#### Abstract

Two-photon excitation (TPE) spectra of the  $4f^1 \rightarrow 5d^1$  transitions of  $Ce^{3+}$  in LuPO<sub>4</sub> and YPO<sub>4</sub> have been investigated. For  $Ce^{3+}$  in LuPO<sub>4</sub>, transitions to four out of the five  $5d^1$  levels are observed as zero-phonon lines. The symmetry properties of the levels were obtained from the polarization dependence of the TPE signals. Measurements on  $Ce^{3+}$  in YPO<sub>4</sub> support the given assignments. Although a crystal-field fit yields a satisfactory RMS energy deviation, an unrealistic value of the spin-orbit coupling parameter,  $\zeta_{5d^1}$ , is obtained. The vibronic coupling appears to be smaller than for the single-photon absorption spectra, and the vibronic bands show a rich structure. There are striking differences between the energies and the relative intensities of the vibronic lines and the associated zero-phonon lines. The vibronic coupling is also found to be strongly dependent on the  $Ce^{3+}$  concentration.

#### I. INTRODUCTION

The past decade has witnessed an increasing interest in the two-photon spectroscopy of lanthanide ions. This type of spectroscopy can be divided in two groups: i.e. (a) two-photon excitation (TPE), in which two photons are absorbed simultaneously by the lanthanide ion and (b) electronic Raman scattering (ERS), in which a photon is inelastically scattered from an ion such that the ion is excited to a different electronic state. Both processes are parity allowed for the  $4f \rightarrow 4f$  transitions and are to be considered as complementary to single-photon spectroscopy.

ERS is especially suited to the study of low lying energy levels. Koningstein<sup>1</sup> and Becker et  $al^{2-4}$  have published ERS measurements for many lanthanide ions, and Williams et  $al^{5,6}$  and Piehler and Edelstein<sup>7</sup> have previously reported ERS for  $Ce^{3+}$  in LuPO<sub>4</sub>. One practical stimulus to the study of  $Ce^{3+}$  in orthophosphates hosts is their very promising scintillator characteristics<sup>8</sup>, plus their potential as nuclear waste storage hosts<sup>9</sup> and as a tunable UV laser material<sup>10</sup>. The 4f<sup>1</sup> crystal-field components of  $Ce^{3+}$  have energies up to  $\approx 2500$  cm<sup>-1</sup>. The positions of all seven crystal-field components were determined previously<sup>5</sup> and resonance-enhancement effects were studied<sup>5-7</sup>. Calculations of these effects rely heavily on the positions and symmetry assignments of the 5d<sup>1</sup> levels<sup>11</sup>. Despite a large amount of single-photon spectroscopic data for  $Ce^{3+}$  in the orthophosphates, only the first 5d<sup>1</sup> level has been determined accurately. Our goal was to apply TPE to  $Ce^{3+}$  in LuPO<sub>4</sub> in order to obtain this information for the other 5d<sup>1</sup> levels as well. Measurements were also performed for  $Ce^{3+}$  in YPO<sub>4</sub> in order to confirm the LuPO<sub>4</sub> results.

Although TPE was discovered in 1962<sup>12</sup>, the work by Downer et al<sup>13</sup> reawakened interest in TPE for the lanthanides<sup>14</sup>. Downer et al showed that the original theory proposed by Axe<sup>15</sup> does not provide satisfactory agreement with the experimental data for the ions Gd<sup>3+</sup> and Eu<sup>2+</sup>. Selection rules were violated, the polarization anisotropy was not predicted correctly, and the experimental intensities were anomalously large. The inclusion of higher-order terms in the calculations has been shown<sup>16,17</sup> to overcome these discrepancies. Judd and Pooler<sup>18</sup> have suggested that the deviation from Axe's theory will be most pronounced for Gd<sup>3+</sup> and Eu<sup>2+</sup> because of their half-filled f shell. Axe's theory, however, does not work well for the case of Pr<sup>3+</sup> either<sup>19</sup>. Calculations for Pr<sup>3+</sup> have unfortunately not been published based on Downer's theory at the present time, so a comparison is not possible for this case.

 ${
m Ce^{3+}}$  has a unique position among the lanthanide ions since the total 4f splitting is  $\approx 2500~{
m cm^{-1}}$ . Therefore, for  ${
m Ce^{3+}}$  ERS will be the only practical parity-allowed two-photon spectroscopy technique. The next-highest levels are from the 5d¹ configuration and typically start at 30 000 cm<sup>-1</sup>. In principle, TPE to these levels is parity forbidden. For  ${
m Ce^{3+}}$  at a non-centrosymmetric site, however, odd crystal-field components will mix opposite-parity configurations with the 5d configuration. Interactions with odd-parity phonons will result in a similar configuration mixing. This makes the 4f  $\rightarrow$  5d TPE transitions forced-electric-dipole allowed. These are essentially the same mechanisms that make 4f  $\rightarrow$  4f single-photon forced-electric-dipole transitions allowed.

