ϕ_1 ($= \beta$), ϕ_2 ($= \alpha$), and ϕ_3 ($= \gamma$).

a number of constraints have been found to be in not-so-good agreement, and such tensions in the data have led to speculation of possible new physics scenarios, however the Standard Model persists.

The Tevatron and LHC experiments (CDF, DØ, AT-LAS, CMS, and LHCb) have also produced results that can be used to test the *CP*-violating flavor parameters related to the Standard Model description of B meson decays. While a detailed discussion is beyond the scope of this book, it should be noted that measurements from these experiments are compatible with results from the B Factories. At the time of writing this book, there is no significant evidence for a departure from the KM picture of *CP* violation and the CKM matrix description of quark mixing.

It should be noted that it is still possible for sources of new physics to exist. Indeed given our understanding of the cosmological model of the Big Bang, it is thought that new sources of *CP* violation must exist. Any higher

order contributions to *CP* violation in the quark sector that might be manifest in a hypothetical new physics scenario are constrained by the results discussed in this section: *i.e. CP* violation in the quark sector beyond the SM cannot be $\mathcal{O}(1)$. In the absence of experimental indications of a departure from the CKM picture the particle physics community chooses to explore the space of possible new physics models. Given the variety of such models, one has to focus on the predictions and behavior of specific benchmark models, a number of which are discussed in Section 25.2.

25.2 Benchmark new physics models

Editors:
Emi Kou, Jure Zupan (theory)

In this section we review the impact of the B Factories on our understanding of the flavor structure in the Standard Model (SM) and on constraining new physics (NP) models. The most important overall result of the B Factories physics program is the fact that the CP violation observed in flavor changing processes with quarks is due to the Kobayashi-Maskawa (KM) mechanism (Kobayashi and Maskawa, 1973). For instance, prior to the B Factories, the kaon sector was the only system where CP violation was observed (see Section 16.1). The observed strength of the CP violation in mixing, $\epsilon_K \simeq 2.3 \times 10^{-3}$, was consistent with the KM mechanism with an $\mathcal{O}(1)$ CP phase in the CKM matrix. While encouraging, this by no means constituted a proof that the KM mechanism was really the origin of the observed CP violation. The first test of the KM mechanism was then done by the measurement of $\sin 2\phi_1$ by the B Factories.

By now the KM mechanism has been tested at the level of $\sim \mathcal{O}(10\%)$, while deviations from its predictions at levels smaller than this are still allowed. In the KM mechanism there is only one weak phase, providing a single source of CP violation. The consistency of ϵ_K with the observed CP violation in $B_d^0 - \bar{B}_d^0$ mixing and the measurements of the sides and angles of the standard CKM Unitarity Triangle all point to this common origin of CP violation. In addition, the size of Δm_s and the recent LHCb bound on the size of the weak phase in $B_s^0 - \bar{B}_s^0$ mixing both agree with the KM mechanism within errors. This agreement between $b \to d$, $b \to s$ and $s \to d$ transitions is nicely summarized in the CKM fit plot (see Fig. 25.1.1). Another important indicator that the CP violation we are observing in flavor changing processes of quarks is due to the KM mechanism, comes from a comparison of a fit with only CP conserving observables with a fit with only CP violating observables. Both fits point to the same region in the $\bar{\rho}$ and $\bar{\eta}$ plane, which is a strong test of KM nature of CP violation (see Fig. 25.1.2).

The measurements at the B Factories also had a direct impact on new physics models. For instance, a measurement that $\sin 2\phi_1$ is $\mathcal{O}(1)$ immediately excluded approximate CP models. In these models all the couplings which govern the low energy phenomena are real or almost real, with imaginary components always much smaller than the real ones. In the SM, the observed ϵ_K and ϵ', representing the CP violation in the kaon sector, are small, which can be explained by the smallness of the CKM matrix elements entering into the description of these observables. In the approximate CP models it would be small because CP symmetry is only slightly broken and thus all CP violating phases are small. A set of well motivated realizations in the SUSY framework was put forward (Abel and Frere, 1997; Babu and Barr, 1994; Babu, Dutta, and Mohapatra, 2000; Eyal, Masiero, Nir, and Silvestrini, 1999; Eyal and Nir, 1998). For instance approximate CP conservation could naturally solve the "SUSY CP problem" explaining

why EDMs are so small. All these models were excluded once $\sin 2\phi_1$ was measured and its value turned out to be large, *i.e.* $\mathcal{O}(1)$.

Another set of models that was excluded by the fact that $\sin 2\phi_1$ was found to be bigger than 0.1, were the left-right symmetric models with spontaneous CP breaking (Ball and Fleischer, 2000; Ball, Frere, and Matias, 2000; Bergmann and Perez, 2001). In these models Yukawa interactions are CP conserving, while the CP violation arises from the complex vacuum expectation values of the Higgs fields. Because of this the value of the CKM phase δ cannot take any value, but is found to be restricted to be below $|\delta \bmod \pi| < 0.25$ (Ball, Frere, and Matias, 2000). This was experimentally excluded as soon as $\sin 2\phi_1$ was measured with some precision.

After the measurement of $\sin 2\phi_1$ it was still possible that the observed large $\sin 2\phi_1$ value was due to a new superweak-like four fermion interaction and that direct CP violation is small, just as it is small in kaon decays (Wolfenstein, 2002). This (somewhat artificial) possibility was excluded by the discovery of direct CP violation in $B \to K^+ \pi^-$ decays (Aubert, 2004u; Chao, 2005).

The constraints on general NP are best illustrated on the case of mixing. The NP contributions to $B_{d,s}^0 - \bar{B}_{d,s}^0$ mixing can be completely generally parameterized by

$$M_{12}^{d,s} = \left(M_{12}^{d,s} \right)^{\text{SM}} \left(1 + h_{d,s}\, e^{2i\sigma_{d,s}} \right), \qquad (25.2.1)$$

where $\left(M_{12}^{d,s} \right)^{\text{SM}}$ are the matrix elements of the SM effective weak Hamiltonian for $B_{d,s}^0 - \bar{B}_{d,s}^0$ mixing. The magnitudes of NP contributions relative to the SM are given by h_d and h_s for $B_d^0 - \bar{B}_d^0$ and $B_s^0 - \bar{B}_s^0$ mixing, respectively, while $\sigma_{d,s}$ are the corresponding NP weak phases. If NP models do not lead to diagrams which can induce the $B_d^0 - \bar{B}_d^0$ and $B_s^0 - \bar{B}_s^0$ mixing, then we have $h_s = h_d = 0$. Fig. 25.2.1 shows the present experimental constraints on the parameters $h_{d,s}$ and $\sigma_{d,s}$. One sees that contributions at the level of $\sim 10\%-20\%$ are allowed for any weak phase (if one includes $B \to \tau\nu$ in the fit there is a slight preference for a nonzero phase), but corrections larger than 50% are also still possible.

Note that the SM contributions to the meson mixing are both loop and CKM suppressed. The CKM suppression for $B_d^0 - \bar{B}_d^0$ mixing is $|V_{td}^* V_{tb}|^2 \sim \mathcal{O}(\lambda^6)$. The expansion parameter, $\lambda \simeq 0.23$, in the Wolfenstein parameterization of the CKM matrix equals the sine of the Cabibbo angle. Similarly, there is a CKM suppression of $B_s^0 - \bar{B}_s^0$ mixing of $|V_{ts}^* V_{tb}|^2 \sim \mathcal{O}(\lambda^4)$ and a CKM suppression of $K^0 - \bar{K}^0$ mixing proportional to $|V_{td}^* V_{ts}|^2 \sim \mathcal{O}(\lambda^{10})$. This means that, if there is new physics at the TeV scale which contributes to the mixing amplitudes at tree level or at the loop level, it has to have a very non-generic flavor structure. The upper bounds on the coupling strengths for a 1 TeV suppression scale are given in Table 25.2.1. The same table also shows the alternative interpretation of the data – giving the lower bounds on NP scale, if the coupling strengths are assumed to be large, $\mathcal{O}(1)$.
Figure 25.2.1. The present constraints on contributions from NP processes in B_s^0 mixing (left) and B_d^0 mixing (right), normalized to the SM contributions. From (Ligeti, 2011).

Table 25.2.1. Bounds on $\Delta F = 2$ operators of the form $(C/\Lambda^2)\,\mathcal{O}$, with $\mathcal{O}$ given in the first column. The bounds on Λ assume $C = 1$, and the bounds on C assume $\Lambda = 1\,\text{TeV}$. From (Hewett et al., 2012).

25.2.1 Short description of NP models

We first quickly describe the NP models we will consider. These are the models which could induce a significant deviation from the SM in the various observables measured at the B Factories and thus, have been considered as benchmark NP models. The expected deviations in B meson observables and the results from the B Factories are described in the next section, where one can also find detailed references for further reading.

Fourth generation

Since the origin of the three generations in the SM is unclear, it is natural to consider a possibility that additional generations exist. An extension of the SM by a 4th generation means that in addition to the particles in the SM there is an extra pair of heavy quarks, the t' (up-type) and b' (down-type), as well as a new heavy charged lepton and an additional heavy neutrino. We focus on the effects due

to additional heavy quarks. The CKM matrix described in Chapter 16 is now a 4×4 unitary matrix. With three generations there are four physical parameters in the CKM matrix: three rotation angles and a single complex phase, where the phase is responsible for CP violation. In a four generation model there are 3 extra rotation angles and 2 new CP violating phases compared to the SM.[183] In this model, the CKM elements obey quadrilateral and not triangle unitarity relations as in the SM. The new CP violating phases can lead to additional CP violation beyond the SM predictions (*e.g.* in the penguin $b \to s$ transitions). The violation of Unitarity Triangle relations is checked by global CKM fits (see Section 25.1, the fits were also extended to include the 4th generation).

---

[183] An $n \times n$ unitary matrix contains $2n^2 - (n + (n^2 - n)) = n^2$ real parameters while we can absorb $2n - 1$ phases in the definition of the quark fields, which results in $(n-1)^2$ real parameters. Here we assign the $n(n-1)/2$ parameters as rotation angles and the rest as phases.

Two Higgs Doublet Models

In the SM, the so-called Higgs field, an $SU(2)$ doublet scalar field, is introduced. The electroweak symmetry is broken spontaneously by its non-zero vacuum expectation value, which leads to the particle masses. This feature is retained also, if there is more than one Higgs doublet. The Two Higgs Doublet Model (2HDM) is the simplest extension of this kind, introducing one more Higgs doublet. In the particle spectrum we then have three neutral and one charged scalar. For B physics the form of the Yukawa couplings is especially important. Several interesting limits are discussed in the literature. Here we mostly focus on the so-called Type II 2HDM where each of the two Higgs doublets only couple to down or up quarks. In this way phenomenologically unacceptable FCNCs due to tree level neutral Higgs exchanges do not arise. As a result, the main effects in flavor physics are due to the charged Higgs contributions. Even though the LHC searches for the charged Higgs directly, the constraints on the properties of this new particle, its mass and its couplings, come mainly indirectly from B decays. Note that Type II 2HDM also describes the Higgs sector of the Minimal Supersymmetric Standard Model at tree level.

Minimal Flavor Violation

Minimal Flavor Violation (MFV) is a general hypothesis that can apply to a large class of NP models. The central assumption is that the *only* source of flavor violation – also in the NP sector – are the SM Yukawa coupling matrices, $Y_{U,D}$. This is the minimal amount of flavor breaking in any NP model. The flavor breaking due to $Y_{U,D}$ will at least through loop corrections then also propagate to other sectors of the NP theory.

For MFV NP, generically the FCNCs are of the same order as in the SM (but can be smaller, if NP particles involved in the FCNC process are heavy). In MFV the form of flavor violation is fixed, implying strict correlations between different processes. This is especially true for the constrained MFV (cMFV) where CP violation is only due to the CKM phase and the effective weak Hamiltonian has exactly the same form as in the SM. For instance, in the cMFV the NP contributions to $B_d^0 - \bar{B}_d^0$ mixing and $B_s^0 - \bar{B}_s^0$ mixing, when normalized to the SM, are exactly the same. A sign of cMFV would be a deviation from the SM that can be described without new CP violating phases and without enlarging the SM operator basis. A discrepancy in ϕ_1 determined from $B \to J/\psi K_S^0$ and the global Unitarity Triangle fit, on the other hand, would rule out the cMFV framework.

Extensions of MFV

One can have viable TeV NP with not too large FCNCs even, if the flavor breaking is not just due to the SM Yukawa couplings. It suffices that all the flavor breaking has a structure similar to the SM one. The most important feature is that there is a hierarchy similar to the one in the quark flavor sector of the SM. The first two generations are much lighter than the third generation. Also, the mixing between the third and the first two generations is much smaller than the one between the first two generations (*i.e.* $V_{cb}, V_{ub} \ll V_{us}$). If this pattern is also present in NP with roughly the same hierarchies and directions of flavor breaking as in the SM, then FCNCs generated by NP will not be dangerously large. This insight can be formalized using symmetries and goes by the name of general MFV (GMFV). It is more general than cMFV, but coincides with the most general form of MFV, if Yukawa couplings are perturbative. Since GMFV is more general, there are also less correlations between observables. For instance, depending on which operators dominate, the new CP violating phases in $B_d^0 - \bar{B}_d^0$ and $B_s^0 - \bar{B}_s^0$ mixing are either exactly the same or there is a new CP violating phase only in $B_s^0 - \bar{B}_s^0$ mixing as we will see below.

