Professor Ming-Hsuan Yang, Chair

We propose a Bayesian framework for modeling and predicting traffic patterns using information obtained from wireless sensor networks. For concreteness, we apply the proposed framework to a smart building application in which traffic patterns of humans are modeled and predicted through detection and matching of their images taken from cameras at different locations. Experiments with more than 4,000 images of 20 subjects demonstrate promising results in traffic pattern prediction using the proposed algorithm. The algorithm can also be applied to other applications including surveillance, traffic monitoring, abnormality detection, and location-based services. In addition, the long-term deployment of the network can be used for security, energy conservation and utilization improvement of smart buildings.

Chapter 1

Introduction

In this thesis, we propose a Bayesian framework for modeling traffic pattern of moving objects using information acquired from wireless sensor networks.¹ The traffic pattern here refers to the moving pattern of human, vehicles or other moving objects within the region of interest. We assume that the way objects move around within the network follows some regular patterns, as limited by the constraints of area layouts. Based on the observations, we extract useful information about how the objects move in the scenes. For example, we can predict the transition probability of an object moving from the sensing region of one sensor to another. In addition, we can estimate the expected traveling time for an object moving between sensing regions using the predicted transition probabilities.

In our formulation, no overlapping sensing regions are required and the sensing region of each sensor can have different shapes. The sensors are not calibrated, i.e., we do not know the accurate positions or viewpoints of the sensors. The above-mentioned scenario

¹Some early results of this work $[24]$ is to be published in ICDSC 2010.

entails an efficient and effective data association algorithm to match objects observed by different sensors, as there are multiple objects moving freely in the scenes. For concreteness, we describe our framework using a smart building application in which we show humans can be identified and matched based on their images taken from cameras with different field of views. The proposed framework can be applied, with different sensing devices, to numerous problems, to list a few:

- Abnormality detection. To monitor some places and detect the abnormality, we can first model the traffic pattern there. With the learned traffic pattern, an abnormal event can be identified if the network detects an unusual pattern significantly different from what we modeled. Such information can be useful and important for operators to respond.
- Surveillance. In public places such as shopping mall, airports, and parking lots, we can use the traffic pattern to infer the entrances or exits that are likely to have a large number of pedestrians or vehicles during some period of time. Consequently, sufficient labor or physical resources can be appropriated to handle potential congested traffic or emergency. On the other hand, some little-used mall exits may be closed to reduce the cost without affecting the influx or outflux of shoppers.
- Location-based services. When a moving object is detected by a sensor, such information can be passed to the nodes at its possible next stop. Consequently, with controlled focus and zoom, better images of that object can be obtained. Such traffic information is of critical importance for smart sensing, compared to conventional

passive sensing.

• Energy conservation. The long-time deployment of our system can also benefit energy conservation. With the learned traffic pattern, we can form a global view of traffic flow and provide occupancy information, which is useful for controlling the a/c , lighting and other appliances in the region of interest.

We conduct experiments in a smart building with a low-power, low-bandwidth distributed camera sensor network. With five CITRIC camera motes [\[2\]](#page-50-0) placed at the intersections of stairways, hallways and elevators, we show that the traffic pattern of dwellers can be modeled and predicted well with the proposed model.

The contributions of our work are summarized as follows. We propose a Bayesian framework, based on semi-Markov process, for modeling the traffic patterns. The proposed approach deals with identity uncertainty, and hence it is applicable for realistic situations where a large number of objects move among the region of interest and their identities are not known a priori. Due to intrinsic characteristics of cameras, the association results are not guaranteed to be accurate, not to mention that the images from different camera are always under different viewpoint or lighting conditions. Thus, we derive a maximumlikelihood solution to exploit the association results in a probabilistic way. Furthermore, the proposed framework exploits both spatial and temporal information such that only local information between neighboring sensors is used and thus the computational load can be reduced.

Chapter 2

Related Work

There is a rich literature on wireless sensor networks [\[1,](#page-50-0) [26\]](#page-53-0) and a comprehensive review is beyond the scope of this thesis. In this chapter, we discuss the most relevant works in camera sensor networks, and their applications for modeling human activities.

There has been a consistent interest in applications with smart cameras, especially in tracking objects using multiple cameras [\[10,](#page-51-0) [25,](#page-53-0) [13,](#page-51-0) [9,](#page-51-0) [22,](#page-53-0) [14\]](#page-52-0), object identification [\[11\]](#page-51-0), learning network topology [\[20\]](#page-53-0), people counting [\[30\]](#page-54-0), etc. In [\[11\]](#page-51-0), a traffic monitoring system is presented in which image matching and known traveling time are combined to establish vehicle correspondence between deployed camera sensors along a highway. However, it only models one single traffic pattern where the traffic generally follows highway lanes. Kettnaker and Zabih [\[16\]](#page-52-0) introduce a Bayesian formalization to reconstruct the paths of objects across multiple cameras. While the cameras have non-overlapping field of view (FOV), they need to be calibrated. Their system requires a pre-defined set of allowable paths, transition probabilities and expected duration as a prior. Consequently, the proposed method has rather limited application domains. A method that exploits space-time cues (e.g., location of exits and entrances, moving directions, average traveling time and object appearance) to establish object correspondences is presented in [\[13\]](#page-51-0). Although the results are promising, the proposed method does not predict the traveling time of moving objects. To track people moving across cameras, a method based on a stochastic transition matrix is proposed [\[6\]](#page-50-0) in which both Kalman filter and Markov model are used. The Kalman filter is used to resolve short tracks between frames, whereas the Markov model is applied to cope with discontinuity and track fast motion or motion that the Kalman filter cannot predict. However, this method relies on background subtraction which is known to be problematic for long-term deployment. In addition, it does not model the traveling time of moving people. Spatial and visual cues are used in [\[14\]](#page-52-0) for tracking objects in multiple non-overlapping cameras. The non-parametric Parzen kernel function is used to estimate the space-time probability density function between each pair of cameras, thereby facilitating tracking with non-overlapping views. A method proposed in [\[9\]](#page-51-0) incrementally updates transition matrix and color calibration mappings for tracking people across disjoint camera views. Song and Roy-Chowdhury [\[25\]](#page-53-0) propose a stochastic, adaptive strategy for tracking multiple people in non-overlapping camera networks. With its long-term feature dependency models, their system can adaptively determine feature correspondence and correct association errors. However, they assume that the distribution of the travel time between two nodes is known and people can be tracked within the view of each camera, which is a strong assumption.