In earlier work using TPE for the case of Ce<sup>3+</sup>, the Ce<sup>3+</sup> ion occupied several sites in the host lattices. This significantly hampered an accurate assignment, especially for the symmetries of the components. Gayen and Hamilton were the first to report on the TPE

of  $Ce^{3+}$  in  $CaF_2^{20,21}$ . They observed the zero-phonon transition from the  $4f^1(^2F_{5/2})$  ground state to the first component of the  $5d^1$  configuration and measured the absolute cross section,  $\sigma(\theta=0^\circ)=2\cdot 10^{-54}\,\mathrm{cm}^4\mathrm{s}$ , with an estimated factor of five uncertainty. Calculations of the cross section turn out to give much larger values<sup>21</sup>. Leavitt has elaborated on the static and dynamic contributions to the lowest  $4f\to 5d$  TPE transition and found better agreement<sup>22</sup>. Using a different approach, Makhanek et al also found good agreement<sup>23</sup>.

The Ce<sup>3+</sup> ions do not have a unique site symmetry in Ce<sup>3+</sup>:CaF<sub>2</sub> because of the charge compensation which is necessary for the trivalent cerium ion substituting for the divalent calcium ion. Instead, there are several Ce<sup>3+</sup> sites, each with slightly different energy splittings. Consequently, the inhomogeneous broadening is considerable<sup>20,24,25</sup>. Pedrini et al<sup>26</sup> used TPE to study Ce<sup>3+</sup> in LaF<sub>3</sub>. The resolution they show, however, is not sufficient to determine zero-phonon line positions; moreover, they conclude that for larger concentrations several sites and numerous traps are present.

All of the experimental studies <sup>20,24-26</sup> show that vibronic effects play an important role in the TPE of Ce<sup>3+</sup>. A major part of the intensity arises from TPE transitions to a final state in which the electronic state is coupled to a vibrational state. For Ce<sup>3+</sup> in CaF<sub>2</sub>, the vibronic contribution in the TPE transitions to higher 5d<sup>1</sup> levels is so large that the zero-phonon lines are unobservable<sup>24,25</sup>. In addition, the vibronic bands tend to be structureless, i.e. transitions to different vibrational states do not show up as distinctive peaks. This is also the case for Ce<sup>3+</sup> in LiYF<sub>4</sub> <sup>27</sup>.

For the TPE of Ce<sup>3+</sup> in LuPO<sub>4</sub>, transitions to four out of the five 5d<sup>1</sup> levels are observed as zero-phonon lines. As far as we know, this is the first time that the positions of these levels have been measured directly. (The wavelengths necessary for TPE to the fifth component were not attainable with our equipment.) The vibronic coupling is small, and the vibronic bands show a rich structure. The respective symmetry labels for the 5d<sup>1</sup> levels were obtained from the polarization dependence of the TPE signal. The derived symmetry labels are supported by TPE data obtained for the isostructural YPO<sub>4</sub> host.

#### II. SAMPLE PREPARATION AND PROPERTIES

#### A. The orthophosphates LuPO<sub>4</sub> and YPO<sub>4</sub>

Single crystals of LuPO<sub>4</sub> and YPO<sub>4</sub> were grown using a flux method described previously<sup>28</sup>. Typical sample dimensions were  $0.5 \text{ mm} \times 4 \text{ mm} \times 10 \text{ mm}$ . Only crystals exhibiting good optical quality were selected.

The host lattices LuPO<sub>4</sub> and YPO<sub>4</sub> both have the tetragonal zircon-type structure with space group  $D_{4h}^{19}$ . We write the reference axes for the space-group symmetry as  $\hat{X}$ ,  $\hat{Y}$  and  $\hat{Z}$ .  $\hat{Z}$  is the optical axis of the crystal, while  $\hat{X}$  and  $\hat{Y}$  are two equivalent axes. The site symmetry for the rare-earth ions is  $D_{2d}$ . The Ce<sup>3+</sup> ion substitutes for the Lu<sup>3+</sup> or Y<sup>3+</sup> ion. The reference axes for the  $D_{2d}$  operations, which we write as  $\hat{x}$ ,  $\hat{y}$  and  $\hat{z}$ , are different from the axes for the crystal-symmetry operations. The  $\hat{x}$  and  $\hat{y}$  axes are obtained by a rotation of  $\pi/4$  about the  $\hat{Z}$  axes (see figure 1). The crystals are birefringent with indices of refraction  $n_0 = 1.694$  and  $n_e = 1.728$  for LuPO<sub>4</sub> <sup>29</sup> and  $n_0 = 1.721$  and  $n_e = 1.816$  for YPO<sub>4</sub> <sup>30</sup> at  $\lambda = 589.3$  nm.