Supersymmetry

The supersymmetric (SUSY) extensions of the SM are some of the most popular NP models. SUSY relates fermions and bosons. For example, the gauge bosons have their fermion superpartners and fermions have their scalar superpartners. SUSY at the TeV scale is motivated by the fact that it solves the SM hierarchy problem. The quantum corrections to the Higgs mass are quadratically divergent and would drive the Higgs mass to the Planck scale $\sim 10^{19}$ GeV, unless the contributions are canceled. In SUSY models they are canceled by the virtual corrections from the superpartners. The minimal SUSY extension of the SM refers to the scenario where all the SM fields obtain superpartners but there are no other additional fields. This is the Minimal Supersymmetric Standard Model (MSSM). SUSY cannot be an exact symmetry since in that case superpartners would have the same masses as the SM particles, in clear conflict with observations. Different mechanisms of SUSY breaking have very different consequences for flavor observables. In complete generality the MSSM has more than a hundred parameters, most of them coming from the so-called soft SUSY breaking terms (the SUSY breaking terms with dimensionful couplings, such as *e.g.* masses, so that the divergence is at most logarithmic). If superpartners exist at the TeV scale the most general form with $\mathcal{O}(1)$ flavor breaking coefficients is excluded due to flavor constraints. This has been dubbed the SUSY flavor problem (or in general the NP flavor problem).

MFV SUSY

A popular solution to the SUSY flavor problem is to assume that the SUSY breaking mechanism and the induced interactions are flavor "universal". The flavor universality is often imposed at a very high scale corresponding

to the SUSY breaking mechanism. It could be at, for instance, the Planck scale ($\sim 10^{19}$ GeV), the GUT scale ($\sim 10^{16}$ GeV) or some intermediate scale such as the gauge mediation scale ($\sim 10^6$ GeV). The flavor breaking can then be transferred only from the SM Yukawa couplings to the other interactions through renormalization group running from the higher scale to the weak scale. As a result, the flavor breaking comes entirely from the SM Yukawa couplings (thus, an example of a concrete MFV NP scenario). Since the soft SUSY breaking terms are flavor-blind, the squark masses are degenerate at the high energy scale. The squark mass splitting occurs only due to quark Yukawa couplings, where only top Yukawa and potentially bottom Yukawa couplings are large. Thus the first two generation squarks remain degenerate to very good approximation, while the third generation squarks are split.

nonMFV-SUSY

While flavor blind SUSY breaking is well motivated, it is important to keep track of other possibilities – with more general flavor breaking patterns. A very useful approach is the mass insertion approximation (MIA). The approximation is easiest to explain in the basis, where the SM fermions have diagonal masses, while the sfermions have undergone exactly the same flavor transformations as their SM fermion partners (this is the so-called super-CKM basis). All neutral gauge interactions are still flavor diagonal, charged currents are proportional to the CKM elements, while the sfermion mass matrices have also off-diagonal flavor violating entries. Phenomenologically, the off-diagonal entries need to be small. They can thus be treated as perturbations, compared to the diagonal ones. The size of the resulting flavor violation is usually parametrized by dimensionless ratios of off-diagonal and (the average of) diagonal entries in mass matrices, $(\delta^q_{AB})_{ij}$, where A, B are the chiralities (L, R) and q indicates the (u, d) type. In principle $(\delta^q_{AB})_{ij}$ are only bounded by the experiments, but are otherwise completely general.

SUSY alignment models

If the squark mass basis is almost the same as the quark mass basis, then the FCNCs due to squarks and gluinos running in the loops are suppressed. Alignment of squark and quark mass matrices is easily achieved in flavor model building and could be a remnant of the underlying symmetry. The alignment models are very close in spirit to MFV models – that there is a relation between the flavor breaking in squark and quark sectors – but differ in details. For instance, in alignment models the squark matrices can carry arbitrary phases, the relation between squark and quark mass eigenstate bases is only approximate and most importantly, the first two generations squarks need not be degenerate but can have $\mathcal{O}(1)$ splitting in their mass spectra.

The bounds on FCNCs in up and down quark sectors put strong constraints on alignment models. For instance the measured values of $D^0 - \bar{D}^0$ and $K^0 - \bar{K}^0$ mixing require that the splitting between the first two generations of left-handed squarks is less than $\mathcal{O}(0.1)$ for TeV squarks masses.

Randall-Sundrum models of flavor

The Randall-Sundrum (RS) model introduces a "warped" extra dimension, *i.e.* a fifth dimension for which the metric of the five dimensional space time contains an exponential "warp" factor. The Higgs of the SM is confined to a four dimensional subspace, the "TeV brane", while the full five dimensional space is called the "bulk". This idea provides an interesting solution to the hierarchy problem by generating the weak scale from the Planck scale through this exponential warp factor. The RS model can also explain the hierarchy of fermion masses. The fermionic wave functions extend in the bulk with the heavier particles located closer to the TeV brane. Then, the fermion wave function profiles (locations of different fermions in the bulk) can also provide the exponential warp factor and an $\mathcal{O}(1)$ change in the parameters in the 5 dimensional theory can lead to the hierarchical flavor structure in the 4 dimensional theory. The existence of an extra dimension results in each SM particle to be accompanied by a whole tower of excited "Kaluza-Klein" (KK) states. The exchanges of KK excitations of gluons and the distortion of the Z boson's 5D profile then generate FCNCs at tree level. These effects are naturally suppressed, however, by the same mechanism that explains the hierarchy of fermion masses. The resulting FCNCs are not too large for the light quarks, with the exception of $K^0 - \bar{K}^0$ mixing, where modest cancellations between different contributions are required if the KK mass scale is 2-3 TeV. In this case large effects in several B physics observables are also expected. The 5D masses are complex in general, so that there are many new sources of CP violation. $\mathcal{O}(1)$ NP weak phases in $B^0_d - \bar{B}^0_d$ mixing and $B^0_s - \bar{B}^0_s$ mixing would thus be expected.

Little Higgs Models

Little Higgs models are an alternative way to solve the hierarchy problem. The mass of a scalar particle is stabilized, if it is a Goldstone boson of a spontaneously broken global symmetry. The Goldstone boson is massless, if the original global symmetry is exact, and has a small nonzero mass, if there is already a small explicit breaking of the global symmetry. Little Higgs models implement this idea by constructing an extension of the SM such that the SM Higgs particle is the Goldstone mode of an enlarged symmetry. This symmetry is also explicitly broken in order to achieve a small mass for the Goldstone modes. Unlike SUSY, the solution to the hierarchy problem in Little Higgs models is only partial – just for 1-loop corrections to the Higgs mass. The models therefore require UV completion at a scale of a few TeV, *i.e.* the models are not

valid to arbitrary high energies but need to be supplemented with extra fields and/or interactions. One of the more interesting realizations is the Littlest Higgs model with T parity. In it the SM fields are supplemented by a new heavy top quark (T_+), a triplet of heavy scalars (Φ) as well as a new set of heavy gauge bosons $W_H^\pm, Z_H^0, A_H$. It has an interesting non-MFV flavor structure with only 10 new parameters in the quark sector. As a result there are still correlations between FCNC processes in the down and up-quark sectors. The constraints from $B \to X_s\gamma$ are easily satisfied, while significant effects would be expected in B_s mixing and in $K \to \pi\nu\bar{\nu}$ and $K_L \to \pi^0\ell^+\ell^-$ decays.

25.2.2 Detailed description of NP models

We now give a more detailed description of the models, focusing especially on the impact the B Factory observables had on constraining the models. We highlight the following observables in particular, $\sin 2\phi_1$, $B \to X_s\gamma$, $B \to \tau\nu$, $D^0 - \bar{D}^0$ mixing, $B \to \phi K_s^0$, all of which are listed in Table 25.2.2. We also include the anomalous moment of the muon, $(g-2)_\mu$, as another important observable. Even though it was not measured at the B Factories, the ISR results obtained at the B Factories provide crucial inputs to the SM predictions (see Section 21.3.4 for detailed discussions on the impact of the B Factories ISR result on the muon $g-2$). For ease of comparison a star system is used in Table 25.2.2, where more stars mean that the generic predictions of the model agree better with the observations (from 1 to 3 stars).

25.2.2.1 Fourth generation

There is no compelling theoretical reason for having only three generations of fermions. It is thus important to search for additional heavier quarks. The simplest possibility is a sequential 4th generation, where new heavy quarks have the same quantum numbers as in the SM – the left-handed t' and b' form an $SU(2)_L$ doublet, while the right-handed t' and b' are singlets (for a review see (Frampton, Hung, and Sher, 2000)). In this model the 3×3 CKM matrix is no longer unitary since it is only a part of the full 4×4 matrix

$$\left(\begin{array}{ccc|c} V_{ud} & V_{us} & V_{ub} & V_{ub'} \\ V_{cd} & V_{cs} & V_{cb} & V_{cb'} \\ V_{td} & V_{ts} & V_{tb} & V_{tb'} \\ \hline V_{t'd} & V_{t's} & V_{t'b} & V_{t'b'} \end{array}\right). \qquad (25.2.2)$$

This means that the global fits of the CKM unitarity must be supplemented with 3×3 unitarity relaxed, see, e.g., (Bobrowski, Lenz, Riedl, and Rohrwild, 2009).

The heavy quarks can contribute to any loop type diagrams. In particular, since the loop function of the box and the penguin diagrams grow with the mass of the heavy quark in the loop, these contributions can be large. Therefore, the precise measurements obtained by the B Factories lead to very strong constraints on the fourth row and column of the enlarged 4×4 quark mixing matrix.

We first focus on the impact of the $\sin 2\phi_1$ measurement by the B Factories. The $B_d^0 - \bar{B}_d^0$ box diagram now also has a heavy top quark, t', running in the loop. After imposing the 4×4 unitarity the mixing matrix element is given by

$$M_{12} = \frac{G_F^2 m_W^2}{6\pi^2} \hat{\eta}_B m_B \hat{B}_{B_d} f_{B_d}^2 \big[\lambda_t^2 S_0(x_t) + \\ 2\lambda_t\lambda_{t'} S_0(x_t, x_{t'}) + \lambda_{t'}^2 S_0(x_{t'})\big], \qquad (25.2.3)$$

where the Inami-Lim functions, S_0, describe the t and t' quark contributions in the loop in terms of their masses $x_i \equiv m_i^2/m_W^2$ (Inami and Lim, 1981). The CKM matrix elements are included in $\lambda_i \equiv V_{ib}^* V_{id}$ and the NLO QCD correction $\hat{\eta}_B$ is taken as $\hat{\eta}_B = 0.55$ (Buchalla, Buras, and Lautenbacher, 1996). The non-perturbative QCD effects are absorbed in the bag parameter $\hat{B}_{B_d}$ and the decay constant f_{B_d}, for which we use $(\hat{B}_{B_d})^{1/2} f_{B_d} = (216 \pm 16)$ MeV (Nakamura et al., 2010). Introduction of the fourth generation quarks has two effects. First, the value of the CKM element λ_t multiplying the top contribution can differ from the one obtained from the CKM fits where 3×3 unitarity is assumed. Second, there is an additional contribution from the t' in the loop.

The two effects are related through the 4×4 unitarity condition, $\lambda_u + \lambda_c + \lambda_t + \lambda_{t'} = 0$ with $\lambda_u = (3.8 \pm 0.5) \times 10^{-3} e^{i(-68\pm10)^\circ}$ and $\lambda_c = (-9.4 \pm 0.5) \times 10^{-3}$ extracted from the processes involving only tree level diagrams (Nakamura et al., 2010). The predictions

$$\Delta m_d = 2|M_{12}^{4SM}|, \quad S_{b \to c\bar{c}s} = -\text{Im}\sqrt{\frac{M_{12}^{*4SM}}{M_{12}^{4SM}}}, \quad (25.2.4)$$

then depend only one complex parameter, $\lambda_{t'}$ (or equivalently λ_t by using the unitarity relation), and the mass of t'. The experimental world averages, $\Delta m_d = (0.510 \pm 0.004)$ ps^{-1} and $S_{b \to c\bar{c}s} = 0.677 \pm 0.020$ (see Sections 17.5.2 and 17.6 for the experimental extraction of these values), are consistent with the SM predictions within errors, $\Delta m_d^{SM} = (0.51 \pm 0.12)$ ps^{-1} and $S_{b \to c\bar{c}s} = 0.74 \pm 0.09$. Fixing the mass of t' to 600 GeV the constraints on $\lambda_{t'}$ are shown in Fig. 25.2.2. The dashed line is the constraint from the mass difference Δm_d, which was known before the B Factories but with much larger uncertainty. The $\sin 2\phi_1$ measurement (solid line) gives a strong constraint $|\lambda_{t'}| < 0.005$. Combined constraints exclude the colored regions.