In our experiment, a camera sensor network is formed using CITRIC camera motes [\[2\]](#page-50-0). Besides the CITRIC mote, there are numerous camera sensor platforms [\[23,](#page-53-0)

[19,](#page-52-0) [8,](#page-51-0) [17,](#page-52-0) [7\]](#page-51-0). These platforms vary in configuration, processing capability, memory and image resolutions. In the last few years, there has been a growing interest in applications of camera sensor networks [\[18,](#page-52-0) [29,](#page-54-0) [27\]](#page-53-0). Yan et al. [\[29\]](#page-54-0) implement a distributed image search system over a camera sensor network where each node is a search engine that senses, stores and searches for visual information. The node consists of a iMote2 mote [\[3\]](#page-50-0) and low-power cameras with extended flash storage. Sundarraj et al. [\[27\]](#page-53-0) propose an algorithm that matches images from multiple camera sensors, using spatial and temporal consistency. In [\[5\]](#page-50-0), a real-time surveillance application for object tracking is proposed using WiCa [\[17\]](#page-52-0) platform. Recently, Kamthe et al. [\[15\]](#page-52-0) present a smart cameras object position estimation system using Cyclops [\[23\]](#page-53-0) sensor network. Notwithstanding the demonstrated success in these applications, none of these applications develop efficient and effective data association algorithm to model the traffic pattern of moving objects.

What distinguishes our work from prior art is as follows. First, it is not necessary for our algorithm to track objects or to reconstruct their whole paths in sequences in order to analyze traffic patterns. Instead, the proposed algorithm entails only the local motion pattern of objects. Second, our framework is able to model the traveling time of moving objects. Furthermore, while our objective is not to track objects in the network, we can actually estimate the object paths probabilistically. We can also estimate the number of objects in the region of interest. With each mote reporting the number of objects entering/leaving the states (based on the human detection result) at any duration, the server can form a global view of the traffic flow.

Chapter 3

Modeling and Predicting Traffic Pattern

In this chapter, we present the proposed framework for modeling and predicting traffic patterns. Our framework is generic and can be applied to numerous problems as we do not assume the specific sensing region or topology of sensors. It is also applicable to other sensor networks with different sensing devices (e.g., infrared, motion, and image sensors). For concreteness, we present the proposed framework with an application where traffic patterns of humans are modeled and predicted via images acquired from a camera sensor network.

3.1 Sensor Placement

Assume there are N sensors in the network, we denote $\mathcal R$ as the entire region of interest which covers the sensing area of all the sensors, i.e., $\{R_1, \dots, R_N\} \subset \mathcal{R}$, where R_i

is the sensing region of sensor i . They may be overlapped or not. Note that there exist regions uncovered by the sensors, so the union of R_1, \ldots, R_N is subset of \mathcal{R} . These sensing regions do not assume any particular structure in our formulation. As shown in Fig. [3.1,](#page-19-0) there are five regions ($N = 5$) in this sensor network where R_3 and R_4 are overlapped.

The possible entry/exit points within the whole sensing region are represented by S states Z_1, \ldots, Z_S , and usually $S \geq N$, as shown in Fig. [3.1,](#page-19-0) where the states are denoted by purple circles. In this example, each sensing region covers one or more states and one state may be covered by both sensors, like Z_9 , which means the state index is unique regardless of which sensor it belongs to. Assume a set of states, S_i , is covered by sensor *i*, then $\sum_{i=1}^{N} S_i = S + L$, where L is the total number of states that are covered by more than one sensor. In Fig. [3.1,](#page-19-0) there are 10 ($S = 10$) states and one ($L = 1$) of them is covered by more than one sensors. With this formulation, the traffic pattern of interest refers to how objects travel from one state to another. We only consider the traffic pattern between R_i .

The activity graph describes how objects move in the region of interest \mathcal{R} . Fig. [3.1\(](#page-19-0)b) shows an example. Here each vertex represents a state, and each edge in the activity graph describes the possible path the objects can take between states. The activity graph differentiates traffic patterns such as u-turn $(Z_1 \leftrightarrow Z_1)$ and through traffic $(Z_1 \leftrightarrow Z_6)$.

3.2 Mobility Model and Observation Model

We model the traffic pattern of moving objects using a semi-Markov chain over the activity graph. Let X_k be the state of an object at time t_k . Then the state transition

Figure 3.1: Sensing regions and corresponding activity graph. (a) The sensing region of each sensor may be overlapped or not. They can have different shape. (b) An activity graph. Z_1 , Z_2 and Z_6 , Z_7 are possible entrance/exit points in sensing region R_2 and R_5 , respectively. These two regions are connected by a path $(Z_1 \leftrightarrow Z_6)$. The graph representation distinguishes the U-turn and through traffic. The possible paths within and between R_i are represented by dotted and solid lines, respectively. For brevity, not all possible paths are shown.

is modeled as a Markov chain:

$$
P(X_k = j | X_{k-1} = i) = p_{ij},
$$
\n(3.1)

where i and j denote states Z_i and Z_j , respectively. However, unlike the conventional Markov chain, where the state transition happens instantaneously, we assume there is a delay at each transition. Let T_k be the traveling time between X_{k-1} and X_k and it has the exponential distribution with the following probability density function:

$$
f(T_k = t | X_{k-1} = i, X_k = j) = \lambda_{ij} \exp(-\lambda_{ij} t).
$$
 (3.2)

With our semi-Markov chain model, there is no restriction on the amount of time an object stays in the same state. Also, while the instantaneous transition between states of the conventional Markov chain is unrealistic, the traveling times are accounted in this model.