Rare-earth orthophosphates crystallize in two different crystal structures. For the smaller rare-earth ions, (Tb<sup>3+</sup> to Lu<sup>3+</sup>), the structure is that of YPO<sub>4</sub> (xenotime), the tetragonal zircon structure. For the larger rare-earth ions, (Ce<sup>3+</sup> to Gd<sup>3+</sup>), the structure is monoclinic (monazite)<sup>31</sup>. This difference in crystal structure will limit the amount of Ce<sup>3+</sup> that can be doped into LuPO<sub>4</sub> and YPO<sub>4</sub> without changing the crystal structure. We have used crystals with, at most, 8 mole % of cerium relative to lutetium in the starting materials. X-ray fluorescence and mass spectrometric analysis show that the actual Ce<sup>3+</sup> concentration in the crystals is much smaller, approximately 2 % of the starting material concentration<sup>6,8</sup>.

#### B. The 5d<sup>1</sup> configuration of Ce<sup>3+</sup> in orthophosphates

The  $5d^1$  configuration of  $Ce^{3+}$  in  $D_{2d}$  symmetry is split into four components by the crystal-field. Inclusion of the spin-orbit coupling gives an additional splitting for one of the components, but this splitting will be small compared to the crystal-field splitting. Figure 2 shows the splittings of the  $5d^1$  configuration with labels of the irreducible representation of the  $D_{2d}$  group and inclusion of the spin-orbit coupling.

Single-photon spectroscopy of Ce<sup>3+</sup> in LuPO<sub>4</sub> has been reported previously by Hoshina and Kuboniwa<sup>32</sup>, Nakazawa and Shionoya<sup>33</sup>, Williams et al<sup>5</sup>, and Piehler and Edelstein<sup>7</sup>. These papers report, for the most part, either in absorption or in emission, transitions between the 4f<sup>1</sup> levels (<sup>2</sup>F<sub>5/2</sub> and <sup>2</sup>F<sub>7/2</sub>) and the lowest component of the 5d<sup>1</sup> configuration. Williams et al<sup>5</sup> did experiments in which the positions of all the components of both the 4f<sup>1</sup> and the 5d<sup>1</sup> configurations were determined. Symmetry assignments were based on electronic-Raman-scattering selection rules for the 4f<sup>1</sup> configuration and on a crystal-field fit for the 5d<sup>1</sup> configuration. Earlier work on Ce<sup>3+</sup> in YPO<sub>4</sub>, giving only the energy positions of the 5d<sup>1</sup> configuration, was reported by Blasse and Bril<sup>34</sup> and Ropp<sup>35</sup>. In later investigations, symmetries were assigned by Briffault and Denis<sup>36</sup> and Balasubramian and Newman<sup>37</sup>. Both of these latter reports neglected spin-orbit coupling and did not use the double-group representation to label the symmetries. Additionally Naik and Karanjikar<sup>38</sup> have reported X-ray excited luminescence and excitation spectra of powders of 1 % Ce<sup>3+</sup> in YPO<sub>4</sub>.

In all of these previous studies, the only allowed, directly observed zero-phonon line was from the  $4f^1(^2F_J) \rightarrow 5d_1^1(J=5/2,7/2)$  transition,  $5d_i^1$  denoting the  $i^{th}$   $5d^1$  component. Note that reference 32 reports five zero-phonon lines, but in fact several vibronic lines were incorrectly assigned as zero-phonon lines. Positions of the higher lying  $5d^1$  components were estimated either from the origin and width of vibronic bands or from crystal-field fits. All of this work is summarized in tables I and II.

#### III. EXPERIMENTAL

#### A. The experimental instrumentation

All measurements described here were performed at liquid helium temperature. We used an Oxford CF 1204 optical cryostat to cool the samples to  $\sim 4.2 \, \text{K}$ .

Single-photon, high-resolution measurements were made using a 60 W D<sub>2</sub> lamp with the light focused on the sample by a lens with f = 7.5 cm. The transmitted light was collected by an f = 20 cm lens, focused on the entrance slits of a Spex 1403 double monochromator and was detected with a cooled Hamamatsu 943-02 photo multiplier (PMT). Typically, the slit widths were  $200\mu\text{m}$ , which resulted in a resolution of  $\leq 2$  cm<sup>-1</sup>. Since the monochromator does not operate above  $30\,500$  cm<sup>-1</sup>, it was used in second order. A Corning 7-54 filter was used to stop the visible part of the lamp spectrum.