The next example is the $B \to X_s\gamma$ branching ratio, which also receives a contribution from a t' quark running in the loop. The experimental measurements agree with the SM prediction from up, charm and top quarks running in the loop. However, as in the case of $B^0 - \bar{B}^0$ mixing, the top contribution in the 4th generation scenario can differ from the SM due to a different $V_{tb}^* V_{ts}$ obtained from 4×4 CKM fits. This can then leave some more space for the non-zero t' contribution. The obtained constraint on $V_{t'b}^* V_{t's}$ is not so strong since the branching ratio is dominated by the tree level $\mathcal{O}_2$ contributions which are proportional to $V_{cb}^* V_{cs}$. The $B \to X_s\gamma$ branching ratio

Table 25.2.2. The agreement of NP models and the SM with the experimental results including the measurements from the B Factories (more stars means better agreement). See text for further explanations. The $-$ sign means there is no clear expectation.

Observable	4th gen.	2HDM	MFV	eMFV	MFV-SUSY	genSUSY	aligSUSY	RS	Little H	SM
$\sin 2\phi_1$	★★★	★★★	★★★	★★	★★★	★	★★★	★★	★★	★★★
$B \to X_s\gamma$	★★★	★	★★	★★	★★	★	★★★	★★	★★★	★★★
$B \to \tau\nu$	★★	★★	★★	★★	★★	★★	★★	★★	★★	★★
$D^0 - \bar{D}^0$ mixing	★★	★★★	★★★	★★★	★★★	★	★	★★	★★	★★
$B \to \phi K_S^0$	★★★	★★	★★	★★★	★★★	★★	★★	★★★	★	★★
$(g-2)_\mu$	★	★	$-$	$-$	★★	★★	$-$	★★	★★	★

allows $V_{t'b}^* V_{t's} \sim \mathcal{O}(\lambda)$ which is a much weaker bound than the constraints obtained from other measurements such as $B_s^0 - \bar{B}_s^0$ oscillation.

Another example is $D^0 - \bar{D}^0$ mixing where the b' quark could contribute in the loop diagram in addition to the SM particles. Saturating the experimental value of x_D gives

$$|V_{cb'}^* V_{ub'}|^2 \lesssim 10^{-2}, \qquad (25.2.5)$$

for a 600 GeV b'.

The other observables receive some contributions from the 4th generation, though so far, the constraints are not as strong as from $B^0 - \bar{B}^0$ mixing and $D^0 - \bar{D}^0$ mixing. Namely, the CP asymmetry of $B \to \phi K_s^0$, to which t' can contribute both in $B^0 - \bar{B}^0$ oscillations (box diagram) and the $b \to s$ decay (gluon penguin diagram). The oscillation part is constrained very strongly by the $B \to J/\psi K_S^0$ channel. The decay part could constrain the 4th generation parameters although it turns out that the obtained constraint is not very strong. Another observable, the decay $B \to \tau\nu$ is tree dominated. Thus, the 4th generation contribution appears only through the modification of the CKM matrix element, namely, V_{ub}, due to the broken unitarity. This can be detected by observing different values of V_{ub} in the measurements through tree and loop processes. So far, the observed difference is not statistically significant. The muon $g - 2$ can receive a contribution from the 4th generation neutrino (Lynch, 2001). However, the contribution is not large enough to explain the observed deviation from the SM.

The main message of this section is that the CKM matrix elements for the heavy fermions can be very strongly constrained from the B Factory observables. A sizable mixing of SM quarks with 4th generation quarks is excluded. If, on the other hand, one naïvely extrapolates the Wolfenstein structure of the CKM to 4 generations, one may expect that $\lambda_{t'} \sim \lambda^4$ so that an order of magnitude improvement in precision of flavor observables would be most welcome. Also, the direct searches at the LHC now exclude heavy fermions with masses below ~ 600 GeV. This limit is high enough that the unitarity mass limit has been reached – the fermion-fermion scattering amplitude becomes larger than one and the fermions become strongly coupled. This means that the loop corrections we discussed above must be taken with a grain of salt as they were obtained using perturbative calculations. Finally, the discovery of the Higgs-like particle with a mass of about
Figure 25.2.2. Constraints on the real and imaginary parts of $V_{t'b}^* V_{t'd}$ from Δm_d (dashed) and $\sin 2\phi_1$ (solid) are shown for $m_{t'} = 600$ GeV. The blue regions are excluded at 1σ, 2σ and 3σ (from lighter to darker) assuming Gaussian errors.

125 GeV also excludes the perturbative 4th generation, since in that case the production and decays of the Higgs would be modified significantly (Eberhardt et al., 2012; Kuflik, Nir, and Volansky, 2012).

25.2.2.2 Two Higgs Doublet Models

A simple extension of the Standard Model is to add an extra Higgs doublet to the field content. Despite being a very simple modification, it can lead to drastic changes in low energy flavor phenomenology. If all Yukawa interactions between the two Higgs doublets and quarks are allowed, then this leads to FCNCs from neutral Higgs exchanges that are orders of magnitude above the experimentally allowed values. No FCNCs arise if only one Higgs doublet couples to quarks, while the other is inert (this is the Type I 2HDM). The other option is that one of the Higgs doublets, H_1, couples to the right-handed down quarks, while the other Higgs doublet, H_2 couples to the right-handed up quarks only. This is the Type II 2HDM, and corresponds to the Higgs sector of the MSSM when loop corrections from sparticles are neglected. A more general

way to avoid tree-level FCNCs is to require alignment between the Yukawa couplings of the two Higgs doublets. Alignment is parameterized by three complex parameters and covers the above two types of the 2HDM models as special cases (Pich and Tuzon, 2009).

From now on we focus on the Type II 2HDM for which the expectations regarding flavor observables are collected in Table 25.2.2. In the 2HDM there are 3 real scalars, two CP-even and one CP-odd neutral Higgs bosons, and one charged Higgs boson $H^{\pm}$. In Type II 2HDM the interactions of the neutral Higgses are flavor diagonal, so that the flavor violation arises only at loop level like in the SM. The exchange of a charged Higgs, $H^{\pm}$, can lead to significant contributions to the B physics observables. The interactions with quarks are given by

$$
\begin{aligned}
\mathcal{L} =& (2\sqrt{2}G_F)^{1/2} \sum_{i,j=1}^{3} \overline{u}_i \big(A_u m_{u_i} V_{ij} P_L \\
&- A_d V_{ij} m_{d_i} P_R \big) d_j H^+ + h.c.,
\end{aligned}
\tag{25.2.6}
$$

where $P_{L,R} \equiv (1 \mp \gamma_5)/2$. u_i and d_j are the mass eigenstate fields, i, j the generation indices, $m_{u,d}$ the diagonal quark mass matrices and V_{ij} the CKM matrix elements. In the Type II 2HDM the coefficients $A_{u,d}$ depend only on the ratio of the H_2 and H_1 Higgs vacuum expectation values, $\tan\beta = v_2/v_1$,

$$
A_u = \cot\beta, \quad A_d = -\tan\beta. \tag{25.2.7}
$$

We expect a significant contribution from the loop induced diagrams with a charged Higgs and a top quark in the loop such as $B_d - \overline{B}_d$ oscillation and the decay $B \to X_s\gamma$. A large enhancement of the charged Higgs contribution is possible because of the first term in Eq. (25.2.6) with $u_i = t$ due to the large top quark mass. While the experimental measurements of the $B_d - \overline{B}_d$ oscillation frequency can constrain part of the parameter space, in particular for small $\tan\beta$, the constraint from $B \to X_s\gamma$ is generically more important. At LO the Wilson coefficient relevant for $B \to X_s\gamma$ including the NP contributions is (Ciuchini, Degrassi, Gambino, and Giudice, 1998b; Grinstein, Springer, and Wise, 1990; Hou and Willey, 1988)

$$
\begin{aligned}
C_{7,8}(M_W) =& C_{7,8}^{\mathrm{SM}}\left(\frac{m_t^2}{m_{W^{\pm}}^2}\right) + \frac{A_u^2}{3} G_{7,8}\left(\frac{m_t^2}{m_{H^{\pm}}^2}\right) \\
&- A_u A_d F_{7,8}\left(\frac{m_t^2}{m_{H^{\pm}}^2}\right).
\end{aligned}
\tag{25.2.8}
$$

The second and the third terms give charged Higgs contributions and are enhanced by m_t^2, as expected. The signs of A_u and A_d are opposite in Type II 2HDM (see Eq. 25.2.7) so that both terms interfere constructively with the SM term. The term proportional to A_u^2 is relevant only for small $\tan\beta$, while the term proportional to $A_u A_d$ is important almost independently of $\tan\beta$.

The SM prediction for the branching ratio of $B \to X_s\gamma$ has been drastically improved in the past 10 years. The NNLO predictions are available both for the SM and

for the charged Higgs contributions (Misiak et al., 2007). The most recent analysis shows that the SM prediction is roughly 1 sigma below the experimental value (see Section 17.9 for more details) and the following lower limit on the charged Higgs mass is obtained for any value of $\tan\beta$

$$
m_{H^{\pm}} > 295 \text{ GeV}. \tag{25.2.9}
$$

Another very important constraint on the Type II 2HDM has been obtained from the B Factory measurements of $\mathcal{B}(B \to \tau\nu)$ (see Section 17.10 for more discussions on this process). This tree level process occurs in the SM with a diagram in which the B meson annihilates into a W boson followed by its decay into $\tau\nu$. In the 2HDM, a similar process is possible but the W is replaced with the charged Higgs. The resulting branching ratio can be expressed as

$$
\mathcal{B}(B \to \tau\nu) = \mathcal{B}(B \to \tau\nu)_{\mathrm{SM}}\left(1 - \tan^2\beta\frac{m_B^2}{m_{H^{\pm}}^2}\right)^2,
\tag{25.2.10}
$$

where

$$
\mathcal{B}(B \to \tau\nu)_{\mathrm{SM}} = \frac{G_F^2 m_B m_\tau^2}{8\pi}\left(1 - \frac{m_\tau^2}{m_B^2}\right)^2 f_B^2 |V_{ub}|^2 \tau_B.
\tag{25.2.11}
$$

The second term in the parenthesis of Eq. (25.2.10) is due to the charged Higgs.

Replacing the left hand side of Eq. (25.2.10) with the experimental bound obtained by the B Factories, a combination of the parameters $m_{H^{\pm}}/\tan\beta$ can be constrained. The two solutions

$$
\frac{m_{H^{\pm}}}{m_B \tan\beta} = \left(1 \pm \sqrt{r_{\exp}^{B \to \tau\nu}}\right)^{-1/2}, \tag{25.2.12}
$$

with

$$
r_{\exp}^{B \to \tau\nu} = \frac{\mathcal{B}(B \to \tau\nu)_{\exp}}{\mathcal{B}(B \to \tau\nu)_{\mathrm{SM}}} \tag{25.2.13}
$$

are plotted, respectively, as grey and black lines in Fig. 25.2.3. Here we use the SM prediction for the branching ratio, $\mathcal{B}(B \to \tau\nu)_{\mathrm{SM}} = (1.01 \pm 0.29) \times 10^{-4}$, as quoted in Section 17.10. The vertical lines indicate the current world average (see also Section 17.10)

$$
\mathcal{B}(B \to \tau\nu)_{\exp} = (1.15 \pm 0.23) \times 10^{-6}, \tag{25.2.14}
$$

with 1σ (dotted), 2σ (dashed) and 3σ (solid) errors. The two vertical yellow regions are excluded at 95% C.L. Note that the theoretical error to the SM prediction denoted above is indicated in the right top corner of Fig. 25.2.3. It results in additional uncertainties on top of the experimental ones. The horizontal yellow region is excluded by the $\mathcal{B}(B \to X_s\gamma)$ measurement.

The first solution (gray lines) are already excluded by the constraints from $B \to X_s\gamma$ as well as from $B \to D\tau\nu$. The second solutions (black lines) can give a constraint on $m_H^{\pm}$ stronger than $\mathcal{B}(B \to X_s\gamma)$. By taking into account

the 3σ experimental error, for instance, one obtains a lower bound $m_{H^\pm} \geq 370$ (556) GeV for $\tan\beta = 40$ (60). Note that this bound is very sensitive to the theoretical input and could be lowered by over 100 (150) GeV by taking into account the theoretical uncertainty discussed above. It is clear that further reduction of both theoretical and experimental errors will shed light on the charged Higgs searches in this model in the future.