The initial state distribution is defined similarly to the conventional Markov chain. The semi-Markov chain describes the traffic pattern in the activity graph.

If an object is in R_n which covers Z_i from time t_{k-1} to t_k , the observation is modeled by the following function:

$$
Y_t^n = h_n(\chi_t) + v^n,\tag{3.3}
$$

where Y_t^n is the observation at time t by sensor n, h_n is the observation function which maps the intrinsic state χ of the object to observation Y for sensor n, and v^n accounts for noise.

In the activity graph, the traveling time on each edge can be measured by the state entry and exit times. In our camera sensor network system, both images and traveling times are used as observations.

3.3 Learning With Known Identities

There are two sets of parameters we need to estimate in order to use our semi-Markov chain model. They are state transition probabilities $\{p_{ij}\}\$ and traveling time rates $\{\lambda_{ij}\}.$ ¹ In Section [3.2,](#page-18-0) we assume a single object and the parameter estimation is trivial since there is no uncertainty about object's identity. However, in a general setup, we need to consider the case with a large number of moving objects and the parameters cannot be estimated unless their identities are known. In the next two sections, we describe how we can resolve this identity uncertainty (i.e., data association) problem and robustly estimate

 1 We also need to estimate the initial state distribution but it is ignored here since its estimation is trivial.

the parameters of the semi-Markov chain. In this section, we first assume the identities are known.

For ease of exposition, we show the method for estimating parameters for the outgoing transition from a single state Z_i . The parameters associated to other states can be estimated in a similar manner. Now suppose that there are N_e objects that exited the state Z_i . Then we can compute the log likelihood of the out-going transitions from state Z_i as:

$$
\prod_{k=1}^{N_e} \prod_{j=1}^{S} p_{ij}^{\gamma_{kj}},\tag{3.4}
$$

where $\gamma_{kj} = 1$ if the object k exited Z_i at time t_k is the same object that entered to Z_j for the first time after t_k and $\gamma_{kj} = 0$, otherwise. If no object entered to Z_j after time t_k , we also have $\gamma_{kj} = 0$. Once we know object identities, i.e., γ 's, we can easily estimate the maximum likelihood of the transition probabilities by solving a constrained optimization problem²

$$
\max_{p_{ij}} \prod_{k=1}^{N_e} \prod_{j=1}^{S} p_{ij}^{\gamma_{kj}} \quad \text{s.t. } \sum_{j=1}^{S} p_{ij} = 1,
$$
\n(3.5)

which is equivalent to maximize $L(p_{ij}),$

$$
L(p_{ij}) = \log\left(\prod_{k=1}^{N_e} \prod_{j=1}^{S} p_{ij}^{\gamma_{kj}}\right) - \nu\left(\sum_{j=1}^{S} p_{ij} - 1\right),\tag{3.6}
$$

$$
= \sum_{k=1}^{N_e} \sum_{j=1}^{S} \gamma_{kj} \log(p_{ij}) - \nu (\sum_{j=1}^{S} p_{ij} - 1), \qquad (3.7)
$$

where ν is the Lagrange multiplier. For $j = 1, \dots, S$, we require that $\frac{\partial l(p_{ij})}{\partial p_{ij}} = 0$ which gives

$$
\hat{p}_{ij} = \frac{\sum_{k=1}^{N_e} \gamma_{kj}}{\nu}.
$$
\n(3.8)

² The constraint is the normalization property of the transition probabilities.

By using the constraint $\sum_{j=1}^{S} p_{ij} = 1$, we find

$$
\hat{p}_{ij} = \frac{\sum_{k=1}^{N_e} \gamma_{kj}}{\sum_{k=1}^{N_e} \sum_{j=1}^{S} \gamma_{kj}}.
$$
\n(3.9)

The traveling time rates can be solved similarly. The log likelihood of traveling times from state Z_i is

$$
\prod_{k=1}^{N_e} \prod_{j=1}^S \left(\lambda_{ij} \exp(-\lambda_{ij} t_{ij}) \right)^{\gamma_{kj}}, \tag{3.10}
$$

where t_{ij} is the traveling time when $\gamma_{kj} = 1$. The optimization problem is formed as

$$
\max_{\lambda_{ij}} L(\lambda_{ij}),\tag{3.11}
$$

where

$$
L(\lambda_{ij}) = \log\left(\prod_{k=1}^{N_e} \prod_{j=1}^S \left(\lambda_{ij} \exp(-\lambda_{ij} t_{ij})\right)^{\gamma_{kj}}\right),\tag{3.12}
$$

$$
= \sum_{k=1}^{N_e} \sum_{j=1}^{S} \gamma_{kj} \log \left(\lambda_{ij} \exp(-\lambda_{ij} t_{ij}) \right).
$$
 (3.13)

By solving

$$
\frac{\partial L(\lambda_{ij})}{\partial \lambda_{ij}} = 0,\t\t(3.14)
$$

$$
\sum_{k=1}^{N_e} \sum_{j=1}^{S} \frac{\gamma_{kj} (1 - \lambda_{ij} t_{ij}) \exp(-\lambda_{ij} t_{ij})}{\lambda_{ij} \exp(-\lambda_{ij} t_{ij})} = 0,
$$
\n(3.15)

we get the maximum likelihood estimate of the traveling time rate as

$$
\frac{1}{\hat{\lambda}_{ij}} = \frac{\sum_{k=1}^{N_e} \gamma_{kj} t_{ij}}{\sum_{k=1}^{N_e} \gamma_{kj}}.
$$
\n(3.16)

The maximum likelihood estimation of \hat{p}_{ij} and $\hat{\lambda}_{ij}$ in (3.9) and (3.16) is intuitively correct. In (3.9), the numerator $\sum_{k=1}^{N_e} \gamma_{kj}$ stands for how many objects leaving from Z_i to Z_j , while the denominator $\sum_{k=1}^{N_e} \sum_{j=1}^{S} \gamma_{kj}$ is the number of all objects leaving Z_i . The transition probability \hat{p}_{ij} is then obtained by counting the frequency of objects entering state Z_j , of all the objects leaving state Z_i . Similarly, in [\(3.16\)](#page-22-0), the averaging traveling time from Z_i to Z_j , i.e., the reciprocal of traveling time rate $\hat{\lambda}_{ij}$, is estimated as the average time it takes for all the objects traveling from Z_i to Z_j .