The core of the experimental instrumentation for the TPE is a PDL-1 dye laser pumped by a DCR-1A Nd-YAG laser, both from Quanta Ray. This system gives tunable, vertically polarized light. To cover the region from 615 nm to 675 nm, we used the second harmonic of the Nd-YAG laser to pump a solution of DCM dissolved in methanol. For the region from 445 to 525 nm, we used the dyes Coumarin 460 and LD 489 in methanol and the third harmonic of the Nd-YAG laser as a pump beam. The scanning of the dye laser was controlled by a program running on an AT microcomputer.

The polarization of the excitation light was controlled with a Soleil Babinet Compensator (SB-10) from Optics for Research. The beam passed a 10 % reflector and was focused on the sample with an aplanant lens (f=15 cm). Light from the reflector was detected by an EG&G SGD-100A photodiode for normalization purposes. TPE was detected by monitoring the overall Ce<sup>3+</sup> emission. This luminescence was detected by a Hamamatsu 928 PMT located at an angle of 90° to the laser beam (see figure 3).

The polarization vector  $\hat{\boldsymbol{\epsilon}}$  has to be given with respect to the local symmetry axes, i.e. with respect to  $\hat{\boldsymbol{x}}$ ,  $\hat{\boldsymbol{y}}$  and  $\hat{\boldsymbol{z}}$ . The sample was placed in the cryostat such that the laser beam hit the sample surface at an angle  $\phi_0$  of 45°. This implies that, at the surface of the sample,  $\hat{\boldsymbol{k}} \parallel \hat{\boldsymbol{y}}$ , with  $\hat{\boldsymbol{k}}$  the wave vector of the excitation light. The angle of refraction will then be  $\approx 25^{\circ}$  (see figure 1). The PMT was covered with the appropriate filter to reduce detection of direct scattered laser light.

For each laser pulse, the signals from the PMT and the photodiode were sent to SR 250 boxcar integrators (Stanford Research Systems). The boxcars were triggered by a pulse from a second photodiode, monitoring a residue of the second harmonic of the Nd-YAG laser. To discriminate the luminescence further from direct reflected laser light, we used a delay of 10 ns on the boxcar integrating the PMT signal. A gate width of 30 ns was used, since the lifetime of the main luminescence is 20 ns<sup>10</sup> (see figure 3).

Single-shot intensities from both boxcars were directed to an SR 245 computer interface and read by the AT microcomputer. The luminescence intensity was normalized versus the square of the laser intensity. For each point in a spectrum, typically 60 shots were averaged. Both the normalized intensity and the laser intensity were stored as a function of the wavelength. This permitted checks on the whether the spectral features were 'real' or were induced by transients in the laser intensity during the normalization procedure. Polarization dependency curves were corrected for the polarization dependence of the normalization reflection.

#### B. Results

TPE spectra were measured for different concentrations of  $Ce^{3+}$ . Within the experimental accuracy,  $\pm 1 \, \text{cm}^{-1}$ , we do not observe a change in the positions of the transitions. (The

positions are given in vacuum wavenumbers.)

Figure 4 shows the two-photon excitation spectrum of  $Ce^{3+}$  in  $LuPO_4$  which consists of a sharp zero-phonon line at  $15\,227.8$  cm<sup>-1</sup> (=  $1/2\cdot30\,455.6$  cm<sup>-1</sup>) and a large number of vibronic lines extending to  $15\,950$  cm<sup>-1</sup> (=  $1/2\cdot31\,900$  cm<sup>-1</sup>). In the same figure, a high-resolution single-photon absorption spectrum is shown for comparison. This absorption spectrum is essentially the same as the one shown in references 5 and 7. From the comparison with the single-photon absorption spectrum, we attribute the line at 15 227.8 cm<sup>-1</sup> to TPE to the lowest component of the  $5d^1$  configuration. Vibrational modes with energies up to 1500 cm<sup>-1</sup> are involved in the two-photon transition. Surprisingly, the ratio of vibronic intensity to zero-phonon intensity, r, is largest for the single-photon absorption spectrum. Since TPE is only possible through parity mixing by odd crystal-field terms and odd-parity vibrational modes, one might expect this to be reversed. Figure 5 shows a drastic increase in vibronic intensity, for increasing  $Ce^{3+}$  concentration.