We discuss next briefly the other observables, for details see (Barger, Hewett, and Phillips, 1990; Grossman, 1994; Krawczyk and Pokorski, 1991; Wahab El Kaffas, Osland, and Ogreid, 2007). For the $\Delta F = 2$ (F is strangeness or bottomness) processes, the impact on the $B^0 - \overline{B}^0$ mixing frequency and phase is small while the $D^0 - \overline{D}^0$ mixing could receive a large contribution, in particular for large $\tan\beta$ (Golowich, Hewett, Pakvasa, and Petrov, 2007). However, since the SM value of the $D^0 - \overline{D}^0$ mixing parameter is not well determined it is difficult to obtain a strict constraint, even though order of magnitude estimates are already interesting. Since this model does not include a large CP violating phase in the $b \to s$ transition part, the CP violation in $B \to \phi K_S^0$ does not receive a significant NP contribution. The recent *BABAR* measurement of the ratio $\mathcal{R}(D^{(*)}) \equiv \mathcal{B}(B \to D^{(*)}\tau\nu)/\mathcal{B}(B \to D^{(*)}l\nu)$ shows some deviation from the SM (Lees, 2012e). The charged Higgs can contribute to this process, however, the deviation in $\mathcal{R}(D)$ and $\mathcal{R}(D^*)$ cannot be explained simultaneously within Type II 2HDM (Lees, 2012e) (see Section 17.10 for more details). It is, however, possible to explain the observed pattern using 2HDM with more general flavor structure (Fajfer, Kamenik, Nisandzic, and Zupan, 2012). The muon magnetic moment, $(g - 2)_\mu$, is found not to provide a significant contribution after taking into account the constraints discussed in this Section (Jegerlehner and Nyffeler, 2009; Krawczyk, 2002; Wahab El Kaffas, Osland, and Ogreid, 2007).

25.2.2.3 Minimal Flavor Violation

The MFV hypothesis states that flavor violation in NP comes from the same source as in the SM, the SM Yukawa couplings (Buras, 2003; Buras, Gambino, Gorbahn, Jager, and Silvestrini, 2001; Chivukula and Georgi, 1987; Ciuchini, Degrassi, Gambino, and Giudice, 1998a; D'Ambrosio, Giudice, Isidori, and Strumia, 2002; Hall and Randall, 1990). The reasoning behind this hypothesis on one hand is that this is the minimal amount of flavor breaking that needs to be present, since it is already seen in the SM. On the other hand, it also leads to relatively small deviations from the SM in flavor observables and is not excluded experimentally. In principle many different NP models can be of MFV type, but the best known example is low energy SUSY with gauge mediated SUSY breaking (that we discuss separately below). Another example are universal extra dimensions with universal boundary conditions. In both cases the only source of flavor violation are the SM Yukawa couplings.

An important benefit of the MFV hypothesis is that the effects of NP on flavor observables can be worked out
Figure 25.2.3. Constraints on the charged Higgs mass in the Type II 2HDM from the B Factory measurements of $\mathcal{B}(B \to \tau\nu)$ and $\mathcal{B}(B \to X_s\gamma)$. The x-axis represents the present experimental value of $\mathcal{B}(B \to \tau\nu)$ normalized to the SM prediction (see text for details). The vertical yellow regions are excluded by the current world average experimental value, $\mathcal{B}(B \to \tau\nu)_{\exp} = (1.15 \pm 0.23) \times 10^{-6}$, at 95% C.L., while the 1σ, 2σ, 3σ errors on the same experimental value are denoted by the dotted, dashed, and solid lines, respectively. The horizontal yellow region is excluded by the $\mathcal{B}(B \to X_s\gamma)$ measurement (see Eq. 25.2.9). The grey and the black lines correspond to the predictions of the Type II 2HDM given in Eq. (25.2.12), respectively, with labels denoting the different values of $\tan\beta$.

without committing to a concrete model. This is done using a so-called spurion analysis (D'Ambrosio, Giudice, Isidori, and Strumia, 2002), which we review quickly. The SM Yukawa interactions for quarks are

$$\mathcal{L}_Y = \overline{Q}_L Y_D d_R H + \overline{Q}_L Y_U u_R H^c + h.c., \quad (25.2.15)$$

where the generation indices i on the left-handed quarks $Q_i = (u_L, d_L)_i$, and on right-handed quarks $(u_R)_i, (d_R)_i$ were suppressed, while $H^c \equiv i\tau_2 H^*$, where τ_2 is the $SU(2)$ generator, was used. If the Yukawa coupling matrices Y_D, Y_U were zero, it would not be possible to distinguish the three generations of quarks. Thus, the theory would have a global symmetry, $G_F = SU(3)_Q \times SU(3)_{U_R} \times SU(3)_{D_R}$, since any of the quark fields Q_L, u_R, d_R can be rotated independently. In other words, the global symmetry G_F is explicitly broken by the fact that Yukawa couplings are not zero – quarks have nonzero masses in the SM. One can then use a formal trick and pretend that Yukawa coupling matrices do transform under G_F as $Y_U \sim (3, \overline{3}, 1), Y_D \sim (3, 1, \overline{3})$ (The jargon used is that $Y_{U,D}$ are promoted to be spurions, where the name comes from the fact that these are now fictitious or spurious auxiliary fields.). All the interactions are then formally invariant under G_F. Under the MFV hypothesis also NP is assumed to be invariant under G_F.

Integrating out NP particles we obtain corrections to the effective weak Hamiltonian. However, since NP is formally invariant under G_F we know its flavor structure. We just need to construct an effective weak Hamiltonian that is G_F invariant, and all the breaking comes from Y_U and Y_D. This then also fixes the allowed flavor breaking. The Yukawa coupling matrices Y_U and Y_D are not aligned and are diagonal in different bases for Q_L. The misalignment leads to flavor changing charged currents, $J_C^\mu = \bar{u}_L \gamma^\mu V d_L$, with V being the same as the CKM matrix.

In this section we focus on a particular realization of MFV – the so-called constrained minimal flavor violation (cMFV) (Blanke, Buras, Guadagnoli, and Tarantino, 2006; Buras, Gambino, Gorbahn, Jager, and Silvestrini, 2001). The assumptions that underlie cMFV are (i) the SM fields are the only light degrees of freedom in the theory, (ii) there is only one light Higgs and (iii) the SM Yukawa couplings are the only sources of flavor violation. The NP effective Hamiltonian for $q_j \to q_i$ processes following from these assumptions thus has exactly the same CKM suppression and form of the effective operators as in the SM. This is sometimes taken to be the definition of cMFV (Blanke, Buras, Guadagnoli, and Tarantino, 2006; Buras, 2003; Buras, Gambino, Gorbahn, Jager, and Silvestrini, 2001). For instance, the effective Hamiltonian for the $\Delta F = 2$ transitions is

$$\mathcal{H}_{\rm eff}^{\rm NP} = \frac{C^{\rm NP}}{\Lambda_{\rm NP}^2} \left(V_{ti}^* V_{tj} \right)^2 Q_{ij}, \qquad (25.2.16)$$

where the Wilson coefficient $C^{\rm NP}$ is real, while Q_{ij} are exactly the same operators as in the SM effective weak Hamiltonian. For $B_d^0 - \bar{B}_d^0$ this is $Q_{bd} = (\bar{b}_L \gamma^\mu d_L)^2$. Note that $C^{\rm NP}$ is universal – it is the same for $K^0 - \bar{K}^0$, $B_d^0 - \bar{B}_d^0$ and $B_s^0 - \bar{B}_s^0$ mixing. The relative sizes of the NP contributions are given entirely by the CKM matrix elements which are the same as in the SM. As a consequence Eq. (25.2.16) provides a very strong constraint on the scale of NP masses. Note that two-Higgs doublet models or MFV MSSM even with small $\tan\beta$ does not fit in the cMFV and sizable contributions from operators with non-SM chiral structures in addition to Eq. (25.2.16) are possible.

Because cMFV is a very constrained modification of the weak Hamiltonian, Eq. (25.2.16), one can experimentally distinguish it from the other BSM scenarios by looking at the correlations between observables in K and B decays. A sign of cMFV would be a deviation from the SM predictions that can be described without new CP violating phases and without enlarging the SM operator basis. For instance, in $B_d^0 - \bar{B}_d^0$ and $B_s^0 - \bar{B}_s^0$ mixing observables the discrepancy from the SM is possible only in the value of Δm_d and Δm_s and not in the mixing phases. Furthermore, the corrections normalized to the SM are universal, so that $h_s = h_d$ in Eq. (25.2.1), while the additional weak phases are zero, i.e. $\sigma_s = \sigma_d = 0$ or $\sigma_s = \sigma_d = \pi/2$. A discrepancy in ϕ_1 determined from $B \to J/\psi K_S^0$ and the global Unitarity Triangle fit would rule out the cMFV framework. Similarly, a sizable $B_s^0 - \bar{B}_s^0$ mixing phase would rule out cMFV NP.

Since the CKM-like suppression is automatically encoded in the NP contributions to flavor transitions, no large flavor violations are expected from TeV scale NP. The results from the B Factories are precise enough, however, that the energy scale probed is in the multi-TeV regime already. The most stringent constraints are coming from $b \to s\gamma$ and $b \to sl^+l^-$ decays. Setting the NP Wilson coefficients $C_i^{\rm NP} = 1$ in Eq. (25.2.16), one has $\Lambda_{\rm NP} > 6.1$ TeV (Hurth, Isidori, Kamenik, and Mescia, 2009 and update by Hurth and Mahmoudi, 2012). If the NP states are exchanged at tree level, this would mean that they need to be heavier than about 6 TeV. If they only contribute through loops, they need to be heavier than about $\sim 6\,{\rm TeV}/4\pi = 0.5$ TeV for $\mathcal{O}(1)$ couplings. The precise value depends on the spin and charge of the exchanged particle.

Similarly, one has a bound $\Lambda_{\rm NP} > 5.9$ TeV for contributions to meson mixing (Bona et al., 2006, 2008). The NP modifications to $K^0 - \bar{K}^0$, $D^0 - \bar{D}^0$, $B_d^0 - \bar{B}_d^0$ and $B_s^0 - \bar{B}_s^0$ are rigidly related in cMFV. There is only one operator, $(\bar{q}_{Lj} \gamma^\mu q_{Lj})^2$, and the flavors of quarks fix the CKM suppressions. The bound on $\Lambda_{\rm NP}$ is predominantly due to the ϵ_K constraint. This means that no effects in $D^0 - \bar{D}^0$, $B_d^0 - \bar{B}_d^0$ and $B_s^0 - \bar{B}_s^0$ mixing are expected in cMFV with the present experimental precision. Similarly, since there are no new CP violating phases beyond the CKM phase, the ϕ_1 phase determined from $b \to s$ penguin transitions $B \to \phi K_S^0$ is expected to be the same as obtained from $B \to J/\psi K_S^0$.

The MFV also relates the $b \to u\tau\nu$ and $b \to c\tau\nu$ charged current transitions. In the SM the amplitudes for these two transitions are proportional to the V_{ub} and V_{cb} matrix elements. The same is true for NP contributions. Normalized to the SM the deviations in both of these two transitions thus need to be the same, if NP is of MFV type. There are indications of deviations from the SM in $B^- \to \tau^- \nu$ and in $B \to D^{(*)} \tau\nu$ (Lees, 2012e), which proceed through $b \to u\tau\nu$ and $b \to c\tau\nu$ quark level transitions, respectively, (see Sections 17.10 and 25.1). The relative sizes of the two discrepancies, however, differ from the universal behavior predicted by the MFV. Therefore MFV is not preferred as an explanation of the anomalies (Fajfer, Kamenik, Nisandzic, and Zupan, 2012).

Finally, the minimal incarnation of MFV – cMFV – is a hypothesis about the flavor violation in the quark sector. Therefore there is no clear prediction about the size of the muon anomalous magnetic moment, $(g-2)_\mu$.

25.2.2.4 Extensions of MFV

The phenomenologically most important extensions of cMFV hypothesis are: i) relaxing the assumption that the CP violation is only due to the CKM phase, allowing also for nonzero flavor diagonal weak phases, and ii) to allow for larger higher order terms in the spurion expansion. This General MFV (GMFV) hypothesis was formalized by Kagan, Perez, Volansky, and Zupan (2009), who identified the new small spurions: the off-diagonal CKM

matrix elements and the masses of the first two generation quarks. For an earlier discussion of flavor diagonal CP phases within the MSSM see (Colangelo, Nikolidakis, and Smith, 2009), for a nonlinear realization of MFV see (Albrecht, Feldmann, and Mannel, 2010; Feldmann, Jung, and Mannel, 2009; Feldmann and Mannel, 2008)

The important difference between cMFV and GMFV is that in cMFV there are relations between $s \leftrightarrow d$, $b \leftrightarrow d$ and $b \leftrightarrow s$ transitions, in GMFV only $b \leftrightarrow d$ and $b \leftrightarrow s$ transitions are directly related. There are two classes of NP contributions. Class-1 operators *do not* contain light right-handed quarks, and class-2 operators do. An example of a class-1 operator is, for instance, $(\bar{q}_L \gamma_\mu b_L)^2$, and an example of a class-2 operator is $(\bar{q}_L b_R)(\bar{q}_R b_L)$. The distinction is phenomenologically important, since the Wilson coefficients of the class-2 operators are proportional to light-quark masses. In $B_{d,s}^0 - \bar{B}_{d,s}^0$ mixing then the class-2 operators only contribute to $B_s^0 - \bar{B}_s^0$ mixing (up to m_d/m_s corrections) and would give $h_d \ll h_s$. Thus one would expect a deviation from the SM in the CP violating phase of the B_s oscillation measurements but not in measurements of $\sin 2\phi_1$ from $B \to J/\psi K_S^0$. In contrast, class-1 operators contribute universally to both (relative to the SM) and would give $h_d = h_s$ and $\sigma_d = \sigma_s$ in Eq. (25.2.1). In many realistic models we would expect both class-1 and class-2 NP contributions, so the predictions would be somewhere in between: smaller effects in $B_d^0 - \bar{B}_d^0$ mixing than in $B_s^0 - \bar{B}_s^0$ mixing, yet still nonzero.