However, in general, we do not have the identity information and γ_{kj} are random variables. Hence, we cannot directly solve for the maximum likelihood estimates as stated above. To address this problem, we need to first resolve the identity uncertainty.

3.4 Object Association

Using the observations from each sensor as an input, the object association process is to compute the matching probability of these observations. While it is impossible to achieve an accurate hard decision about the identity of each object, the matching probability serves as a good candidate of soft decision, i.e., to use the object association result probabilistically. Let m be an object detected by sensor n covering state Z_i and let $Y_k^{n,m} = \{Y_t^{n,m}$ $t^{n,m}$: $t_{k-1} \leq t \leq t_k$ be the collection of measurements from the time the object m entered R_n (at time t_{k-1}) to the time the object exited (at time t_k). Without loss of generality, we assume that $Y_k^{n,m}$ $\mathbf{g}_k^{n,m}$ are a series of color histograms $\boldsymbol{q}_k^{n,m} = \{\boldsymbol{q}_t^{n,m}$ $t^{n,m}_t : t_{k-1} \le t \le t_k$. Each q is a vector of H -bin histogram, and

$$
\mathbf{q} = \{q_h\}_{h=1...H}, \quad \sum_{h=1}^{H} q_h = 1,\tag{3.17}
$$

and the mean value of $q_k^{n,m}$ $\mu_k^{n,m}$ is denoted by μ_k .

Assume there are L collections of measurements from other sensors. They are listed as candidates to be compared with the measurement $Y_k^{n,m}$ $\kappa^{n,m}$. For ease of exposition, $Y_k^{n,m}$ $k_k^{n,m}$ is simply denoted as Y_k and other L collections of measurements are denoted as ${Y_l}_{l=1...L}$. The corresponding object of Y_k , as mentioned above, entered R_n from state Z_i . Measurements Y_l are selected as candidates since their corresponding objects exited from those states $\{Z_l\}$ that are possible previous-states of state Z_i , i.e., there are paths in the activity graph that connect state $\{Z_l\}$ to Z_i .

Color histograms, $q_k^{n,m}$ $k_k^{n,m}$ are compared to those of other candidate objects in order to determine its identity, i.e, how likely the object m is the candidate objects based on the measurements Y_k and $\{Y_l\}_{l=1...L}$. Assume that the collection of measurements $\{Y_l\}$ corresponds to object l. We compute $s_{\mu_l, q_t^{n,m}}$, the similarity of each $q_t^{n,m}$ $t^{n,m}$ to μ_l , the mean value of q_l , based on histogram intersection algorithm [\[28\]](#page-54-0). Intuitively, the output similarity between two color histograms of the same object should be much larger than those of different objects. Let W be the set of similarities $\{s_{\mu_l, q_l^{n,m}} : t_{k-1} \le t \le t_k\}$, and we compute $d_{\boldsymbol{\mu}_l, \boldsymbol{q}_t^{n,m}}$, the distance between $\boldsymbol{q}_t^{n,m}$ $t^{n,m}$ and $\boldsymbol{\mu}_l$, as:

$$
d_{\mu_l, \mathbf{q}_t^{n,m}} = 1 - \frac{s_{\mu_l, \mathbf{q}_t^{n,m}} - \min(W)}{\max(W) - \min(W)}.
$$
\n(3.18)

Similar to the softmax function, the probability of new observation labeled as l given its $t_k - t_{k-1} + 1$ samples of color histograms is:

$$
p(m=l|\mathbf{q}_{k}^{n,m}) = \frac{\prod_{t=t_{k-1}}^{t_k} \exp(-d_{\mu_l, \mathbf{q}_{t}^{n,m}})}{\sum_{l'=1}^{L} \prod_{t=t_{k-1}}^{t_k} \exp(-d_{\mu_{l'} \mathbf{q}_{t}^{n,m}})}.
$$
(3.19)

The computed probabilities are the association probabilities and we use them as approximations to $\mathbb{E}(\gamma_{li})$, i.e., the probability of an object leaving Z_l entering state Z_i .

3.5 Learning Under Identity Uncertainty

While we cannot directly solve for \hat{p}_{ij} and $\hat{\lambda}_{ij}$ in [\(3.9\)](#page-22-0) and [\(3.16\)](#page-22-0) since we do not know the identities of objects, we can use the association probabilities computed above to resolve this issue.