The polarization has two degrees of freedom:  $\phi$ , the angle of  $\hat{\epsilon}$  with respect to the  $\hat{x}$  axis and  $\theta$ , the angle of  $\hat{\epsilon}$  with respect to the  $\hat{z}$  axis. Since the crystals are so thin (typically 1 mm), we were only able to measure the  $\theta$  dependence of the TPE luminescence intensity. For the zero-phonon line at 15227.8 cm<sup>-1</sup> the result is shown in figure 6.

According to Williams et  $al^5$ , the  $5d_2^1$  and  $5d_3^1$  components are expected to be at 39 931 and 41 626 cm<sup>-1</sup>, respectively. TPE to these components is thus expected around 19 415 and 20 811 cm<sup>-1</sup>, respectively. Instead, we observe two lines near 19 847 cm<sup>-1</sup> (=  $1/2 \cdot 39694 \, \text{cm}^{-1}$ ) separated only by 4.5 cm<sup>-1</sup> (figure 7). The polarization dependence and the coupling to lattice vibrations of the two lines are strikingly different. No additional zero-phonon lines are observed up to 21 050 cm<sup>-1</sup> (=  $1/2 \cdot 42100 \, \text{cm}^{-1}$ ). Changing the delay and gate widths of the boxcar integrator does not change the relative intensities of the two lines, nor does changes of the filter in front of the PMT. The spectral and temporal characteristics of the TPE luminescence are thus the same for both excitation transitions.

TPE was also measured for  $Ce^{3+}$  in the isostructural host YPO<sub>4</sub> in the region of 19 000 to 20 000 cm<sup>-1</sup>. Again, two zero-phonon lines were detected at only slightly different positions than for  $Ce^{3+}$  in LuPO<sub>4</sub>. The polarization-dependency curves show a similar behavior as for  $Ce^{3+}$  in LuPO<sub>4</sub>. The coupling to lattice vibrations differs strongly for these two lines, similar to what was observed for  $Ce^{3+}$  in LuPO<sub>4</sub> (see figure 8). A fourth line was observed at  $22\,196.5$  cm<sup>-1</sup> (=  $1/2\cdot44\,393$  cm<sup>-1</sup>), as is shown in figure 9. This is, again, in good agreement with the data from Ref. 5. The intensity is considerable weaker than the intensities of the other lines. The polarization dependence of this line is shown in figure 9 as well.

The positions of the observed zero-phonon lines are summarized in table IV. The fifth  $5d^1$  component is expected at about  $50\,000~\rm cm^{-1}$ . For TPE this requires tunability around 400 nm, whereas the lowest possible wavelength from the PDL-1 is  $\approx 440$  nm.

#### IV. DISCUSSION

#### A. Theoretical considerations

#### 1. Polarization dependence

The site symmetry of the  $Ce^{3+}$  ion imposes selection rules on the TPE transitions. From these rules one can deduce the symmetry of the  $5d^1$  components. Qualitative group theory analysis shows that the selection rules for  $D_{2d}$  symmetry are:

$$\Gamma_6 \to \Gamma_6$$
 allowed for  $\hat{\boldsymbol{\epsilon}} \parallel \hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}, \hat{\boldsymbol{z}}$   
 $\Gamma_6 \to \Gamma_7$  allowed for  $\hat{\boldsymbol{\epsilon}} \parallel \hat{\boldsymbol{x}}, \hat{\boldsymbol{y}}$ .

The  $4f^1$  ground state has  $\Gamma_6$  symmetry, and the  $5d^1$  components have either  $\Gamma_6$  or  $\Gamma_7$  symmetry.

A more quantitative analysis<sup>39-41</sup> gave the dependence of the TPE luminescence intensity  $S_{\Gamma_i \to \Gamma_f}$  on the polar angles of  $\hat{\epsilon}$ . For a  $\Gamma_6 \to \Gamma_7$  transition, this dependence is given by<sup>39</sup>

$$S_{\Gamma_6 \to \Gamma_7} = \sin^4(\theta) \cos^2(2\phi) + c_1 \sin^4(\theta) \sin^2(2\phi) + c_2 \sin^2(2\theta). \tag{1}$$

Here,  $\phi$  and  $\theta$  are the polar angles of  $\hat{\epsilon}$  with respect to the  $\hat{x}$  and  $\hat{z}$  axes. Daoud and Kibler<sup>41</sup> have given explicit expressions for the coefficients, but we will use them as empirical parameters since in this case it is not necessary to know the absolute intensities of the TPE transitions. Since the crystals are relatively thin, we were only able to vary  $\theta$ . The dependence on  $\phi$  is taken as an empirical parameter, since  $\phi$  is constant. Equation 1 then simplifies to

$$S_{\Gamma_6 \to \Gamma_7} = c_1' \sin^4(\theta) + c_2 \sin^2(2\theta). \tag{2}$$

For the  $\Gamma_6 \to \Gamma_6$  transition the relation is<sup>39</sup>

$$S_{\Gamma_6 \to \Gamma_6} = \lambda^2 + (\lambda - 1)(\lambda - 3)\sin^2(\theta) + \left[c_3 - \frac{1}{4}(\lambda - 1)^2\right]\sin^2(2\theta),\tag{3}$$

which is independent of  $\phi$ .

