ABSTRACT

The large number of different experiments performed at the 88-Inch Cyclotron requires great variety and flexibility in the production of ion beams. This flexibility is provided by the two high performance ECR ion sources, the LBL ECR and the AECR-U, which can produce beams of ions as light as hydrogen and as heavy as uranium. With these two sources up to six different metals can be preloaded using two types of ovens. The ovens are mounted radially on the ion sources and inject the metal vapor through the open sextupole structure into the plasma chamber. For the superconducting ECR ion source VENUS, which is under construction at LBNL, the use of radial ovens is no longer possible, because the magnetic structure is closed radially. Therefore, we are developing two new axial oven types for low and high temperature applications.

Metal ion beam production in ECR ion sources using the oven technique is discussed. The design of the axial oven is presented. Finally the efficiency of the axial oven is compared with the radial oven for the production of Ca.

I. INTRODUCTION

The increasing demand for high intensity high charge state heavy ion beams for nuclear and high-energy physics has driven the development of various methods to feed solids into ECR ion source plasmas. The most important techniques are (1) evaporation from external furnaces, (2) use of volatile chemical compounds, (3) online chemical synthesis, (4) sputtering, (5) evaporation by vacuum arc or laser beam, and (6) direct insertion [1]. From all these methods mentioned above the oven technique is the least intrusive to produce metal ion beams, especially if pure metals can be used. The production methods at LBNL include the use of gaseous compounds, the oven technique, the direct insertion method, and the MIVOC method. 41 different metal ion beams have been produced with the LBL ECR or the AECR-U ion sources so far. Figure 1 shows the periodic system with all the metals tested in our ion sources so far and Table 1 shows a few high and medium charge states metal ion beams produced by the LBNL AECR-U.

II. METAL ION BEAM PRODUCTION USING THE OVEN TECHNIQUE

Both the LBL ECR and the AECR-U ion sources are built with radial access. Six radial slots between the sextupole magnet bars provide additional pumping and easy access to the plasma chamber for ovens and feedthroughs. Two types of radial ovens are used at LBNL. The low temperature oven is indirectly heated and can be operated at temperatures up to 650 C [2]. The high temperature oven consist of a resistance heated Ta or W furnace operating at temperatures up to 2100 °C [2]. Generally a metal vapor pressure of about 10^{-3} to 10^{-2} mmHg is required inside the oven (at an oven aperture of about 3mm diameter) to supply the right amount of atoms to the ECR plasma. The temperature needed to produce a new metal ion beam can be estimated from the vapor pressure curve of the respective metal. Beside the temperature required to evaporate the metal, chemical compatibility of the hot liquid metal and the crucible must be considered [3]. For

metals with temperature requirements less than 1600° ceramic inserts such as zirconia, alumina or yttria can be used to prevent alloying of the heating crucible with the molten metal. For higher temperatures, ceramics begin to sublime and cannot be used. The material has to be either loaded directly into the W or Ta furnace or a special crucible must be used: Chemical compatibility of crucibles for most elements is discussed in references 3 and 4.

If the pure metal is too aggressive (e.g. alkaloids) or the isotope is not available as pure metal, online chemical synthesis can be used (see figure 1). For example alkali metals can be loaded in as alkalichlorides and mixed with calcium. When heated in the low temperature oven CaCl is formed and the pure alkali metal is released into the plasma [5].

If the temperature required is too high, chemical compounds can be utilized to produce the desired metal ion beam. However, careful consideration should be given when choosing the compound. Oxides, which sublime at lower temperatures, are the best choice for refractory metals since oxygen is an excellent mixing gas. For example rhenium oxide (Re_2O_7) sublimes sufficiently at temperatures above 140 °C, whereas for the pure metal 2790 °C is needed to reach a vapor pressure of 10^{-3} mmHg.

Chemical compounds such as fluoride, chlorides or organic compounds (MIVOC) require very low temperatures or even no heating at all. Their major drawbacks are the impurities (carbon, fluorine or chlorine), that are released from the compound as well and contaminate the plasma chamber walls. Therefore, the ion source performance and stability can be compromised particularly for long, high intensity applications.

III. HIGH INTENSITY BISMUTH AND ION BEAM EMITTANCE

For the next generation Radioactive Isotope Accelerator (RIA) up to 10 pμA of uranium 30+ will be needed for the heavy ion driver linac [6]. To predict the expected ion beam emittance for heavy ion beams extracted from an ECR ion source for injection into the RIA RFQ [7], ^{209}Bi emittance measurements were performed with the AECR-U. The emittance has been measured over a range of charge states from 21^{+} to 41^{+}after the AECR-U was optimized on $^{209}Bi^{27+}$ to produce about 1pμA. Figure 2a shows the charge state distribution peaked at 27^{+} (30 eμA or 1.1 pμA). Figure 2b shows the dependence of the normalized xx' emittance values on the Bi charge state for an unchanged ion source tune. From Fig. 2 it is evident, that at these ion beam intensities the normalized emittance is predominantly dependent on the charge state and not on the current. For instance the ion beam emittance of 18.8 eμA of Bi^{21+} was measured to be 0.07 π·mm·mrad, while the emittance of 18eμA of Bi^{32+} was 0.03 π·mm·mrad. This is consistent with the model that high charge state ions are extracted closer to the axis of the ECR ion source plasma [8, 9]

IV. AXIAL OVENS

Two off-axis axial ovens have been developed at the 88-Inch Cyclotron. There are two main motivations for this new oven developments. For the superconducting ECR ion source VENUS, which is now under construction at LBNL [10], the use of radial ovens is no longer possible, because the magnetic structure is closed radially.