Instead of maximizing the log likelihood to estimate the parameters, we maximize the expected complete log likelihood. The expected complete log likelihood for the transition probabilities are

$$
\mathbb{E}[L(p)] = \mathbb{E}\left[\log\left(\prod_{k=1}^{N_e}\prod_{j=1}^S p_{ij}^{\gamma_{kj}}\right)\right]
$$

\n
$$
= \mathbb{E}\left[\sum_{k=1}^{N_e}\sum_{j=1}^S \gamma_{kj}\log(p_{ij})\right]
$$

\n
$$
= \sum_{k=1}^{N_e}\sum_{j=1}^S \mathbb{E}(\gamma_{kj})\log(p_{ij}),
$$

which we can solve using the estimates found in the previous section. Then our estimates are

$$
\hat{p}_{ij} = \frac{\sum_{k=1}^{N_e} \mathbb{E}(\gamma_{kj})}{\sum_{k=1}^{N_e} \sum_{j=1}^{S} \mathbb{E}(\gamma_{kj})}.
$$
\n(3.20)

Similarly, the traveling times can be estimated as

$$
\frac{1}{\hat{\lambda}_{ij}} = \frac{\sum_{k=1}^{N_e} \mathbb{E}(\gamma_{kj}) t_{ij}}{\sum_{k=1}^{N_e} \mathbb{E}(\gamma_{kj})}.
$$
\n(3.21)

Note that our approach resembles the EM algorithm where the computation of the association probabilities $\mathbb{E}(\gamma_{kj})$ is the E-step and the parameter estimation is the M-step. But no iteration is required in our formulation since the results from the M-step does not affect the computation of association probabilities. However, it is possible to incorporate traveling times into association probabilities, and then an EM algorithm can be used to estimate the parameters.

Chapter 4

A Case Study: Traffic Modeling in Smart Building

4.1 Platform: CITRIC mote

Our experiments are carried out using a network of lightweight CITRIC motes [\[2\]](#page-50-0). The CITRIC mote is a wireless camera system, consisting of a camera daughter board and a Tmote Sky board. The camera daughter board is equipped with a CCD camera, a frequency-scalable (up to 624MHz) CPU, 16MB FLASH, and 64MB RAM (see Fig. [4.1\)](#page-28-0). The CITRIC mote uses the OmniVision OV9655 CMOS image sensor [\[21\]](#page-53-0), which offers the full functionality of a camera and an image processor on a single chip supporting various capture modes (e.g., SXGA, VGA, and CIF). It is able to capture images up to 30 frames per second in VGA and CIF modes, and 15 frames per second in SXGA mode.

The computing unit of CITRIC is Intel PXA270 [\[12\]](#page-51-0). It is a fixed-pointed pro-

Figure 4.1: CITRIC camera mote. (a) An assembled camera daughter board with Tmote Sky board. (b) A camera daughter board with major functional units outlined.

cessor with a maximum speed of 624MHz, 256KB of internal SRAM, and a wireless MMX coprocessor to accelerate multimedia operations. The PXA270 features the Intel Quick Capture Interface that eliminates the need for external preprocessors to connect the processor to the camera sensor. The PXA270 is connected to 64MB of 1.8V Qimonda Mobile SDRAM and 16MB of 1.8V Intel NOR FLASH. The SDRAM is used for storing image frames during processing and the FLASH is for storing code.

The camera daughter board uses the Silicon Laboratories CP2102 USB-to-UART bridge controller to connect the UART port of the PXA270 with a USB port on a personal computer for programming and data retrieval. Silicon Laboratories provides royalty-free Virtual COM Port (VCP) device drivers that allow the camera mote to appear as a COM port to PC applications. The CITRIC mote also provides wireless communications over the IEEE 802.15.4 protocol, which makes it convenient to collaborate with other motes.

As it provides more computing power and tighter integration of physical compo-

Figure 4.2: Experimental setup. (a) Four camera motes are placed on the second floor of a building. The FOV (colored region) of each camera sensing region has different shape and Z_1 to Z_9 are possible entrance/exit points (states) of each region (R_2 and R_3 are shown in a larger region on the lower left). Note that the sensing region of cameras C_2 and C_3 are overlapped. (b) One camera is placed on the first floor. A person passing state Z_{11} can either take the elevator or the stairways to the second floor, thereby reaching state Z_3 (out of elevator and turn right immediately), Z_4 (out of elevator and walk straight), or Z_5 (take stairway and reach Z_5).

nents while still consuming relatively little power, the CITRIC mote enables a wider variety of distributed pattern recognition applications than traditional platforms and enables innetwork processing of images to reduce communication requirements.

4.2 Experiments and Results

We carry out experiments in a smart building equipped with a network of CITRIC camera motes for modeling and predicting traffic patterns of dwellers. Fig. 4.2 shows the building layout and the placements of CITRIC motes. Five CITRIC motes are placed on two floors in a building at intersections of hallways as well as stairways, with four on the second floor of the building, and the other one on the first floor. Over 28,000 image frames are captured and saved by these motes. In our experiment, the image are captured at a resolution of 320×240 pixels, which is sufficient for human detection. After applying human detection techniques, about 5,800 images of humans are detected. Our training set consists of 2,902 images and the test set contains 1,136 images. In the training phase, we estimate the model parameters, $\{p_{ij}\}\$ and $\{\lambda_{ij}\}\$ as described in Chapter [3,](#page-17-0) using the images of dwellers detected from the motes. The observations used for human matching are the normalized RGB histograms of the upper-body part of the detected subjects. Once a subject is detected, its next state and expected arrival time can be predicted using the learned traffic model.

4.2.1 Experimental Setup

The FOVs of five cameras are denoted by R_1 to R_5 and their corresponding states are denoted by Z_1 to Z_{12} , as shown in Fig. [4.2](#page-29-0) (where R_2 and R_3 are shown with larger images). Four cameras are placed on the second floor near the stairways and the other one is placed on the first floor near the entrance. Cameras are deployed on the side of the hallways, to make human detection techniques feasible. The states are determined manually based on the approximate camera position and their FOVs. Basically, one possible entry/exit point corresponds to one state. As constrained by the physical structure of the building, the sensing regions have different shapes, and some states are covered by more than one region (e.g., Z_5 is covered by R_2 and R_3). As the states represent the entry and exit points of a region, it is easy to see that states Z_4 and Z'_4 are actually connected seamlessly, i.e., objects walking through state Z_4 will definitely arrive at state Z'_4 .¹ Therefore, we consider

¹Considering that there is little chance one subject will enter state Z_4 and return, before reach state Z'_4 .

Figure 4.3: Activity Graph Representation in our specific experimental setting. Only selected states are shown.

them as one state (likewise for Z_6 and Z'_6) in the following discussions.