Under  $D_{2d}$  symmetry, the metal ion site is uniaxial. This anisotropy is taken into account in the derivation of equations 2 and  $3^{40}$ . The transmittance of light in the crystal is dependent on the direction of the polarization with respect to the plane of incidence. The dependence is given by the well-known Fresnel coefficients

$$T_{\perp} = rac{\sin(2lpha_0)\sin(2lpha)}{\sin^2(lpha_0+lpha)} \ T_{\parallel} = rac{T_{\perp}}{\cos^2(lpha_0-lpha)},$$

where  $T_{\perp(||)}$  is the transmittance for light polarized perpendicular (parallel) to the plane of incidence,  $\alpha_0$  is the angle of incidence and  $\alpha$  is the angle of refraction. In our case, the plane

of incidence is the  $\hat{x}\hat{y}$  plane, so  $T_{\perp(\parallel)}$  is the transmittance for light  $\parallel(\perp)$  to the  $\hat{z}$  axis and  $\alpha = \phi$ . To account for the difference in transmittance we rewrite<sup>42</sup> equations 2 and 3 as

$$S_{\Gamma_6 \to \Gamma_7} = T_{\parallel}^2 c_1' \sin^4(\theta) + T_{\perp} T_{\parallel} c_2 \sin^2(2\theta) \tag{4}$$

$$S_{\Gamma_6 \to \Gamma_6} = \lambda^2 T_{\perp}^2 + (\lambda T_{\perp} - T_{||})(\lambda T_{\perp} - 3T_{||})\sin^2(\theta) + [c_3 T_{\perp} T_{||} - \frac{1}{4}(\lambda T_{\perp} - T_{||})^2]\sin^2(2\theta).$$
 (5)

 $T_{\perp}$  and  $T_{||}$  depend only on the angle of incidence and the index of refraction. These are constant parameters during the experiments and thus  $T_{\perp}$  and  $T_{||}$  are constant. With  $\phi_0 = 45^{\circ}$  and the index of refraction 1.7 we have  $\phi = 24.5^{\circ}$ ,  $T_{\perp} = 0.86$  and  $T_{||} = 0.98$ .

Two features of the functions given in equations 4 and 5 permit a definitive symmetry assignment for the components of the 5d<sup>1</sup> configuration. First, equation 4 becomes zero for  $\theta = 0$ , and thus, the transition  $\Gamma_6 \to \Gamma_7$  is forbidden for  $\hat{\epsilon} \parallel \hat{z}$ . The  $\Gamma_6 \to \Gamma_6$  transition is, according to equation 5, allowed for  $\theta = 0$ . This is according the qualitative selection rules given previously. Second, all of the fit parameters  $c_i$  and  $\lambda$  have to be real and, except for  $\lambda$ , positive<sup>39</sup>.

It is obvious from the spectra (figures 4 and 8) that TPE occurs to final states in which the electronic and vibrational states are coupled. The symmetries of such a state will be the direct product of the irreducible representations of the purely electronic state and the vibrational state. Thus the vibronic part of the spectrum will not have a uniform polarization behavior, and it may differ from the polarization dependence of the zero-phonon line. To assign symmetry labels to the 5d¹ components, we have to measure the polarization dependence of only the zero-phonon lines, not somewhere in the vibronic spectrum. Therefore, the exact position of the 5d¹ components have to be known.

#### 2. Crystal field model

The positions and symmetry assignments of the four 5d<sup>1</sup> components were fitted with a semi-empirical Hamiltonian. The wave functions obtained from diagonalizing this Hamiltonian can be used in calculations of absolute cross sections of the ERS transitions<sup>5,7</sup>. The Hamiltonian is of the form

$$\mathcal{H} = F_0 + \mathcal{H}_{\text{spin-orbit}} + \mathcal{H}_{\text{crystal field}}, \tag{6}$$

where

$$\mathcal{H}_{\text{spin-orbit}} = \zeta_{5d^1}(\boldsymbol{s} \cdot \boldsymbol{l})$$

$$\mathcal{H}_{\text{crystal field}} = B_0^2 C_0^2 + B_0^4 C_0^4 + B_4^4 (C_4^4 + C_{-4}^4).$$