Secondly, for the production of superheavy elements intense metal ion beams of rare isotopes like ^{48}Ca, ^{36}S, or ^{85}Rb are required. Since those isotopes are very expensive a minimal consumption is desired. As shown by the Dubna group [11], a hot liner covering the plasma chamber walls can be very effective in increasing the overall ion source efficiency. For this purpose an axial oven is much better suited than a radial one.

If the axial oven is placed on or close to the center of the ion source axis, plasma heating can prevent a precise temperature control at lower temperatures [9]. To de-couple the heating of the oven from the plasma we have decided to insert the oven off axis between the plasma flutes. At this position the oven can be inserted up to 5 cm into the plasma chamber without being effected by the plasma. In addition, the off-axis oven does not interfere with the biased disk mounted on axis or with an axial iron plug, which is used to enhance the magnetic field.

4A. MINIATURE HIGH TEMPERATURE OVEN

Figure 3a shows the mechanical drawing of the new miniature high temperature oven. It is designed to fit through a standard 35-mm ConFlat flange. The oven consists of a resistance heated tantalum or tungsten furnace, which is designed to have the same electrical resistance over the whole geometry to avoid temperature gradients due to changes in electrical resistance. Three layers of Mo heat shields surround the crucible. The outer copper shell and the current leads are water cooled to de-couple the oven heating from the plasma. The oven has been tested off line to temperatures up to 2100 C and in the LBL ECR for the production of titanium. A maximum power of 380W is needed to reach 2100 C. The same oven design will be used for the VENUS ion source.

4B. MINIATURE AXIAL LOW TEMPERATURE OVEN

Figure 3b shows the mechanical drawing of the low temperature axial oven. The demountable copper furnace is fastened to a copper block, which is indirectly heated by a cartridge heater. The oven can be reliably used for temperatures up to 650 °C. A thermocouple is inserted into the heated copper block to monitor the temperature. A proportional temperature-controller unit maintains the temperature variation within less than .1 degree Celsius, which is required to assure

stable ion beam output. The oven was successfully tested for the production of Mg (120 eμA of Mg^{8+}) and Ca (60 eμA of Ca^{11+}) beams.

V. OVEN EFFICIENCIES

For medium to high intensity ion beams, typical consumption rates for the radial ovens are between 1 and 3 mg/hr, resulting in an ionization efficiency into a single charge state of about .1 to .2 % for the high temperature oven and .2 to .6% for the low temperature oven. These low efficiencies are due to the radial oven geometry, where the vapor has to diffuse through a 6mm wide and 4 cm deep narrow slit in the water-cooled sextupole housing. Therefore, a major part of the metal condenses on the cold surfaces of this slit channel. If inexpensive metals are used, consumption rates are not critical since the oven crucible volume of about 1 cm^3 is large enough to produce high intensity ion beams for 1 to 2 weeks of continuous operation. However, for high intensity ion beams from rare isotopes (e.g.10 particleμA of ^{48}Ca), the consumption has to be minimized. By using an axial oven as described in section 4B instead of the radial one, the ion source efficiency was improved by a factor of 3 to 4 (see efficiency values in table 2). As a next step a tantalum-liner was installed inside the plasma chamber. The liner, which is heated by the lost plasma particles and microwave power, minimizes the condensation of metal vapor on the chamber wall. A thermocouple was installed through one of the radial ports to measure the temperature during operation. At a microwave power of 300 W the liner reached a temperature of 400 C, which corresponds to a vapor pressure of 10^{-4} mmHg for Ca. With the liner installed the peak charge state was shifted to 9+ (from 11+), which is still sufficient to reach the required energy of 5MeV/nucleon with the 88-Inch Cyclotron. An efficiency of about 3.1 % was achieved for Ca^{9+} and about 2.9% for Ca^{8+}. Table 2 shows a comparison of the measured ionization efficiencies with results from other groups [11,13]. With the hot tantalum-liner installed a total

system efficiency of 14 % (with all the Ca charge states summed up) was measured after the analyzing magnet. The ion beam transport efficiency through the analyzing section is about 60%. However, for rare gases a typical ionization efficiency of 60 to 80 % has been measured for the AECR-U ion source [14], which shows there is still room for improvement

To further improve the ionization efficiency for Ca, we plan to modify the hot Ta-liner to allow externally controlled heating or cooling in order to de-couple the liner temperature from the ion source plasma tune. Another improvement would be to cover the plasma vessel end plates (extraction plate and biased disk) with a hot liner, too. These surfaces were not covered by the described Ta-liner resulting in metal vapor condensation on these surfaces.