The activity graph for this experimental setting is shown in Fig. 4.3. The prior knowledge of building layout is used to determine the connectivity between states. Most states are connected by paths through corridors. Specifically, Z_{11} is connected to Z_3 and Z_4 via elevator. That is, a person detected by C_5 in R_5 is likely to appear in R_1 and detected by C_1 if the person takes the elevator and walks directly toward R_1 (note that the sensing region of C_2 does not cover the corridor region right in front of the elevator), or R_2 (and detected by C_2) if the person walks toward R_2 after taking elevator or stairway. Likewise, Z_5 is connected to Z_{11} as a subject may take stairway from the first floor and walk toward $R₂$. These paths in the activity graph match real-world traffic patterns of dwellers in this building.

4.2.2 Image Capturing

At each camera, two image sequences are collected with more than 20 people walking through this building. Totally above 28,000 image frames are captured saved on CITRIC motes at about 4 frames per second. All the raw images are transmitted to a central server for off-line training. While it is not necessary to put all the training process on-board, some of them could potentially be done on-line, e.g., human detection, feature extraction, clustering, etc.

4.2.3 Human Detection

As only those frames with human are informative in our experiment, we use a detector with Histogram of Oriented Gradient (HOG) [\[4\]](#page-50-0) to detect humans in these images, where the outputs are their image coordinates in the scenes.

Overall, the HOG-based detector performs well with our dataset with few false negatives and false positives. Of all the 28736 images collected, there are 5842 detections with only 190 false positives and 537 false negatives. And we partition the image frames into two parts, with 2902 frames for training and 1136 frames for test. Fig. [4.4](#page-33-0) shows some human detection results. When one object walks across the FOV of a camera, multiple frames of this object will be captured by the camera. Consequently, even if an object is not detected in some frames (i.e., false negatives), the negative effects on final results are negligible.

As the camera positions are fixed, we can exploit prior spatial and temporal knowledge of human subjects to eliminate most of the false positives. For example, we know a

(d) (e) (f)

 (g) (h) (i)

Figure 4.4: Human detection results. Images (a)-(l) are shots at states Z_1 to Z_{12} , respectively. We can see from the images that detected subjects are of different viewpoints, different size and under different lighting conditions, which makes the object association problem more difficult. The coordinates of the bounding box could help in turn identify the entering/leaving state of the subjects.

Figure 4.5: Some false positive from our HOG-based detector. Most of the false positives can be removed using prior spatial knowledge. (a) One bounding box is embedded in the other. (b) The y_{min} coordinate of the bounding box is too large (i.e., the detected person is too small). (c) The y_{max} coordinate of the bounding box is too small (i.e., the detected person is not on the floor).

priori that no person would appear in the air when walking, and thus any detected results violate this rule are false positives and can be removed. Some false positive examples are shown in Fig. 4.5^2 . Furthermore, we can also remove some false positives based on temporal consistency. As we have continuous captured frames, so if at some frames the detection result (i.e., the coordinates of the bounding box) deviates from the results of other frames significantly, we can remove this frame, as either it is a false positive or there is another subject in that position (see Fig. [4.6\)](#page-35-0). In both cases, the result from such frames can be removed without affecting learning the traffic pattern in our model.

It is worth mentioning that human detection provides more useful information than methods with simple background subtraction with blob models. For example, multiple humans can be detected and differentiated in a scene, thereby facilitating flow analysis of groups. We'll have discussion in section [4.3.2.](#page-45-0)

²Let the upper-left corner of the image be the origin, the coordinates of the bounding box are full determined by four values: $\{y_{min}, y_{max}, x_{min}, x_{max}\}.$

Figure 4.6: Human detection results from three continuous frames. (a) and (c) are true positives, but (b) is a false positive, which can be easily identified and removed by maintaining temporal consistency of their bounding box coordinates (i.e., a person is very unlikely to impulsively jump to the ceiling while walking).

4.2.4 Measurements

Assume the camera motes are time synchronized, and a unique time stamp is assigned to each image frame from all five cameras. The time stamps and image coordinates from human detection provide strong cues for inferring which frames are belonging to the same subject from all sequences acquired by one camera. For each detected subject, the entering time $t_-\,$ and the leaving time t_+ of a scene are recorded.

Image coordinates of the detected subject at the entering/leaving time and the moving direction help in determining the entering state and leaving state of one subject, as the placements of cameras are approximately known. That is, the expected size and position of a detected human with respect to a camera can be exploited for inference. For example, at camera C_1 in Fig. [4.2\(](#page-29-0)a), if the subject is observed to enter from left of the scene, then the entering state must be Z_1 . If the subject is observed to leave from the far right end (with smaller bounding box), the leaving state is Z_3 . Otherwise, if the bounding box is large, on the right side of the frame observed from C_1 when the subject leaves the

Figure 4.7: Representative normalized RGB histograms. The x- and y-axis stands for the R, G channel. We can see that the components are mainly in (10:30,10:30) range, thereby we use the 20×20 bins to represent human.

scene, its leaving state is Z_2 .

To extract the color histogram features, we first fit an ellipse within the bounding box of a detected human to remove background pixels. As inside the bounding box, there are still large parts of the pixels coming from the background. Here, we use a heuristic method to extract the color features. As from the HOG result, the subject always lies in the center of the detected bounding box, so we use an ellipse to bound the subject tightly. The size of the ellipse is adaptive with that of the bounding box. This is intuitively correct, as the size of the subject is small when it's far away from the camera, in which case the detected bounding box is small as well. This method is simple yet effective.