Here,  $F_0$  fixes the average energy of the 5d<sup>1</sup> configuration relative to the ground state and  $\zeta_{5d^1}$  is the spin-orbit coupling parameter that determines the splitting of the  $\Gamma_5$  state into  $\Gamma_6$  and  $\Gamma_7$  components (figure 2). It is expected to be close to the value of free-ion spin-orbit coupling parameter. The  $B_q^k$ 's are the crystal-field parameters and determine the overall splitting. Since we are considering a 5d configuration,  $k \leq 4$ .  $F_0$ ,  $\zeta_{5d^1}$ , and  $B_q^k$  are treated as empirical parameters. In the fits, a fifth level was assumed at to lie 50 000 cm<sup>-1</sup>.

#### B. Discussion of the results

From the comparison with the single-photon absorption spectrum, we already attributed the TPE line at  $15\,227.8~{\rm cm^{-1}}$  to the transition of the  $4f^1(^2F_{5/2})$  ground state to the first component of the  $5d^1$  configuration. Williams et al assigned a  $\Gamma_7$  symmetry to this component on the basis of the single-photon-absorption selection rules<sup>5</sup>. Therefore, we fitted the polarization curve for this transition (figure 6) to equation 4. This gives good results, as can be seen in figure 6 and confirms the earlier symmetry assignment. The fit parameters obtained from this fit are given in table III.

The Raman and infra-red-active lattice vibrations have energies up to 1170 cm<sup>-1</sup> <sup>43,44</sup>. Since the vibronic side band extends to more than 1500 cm<sup>-1</sup> away from the zero-phonon line, it is clear that excitation can involve more than one vibrational mode. Polarization effects will reflect the symmetries of the zero-phonon line and of the vibrations involved. To derive the symmetries of the purely electronic states from polarization effects in the vibronic side band, one has to know the symmetries of all vibrations involved. When there are more than one mode involved, this is a formidable task and has not been attempted.

It is much more difficult to assign the second and third  $5d^1$  components. Williams et  $al^5$  locate them at 39 931 and 41 626 cm<sup>-1</sup> and have assigned the symmetry labels  $\Gamma_6$  and  $\Gamma_7$ , respectively. Their relative starting-material concentration was much higher than the one used here (viz. 20% versus 1%). This large concentration difference leads to shifts in the energy positions of the  $5d^1$  components, as is apparent from the position of the first component (30 468 versus 30 455 cm<sup>-1</sup>, see tables II and IV). It is thus reasonable to assume that one of the lines in figure 7 must be attributed to the  ${}^2F_{5/2} \rightarrow 5d_2^1$  transition, having  $\Gamma_6$  polarization characteristics. The question is, which one and how does the other line arise? No previous study has reported the second and third components so close to each other as shown in figure 7. We observed such closely separated lines for different concentrations of  $Ce^{3+}$  in  $YPO_4$ . From the spectroscopic measurements it seems reasonable to assign these lines to the TPE transitions of  ${}^2F_{5/2}$  to the  $5d_2^1$  and  $5d_3^1$  components.

Since the spectral and temporal characteristics of the TPE signals are the same for both lines, both features can be assigned to  $4f^1 \rightarrow 5d^1$  transitions of the Ce<sup>3+</sup> ion. Increasing the Ce<sup>3+</sup> concentration results in broadening and eventually the merging of both lines. The relative intensities of both lines remains approximately the same as the Ce<sup>3+</sup> concentration is lowered. The energy-level diagrams of Carnall<sup>45</sup> show that no other rare-earth ion, the most likely impurity, has a transition in this region.

The observed small separation suggests that there are two different sites available for the Ce<sup>3+</sup> ion, which is not unreasonable from the structural point of view, since LuPO<sub>4</sub> crystallizes in a different crystal structure than CePO<sub>4</sub>. Even the highest resolution measurements possible on the transitions to the first and fourth (see below) components, however, do not reveal two closely separated zero-phonon lines, which rules out the presence of two different sites. Moreover, the intensity ratio of the two lines is approximately the same for different Ce<sup>3+</sup> concentrations.

The lowest transition of the two features, at 19845.3 cm<sup>-1</sup>, shows a distinctly different polarization dependence (figure 7) than the transition to the first component (figure 6). A fit to equation 5 gives a good result (figure 7) whereas a fit to equation 4 yields the unrealistic result of  $c'_1 < 0$ . The line at 19849.8 cm<sup>-1</sup> shows a similar polarization dependence as

the transition to the first 5d<sup>1</sup> component and can indeed be fitted to equation 4. The fit parameters obtained from these fits are also given in table III.

