Abstract

Abstract: Background: The coronavirus disease 2019 (COVID-19) pandemic has disrupted breast cancer control through short-term declines in screening and delays in diagnosis and treatments. We projected the impact of COVID-19 on future breast cancer mortality between 2020 and 2030. **Methods:** Three established Cancer Intervention and Surveillance Modeling Network breast cancer models modeled reductions in mammography screening use, delays in symptomatic cancer diagnosis, and reduced use of chemotherapy for women with early-stage disease for the first 6 months of the pandemic with return to prepandemic patterns after that time. Sensitivity analyses were performed to determine the effect of key model parameters, including the duration of the pandemic impact. **Results:** By 2030, the models project 950 (model range = 860-1297) cumulative excess breast cancer deaths related to reduced screening, 1314 (model range = 266-1325) associated with delayed diagnosis of symptomatic cases, and 151 (model range = 146-207) associated with reduced chemotherapy use in women with hormone positive, early-stage cancer. Jointly, 2487 (model range = 1713-2575) excess breast cancer deaths were estimated, representing a 0.52% (model range = 0.36%-0.56%) cumulative increase over breast cancer deaths expected by 2030 in the absence of the pandemic's disruptions. Sensitivity analyses indicated that the breast cancer mortality impact would be approximately double if the modeled pandemic effects on screening, symptomatic diagnosis, and chemotherapy extended for 12 months. **Conclusions:** Initial pandemic-related disruptions in breast cancer care will have a small long-term cumulative impact on breast cancer mortality. Continued efforts to ensure prompt return to screening and minimize delays in evaluation of symptomatic women can largely mitigate the effects of the initial pandemic-associated disruptions.

The novel coronavirus disease 2019 (COVID-19) pandemic has led to broad disruptions in health care in the United States, including major impacts on breast cancer control activities. Early in the pandemic, public health measures barred elective

procedures, including screening mammography (1). Hospitals faced concerns with capacity and shortages of personal protective equipment, and women weighed the benefits of attending medical care facilities vs the risks of possible exposure.

In the initial months of the pandemic in 2020, there were severe declines in screening mammography (2-7) and reductions in diagnostic mammography of up to 80% (8,9). Breast cancer treatment protocols were also modified, with patient-reported delays in treatment (10) and reductions in chemotherapy administration (11).

Although weekly mammography volumes nearly recovered to prepandemic levels within 6 months (2,9,12-14), the impact of these disruptions on long-term breast cancer mortality remains unclear. We used 3 independently developed breast cancer simulation models from the National Cancer Institute's Cancer Intervention and Surveillance Modeling Network (CISNET) (15-18) to estimate the cumulative, long-term effect of COVID-19-related disruptions on breast cancer mortality. The results are intended to inform plans for mitigating these effects during and after the pandemic.

Methods

The study was determined to be other than human participant research by institutional review boards at each institution.

Model Descriptions

The study included 3 CISNET models (15): model D (Dana-Farber Cancer Institute) (19), model G-E (Georgetown University-Albert Einstein College of Medicine) (20), and model W-H (University of Wisconsin-Madison and Harvard Medical School) (21). The models are briefly summarized below; details are included in the [Supplementary Methods](#) (available online), previous publications, and online (15,16,18-22). CISNET breast cancer models have been previously used to inform breast cancer-screening guideline development by the US Preventive Services Task Force in 2009 and 2016 (17,18).

Briefly, the models estimate breast cancer incidence and mortality in the absence of screening and treatment and then overlay screening, diagnosis, and treatment effects to replicate US breast cancer trends over time (15). They account for differences in 4 molecular breast cancer subtypes based on estrogen receptors (ER) and HER2. All 3 models have the ability to follow multiple birth cohorts over time. Although the models share inputs, they utilize different structures, assumptions, and approaches ([Supplementary Table 1](#), available online). For example, in model W-H, earlier diagnosis without a change in cancer staging can reduce mortality, whereas model G-E assumes a mortality benefit only if earlier diagnosis leads to a stage shift. The range of results across the models provides a measure of uncertainty due to unobservable factors such as breast cancer natural history and incidence in the absence of screening (16).

CISNET models use common inputs for key parameters informed by high-quality data sources ([Table 1](#)). The models successfully replicated US breast cancer incidence and mortality trends over time and were recently validated against the UK AGE trial results (16,18,23). In addition, the models have been validated individually. For example, model W-H was cross-validated against incidence and mortality data from Wisconsin Cancer Reporting System (21).