After fitting an ellipse in the bounding box of a detected human to remove background pixels, we compute the normalized RGB histogram for the foreground part (within the ellipse). Normalized RGB color histogram is used as it is invariant to change in scale and viewpoint, thereby facilitating the matching process. The normalized RGB histogram used has 64×64 bins (64 bins for R, G channel respectively). In the experiments (as shown in Fig. 4.7), we found that the components are mainly in (10:30, 10:30) range. Therefore,

to reduce computational cost and also to increase the matching capability, we use the 20 \times 20 bins to represent human. We tried other representations as well, such as normal RGB histogram, Kernel RGB histogram, gray-scale histogram, etc. We have also conducted experiments to evaluate the matching performance using the histogram from upper torso (upper-part ellipse) or from the entire torso (the whole ellipse). It turns out that the former is better. The reason may be that the color of lower torso, i.e., the color of pants has little variation compared to the upper part. Including them in the matching process may instead reduce the discrimination. In addition, the lower part of the ellipse inevitably includes some background pixels (always more than the portion in upper-part), which further reduces the identification capability. We have experimented with various representations and parameters, and found that the combination of normalized RGB histogram with 20×20 bins of upper human torso performs best. Fig. [4.8](#page-38-0) gives the matching accuracy conducted on a 4 subject database. The typical number of subjects to be compared with in our experiment is 4. As seen in the figure, with color histogram of upper body, the performance is constantly better than that with full body histogram.

4.2.5 Human Matching

We exploit both spatial and temporal prior information for matching between clusters. In our context, a cluster is defined as the frames continuously captured by one camera and belongs to one subject. For example, if a subject entered R_1 at Z_1 and exited at Z_3 after some time, then all the frames captured by C_1 during this time are one cluster. If the same subject entered Z_3 again after this, the frames captured later will be counted

Figure 4.8: A comparison between different matching metric, different ellipse size and upper-body/full body color histogram choice, which runs on a small database. The 4-digit in the x-axis label refers to the size of the ellipse fit in the bounding box, e.g., 1122 means the distances from the four vertices of ellipse to $y_{min}, y_{max}, x_{min}, x_{max}$, respectively, is $0.1 \times$, $0.1\times$ the height of the bounding box h, and $0.2\times$, $0.2\times$ the width of the bounding box w. From left to right, the x-axis labels indicate (1) Full body, ellipse size $0.8h \times 0.6w$, no ellipse. (2) Full body, ellipse size $0.6h \times 0.4w$, no ellipse. (3) Full body, ellipse size $0.6h \times 0.4w$, fit ellipse. (4) Upper body, ellipse size $0.8h \times 0.6w$, no ellipse. (5) Upper body, ellipse size $0.6h \times 0.4w$, no ellipse. (6) Upper body, ellipse size $0.6h \times 0.4w$, fit ellipse.

as another cluster. Clusters are processed and matched in chronological order. First, with prior spatial knowledge of camera placements and structure constraints, we know all the possible state transitions. For example, as seen in Fig. [4.3,](#page-31-0) the possible next states for Z_4 are $\{Z_0, Z_3, Z_4, Z_{11}\}.$ We define another state Z_0 to accounts for situations when $\forall j, \gamma_{kj} = 0$ (defined in [\(3.4\)](#page-21-0)), i.e., the object k didn't enter any state Z_j after exiting Z_i . Thus, Z_0 is a "sink" state which accounts for the areas not observed by all other cameras (i.e., there are some blind spots not covered by cameras). When a new object is first detected in the scene, it is considered to start from state Z_0 . Likewise, an object arrives at state Z_0 when it is last detected by any camera.

Assume at time $t_-,$, there is a detection by camera n. As mentioned above, we can infer the entering state of an object, say, Z_i , from the coordinates of bounding box. Let the list of possible previous-states of Z_i be E_i : $\{Z_{i1}, \cdots, Z_{im}\}$, where m is the total number of possible state transitions end to Z_i . It follows that only the image clusters, within a time window, associated with those states in E_i are considered for matching. The threshold for the time window is determined based on the prior knowledge of camera placements (e.g., larger threshold values for two states with long distance or connected via an elevator) and typical speed of moving objects. Let A_i denote the set of all possible clusters satisfying the spatial and temporal constraints. If A_i is empty, it means there are no other suitable image clusters to compare with, and the subject is also regarded as new person. If A_i is not empty, we first compute the distances between the image cluster at Z_i and each cluster in A_i . The corresponding distances and matching probabilities are computed according to [\(3.18\)](#page-24-0) and [\(3.19\)](#page-24-0). If all the matching probabilities are relatively small, the subject is regarded as a new person appearing from some blind spots, i.e., entering the scene from Z_0 . For each cluster, if there exists no other cluster to choose it as matching candidate, the corresponding subject is considered as disappearing in the scene, i.e., arriving at state Z_0 .

We have done a series of experiments to find an appropriate matching metric. The candidates include histogram intersection, Bhattacharyya distance, chi-square distance, sum of squared differences (SSD) and EMD. Histogram intersection proves to be simple yet effective. For example, in a 6-subject matching experiment, with 20×20 normalized RGB histogram, only histogram intersection and Bhattacharyya distance have perfect matching performance. Fig. [4.8](#page-38-0) shows another comparison result over different matching metric. And histogram intersection metric is more attractive for its simpleness if we want to have a real-time online system in the future.

4.2.6 Modeling

As the goal here is to model and predict the traffic patterns of all dwellers in a building, we need to estimate the transition probabilities of all states from all recorded sequences. The state transition probability and traveling time can be estimated as described in Chapter [3.](#page-17-0)

Fig. [4.9](#page-41-0) shows some example sequences used in the training phase where each trajectory describes one possible path. Note that not all the states are shown in the figure, as some of them do not contribute to the traffic model, e.g., Z_2 and Z_9 (where subjects enter into regions not monitored by the cameras).³ These paths indicate that subjects move freely

³To be clear, the sequences contributing to our model are those entering/leaving from state Z_3 , Z_4 , Z_5 , Z_6 , Z_7 and Z_{11} .

Figure 4.9: Sample sequences used in our experiment. The x-axis and y-axis represent time and state (entry/exit node), respectively. The trajectories of different subjects are shown in solid lines of different colors, and the solid red dots stand for the states. Sample images acquired at five cameras are also shown next to the states (best viewed on a high-resolution LCD display).