Finally, we note that no other zero-phonon lines are observed up to  $1/2 \cdot (42100) \, \mathrm{cm^{-1}}$ , well beyond the energy where Williams et al locate the  $5d_3^1$  component. Therefore we suggest that the second component of the  $5d^1$  configuration is at  $2 \times 19\,845.3 = 39\,690.6 \, \mathrm{cm^{-1}}$  and has  $\Gamma_6$  symmetry, and the third component is at  $2 \times 19\,849.8 = 39\,699.6 \, \mathrm{cm^{-1}}$  and has  $\Gamma_7$  symmetry. We can apply a similar assignments for the case of  $\mathrm{Ce^{3+}}$  in  $\mathrm{YPO_4}$ . We ascribe the line at  $22\,196.5 \, \mathrm{cm^{-1}}$  to a TPE transition to the  $5d_4^1$  component. The position for this component is in reasonable agreement with the assignment by Williams et al. The fit for the polarization curve in figure 9 is to equation 4 and the parameters are given in table III. This makes it clear that this is a  $\Gamma_6 \to \Gamma_7$  transition, and thus, the  $5d_4^1$  component has  $\Gamma_7$  symmetry. The positions and the assigned symmetry labels for the  $\mathrm{Ce^{3+}}$   $5d^1$  components in LuPO<sub>4</sub> and YPO<sub>4</sub> are presented in table IV.

The crystal-field fit for  $Ce^{3+}$  in LuPO<sub>4</sub> yields an RMS energy deviation of only 4.2 cm<sup>-1</sup>. The final-fit parameters are given in table V. Even though the general agreement between experimental and calculated positions is very good, table V shows a disturbing result. The spin-orbit coupling parameter,  $\zeta_{5d^1}$ , is much smaller than expected, the free-ion value being 995.6 cm<sup>-1 46</sup>. It can be argued that a purely electrostatic crystal-field Hamiltonian will not correctly describe covalency between the excited  $Ce^{3+}$  ion and the ligand ions. The major effect of the spin-orbit coupling, however, is to split the  $\Gamma_5$  crystal-field component into a  $\Gamma_6$  and a  $\Gamma_7$  component. The validity of the crystal-field Hamiltonian does not consequently affect the value of  $\zeta_{5d^1}$ . The spin-orbit coupling parameter has to be close to the separation between these two components. With  $\zeta_{5d^1} = 9.29$  and  $\Delta E_{\Gamma_6\Gamma_7} = 9.3$  we find a consistency between the data and the fit.

If we fix  $\zeta_{5d^1}$  at the free-ion value, we obtain an RMS deviation of approximately 340 cm<sup>-1</sup>. For a d configuration, this is not an unreasonable accuracy, but of course, in this case the spin-orbit coupling parameter is not consistent with the data. The value of the parameters for this fit are shown in table V.

The value of the spin-orbit coupling constant,  $\zeta_{5d^1}$ , obtained from the above fit is unreasonable. Nevertheless we are unable to make another assignment of the sharp lines in the spectra that will lead to a more reasonable number. It is possible that one of the lines observed around 19 847 cm<sup>-1</sup> is not due to the Ce<sup>3+</sup> ion, but all of the experimental evidence is consistent with both of the sharp lines assigned in this manner.

It should be noted that three vibronic effects are observed but are not clearly understood. First, for the first  $4f \rightarrow 5d$  transition, there is a significant difference between the one-photon absorption spectrum and the TPE spectrum, - with the latter showing much weaker vibronic transitions. In this case, this may be due to the fact that the zero-phonon transition is a fully allowed  $4f \rightarrow 5d$  transition including the vibronic transitions. For TPE, however, only the coupling of the 4f and 5d configurations by the odd components of the crystal-field makes this transition observable. This second order process may result in diminished intensities for the vibronic transitions. Second, for the various TPE lines reported here, there are striking differences between the energies and the relative intensities of the vibronic lines and their associated zero-phonon lines. Finally, the concentration of  $Ce^{3+}$  has also been found to play an important role in the vibronic-coupling strength (see figure 5). Since the  $5d^1$  configuration is not shielded from the crystal environment, as is the  $4f^1$  configuration, this effect in itself

is expected but is surprisingly noticeable for small changes in the Ce<sup>3+</sup> concentration.

In order to understand TPE of Ce<sup>3+</sup> it is essential to have a systematic study of these vibronic effects. A comparison should be made for Ce<sup>3+</sup> in different host lattices in a manner similar to that used in the case of single-photon spectroscopic studies of Gd<sup>3+</sup> <sup>47</sup>.