An example of such GMFV NP is MSSM with $U(2)^3$ flavor symmetry (Barbieri, Isidori, Jones-Perez, Lodone, and Straub, 2011), which is broken by the light-quark masses and the off-diagonal CKM elements. Gluino mediated amplitudes are the dominant non-standard effect in $\Delta F = 2$ observables and are of class-1. All class-2 contributions are suppressed. As a result the size of the correction is proportional to the CKM combination of the corresponding SM amplitude, a signature of class-1 MFV contributions. The proportionality coefficients are the same for the B_d and B_s systems, while it may be different in the kaon system – a signature of GMFV. Another GMFV characteristic is that new CP violating phases can only appear in the B_d and B_s systems. Since in the $U(2)^3$ symmetric MSSM they would come from class-1 contributions, the phase shifts would be universal. From the still allowed deviations in $S_{B_d \to \psi K_S^0}$ from $\sin 2\phi_1$ Barbieri, Isidori, Jones-Perez, Lodone, and Straub (2011) deduce that $0.05 \lesssim S_{B_s \to \psi\phi} \lesssim 0.2$.

The expectation for the $B \to X_s \gamma$ branching ratio are the same as in cMFV, discussed in Section 25.2.2.3. For weak scale NP particles with masses of a few 100 GeV we would thus expect a deviation in $B \to X_s \gamma$ already in the present measurements, even though the particles only enter in loops. On top of this, in GMFV there are additional CP violating phases, which can lead to an enhanced direct CP asymmetry in $B \to X_{d,s}\gamma$. The CP violating effects are also expected in $D^0 - \bar{D}^0$ mixing, with $\arg(M_{12}/\Gamma_{12}) \sim \mathcal{O}(5\%)$ for $\Lambda_{\text{GMFV}} = 1$ TeV (Kagan, Perez, Volansky, and Zupan, 2009). At present, the experimental error is roughly twice as large as this ex-

pectation. There is also no clear prediction for the flavor diagonal observable $(g-2)_\mu$.

There are also other extensions of the MFV hypothesis, beside GMFV. At the practical level the GMFV is equivalent to the Next-to-Minimal Flavor Violation (NMFV) hypothesis, even though the original motivations were different. NMFV was put forward in (Agashe, Papucci, Perez, and Pirjol, 2005) by demanding that NP contributions only roughly obey the CKM hierarchy, and in particular can have $\mathcal{O}(1)$ new weak phases. The consequences of spurions that transform differently under G_F than the SM Yukawa coupling matrices have been worked out by Feldmann and Mannel (2007). The MFV hypothesis has also been extended to the leptonic sector (MLFV) in (Cirigliano and Grinstein, 2006; Cirigliano, Grinstein, Isidori, and Wise, 2005). In MLFV the most sensitive FCNC probe in the leptonic sector is $\mu \to e\gamma$, while $\tau \to \mu\gamma$ could be suppressed below the sensitivity of future super flavor factories.

25.2.2.5 MFV SUSY

Low energy supersymmetry (SUSY), where the superpartners have ∼TeV scale masses is one of the most popular solutions to the hierarchy problem. Since this model is perturbative one can make reliable predictions. This aids the popularity of SUSY among theorists. Already its minimal incarnation – the Minimal Supersymmetric Standard Model – has the salient features of gauge coupling unification and contains a viable dark matter candidate. The "Minimal" in the MSSM refers to the field content. Each SM particle obtains only one superpartner, and also the extension of the Higgs sector is minimal. However, the flavor structure need not be minimal. The parameters that describe the supersymmetry breaking, *e.g.*, the squark masses and trilinear couplings can in principle carry very different flavor structures from the one seen in the quark sector of the SM. In total there are 124 parameters in the MSSM, much more than the 19 parameters of the SM (Berger and Grossman, 2009; Dimopoulos and Sutter, 1995; Haber, 2001). Of these parameters, 110 are in the flavor sector: 30 masses, 39 real mixing angles and 41 phases. If all of the mixing angles and phases were $\mathcal{O}(1)$ this would lead to FCNCs that are orders of magnitude larger than the experimental bounds. The SUSY breaking does have to be non-generic and further assumptions about its structure are required in order to have an acceptable phenomenology. An attractive hypothesis is MFV, which we discussed in general terms in the previous subsections. The flavor breaking is assumed to arise only from the Yukawa interactions (in this case from the superpotential), while the SUSY breaking is flavor blind. This means that the squark masses can be written as

$$\tilde{m}_{q_L}^2 = \tilde{m}^2 (a_1 \mathbb{1} + b_1 Y_U Y_U^\dagger + b_2 Y_D Y_D^\dagger \\ b_3 Y_D Y_D^\dagger Y_U Y_U^\dagger + b_4 Y_U Y_U^\dagger Y_D Y_D^\dagger + \cdots), \tag{25.2.17}$$

and similarly for right-handed squarks. The coefficients $a_1, b_{1,2}$ are real from the hermiticity of the Hamiltonian,

while b_3 and b_4 can in general be complex and be sources of additional CP violating weak phases. For small $\tan\beta$ these terms are negligible since Y_D is much smaller than Y_U. The values of the coefficients are fixed by the model of the SUSY breaking. They can be zero at some high scale M, but are then generated due to the renormalization group running effect from this high scale to the low scale $b_i \sim (1/4\pi^2) \log(M^2/\tilde{m}^2)$. In gauge-mediated SUSY breaking the scale M would be given by the masses of the messengers particles between the SUSY breaking sector and low energy sector.

Since MFV SUSY is an example of the MFV theory our general discussion in the previous two subsections applies. The superpartners can be integrated out and matched onto the effective weak Hamiltonian. Because MFV MSSM is a concrete model the predictions can in fact be more precise (for a review see, *e.g.*, Isidori and Straub, 2012). For $\tan\beta \gg 1$ and/or if the μ parameter, the coupling of bilinear term of the MSSM Higgs sector, is large enough, the resulting low energy operator basis does not contain only the SM operators. This means that in this limit it is not a cMFV model. In the large $\tan\beta$ limit the most sensitive observables are the branching fractions for $B_s \to \mu^+\mu^-$ and $B \to \tau\nu$. For most of the parameter space $\mathcal{B}(B \to \tau\nu)$ is reduced by the charged Higgs correction compared to the SM.

An interesting prediction of MFV MSSM is that the contributions to $\Delta m_{d,s}$ are always positive and increase the oscillation frequency above the SM (Altmannshofer, Buras, and Guadagnoli, 2007). However, the NP effects in $S_{J/\psi K_S^0}$ and $\Delta m_d/\Delta m_s$ are very small and thus do not disrupt the Unitarity Triangle of the SM. There are also only small effects in $B_s \to J/\psi\phi$ expected. Similarly, the contributions to $D^0 - \bar{D}^0$ mixing are small (Altmannshofer, Buras, Gori, Paradisi, and Straub, 2010). If the flavor blind phases are nonzero, then EDMs and $\mathcal{B}(b \to s\gamma)$ are the strongest constraints (Altmannshofer, Buras, and Paradisi, 2008). The dominant NP source in $S_{\phi K_S^0}$ arises from the chromomagnetic operator C_{8g}^{NP}, and the effects in $S_{\phi K_S^0}$ are expected to be significantly larger than in $S_{\eta' K_S^0}$ (both in the same direction), with even $\mathcal{O}(1)$ corrections not too hard to achieve. The effect is also strongly correlated with the size of the direct CP asymmetry $A_{CP}(b \to s\gamma)$, with an effect of up to 0.05 typical. There is also a natural explanation of the small deviation from the SM observed in the muon-magnetic moment $(g-2)_\mu$ as long as sleptons are not much heavier than squarks (see *e.g.* Jegerlehner and Nyffeler, 2009).

25.2.2.6 non-MFV SUSY

In investigations of SUSY models, strong assumptions (such as the MFV ansatz discussed in the previous section) are often imposed in order to reduce the large number of parameters introduced by the unknown SUSY breaking mechanism. A common motivation behind the assumptions is to avoid an unwanted excess of CP violation and FCNC. However, by working within those assumptions,

one could potentially also miss a signal of SUSY particles. In this section we follow a more model independent approach – the mass insertion approximation (MIA) (Hall, Kostelecký, and Raby, 1986). In this approach the flavor off-diagonal part of the squark mass matrix in the Super-CKM basis is parameterized by the mass insertion parameter, $(\delta_{AB}^q)_{ij}$, where A, B denote the chirality (L, R) and q indicates the (u, d) type. Assuming that the off-diagonal elements are smaller than the diagonal ones, the sfermion propagator can be expanded as

$$\langle \tilde{q}_{Ai}\tilde{q}_{Bj}^* \rangle = i(k^2 \mathbf{1} - \tilde{m}^2 \mathbf{1} - \tilde{m}^2 \delta_{AB}^q)_{ij}^{-1} \quad (25.2.18)$$
$$\simeq \frac{i\delta_{ij}}{k^2 - \tilde{m}^2} + \frac{i\tilde{m}^2(\delta_{AB}^q)_{ij}}{(k^2 - \tilde{m}^2)^2} + \cdots,$$

where $\mathbf{1}$ is the unit matrix and $\tilde{m}$ is the averaged squark mass, used also to normalize the off-diagonal mass matrix elements, so that $(\delta_{AB}^q)_{ij}$ are dimensionless. In a general analysis all the mass insertion parameters $(\delta_{AB}^q)_{ij}$ should be taken into account and are then only constrained from various flavor experiments.

The B Factory observables are particularly sensitive to the down type mass insertion elements with $ij = 13$ ($b \to d$ transitions) and $ij = 23$ ($b \to s$ transitions). We also note that the source of flavor violation in this framework comes from the loop diagrams with gluinos and neutralinos whereas the former is dominant due to the large strong coupling constant.

For a general flavor structure significant excesses in FCNC and CP violation are possible for various B Factory observables. The non-observation of large deviations from the SM therefore stringently constrains the mass insertion parameters. As an example let us take the $(\delta_{AB}^d)_{13}$ mass insertions. These are constrained by the Δm_d and $\sin 2\phi_1$ measurements. The $m_{\tilde{g}} \simeq m_{\tilde{q}} = 500$ GeV gluino contribution to Δm_d normalized to the SM is (Gabbiani, Gabrielli, Masiero, and Silvestrini, 1996; Gabrielli and Khalil, 2003)

$$\frac{M_{12}^{\mathrm{SUSY}}}{M_{12}^{\mathrm{SM}}} \simeq \frac{1}{(V_{tb}V_{td}^*)^2}\Big\{ 4.0 \times 10^{-3} \left[(\delta_{23}^d)_{LL}^2 + (\delta_{23}^d)_{RR}^2 \right]$$
$$+ 8.1 \times 10^{-2} \left[(\delta_{23}^d)_{LR}^2 + (\delta_{23}^d)_{RL}^2 \right]$$
$$- 1.3 \times 10^{-1} \left[(\delta_{23}^d)_{LR}(\delta_{23}^d)_{RL} \right]$$
$$- 5.0 \times 10^{-1} \left[(\delta_{23}^d)_{LL}(\delta_{23}^d)_{RR} \right] \Big\}. \quad (25.2.19)$$

Note that in terms of observables one has

$$\Delta m_d = 2|M_{12}^{\mathrm{SM}} + M_{12}^{\mathrm{SUSY}}|, \quad (25.2.20)$$
$$S_{b \to c\bar{c}s} = -\mathrm{Im}\left(\frac{M_{12}^{*\mathrm{SM}} + M_{12}^{*\mathrm{SUSY}}}{M_{12}^{\mathrm{SM}} + M_{12}^{\mathrm{SUSY}}} \right)^{1/2}. \quad (25.2.21)$$

The resulting constraints following from the experimental world averages $\Delta m_d = (0.510 \pm 0.004)$ ps^{-1} and $S_{b \to c\bar{c}s} = 0.677 \pm 0.020$ (see Section 17.5.2 and Section 17.6 for the experimental extraction of these values) are shown in Fig. 25.2.4 (top panels). We use $V_{tb}V_{td}^* = (8.7 \pm 0.8) \times 10^{-3} e^{i(0.41 \pm 0.06)}$, which is obtained in a similar way as in Section 25.2.2.1 by using the unitarity condition with $V_{cb}V_{cd}^*$ and $V_{ub}V_{ud}^*$ extracted from the tree level
Figure 25.2.4. Top: constraints on the down type $ij = 13$ mass insertions from $B_d^0 - \bar{B}_d^0$ oscillation measurements at the B Factories. The dashed lines represent 3σ bounds from Δm_d and the solid lines from $\sin 2\phi_1$. Bottom: constraints on the down type $ij = 23$ mass insertions from the $\mathcal{B}(B \to X_s\gamma)$ measurement (dashed lines) and the time-dependent CP asymmetry in the penguin-dominated $B \to \phi K_S^0$ transition (solid line). The colored regions are excluded at 1, 2 and 3 σ combining the corresponding two measurements.

processes. We assume that only one of four mass insertions is nonzero, and show the constraints on LL and LR mass insertions as representative examples. The RR and RL mass insertion have similar constraints, respectively. The dashed lines show the constraints from Δm_d measurements, while the solid lines show the constraints from the latest $\sin 2\phi_1$ measurement from the B Factories. One finds that typically the chirality preserving mass insertions, $(\delta_{13}^d)_{LL/RR} \lesssim 10^{-1}$, are less constrained than the chirality flipping ones, $(\delta_{13}^d)_{LR/RL} \lesssim 10^{-2}$, (for both their real and imaginary parts).