Key Inputs and Assumptions

We used the same model inputs describing screening utilization and performance, clinical diagnosis, and treatment dissemination and effectiveness as prior analyses (16,18) to simulate

breast cancer mortality from 2020 to 2030. In projecting outcomes for future years, we assumed that current mammography performance and use as well as treatment effectiveness and use remained constant for the 10-year period.

Our scenarios representing pandemic impacts on screening, diagnostic evaluation of breast cancer symptoms, and treatment were based on current literature and expert opinion. In our base case, we assumed a 6-month duration of pandemic-related disruptions (March to September 2020) in screening, diagnosis, and adjuvant chemotherapy, given reports that mammography use recovered to nearly 100% by the end of summer 2020 (2,9,13,14).

Disruptions in screening were informed by data from Epic Health Research Network, which pooled data from 60 health-care organizations representing 10 million women from 306 hospitals in 28 states (2). Based on their findings, we assumed that 50% of the women scheduled to undergo screening mammography missed their mammograms. Data from 2 Breast Cancer Surveillance Consortium registries (Vermont and San Francisco Bay Area) show that breast imaging volume for "evaluation of a breast problem" (ie, women presenting with symptoms for diagnostic imaging) decreased by 21% and 45%, respectively, during March-June 2020 compared with prepandemic levels in 2019 ([Supplementary Figure 1](#), available online); therefore, we assumed that 25% of women delayed evaluation of breast cancer symptoms, resulting in delayed diagnosis and treatment. Finally, because there exist very limited data regarding COVID-19's impact on breast cancer therapy, we based our treatment-related inputs on expert opinion. We base our assumption on treatment disruptions on the results of clinical trials including TAILORx and RxPonder that showed greater chemotherapy benefit for younger than older women, and of population-based studies showing that prepandemic treatment use coincided with these trial results (24-26). We assumed that oncologists would be more likely to recommend against cytotoxic chemotherapy for older women given their higher mortality rates from COVID-19 infection and concerns about treatment-related immunosuppression (27-29). We did not assume reductions in other systemic treatments (eg, endocrine therapy) because they are not immunosuppressive and, for certain medications, are taken at home and thus would be unlikely to be withheld for infection concerns. We modeled no chemotherapy reduction for patients with ER-negative and/or HER2-positive disease or for patients with stage IIB or higher cancer of any subtype because we assumed that oncologists recognize the more favorable risk-benefit ratio of chemotherapy for these higher-risk patients and recommend it despite the pandemic (30-32).

Pandemic Impact Scenarios

We simulated 6 scenarios ([Table 2](#)). Scenario 1 (no COVID-19 impact) assumed that the patterns in screening, diagnosis, and treatment between 2020 and 2030 would remain the same as in 2019. Scenario 2 represents the reduced screening scenario. Because it is not yet known how long women who missed screening during the pandemic will delay their screening, we simulated 3 different subscenarios for varying the time to return to screening (scenarios 2a-2c). In scenarios 2a-2c, women who missed their screening exams could be detected via clinical presentation and could start treatment during the pandemic period. Under scenario 2a (delayed screening), women who missed their screening exam resume screening 6 months after

Table 1. Summary of common inputs used by the models [adapted from Mandelblatt et al. (40)]^a

Name	Description	Source
Population demographics and other-cause mortality		
Population demographic characteristics	Cross-sectional female population in US organized by birth cohorts	US census data (34)
Other-cause mortality	Death from other causes	CDC WONDER Database (41)
Natural history		
Incidence in absence of screening	Breast cancer incidence in absence of screening and treatment	Age-period-cohort models (42, 43)
Survival in absence of screening and treatment	25-y breast cancer survival before adjuvant treatment by joint ER/HER2 status, age group, AJCC/SEER stage, or tumor size	Meta-analyses (44)
Stage distribution	Stage distributions by mode of detection, age group (<50, 50-64, >65 y), screening round (first, subsequent), and screening interval	BCSC (40, 45)
ER/HER2 joint distribution	Probability of ER/HER2 conditional on age and stage/tumor size at diagnosis	BCSC (40, 45)
Screening and diagnosis		
Mammography rates	Use of mammography by different ages over time	NHIS, BCSC (40, 45, 46)
Mammography performance	Sensitivity of initial and subsequent digital mammography by age group (<50, 50-64, >65 y) and screening interval	BCSC (40, 45)
Treatment		
Treatment patterns	Treatments and rates of use by time period, ER/HER2, stage and age at time of breast cancer diagnosis	NCCN and meta-analyses (40, 47)
Treatment effects	Treatment efficacy by ER/HER2 for initial breast cancer diagnosis	Meta-analyses and clinical trial results (48-53)

