Abstract--**We present the construction status of the LBNL Positron Emission Mammography (PEM) camera, which utilizes a PET detector module with depth of interaction measurement consisting of 64 LSO crystals (3x3x30 mm³) coupled on one end to a single photomultiplier tube (PMT) and on the opposite end to a 64 pixel array of silicon photodiodes (PDs). The PMT provides an accurate timing pulse, the PDs identify the crystal of interaction, the sum provides a total energy signal, and the PD/(PD+PMT) ratio determines the depth of interaction. We have completed construction of all 42 PEM detector modules. All data acquisition electronics have been completed, fully tested and loaded onto the gantry. We have demonstrated that all functions of the custom IC work using the production rigid-flex boards and data acquisition system. Preliminary detector module characterization and coincidence data have been taken using the production system, including initial images.**

I. INTRODUCTION

This paper describes the status and construction of the LBNL Positron Emission Mammography (PEM) camera [1]. The geometry for the PEM camera is shown in Fig. 1. The breast is inserted in the gap between the top and bottom 7.5 x 10 cm² detector planes, and the spacing between planes adjusted to provide light compression on the breast. The positions of the 7.5 x 7.5 cm² detector planes on the left and right of the breast are fixed. The volumes represent the active portion of the detector (*i.e.,* the portion sensitive to 511 keV photons), which are divided into 2.5 x 2.5 x 3.0 cm³ modules. Each module is further divided into 64 individual LSO scintillation crystals, each 3 x 3 x 30 mm³. We have currently instrumented only the two side (7.5 x 7.5 cm²) detector planes, using 18 detector modules, which are shown in Fig. 1 as dark gray.

We have previously reported on a PET detector module capable of measuring depth of interaction on an event by event basis [2, 3], shown in Fig. 2. With this design, a single photomultiplier tube (PMT) provides an accurate timing pulse and initial energy discrimination for an 8 x 8 array of LSO [4] scintillator crystals, an 8 x 8 silicon

photodiode array (PDs) identifies the crystal of interaction, the PD/(PD+PMT) ratio measures the depth of interaction, and the sum (PD+PMT) provides a total energy signal. We are planning to use this PET detector module in several tomograph designs [1, 5, 6]; thus we have transformed our prototype detector into one that can be produced in quantity.

We focus in this paper on new results using production versions of the complete system -- custom ICs, rigid-flex boards (used to read out the IC), detector modules, and data acquisition system. The major milestone of reading out coincidence data with the production system has been achieved, and initial images are shown.

II. SYSTEM

A. Detector Modules

We have built all 42 production detector modules to be used in our PEM camera design [1]. Fig. 2 shows a photograph of one production detector module. The end-on "profile" of the module is 2.5 cm square, allowing close packing of multiple detector modules in two dimensions. Communication between the custom integrated circuit (PETRIC) [7] and the remainder of the electronics [8] (which is located "behind" the photomultiplier tube) is accomplished by a 0.008" thick Kapton "flex tail" on the IC printed circuit board that is thin enough to run between adjacent detector modules. The successful production of these rigid-flex boards has proved to be a surprisingly difficult task, but we are now taking data using the working, final versions of the rigid-flex boards. All functions of the PETRIC chip (including the Winner-Take-All circuitry for correct analog and channel address selection of the "winner") have been demonstrated to work with production rigid-flex boards and the final data acquisition system.

Fig. 3 demonstrates that the detector module assembly process is complete. We are now in the process of attaching rigid-flex boards onto each detector module's photodiode, as well as bundling three detector modules (with rigid-flex boards) and assembling them into light tight cans. Fig. 4 shows the details of our "can" assembly. Currently, half of the detector modules have been assembled into cans.

B. Camera

We have instrumented the two side (7.5 x 7.5 cm²) detector planes, using 18 detector modules (*i.e.,* 3 detector

cans per bank). Fig. 5 shows the camera gantry and electronics housing before the modules were put in place.

The detector modules are read out with electronics originally developed by CTI (Knoxville, TN) for the HRRT brain imaging PET camera and modified to use a detector module that incorporates a photodiode [8]. The top level diagram of the electronics system is show in Fig. 6a, and the diagram of the Detector Head Interface (DHI) board is shown in Fig. 6b. The outputs of three detector modules are processed by an Analog Subsection board. Events are detected and assigned an arrival time, the crystal of interaction is identified, energy qualification is performed, and a digital word is formed. The output signals from the Analog Subsection boards are then multiplexed by Detector Head Interface boards. A CTI Coincidence Processor identifies singles events in the different DHI boards that are in coincidence, and the output is sent to a Pentium-based computer system that accumulates the coincident data, reconstructs the images, and displays them.