In the lower panels of Fig. 25.2.4 we show the impact that the B Factory measurements of the $B \to X_s\gamma$ branching ratio have on the chirality flipping ($AB = LR/RL$) mass insertions for $b \to s$ transitions. Again, the constraints are at the $\mathcal{O}(0.01)$ level. The $(\delta_{AB}^d)_{23}$ mass insertions are also constrained by the $B_s^0 - \bar{B}_s^0$ oscillation measurement. However, as we show below, for the case of $AB = LR/RL$ the chiral enhancement makes the $B \to X_s\gamma$ constraints much stronger than the ones from $B_s^0 - \bar{B}_s^0$ oscillations.

The gluino contribution to the $b \to s$ ($\Delta B = 1$) transition is described by the following effective Hamiltonian (Khalil and Kou, 2003)

$$\mathcal{H}_{\text{eff}}^{\Delta B=1} = -\frac{G_F}{\sqrt{2}} V_{tb} V_{ts}^* \left[\sum_{i=3}^{6} C_i O_i \right. \tag{25.2.22}$$

$$\left. + C_\gamma O_\gamma + C_g O_g + \sum_{i=3}^{6} \tilde{C}_i \tilde{O}_i + \tilde{C}_\gamma \tilde{O}_\gamma + \tilde{C}_g \tilde{O}_g \right],$$

with

$$O_{3/4} = \left(\bar{s}_{\alpha/\alpha} b_{\alpha/\beta}\right)_{V-A} \left(\bar{s}_{\beta/\beta} s_{\beta/\alpha}\right)_{V-A}, \tag{25.2.23}$$

$$O_{5/6} = \left(\bar{s}_{\alpha/\alpha} b_{\alpha/\beta}\right)_{V-A} \left(\bar{s}_{\beta/\beta} s_{\beta/\alpha}\right)_{V+A}, \tag{25.2.24}$$

$$O_\gamma = \frac{-1}{3} \frac{e}{4\pi^2} m_b \left(\bar{s}_\alpha \sigma^{\mu\nu} P_R b_\alpha\right) F_{\mu\nu}, \tag{25.2.25}$$

$$O_g = \frac{g_s}{4\pi^2} m_b \left(\bar{s}_\alpha \sigma^{\mu\nu} P_R T_{\alpha\beta}^A b_\beta\right) G_{\mu\nu}^A, \tag{25.2.26}$$

where the Dirac structure of four-fermion operators is $\left(\bar{s}b\right)_{V-A}\left(\bar{s}s\right)_{V\mp A} = 4\left(\bar{s}\gamma^\mu P_L b\right)\left(\bar{s}\gamma_\mu P_R s\right)$, and the summation over the color indices α, β is understood. The terms with a tilde are obtained from $C_{i,g}$ and $O_{i,g}$ through a $L \leftrightarrow R$ replacement. The $B \to X_s\gamma$ branching fraction receives SUSY contributions mainly from O_γ, $\tilde{O}_\gamma$, $\tilde{O}_g$ and O_g. These dimension 5 operators are chirality flipping – the external b and s quark fields have different chiralities. In the SM, the W boson couples only to the left-handed fermions ($V-A$ current) so that the chirality flip comes from the quark mass insertion on the external quark fields. The O_γ and O_g operators are thus suppressed in the SM by one power of m_b/m_W. In non-MFV SUSY, on the other hand, there are additional interactions that can induce the chirality flip inside the loop. The m_b factor is then replaced by the internal heavy particle masses and the chirality flipping coupling (in MIA these will be $(\delta_{LR}^q)_{ij}$). The resulting Wilson coefficients from the gluino-squark loop are (Gabbiani, Gabrielli, Masiero, and Silvestrini, 1996):

$$C_\gamma^{\tilde{g}}(M_S) = -\frac{\sqrt{2}\alpha_S \pi}{2 G_F V_{tb} V_{ts}^* m_{\tilde{q}}^2} \tag{25.2.27}$$

$$\times \left\{ (\delta_{LR}^d)_{23} \frac{m_{\tilde{g}}}{m_b} \frac{8}{3} M_1(x) + (\delta_{LL}^d)_{23} \frac{8}{3} M_3(x) \right\}.$$

$$C_g^{\tilde{g}}(M_S) = -\frac{\sqrt{2}\alpha_S \pi}{2 G_F V_{tb} V_{ts}^* m_{\tilde{q}}^2} \tag{25.2.28}$$

$$\times \left\{ (\delta_{LR}^d)_{23} \frac{m_{\tilde{g}}}{m_b} \left[\frac{1}{3} M_1(x) + 3 M_2(x) \right] \right.$$

$$\left. + (\delta_{LL}^d)_{23} \left[\frac{1}{3} M_3(x) + 3 M_4(x) \right] \right\}.$$

The $\tilde{C}_\gamma$ and $\tilde{C}_g$ coefficients are obtained by making the $L \leftrightarrow R$ replacement. One can see that indeed the terms with the chirality-flipping LR/RL mass insertions are enhanced by the $m_{\tilde{g}}/m_b$ factor. This term could potentially induce large contributions to $b \to s$ penguin transition processes. On the bottom panels of Fig 25.2.4, we present the constraints on the LR and RL mass insertions (dashed line) from the $\mathcal{B}(B \to X_s\gamma)$ measurement. The difference between the two cases comes from the fact that the LR contribution adds coherently to the SM at the amplitude level while the RL contribution does not interfere with the SM and adds in the amplitudes squared.

The corrections to the chromo-magnetic operators O_g and $\tilde{O}_g$ can also have significant effects on the hadronic B decays. An important additional constraint on $(\delta^d_{LR/RL})_{23}$ is thus obtained from the penguin-dominated $B \to \phi K^0_S$ decay. In the SM, the time dependent CP asymmetry for this channel is the same as the one obtained from the decay $B \to c\bar{c}K^0_S$ (where $c\bar{c}$ represents any charmonium state such as J/ψ). If $S_{\phi K^0_S} \neq S_{c\bar{c}K^0_S}$ is found, this would be an indication of new physics. The deviation needs to be larger than the theoretical errors on the difference. A list of estimates for the theory errors on $S_{\phi K^0_S} - S_{c\bar{c}K^0_S}$ and for other $b \to s$ penguin transition dominated channels, e.g., $S_{\eta' K^0_S}$, etc., can be found in (Zupan, 2007). Historically there was an indication for a deviation from the SM, however by now, the deviation has diminished and the current world averages (see Section 17.6.6 for details of experimental extraction of these values),

$$S_{\phi K^0_S} - S_{c\bar{c}K^0_S} = 0.06 \pm 0.12, \qquad (25.2.29)$$

$$S_{\eta' K^0_S} - S_{c\bar{c}K^0_S} = -0.09 \pm 0.07, \qquad (25.2.30)$$

are consistent with the SM, though the experimental errors are still relatively large. The constraints on the LR and RL mass insertions are nontrivial and are comparable to the ones following from $B \to X_s\gamma$, see lower panels in Fig. 25.2.4. The regions excluded by combining the measurements of the $B \to X_s\gamma$ branching fraction and $S_{\phi K^0_S}$ are also shown in Fig. 25.2.4 as colored regions.

Further constraints on the corresponding mass insertions can be obtained from the other loop-induced observables. For instance, $D^0 - \bar{D}^0$ mixing constrains the up-type mass insertions $(\delta^u_{AB})_{12}$, while $(g-2)_\mu$ constrains the slepton mass insertions $(\delta^l_{AB})_{22}$, see, e.g., (Chang, Chang, Keung, Sinha, and Sinha, 2002; Chankowski, Lebedev, and Pokorski, 2005; Gabbiani, Gabrielli, Masiero, and Silvestrini, 1996; Hisano and Tobe, 2001).

25.2.2.7 SUSY Alignment models

The measurement of $D^0 - \bar{D}^0$ mixing at Belle and *BABAR* had important implications for the flavor structure of the MSSM (Ciuchini et al., 2007; Nir, 2007a,b). The squark contributions to $\Delta F = 2$ processes involving the first two generations, i.e. to $K^0 - \bar{K}^0$ and to $D^0 - \bar{D}^0$ mixing, have to be sufficiently suppressed in order not to generate contributions to the mixing larger than what is experimentally observed. The contributions arising from the box diagram with a gluino and the first two generation squark doublets $\tilde{Q}_{L1,2}$ are given by, see e.g. (Raz, 2002),

$$M^D_{12} \propto \frac{1}{m^2_{\tilde{u}}} \frac{(\Delta m^2_{\tilde{u}})^2}{m^4_{\tilde{u}}} (K^u_{21} K^{u*}_{11})^2, \qquad (25.2.31)$$

$$M^K_{12} \propto \frac{1}{m^2_{\tilde{d}}} \frac{(\Delta m^2_{\tilde{d}})^2}{m^4_{\tilde{d}}} (K^d_{21*} K^d_{11})^2. \qquad (25.2.32)$$

Here $m_{\tilde{u},\tilde{d}}$ are the averaged squark masses of the first two up and down generation squarks, $\Delta m^2_{\tilde{u},\tilde{d}}$ are the corresponding mass squared differences, while $K^{u(d)}$ is the mixing matrix for the gluino coupling to left-handed up (down) quarks and the squark partners. The proportionality coefficients depend on the D and K decay constants, the bag parameters and a function of $m_{\tilde{g}}/m_{\tilde{u},\tilde{d}}$.

There are three generic ways how these contributions can be suppressed. The first possibility is that the first two generation squarks are *heavy*, $m_{\tilde{q}} \gg 1$ TeV. Since they contribute to dimension 6 operators, these contributions scale as $\propto 1/m^2_{\tilde{q}}$ and become irrelevant when squarks are much heavier than the weak scale. The second possibility is that the squarks are *degenerate*, i.e. that the mass splitting between the first two generations is small, $\Delta m^2_{\tilde{q}} \ll m^2_{\tilde{q}}$. If they were exactly degenerate, one would be free to choose the flavor basis for squarks anyway one wants – in particular to coincide with the mass basis of first two generation quarks. The flavor breaking effects thus need to be proportional to the splitting between the squarks. Finally, the squarks could be *aligned* with the quarks, so that the mass eigenstate basis for squarks almost coincides with the mass eigenstate basis of quarks and thus $K^{d,u}_{21} \ll 1$.

Alignment naturally arises in Froggatt-Nielsen type flavor models of squark masses (Leurer, Nir, and Seiberg, 1994; Nir and Seiberg, 1993). For left-handed squarks there is also a relation between the matrices that diagonalize up and down squarks. Up to corrections of $m^2_c/m^2_{\tilde{q}} \sim \mathcal{O}(10^{-5})$ one has

$$K^u K^{d\dagger} = V_{\text{CKM}}. \qquad (25.2.33)$$

For the mixing between the first two generations this means that

$$K^u_{21} - K^d_{21} \simeq \sin\theta_C = 0.23. \qquad (25.2.34)$$

Therefore the 21 entries in the quark-squark-gluino coupling matrices cannot be smaller than the mixing between the first two generations in the SM. If squarks have masses of around 1 TeV and non-degenerate this is at odds with either $K^0 - \bar{K}^0$ mixing and $D^0 - \bar{D}^0$ mixing. Barring cancellations there are two possibilities. The first one is that squarks are quasi-degenerate. The level of degeneracy required is $\Delta m_{\tilde{q}}/m_{\tilde{q}} \lesssim 0.12$ (Gedalia, Grossman, Nir, and Perez, 2009; Nir, 2007b). The other option is that squarks are heavy. If one sets $K^u_{21} = 0.23$ and $K^d_{12} \simeq 0$ as in the original alignment model by Nir and Seiberg (1993), then $m_{\tilde{q}} \gtrsim 2$ TeV, and much heavier, if K^d_{12} is nonzero. We thus, can state model-independently that barring cancellations, if the squarks are light enough to be observed at the LHC, then they must be quasi-degenerate. Note that, in order to reach this conclusion the experimental information on $D^0 - \bar{D}^0$ mixing parameters provided by the B Factories (in particular that they are small, $x, y \sim \mathcal{O}(1\%)$), was essential. In the original alignment model the gluino-squark loop induced FCNCs are absent in the down quark sector. Therefore among the observables in Table 25.2.2 the only place we would expect deviations is $D^0 - \bar{D}^0$ mixing.