^aAJCC = American Joint Committee on Cancer; BCSC = Breast Cancer Surveillance Consortium; CDC = Centers for Disease Control and Prevention; ER = estrogen receptor; HER2 = human epidermal growth factor receptor 2; NCCN = National Comprehensive Cancer Network; NHIS = National Health Information Survey; SEER = Surveillance, Epidemiology, and End Results; WONDER = Wide-ranging ONline Data for Epidemiologic Research.

the missed mammogram. Under scenario 2b (skipped screening), women who missed their screening exam do not return until their next scheduled mammogram. Under scenario 2c (hybrid delayed/skipped screening), one-half of women who missed their screening mammogram resume screening 6 months after the missed mammogram, and one-half do not return until their next scheduled mammogram.

Scenario 3 represents the delayed diagnosis of symptomatic cases in which women who delayed evaluation of symptoms experienced a 6-month delay in breast cancer diagnosis relative to their expected diagnosis in the absence of the pandemic (Supplementary Table 2, available online). Scenario 4 represents reduced chemotherapy treatment. Under scenario 4, among women diagnosed with ER+ and HER2- tumors in stages I and IIA who would have received chemotherapy if not for the pandemic, 25% of those younger than age 70 years and 50% of those older than age 70 years did not receive clinically indicated adjuvant chemotherapy. Scenario 5 represents reduced screening and delayed diagnosis and therefore jointly models scenarios 2 and 3. Finally, scenario 6 represents reduced screening, delayed diagnosis, and reduced chemotherapy treatment and hence jointly models scenarios 2, 3, and 4.

Analysis

Each model estimated the effect of COVID-19 disruptions on breast cancer deaths among all women aged 30 to 84 years between 2020 and 2030 in the United States. We modeled each

disruption independently (eg, screening only, diagnosis only, treatment only) and combinations of disruptions (Table 2). For all analyses, results were age adjusted to the US standard population (33,34). We calculated the cumulative number of excess breast cancer deaths from the pandemic as the difference between deaths in analysis vs usual care with no COVID impact. We also calculated the percent increase in cumulative number of additional breast cancer deaths in each scenario vs usual care. Results are reported as the median and range across the 3 models.

Sensitivity Analysis

We conducted a sensitivity analysis on the proportion of women who delayed (scenario 2a) vs skipped (scenario 2b) their mammography exams during the pandemic (ranging from 0% to 100%), who missed screening exams during the pandemic period, who experienced reduced chemotherapy, who had delays in diagnosis, and on the impact of COVID-19 on other-cause mortality. We also conducted a sensitivity analysis on the duration of the pandemic, given the pandemic situation is still evolving, in which we assumed a 12-month duration of pandemic-related disruptions instead of 6 months. In doing so, we extended the baseline assumptions on the effects of disruptions on screening, diagnosis, and treatment. We used only 1 model (model W-H) in the sensitivity analyses, which provided the median estimates by 2030 for the base case.