This final data acquisition system was used to calibrate the detector modules. We have automated calibration software that sets up the electronics and identifies bad channels using test pulses. In addition, we have automated software that acquires (singles or coincidence) data with a ^{68}Ge source (using the PMT signal with a low discriminator threshold for triggering), corrects for channel to channel gain variation in the PMT signal, and cuts events with PMT signal outside the 350-700 keV energy window. However, we currently have not corrected for channel to channel gain variation in the PD signal, and have not scaled the relative PD and PMT signal; thus we have not yet been able to calculate the depth of interaction (DOI) with the production system. Since the calibration procedure is not complete [9], the PD is only used to identify the crystal of interaction.

C. Reconstruction

We have developed and tested both filtered backprojection reconstruction algorithms (2-D [10] and 3-D [11]) and a list mode regularized maximum likelihood reconstruction algorithm [12] using Monte Carlo data. The rectangular geometry and the capability of measuring DOI result in irregular sampling in the sinogram space. In the filtered backprojection algorithm, data are rebinned onto regular grid. In the list mode maximum likelihood algorithm, the irregular sampling and DOI information are explicitly modeled in the projection matrix. To demonstrate the expected system performance, Fig. 7 shows a reconstructed image of simulated spherical sources using the 3D filtered backprojection algorithm. The resolution of the reconstruction varies from 1.54 mm FWHM at the center to 3.10 mm at the corner. As the current camera setup only contains two opposing detector banks, the filtered backprojection algorithm is not directly applicable. Therefore, in Section III we only show the list mode maximum likelihood reconstruction of the real data.

III. RESULTS

The two instrumented detector banks were used to image ^{68}Ge sources in two different configurations, as shown in Fig. 8. The distance between the opposing detector banks was 7 cm. In the first setup, a 1.5 mm diameter ^{68}Ge point source (106 µCi) was placed in the mid-plane between the two planar detector banks. Data was taken at two different point source positions (Fig. 8a), resulting in 10M events each. The images, shown in Fig. 9, were reconstructed with the maximum likelihood algorithm using 1.5 x 1.5 x 3 mm^3 voxels. Normalization factors were measured using a plane source placed in the mid-plane. The reconstructed point in position 1, as shown in Fig. 9a, has a (1.65, 2.85) mm FWHM reconstruction resolution. In position 2, the reconstruction resolution is (2.40, 1.95) mm FWHM. The variation in FWHM is mostly caused by the misalignment between the point source position and the voxel grid. The non-negativity constraint in the maximum likelihood reconstruction did not have a big impact on the resolution measurement here, as we obtained similar results when we reconstructed the point source data after superimposing it with a simulated uniform background.

In the second setup, a point and rod source in different planes were used. The 1.5 mm diameter ^{68}Ge point source (106 µCi) was placed in the mid-plane and a 2.5 mm diameter rod source (118 µCi) was placed in a plane that was 2 cm apart (Fig. 8b). Fig. 10 shows the images of the rod and point source with 10M events. The point source has (3.00, 2.25) mm FWHM reconstruction resolution. Since the concentration of activity in the point source is much stronger than the rod source, background activity in the area of the point source is seen in the rod source plane.

Fig. 11 shows the spectra of the timing difference between two production detector modules, which were read out with the final data acquisition system. Data was taken using the 1.5 mm diameter ^{68}Ge point source (106 µCi) placed in the mid-plane between the two detector modules. Only the PMT information was used, with a low energy threshold. While channel to channel corrections are planned, none were used to acquire these data. The preliminary coincidence timing resolution of 4.8 nsec is expected to improve after timing calibration is complete.

IV. DISCUSSION AND CONCLUSION

Two significant tasks remain before this camera is complete: assembly of the remaining two detector banks needs to be finished and the remainder of the calibration algorithms (especially PD) needs to be developed. However, we feel that major milestones have been achieved with our system. All components are complete -- custom ICs, flex boards, detector modules, data acquisition electronics and the gantry. Production firmware and calibration has been developed. Most importantly, the first images have been acquired using two opposing banks of 3x3 modules each. Initial reconstruction resolutions are in agreement with expectation.