25.2.2.8 Randall-Sundrum models of flavor

The Randall-Sundrum (RS) models of flavor have an ambitious goal. They strive to simultaneously solve the hierarchy problem, the flavor problem of new physics and explain the flavor structure in the SM. The hierarchy problem refers to the Planck scale $\sim 10^{19}$ GeV being so much bigger than the electroweak scale ~ 1 TeV. The flavor problem of new physics is that new physics at 1 TeV (which solves the hierarchy problem) must not enhance FCNCs above the SM level. At the same time the RS models of flavor also provide an explanation for the flavor structure in the Standard Model – the origin of the hierarchy of masses and mixing – through localization of quark fields in the 5$^{\text{th}}$ dimension (Gherghetta and Pomarol, 2000; Grossman and Neubert, 2000).

The RS models are extra dimensional models where a slice of 5-dimensional (5D) space-time (bulk) is truncated by flat 4-dimensional boundaries – the two 4-dimensional (4D) branes. The Planck brane is on the UV side of the bulk, while the TeV brane is on the IR side of the bulk. This setup results in a warped metric for the bulk (Randall and Sundrum, 1999)

$$ds^2 = e^{-2kr_c|\phi|}\eta_{\mu\nu}dx^\mu dx^\nu - r_c^2 d\phi^2, \qquad (25.2.35)$$

where k is the 5D curvature scale, r_c the compactification radius, and $\phi \in [-\pi, \pi]$ the coordinate along the 5$^{\text{th}}$ dimension. The hierarchy problem is solved by the presence of the warp factor $e^{-2kr_c|\phi|}$, which suppresses the fundamental Planck scale $\sim 10^{19}$ GeV down to the weak scale ~ 1 TeV for $kr_c \approx 12$.

In the initial RS models all the SM fields were assumed to be localized on the IR brane and only gravity propagated in the bulk (Davoudiasl, Hewett, and Rizzo, 2000). This immediately lead to phenomenological problems, because the cut-off of the effective 4D theory is also warped down to TeV scale. A viable model is obtained, if the fermions and gauge bosons are allowed to propagate in the bulk, while only the Higgs boson is localized on the IR brane. The 5D profiles of the SM fermions (the zero modes) have an exponential form

$$f_i^{(0)} \sim e^{(1/2-c_i)kr_c\phi}. \qquad (25.2.36)$$

The light fermions have bulk mass parameters $c_i > 1/2$, and are thus localized near the Planck brane. This has two beneficial consequences. On one hand it suppresses FCNCs due to virtual exchanges of Kaluza-Klein (KK) states – the excitations of the SM fields that arise because of the compact extra dimension. The suppression is due to different localizations of zero mode fermions, that peak near the UV brane, and KK modes that peak near the IR brane. Therefore there is only a small overlap between the two (Gherghetta and Pomarol, 2000). Since the Higgs boson is localized on the IR brane this also explains the smallness of the masses of UV localized light fermions – it is due to the fact that they have only a small overlap with the Higgs wave function. The 4D Yukawa coupling matrices are given by

$$(Y_{u,d}^{4D})_{ij} = (Y_{u,d}^{5D})_{ij} f_{Q_i} f_{u_j,d_j}, \qquad (25.2.37)$$

with f_{Q_i} (f_{u_j,d_j}) the values of wave functions for the left-handed (right-handed) fermions at the IR brane, where the Higgs is situated, cf. Eq. (25.2.36). The hierarchy of the SM quark masses is naturally obtained for $\mathcal{O}(1)$ values of 5D Yukawa parameters $(Y_{u,d}^{5D})_{ij}$ and values of c_i, where an order unity change in c_i results in an exponential change in the value of quark masses (Gherghetta and Pomarol, 2000; Grossman and Neubert, 2000; Huber, 2003).

The zero mode (*i.e.* SM) gluons and photons have flat wave functions in the ϕ direction due to unbroken $SU(3)_C \times U(1)_{\text{EM}}$ gauge invariance. The Z and $W^\pm$ wave functions, on the other hand, are distorted near the IR brane, since electroweak symmetry is spontaneously broken. This generates tree level FCNCs mediated by the Z and the KK gauge bosons. This is in contrast to the SM, where due to the GIM mechanism the FCNCs arise only at the one loop level. Still, the FCNCs in the RS models are suppressed despite the fact that they arise at tree level. The reason is that the light quarks are localized at the UV brane, while both the KK modes and the distortion of the Z shape function are all localized near the IR brane. The FCNCs are then suppressed by the small wave function overlaps. This so-called "RS-GIM mechanism" suffices to avoid disastrously large FCNCs, but with some tension in the kaon sector (Agashe, Perez, and Soni, 2004).

The above setup has several phenomenological implications. Because the SM gauge bosons and fermions mix with the corresponding KK modes, the CKM matrix is no longer unitary. The corrections to CKM unitarity are of order $\mathcal{O}(v^2/m_{\text{KK}}^2)$. For KK masses in the few TeV range these corrections are thus very small, at percent level or smaller.

Easier to observe are effects due to additional flavor and *CP* violating sources in the model. The 5D mass matrices C^Q, C^u, C^d have 18 new mixing angles and 9 complex phases beyond the SM Yukawa couplings (Agashe, Perez, and Soni, 2005). The new *CP* violating weak phases can affect low energy *CP* violating observables. For a low KK mass scale, $m_{\text{KK}} \lesssim 3$ TeV, the tree level KK gluon exchanges lead to contributions to $B_d^0 - \bar{B}_d^0$ and $B_s^0 - \bar{B}_s^0$ mixing that are roughly of the same size as the SM contributions, but with arbitrary weak phases (Agashe, Perez, and Soni, 2005). The possibility of such large contributions to the $B_d^0 - \bar{B}_d^0$ mixing was excluded by the B Factories, while large phases in $B_s^0 - \bar{B}_s^0$ mixing are severely constrained by the LHCb results. For $K^0 - \bar{K}^0$ mixing by far the most important is the generation of operators with the left-right (LR) chiral structure from KK gluon exchanges. These are enhanced by the renormalization group running and by chirally enhanced matrix elements. They give a contribution that is a factor 140 larger than the SM LL operator, if the KK scale is around 3 TeV (Bauer, Casagrande, Haisch, and Neubert, 2010; Blanke, Buras, Duling, Gori, and Weiler, 2009; Casagrande, Goertz, Haisch, Neubert, and Pfoh, 2008; Csaki, Falkowski, and Weiler, 2008).

The KK masses below 3 TeV would be allowed by the RS models with additional custodial symmetry which can satisfy the electroweak precision data constraints. (Agashe, Contino, Da Rold, and Pomarol, 2006; Agashe, Delgado,

May, and Sundrum, 2003; Csaki, Grojean, Pilo, and Terning, 2004). In contrast the data on ϵ_K imply a generic lower bound on M_{KK} of roughly 20 TeV for anarchic 5D masses c_i with $\mathcal{O}(1)$ coefficients (Csaki, Falkowski, and Weiler, 2008). With modest fine tuning KK mass scales of 2 to 3 TeV are still allowed (Blanke, Buras, Duling, Gori, and Weiler, 2009), or if additional flavor symmetries are introduced in the 5D Yukawa coupling matrices (Cacciapaglia et al., 2008; Csaki, Falkowski, and Weiler, 2009; Csaki, Perez, Surujon, and Weiler, 2010; Fitzpatrick, Perez, and Randall, 2007). Constraints from $K^0 - \bar{K}^0$ mixing are also reduced in "soft wall" RS models, where the IR brane is removed and the Higgs is free to propagate in the bulk (Archer, Huber, and Jager, 2011).

In RS models there are also potential effects in $\Delta F = 1$ modes (Bauer, Casagrande, Haisch, and Neubert, 2010; Blanke, Buras, Duling, Gori, and Weiler, 2009). Rare $B_{s,d} \to \mu^+\mu^-$ and $B_{s,d} \to X_{s,d}\nu\bar{\nu}$ are not affected much and remain SM like, with the corrections to the branching fractions below 15%. Larger effects in $\mathcal{B}(B \to X_s\gamma)$ are in principle possible from contributions to dipole operators for a somewhat tuned parameter set, which however, are excluded by the data from B Factories. The contributions to EDMs are also generically large, about a factor 20 above the present experimental bounds, leading to additional constraints on RS parameter space. The branching fractions $\mathcal{B}(K \to \pi^0\nu\bar{\nu})$ and $\mathcal{B}(K^+ \to \pi^+\nu\bar{\nu})$ can be enhanced by a factor ~ 2 compared to the SM, however simultaneous enhancements of $S_{B_s \to J/\psi\phi}$ and $K \to \pi\nu\bar{\nu}$ branching ratios are not likely. The corrections to the CKM matrix are dominated by the effects due to the mixing with the KK gauge bosons. The deviations from the SM are small: even for the largest effects for the CKM elements involving third generation quarks, they can be up to $1-2\%$. Modest effects at the order of $\mathcal{O}(5\%)$ are expected on $S_{B \to \phi K_S^0}$ and other $b \to s$ penguin transitions (Agashe, Perez, and Soni, 2005; Bauer, Casagrande, Haisch, and Neubert, 2010). The constraints from $Z \to b\bar{b}$, ϵ_K and $B^0 - \bar{B}^0$ mixing also suffice to predict the mass difference in $D^0 - \bar{D}^0$ mixing to be not much larger then what is observed, however a significant spread in the CP violating mixing phase is possible, with the bulk of the predictions on the phase $|\arg(M_{12}^D/\Gamma_{12}^D)| \lesssim 90°$. The B Factories constraints from $D^0 - \bar{D}^0$ mixing are thus nontrivial and exclude a significant part of the parameter space (Bauer, Casagrande, Haisch, and Neubert, 2010). The corrections to $B \to \tau\nu$ can be at most 1% (Bauer, Casagrande, Haisch, and Neubert, 2010). The first complete calculation of one loop contributions to $(g-2)_\mu$ was completed recently by Beneke, Dey, and Rohrwild (2012), and the result is about an order of magnitude below the present experimental error.

25.2.2.9 Little Higgs models

The Little Higgs models present another direction for a potential solution to the hierarchy problem (for a pedagogical review see Schmaltz and Tucker-Smith, 2005). We focus on a particular model – the Littlest Higgs Model with

T-parity (Cheng and Low, 2003, 2004; Low, 2004) – whose flavor structure was studied in detail by the Munich group (Bigi, Blanke, Buras, and Recksiegel, 2009; Blanke, Buras, Duling, Poschenrieder, and Tarantino, 2007; Blanke, Buras, Duling, Recksiegel, and Tarantino, 2010; Blanke et al., 2007, 2006; Blanke, Buras, Recksiegel, and Tarantino, 2008; Blanke, Buras, Recksiegel, Tarantino, and Uhlig, 2007a,b) and supplemented by Goto, Okada, and Yamamoto (2009) and by del Aguila, Illana, and Jenkins (2009).

The Littlest Higgs Model with T-parity (LHT) has a relatively small number of new parameters that describe the flavor sector – 10 in the quark sector (Blanke, Buras, Duling, Recksiegel, and Tarantino, 2010). The relevant operators in the effective weak Hamiltonian that are generated by integrating out NP contributions are the same as in the SM. The fact that the model has T-parity means that the NP scale f can be quite low, $f = 500$ GeV. This is quite different from for instance the RS models that were described in the previous section (where even in the models with custodial protection the KK scale is in the range of $2-3$ TeV). Another interesting difference with the RS models is that the constraints from $B \to X_s\gamma$ and neutron electric dipole moment are not very strong and are easily satisfied.

In the LHT there are new flavor interactions beyond the CKM matrix V_{CKM}. These new interactions involve the heavy gauge bosons $W_H^\pm, Z_H, A_H$ which get emitted from the SM quarks when they convert to a mirror quark. These interactions of mirror and SM quarks are described by the two 3×3 unitary mixing matrices V_{H_d} and V_{H_u} that are related by $V_{H_u}^\dagger V_{H_d} = V_{CKM}$. This means that the FCNCs in down-quark and up-quark sectors are related.

The main phenomenological features of LHT contributions in the flavor observables are as follows (Buras, 2009). The rare B decays are SM-like to a good extend. For instance $B_{s,d} \to \mu^+\mu^-$ can be enhanced by $\mathcal{O}(30\%)$ compared to the SM, where the largest corrections come from the T-even sector. Typical deviations in $S_{J/\psi\phi}$ are at the order of $\mathcal{O}(5-10\%)$, with the details depending on the spectrum of the mirror fermions. They are thus smaller then in RS. Similar effects would be expected in $\sin 2\phi_1$ determination from $B \to J/\psi K_S^0$ with the corrections to a large extend uncorrelated with the ones in $B_s^0 - \bar{B}_s^0$ mixing (Blanke, Buras, Recksiegel, and Tarantino, 2008). The contributions to $\mathcal{B}(B \to X_s\gamma)$ are relatively small, at the order of up to about 3% of the SM value, which is smaller than the theoretical uncertainty on the SM prediction. The corrections to $B \to \tau\nu$ are very small since there are no tree level contributions. The effects in $S_{\phi K_S^0}$ are also expected to be small, since both $b \to sg$ and electroweak penguin corrections are not sizable.