Table 2. Summary of the simulated scenarios

Scenario	Name	Description	Screening	Diagnosis	Treatment use	Base value (range for sensitivity analysis)
Scenario 1	No COVID-19 impact	Pandemic does not lead to any changes in breast cancer control	Normal	Normal	Normal	—
Scenario 2	Reduced screening	50% of women scheduled to undergo exams miss their screening mammography	Reduced	Normal	Normal	50% (25%-75%)
Scenario 2a	Delayed screening	Catch-up screening exam in 6 mo and push all future screening exams by 6 mo	Reduced	Normal	Normal	—
Scenario 2b	Skipped screening	Never catches up missed mammography exam	Reduced	Normal	Normal	—
Scenario 2c	Hybrid delayed and skipped screening	50% of women who missed their exams follow scenario 2a and 50% follows scenario 2b	Reduced	Normal	Normal	—
Scenario 3	Delayed diagnosis of symptomatic cases	25% of women who would normally be detected via symptoms delay diagnosis for 6 mo	Normal	Delayed	Normal	25% (15%-40%)
Scenario 4	Reduced chemotherapy treatment	Women with ER+/HER2- (node negative) receive reduced chemotherapy at 25% for <70 y and 50% for >70 y but no reduction in use of endocrine therapy	Normal	Normal	Reduced	25% for ages <70y; 50% for ages >70y (12.5%-50% for ages <70y and 25%-75% for ages >70y)
Scenario 5	Reduced screening and delayed diagnosis	—	Reduced	Delayed	Normal	—
Scenario 5a	Delayed screening and delayed diagnosis	Scenario 2a and scenario 3 combined	Reduced	Delayed	Normal	—
Scenario 5b	Skipped screening and delayed diagnosis	Scenario 2b and scenario 3 combined	Reduced	Delayed	Normal	—
Scenario 5c	Hybrid delayed/skipped screening and delayed diagnosis	Scenario 2c and scenario 3 combined	Reduced	Delayed	Normal	—
Scenario 6	Reduced screening and delayed diagnosis and reduced chemotherapy treatment	—	Reduced	Delayed	Reduced	—
Scenario 6a	Delayed screening and delayed diagnosis and reduced chemotherapy treatment	Scenario 5a and scenario 4 combined	Reduced	Delayed	Reduced	—

(continued)

Table 2. (continued)

Scenario	Name	Description	Screening	Diagnosis	Treatment use	Base value (range for sensitivity analysis)
Scenario 6b	Skipped screening and delayed diagnosis and reduced chemotherapy treatment	Scenario 5b and scenario 4 combined	Reduced	Delayed	Reduced	—
Scenario 6c	Hybrid delayed and skipped screening and delayed diagnosis and reduced chemotherapy treatment	Scenario 5c and scenario 4 combined	Reduced	Delayed	Reduced	—

Results

The models reproduced observed age-adjusted breast cancer mortality in the United States over time (Supplementary Figure 2, available online). The models predicted that the cumulative number of excess breast cancer deaths due to the COVID-19 pandemic's impact on screening, diagnosis of symptomatic cases, and chemotherapy treatment could reach 2487 (model range = 1713-2575) by 2030 (Table 3; Supplementary Tables 3-7, and Supplementary Figures 3-4, available online). This corresponds to a 0.52% (model range = 0.36%-0.56%) increase in breast cancer deaths between 2020 and 2030 compared with usual care with no COVID-19 impact. By 2030, the models project 950 (model range = 860-1297) cumulative excess breast cancer deaths related to reduced screening; 1314 (model range = 266-1325) associated with delayed diagnosis of symptomatic cases, and 151 (model range = 146-207) associated with reduced chemotherapy use in women with hormone-positive, early-stage cancer. The effect of excess mortality associated with changes in screening, diagnosis, and treatment accelerated during 2020-2025 and leveled off thereafter (Table 3; Figure 1).

Among the modeled scenarios, reductions in screening use and delays in diagnosis of symptomatic cases contributed the largest numbers of excess deaths. For example, disruptions for these 2 components (scenario 5c) resulted in 2277 (model range = 1576-2365) additional deaths, representing over 90% of the cumulative excess deaths associated with the modeled disruptions in screening, diagnosis, and chemotherapy treatment combined (scenario 6c) during this period (Table 3). The models suggest that the contribution of the modeled delay in diagnosis of symptomatic cases and reduced screening to the additional breast cancer deaths is similar. Disruptions in screening alone (scenario 2c) would lead to 950 (model range = 860-1297) additional deaths, representing 42% of the total excess deaths due to disruptions in screening and diagnosis (Table 3). However, cumulative breast cancer deaths by 2030 were fourfold higher if women skipped their mammogram rather than delayed screening by 6 months (1631 vs 364).