The $\mathcal{B}(\mu \to e\gamma)$ can reach 2×10^{-11} so that some fine tuning of the parameters is required to satisfy MEG bounds (Adam et al., 2013). Also, the contributions in the lepton flavor violating decays, $\mu - e$ conversion, $\mu^- \to e^-e^+e^-$, $\tau \to \mu\gamma$, $\tau \to 3\mu$ clearly distinguish LHT from SUSY. The contributions to $(g-2)_\mu$ are negligible (see (Jegerlehner and Nyffeler, 2009) and references therein). There are CP violating contributions to the

$D^0 - \bar{D}^0$ mixing amplitudes. The weak phase in the mixing can still be large (and would be even much larger if the ϵ_K constraint is omitted). It can lead to effects in $D^0 - \bar{D}^0$ mixing that are of several percent, *e.g.* $-0.02 \lesssim S_{D \to K^0_S \phi} \lesssim +0.01$ (Bigi, Blanke, Buras, and Recksiegel, 2009).

25.2.3 Summary

Flavor physics has a significant potential to discover new physics by its sensitivity to high energy scales through virtual effects. At present, there is no solid experimental hint of an effect beyond the SM. Lacking any preferred theoretical foundation for the observed flavor structure, an analysis of the new physics effects in low energy precision observables must thus make use of well defined and commonly agreed benchmark models. While clearly it is not possible to cover all the possibilities, a large enough set of representative benchmark models gives a picture of what kind of effects are possible. Many of the currently discussed scenarios are already highly constrained or can be strongly constrained at the currently planned experiments.

One of the main motivations to extend the Standard Model with new particles with TeV masses is to solve the hierarchy problem – to stabilize the electroweak scale against radiative corrections. The flavor structure in most cases is not fixed by the rationale behind the model and hence remains mostly arbitrary from the theoretical considerations. Experimentally, on the other hand, the flavor structure in the new physics sector is tightly constrained. The legacy of the B Factories program is that in low energy flavor violating processes the dominant contributions are from the SM. The low energy effects of a viable new physics model have to be minimally flavor violating, or at least have to be close to this limit. In fact, mainly due to the data of the two B Factories, the corners of phase space for non-MFV effects in low energy processes have become very sparse.

Both *BABAR* and Belle have performed a test of the flavor structure, in many cases at a precision level. In this respect the two experiments have performed a similar task in the flavor sector as LEP did for the gauge couplings; still we do not have any substantial hint for a crack in the structure of the SM, neither in the gauge nor in the flavor sector.

Future experiments at both the energy as well as the intensity frontier will have an extended reach and a larger sensitivity. In particular, super flavor factories will refine many of the measurements performed at *BABAR* and Belle and thus improve the reach for new physics. Complementary to this, there will be measurements of leptonic processes at dedicated experiments, focusing especially on lepton-number and lepton-flavor violating processes. These efforts will be augmented further by experiments at the energy frontier, which will be mainly the LHC experiments ATLAS and CMS for the next decade. A direct discovery of new degrees of freedom at the energy frontier – beyond the discovery of a single Higgs particle – will clearly have a significant impact on our understanding of flavor physics in the future.

Appendix A
Glossary of terms

This part of the book summarizes commonly used terms, abbreviations, quantities, and acronyms found elsewhere in the book as a quick reference. References to places where terms are first introduced have been made. Where appropriate the second cross reference is given to sections in which a term is described in more details.

ACC : The Belle aerogel Cherenkov counter (1.4.4; 2.2.3).

Acoplanarity : The acoplanarity of a two-particle final state is defined as $\phi_2 - \phi_1 - \pi$. The azimuthal angles of the final state particles are ϕ_i, where $i = 1, 2$ (17.4.3).

AWG : Analysis Working Group; a physics sub-group within the *BABAR* Collaboration (2.1).

basf : Belle Analysis and Simulation Framework (3.1).

BDT : Boosted (or bagged) decision tree. This is an MVA classification algorithm used widely in the latter years of data analysis at the *B* Factories (5; 4).

BSM : Beyond the Standard Model (18.1; 25.2).

CDC : The Belle central drift chamber (1.4.4; 2.2.2).

CLEO Fisher : The CLEO Fisher discriminant formed of nine energy flow cones. This has been widely used as a variable to discriminate between *B* meson signal-like events and light quark continuum background. Also see Fisher discriminant (9.3).

CKM matrix : Cabibbo-Kobayashi Maskawa quark mixing matrix (1; 16).

CM : Centre of mass (1.2.2).

Continuum background : This is the term given to backgrounds from e^+e^- transitions to light fermion anti-fermion pairs in collisions. Typically continuum background refers to light-quark pairs $q\bar{q}$, where $q = u, d, s$, and c (2.2.5).

cos θ_B : Cosine of the angle between beam axis and B momentum in the $\Upsilon(4S)$ rest frame (9.3).

cos θ_S : Cosine of the angle between sphericity axes of ROE and B candidate (9.3).

cos θ_T : Cosine of the angle between beam and B thrust axes (9.3).

DAQ : Data acquisition (1.4.3.1; 2.2.7).

DCH : The *BABAR* drift chamber (2.1; 2.2.2).

DIRC : The *BABAR* detector of internally reflected Cherenkov light, used for charged particle identification (in particular the π/K separation) in the barrel region (1.4; 2.2.3).

ECOC : Error-correcting output codes (5.2).

ECL : The Belle electromagnetic calorimeter (1.4.4.2; 2.2.4).

EMC : The *BABAR* electromagnetic calorimeter (2.1; 2.2.4).

EML : Extended maximum likelihood (11).

Experiment : An Experiment, with an upper case "E", is the name given in Belle to the different data taking periods. *BABAR* analogy of an Experiment is a Run. Only odd numbers were used for Experiments, there are 31 Belle Experiments. See also Run (3.2).

$\mathcal{F}$: Generic Fisher discriminant: a linear combination of variables (4).

Fisher discriminant : A linear combination of variables which is often used to compute a variable to discriminate between signal-like B meson events and light quark continuum background; see also CLEO Fisher (4).

FPGA : Field-Programmable Gate Array, a configurable integrated circuit (2.2.2).

FOM : Figure of merit, a test statistic often used during optimization (4.3).

FSR : Final state radiation (17.4.4).

H_i : The ith Fox-Wolfram moments (9).

h_l^k : Normalized Fox-Wolfram moments given by Eq. (9.5.2).

HER : High energy ring (1.4.3.1).

HQET : Heavy Quark Effective Theory (17.1; 17.9.1.2).

IFR : The instrumented flux return of *BABAR*, used for K_L^0 and muon detection (1.4.3.1; 2.2.5).

IP : The interaction point (2.1).

IR : The interaction region (1.3).

ISR : Initial state radiation (15.1.1).

KLM : The instrumented flux return of Belle, used for K_L^0 and muon detection (1.4.4; 2.2.5).

KSFW : Fisher discriminant: a linear combination of modified Fox-Wolfram moments given by Eq. (9.5.3).

L_i : The ith 'monomial' corresponding to an angle-weighted energy flow variable given by Eq. (9.4.1).

L1, L3 : The first (hardware-based) and the second (software-based) trigger level, respectively (2.1; 2.2.6).

LCSR : Light cone sum rule, a formulation of QCD sum rules specifically suited for the calculation of heavy-to-light form factors. (17.1).

LER : Low energy ring (1.4.3.1).

Local operator : In quantum field theory local operators are the product of field operators evaluated at the same space-time point (17.1.3).

LQCD : Lattice QCD (17.1).

LST : Limited Streamer Mode, the technology selected by *BABAR* to replace the whole IFR barrel because of a dramatic decrease in performance of the original RPCs (1.4; 2.2.5).

LTDA : *BABAR* long-term data analysis system (3.7).

MC : Monte Carlo (3.1).

MFV : Minimal flavor violation model (25.2).

ML : Maximum likelihood (11).

MLP : A multi-layer perceptron is a common type of artificial neural network used in particle physics. Neural networks have been used widely at the B Factories, most notably in terms of flavor tagging (4; 8).

MSSM : Minimal super-symmetric standard model (25.2).

MVA : A multi-variate analysis is the study of a multi-dimensional problem space in the context of discriminating between different types of event. Practical demonstrations of the use of MVA techniques can be found throughout this book, in particular in the context of PID (4; 5; 9).

NN : Neural Network : multi-layered combination of variables. See also MLP (4; 9).

NP : "New physics", which is any physics not described by the Standard Model (2.2.6; 17.2).

NRQCD : Non-relativistic QCD (17.1.1).

OPE : Operator Product Expansion (17.1.1).

p.d.f. : Probability density function (7.4.4; 11.1).

Penguin : Loop contribution mediating a flavour changing neutral current (7.4).

Penguin pollution : Penguin contributions which carry a weak phase different form the tree contribution, thereby introducing a "pollution" (i,e, hadronic uncertainties) into the extraction of CKM phases. (17.4.4; 17.7).

PID : Charged particle identification (2.1; 2.2.3).

PV : Primary Vertex (6.4).

Planarity : The planarity (or aplanarity) of the event is a measure of the transverse component of momentum of of the event plane. This is related ot the smallest eigen-value of the sphericity tensor λ_3, where the aplanarity A is $3\lambda_3/2$. For a planar event $A = 0$. For an isotropic event $A = 1/2$ (17.4.3).

QCDF : QCD Factorization (17.4; 17.9.1).

Quasi-Two-Body : For a decay to a final state with on resonance and a long-lived particle *e.g.* $B^0 \rightarrow \rho^+ \pi^-$, the quasi-two-body approximation is sometimes invoked. This approximation is the assumption that the resonance can be treated as a particle with definite mass. In practice this means that any interference between the reconstructed resonance of interest and other amplitudes contributing to a same body final state is not explicitly accounted for in a fit to data using a Dalitz plot, but is treated as a systematic effect, or if deemed appropriate neglected. This approximation is commonly used in the study of charmless B decays (17.4).

$\mathcal{R}$: Signal-to-background likelihood ratio used by Belle and given by Eq. (9.5.11).

R_i : Normalized Fox-Wolfram moments (*BABAR* notation; 9).

R_l^{s0}, R_l^{00} : Modified Fox-Wolfram moments (9).

ROE : Rest of the event: Particles found in the detector that are not associated with the reconstructed signal candidate (6.5).

RPC : Resistive plate chamber, the technology selected by *BABAR* and Belle to instrument their muon detectors (1.4; 2.2.5).

Run : A Run, with an upper case "R", is the name given in *BABAR* to the different data taking periods. An analogy of Run at Belle is an Experiment. There are seven *BABAR* Runs, each several month-long. See also Experiment (3.2).

run : A run, with a lower case "r", is the basic unit of *BABAR* and Belle data collection. The full *BABAR* physics dataset contains more than 38,000 such runs (3.2).

SCET : Soft Collinear Effective Theory (17.4; 17.9.1.4).

SFW : Fisher discriminant : linear combination of Fox-

Wolfram moments given by Eq. (9.5.1).

SM : Standard Model of Particle Physics (1).

SNNS : Stuttgart Neural Network Simulator, an implementation of a neural network algorithm (4).

Spectator : A quark, which does not change its flavor in a weak decay process (17.4.4; 17.7)

SOB : The so-called *stand off box* of the *BABAR* DIRC (2.1).

Sphericity : Tensorial representation of energy flow, given by Eq. 9.3.2,

$_s\mathcal{P}lot$: The $_s\mathcal{P}lot$ technique is an event re-weighting technique that is used in order to project out fit components, such as signal or background. The technique was developed at the *B* Factories. This technique has often been used when presenting results from *BABAR* (11; 11.2.3).

SPR : StatPatternRecognition, a ROOT-based package with a number of implemented multivariate methods (4).

Strong phase : A phase that is invariant under the operator CP (13.2.4).

SVT : The *BABAR* silicon vertex tracker (2.1; 2.2.1).

SVTRAD : The *BABAR* silicon vertex radiation monitoring system (2.2.1).

SVD : The Belle silicon vertex detector (2.1; 2.2.1).

Three-Body : Decay to a final state with three long-lived particles *e.g.* $B^+ \to \pi^+\pi^+\pi^-$ (9.4.2).

Thrust : Vectorial representation of energy flow, given by Eq. 9.3.1.

Tree : Contribution to a decay which is mediated by Feynman diagrams without loops. (17.4.4; 17.7)

Two-Body : Decay to a final state with two long-lived particles *e.g.* $B^0 \to \pi^+\pi^-$ (7.1.1).

TMVA : Toolkit for Multivariate Analysis, a ROOT-based package with a number of implemented multivariate methods (4.4.4; 4.5).

TOF : The Belle time-of-flight detector (1.4.4.1; 2.2.3).

Twist : In quantum field theory the twist of an operator is defined as the difference between its dimension and its spin (17.1.4.1).

2HDM : Two-Higgs doublet model (17.10.2.1; 25.2).

VM : Virtual Machine (3.7).

Weak phase : A phase that changes sign under the operator CP (13.2.4).