Varying assumptions about the proportion of women experiencing delays did not change the overall patterns of impact of the pandemic on 2030 breast cancer mortality (Table 4; Supplementary Tables 8-14, available online). Under all modeled scenarios, the increase in breast cancer deaths due to pandemic-related disruptions is not predicted to exceed 1% by 2030. In addition, if cancer diagnosis is delayed by 6 months for only 15% of women during the pandemic, the number of excess deaths exceeds the number observed if 50% of asymptomatic women delay screening for 6 months (758 vs 364) (Supplementary Table 11, available online; Table 3). If the modeled pandemic effects on screening, diagnosis, and treatment lasted for 12 months instead of 6 months, the number of additional deaths approximately doubles (Figure 2; Table 4; Supplementary Figures 5-6, available online). Sensitivity analysis on pandemic-related other-cause mortality input did not lead to any major changes in the results (Supplementary Table 15, available online).

Discussion

This collaborative modeling study provides useful information regarding the likely effects of initial pandemic-related disruptions on breast cancer mortality over time. Three independent models found that the cumulative impact of initial pandemic disruptions would be less than a 1% increase in cumulative

Table 3. Median cumulative excess breast cancer mortality^a by 2022, 2025, and 2030 due to the COVID-19 pandemic effect for selected scenarios across 3 models (range across 3 models)

Scenario	2022			2025			2030

Scenario 5b: disruptions in screening and diagnosis: worst case scenario	1236 (302-1479)	0.99 (0.25-1.34)	1904 (1632-2412)	0.74 (0.65-1.06)	2861 (2476-2966)	0.60 (0.52-0.64)			
Scenario 5c: disruptions in screening and diagnosis	930 (285-1289)	0.74 (0.23-1.17)	1450 (1144-2043)	0.56 (0.46-0.89)	2277 (1576-2365)	0.46 (0.33-0.53)			
Scenario 6a: disruptions in screening and diagnosis and treatment: best case scenario	701 (291-1170)	0.56 (0.24-1.06)	1167 (744-1778)	0.45 (0.30-0.78)	1896 (826-1990)	0.38 (0.17-0.45)			
Scenario 6b: disruptions in screening and diagnosis and treatment: worst case scenario	1311 (315-1549)	1.05 (0.26-1.40)	2067 (1700-2516)	0.80 (0.68-1.10)	2983 (2599-3255)	0.66 (0.55-0.67)			
Scenario 6c: disruptions in screening and diagnosis and treatment	1006 (303-1360)	0.80 (0.25-1.23)	1617 (1222-2147)	0.63 (0.49-0.94)	2487 (1713-2575)	0.52 (0.36-0.56)			

^aThe excess mortality is expressed in terms of both the number of breast cancer deaths and percent increase compared with cumulative number of breast cancer deaths without pandemic effect. The excess number of deaths in a row for a particular scenario is calculated by subtracting the cumulative number of deaths without COVID-19 pandemic (scenario 1) as given in the first row from that obtained under that scenario. Similarly, the percent increase is calculated by dividing this difference by the cumulative number of deaths without COVID-19 pandemic.

Figure 1. Cumulative excess breast cancer mortality according to exemplar model (University of Wisconsin-Madison and Harvard Medical School model) over time. **A)** The number of cumulative excessive deaths when each disruption is modeled separately. **B)** The number of excessive deaths when disruptions are combined.

breast cancer mortality over the next decade. This result is likely to be related to the rapid response of care providers to reinstating screening and the assumption that women diagnosed with advanced-stage and/or poor prognosis cancers did not experience any delays in chemotherapy initiation. If the pandemic effects on care disruptions persist for 12 months, excess mortality would approximately double.

To our knowledge, no previous modeling study has conducted a comprehensive analysis of the impact of disruptions due to the COVID-19 pandemic on breast cancer mortality in the United States. A prior commentary used a preliminary analysis by 1 of the models used in this study (model W-H) and reported a higher mortality impact than that seen in this

study (5391 vs 2487 cumulative excess deaths from 2020 to 2030) (35). However, that early analysis assumed higher reduction in screening (75% vs 50%) and greater delays in diagnosis (delay in diagnosis of all cases vs only symptomatic cases). A modeling study from Canada found that when all scheduled mammograms are skipped for 6 months and are made up gradually, the number of deaths increases by 0.48% by 2029, which is slightly higher than our estimate because we do not assume that all screening stopped during the pandemic (36). Another study focusing on the United Kingdom estimated that the number of breast cancer deaths could increase by 7.9%-9.6% in 5 years due to the pandemic; however, that study assumed that cancers could not be diagnosed after a screening

Table 4. Excess cumulative mortality projections for the sensitivity analyses varying scenario assumptions about magnitude of disruptions for the exemplar model (University of Wisconsin-Madison and Harvard Medical School model)

Sensitivity analysis (SA) scenario	2022		2025		2030	
No COVID-19 impact (scenario 1), cumulative no. of deaths	110 406		228 585		473 903	
	Excess deaths, No. ^a	Increase, %	Excess deaths, No. ^a	Increase, %	Excess deaths, No. ^a	Increase, %
Base case results	1360	1.23	2147	0.94	2487	0.56
SA1: pandemic effects last 12 mo	2504	2.27	4402	1.93	5058	1.14
SA2: screening reduction is 25%	1157	1.05	1818	0.80	2067	0.47
SA3: screening reduction is 75%	1545	1.40	2412	1.06	2860	0.64
SA4: 15% of symptomatic cases are delayed	970	0.88	1551	0.68	1832	0.41
SA5: 40% of symptomatic cases are delayed	1646	1.49	2556	1.12	2969	0.67
SA6: smaller reduced chemotherapy treatment (12.5% for ages <70 y and 25% for ages >70 y)	1324	1.20	2100	0.92	2433	0.55
SA7: larger reduced chemotherapy treatment (50% for ages <70 y and 75% for ages >70 y)	1394	1.26	2217	0.97	2580	0.58

^aThe cumulative excess number of deaths are reported for each scenario representing disruptions in screening, diagnosis, and treatment (scenario 6c). The excess number of deaths for a sensitivity analysis in a row is calculated by subtracting the cumulative number of deaths without the COVID-19 pandemic (scenario 1) as given in the first row from that obtained under that sensitivity analysis scenario. Similarly, the percent increase is calculated by dividing this difference by the cumulative number of deaths without the COVID-19 pandemic. For each of the sensitivity analyses, the cumulative number of deaths without the COVID-19 pandemic (scenario 1) is the same.

exam but only through urgent referrals during the pandemic (37).

Our results suggest that the rapid adaptations of health-care facilities to devise strategies to resume breast cancer screening, diagnosis, and treatment services within a 6-month period greatly mitigated the potential impact on breast cancer mortality (2,9,13). The overall impact of disruptions in screening and delays in diagnosis of symptomatic evaluation were estimated to be similar, because most women due for routine screening will not have breast cancer. Even small disruptions to diagnostic evaluation of symptomatic women translate to substantial numbers of excess breast cancer deaths as demonstrated in the sensitivity analysis. As such, our results reinforce the importance of prompt evaluation of women with breast cancer symptoms during periods of reduced health-care access and capacity. This is consistent with a recent Breast Cancer Surveillance Consortium study, which found that during periods of reduced capacity, triaging individuals most likely to have cancer, including women with symptoms, could result in detecting the most cancers while performing the fewest examinations compared with a nonrisk-based approach (38).

Our findings also suggest that excess breast cancer mortality due to reduced access to screening during the pandemic could be mitigated by facilities giving priority to women who missed a screen during the pandemic. Although imaging volumes had returned to normal or above normal by September 2020, there remains a substantial cumulative deficit in screening and diagnostic evaluations compared with prepandemic years (9,13,39). This deficit may be due to multiple factors, including limited capacity of breast-imaging facilities to accommodate the number of women whose evaluation has been delayed, ongoing concerns from women about the safety of health-care facilities due to the continued pandemic, or reduced access to health care due to COVID-19-related loss of employment-based health insurance. Many of these factors are likely to continue to affect receipt of diagnostic and screening services until control of the

COVID-19 pandemic is achieved. Thus, the true duration of disruption to breast cancer control activities and the impact on long-term breast cancer mortality may ultimately prove to be more substantial than our current models suggest.

Despite the strength of consistent results from 3 established CISNET models, there are several limitations that should be considered in interpreting our results. First, in the absence of detailed information on breast cancer treatment patterns during the pandemic, we based our treatment assumptions on expert opinion. We assumed that during the pandemic, oncologists rationally limited chemotherapy use among patients least likely to benefit (early stage, ER-positive or HER2-negative disease) and at greatest risk for COVID-19-related complications (women older than 70 years) (27-29). We also assumed that oncologists ensured chemotherapy receipt among poor prognosis subtypes (ER-negative and/or HER2-positive or more advanced stages), assuming the benefit of adjuvant chemotherapy outweighed the risk of death due to COVID-19. Furthermore, because oral endocrine therapies (eg, tamoxifen or aromatase inhibitors) neither compromise the immune system nor require in-person visits for administration, we assumed the pandemic did not disrupt their use. It is possible that there were delays or nonuse of treatment, especially with losses of health-care insurance. In this case, the impact of pandemic-related treatment changes on excess breast cancer mortality may be greater than we expect. More data on cancer treatment patterns and longer follow-up will be essential to refine the mortality projections.

Another limitation is that many aspects of screening behavior and diagnostic evaluation during the pandemic remain poorly understood, including whether patterns in resumption of care are differential by age or perceived cancer risk. For example, disruptions in screening continue as women are being encouraged to reschedule screening mammography after receiving the COVID-19 vaccination to prevent false-positive callbacks for vaccination-related lymphadenopathy. Additionally,

Figure 2. Cumulative excess breast cancer mortality according to exemplar model (University of Wisconsin-Madison and Harvard Medical School model) over time when the pandemic-related disruptions last for 12 months. A) The number of cumulative excessive deaths when each disruption is modeled separately. B) The number of excessive deaths when disruptions are combined.

although mammography volumes rebounded over the summer to reach prepandemic levels (2,9,13), it is not clear what portion of these exams are for missed mammograms or regularly scheduled exams. We tested a range of assumptions about these patterns, and results were similar in magnitude across different scenarios. Moreover, our models did not account for potential disparities in the resumption of breast cancer care services. Our recent work has shown that the recovery of breast cancer-screening and diagnostic services has not been equal for

all women, with a slower rebound in use among Hispanic and Asian women as of July 2020 (13). Thus, although the overall impact of the pandemic on cancer outcomes may be small, it may disproportionately affect women in underserved populations and exacerbate health inequities. Therefore, it will be important to focus on resumption of access to screening for racial and ethnic minority women.

Finally, we assumed that future incidence, accuracy of screening and diagnosis, effectiveness of treatment, and other-

cause mortality would carry forward at levels before the pandemic. Because these assumptions applied to the scenarios representing both COVID-19 disruptions and usual care, the relative difference in outcomes is unlikely to be affected.

In conclusion, in this collaborative simulation modeling study, we projected a small number of additional breast cancer deaths among US women from 2020 to 2030 due to the COVID-19 pandemic-related disruptions in breast cancer screening, diagnosis, and treatment. Efforts to ensure prompt access to screening, diagnostic evaluation, and treatment should mitigate the impact of the COVID-19 pandemic on breast cancer mortality.

Funding

This work was supported by the National Institutes of Health under National Cancer Institute Grants U01CA152958, U01CA253911, and R01CA248068. Supported in part by National Cancer Institute at the National Institutes of Health grant R35CA197289 to J.M. Collection of Breast Cancer Surveillance Consortium (BCSC; <http://www.bsc-research.org/>) data used in this study was supported by National Cancer Institute Grants P01CA154292 and U54CA163303; grant R01 HS018366-01A1 from the Agency for Healthcare Research and Quality; and award PCS-1504-30370 from the Patient-Centered Outcomes Research Institute (PCORI).

Notes

Role of the funder: The funding agencies had no role in the design or conduct of the study; collection, management, analysis, or interpretation of the data; or preparation, review, or approval of the manuscript.

Disclosures: OA is a paid consultant for Bristol-Myers Squibb, outside of the submitted work. AK serves as an unpaid consultant for Ambry Genetics, Color Genomics, GeneDx/BioReference, Genentech, and InVita, outside of the submitted work. KL has research funding from Association of University Radiologists/GE Healthcare, outside of the submitted work. No other conflicts to report.

Author contributions: Conception and design: OA, KL, AK, JM, BS, NS. Analysis and interpretation of the data: OA, KL, AK, JM, ME, HH, SL, CS, AT, DM, ATD, SN, KK, BS, NS. Drafting of the article: OA, KL, AK, JM, BS, NS. Critical revision for important intellectual content: OA, KL, AK, JM, ME, HH, SL, CS, AT, DM, ATD, SN, KK, BS, NS. Final approval of the article: OA, KL, AK, JM, ME, HH, SL, CS, AT, DM, ATD, SN, KK, BS, NS. Programming: ME, CS, HH. Analysis of data: OA.