Figure 4.10: Some detection results of the image frames captured by CITRIC motes. The x-axis and y-axis represent the time and camera index.

in various patterns. It is worth noting that these trajectories can be identified and matched through the images acquired at different cameras using our algorithm. Fig. [4.10](#page-41-0) shows detection results from images captured by different cameras (where the detected results are normalized to canonical size). Note that images of subjects in various pose can be detected by our method. Note also that appearances of the same subject may change dramatically as viewed by different cameras, due to variation of lighting and response of CCD sensors.

Experimental results using the training set are shown in the second column of Table [4.1](#page-44-0) which lists the estimated probability $(p_{i\rightarrow j})$ with duration time $(t_{i\rightarrow j}, i.e., \frac{1}{\lambda_{i\rightarrow j}},$ same as in [\(3.21\)](#page-25-0)) in parenthesis of training phase, while the third column presents the corresponding ground truth values. The ground truth values are obtained by visually matching all the frames, and counting the frequency of how the objects move between states. Overall, these estimated probabilities and traveling time of our model match the ground truth values well. Compared with the ground truth, the average error for all state transition estimation is 0.0742 and the standard deviation is 0.09.

There are a few cases that our model does not estimate the state transition probabilities well. For example, from the ground truth data we know there is no subject moving from Z_{11} to Z_{11} , but the estimated probability of moving from Z_{11} to Z_{11} is 0.1884 with an average 27.24-second traveling time. This error results from false matching results, and this effect is expected to be negligible when a large dataset is used. Furthermore, as shown in Fig. [4.2,](#page-29-0) two adjacent cameras, C_2 and C_3 , have overlapped FOVs, and thus most subjects appearing region R_2 and R_3 are likely to be observed by both cameras. Instead of using the images acquired from one camera, it is likely to have fewer false matching by exploiting such additional cues.

4.2.7 Test Phase

We compare our parameter estimation results with the ground truth of test sequences which is obtained by visually inspecting the trajectories of all the subjects. The results of the test sequences are shown in the fourth column of Table [4.1.](#page-44-0) As evident in the table, our model is able to learn the transition probabilities well. The ground truth that we gather from the training set is assumed to be representative (which is assumed by almost all statistical learning frameworks) as long as the number of data points is sufficiently large. The estimated state transition probabilities and traveling time using the training set are consistency smaller than those using the test set. These results indicate that the learned model parameters do not overfit the training data.

4.3 Discussion

4.3.1 What Do The Results Indicate?

The results listed in Table [4.1](#page-44-0) matched well with our expectation. For example, for all the objects leaving from state Z_3 , there is high probability that they will enter Z_0 or Z_4 . Z_3 and Z_4 are connected by a corridor, along which are some offices and lab rooms. So people may enter this corridor from left (from Z_3) and just vanish into the room (some point between Z_3 and Z_4). Moreover, the dean's office is located at a room between Z_6 and Z_7 , which explains why people left Z_3 will enter Z_4 at high probability, as Z_4 and Z_6 are two states which must be passed from Z_3 to dean's office.

State transition	Training	Ground truth	Test
$p_{3\to 0} (t_{3\to 0})$	0.3263 (-)	$0.4(-)$	$0.3333(-)$

Table 4.1: Estimated model parameters and ground truth

Furthermore, by examining the transition probability at state Z_5 , more than half of the out-going objects will end up in state Z_{11} , i.e., people went downstairs to the entrance of the building. About $\frac{3}{10}$ of them will vanish to state Z_0 , that is because the stair also goes up to the third floor of the building.

Another observations is $p_{11\rightarrow 3} + p_{11\rightarrow 4} > p_{11\rightarrow 5}$, which means more people will take the elevator to the second floor than using stairways, although the former way cost much more time. And there are about $\frac{1}{4}$ of people will vanish from Z_{11} , this happens when people take elevator to the third floor of the building which we don't monitor.

4.3.2 Multi-detection Case

As described earlier, multiple subjects can be identified with HOG-based human detection algorithm. This is in contrast to prior works where tracking algorithms are used. One advantage of using HOG to aid feature extraction is that we could handle multidetection cases. During the training phase, there are some frames that more than one subject are detected in a frame or the bounding box coordinates in two consecutive frames are far from each other. Fig. [4.11](#page-46-0) show some mixed-detection examples. The background image is one selected frame of the sequence. The colored rectangles represent the bounding boxes of HOG detection result. In Fig. $4.11(a)$ $4.11(a)$, one subject remains to the right side of the view, another subject walks from left corner to right. In this sequence, their detected bounding boxes are not overlapped, although their detections are time-interleaved. It is obviously incorrect if we cluster all the detections in this sequence to one subject just based on the observation that they are time-continuous. Actually, in the case of Fig. [4.11\(](#page-46-0)a), we

Figure 4.11: Examples of mixed-detection in image sequences. The background image is one selected frame of the sequence. The colored rectangles represent the bounding boxes of HOG detection result. (a) The bounding boxes of two subjects are not overlapped. (b) The bounding boxes of two subjects are overlapped.

can still easily distinguish the detections to two clusters, as the bounding box are clustered.

In the sequence shown in Fig. $4.11(b)$, one subject first walks upstairs from first floor to third floor (the camera is placed on second floor), then another subject appears from the stair and walk towards right of the view. Although the detected bounding boxes are overlapped and time-interleaved, we can still make use of the direction cue, i.e., if the bounding box of the sequence is first moving leftwards, and suddenly appears to the right, then we cannot ensure that those frames belong to the same cluster. To verify it, we can perform a local feature matching, i.e., assume the turning point happens at time t , and we compute the distance between two parts of the detection (before and after t). If the distance is below a threshold, the two parts are classified as the same cluster, i.e., belonging to same subject.

4.3.3 Limitation and Future Work

In our framework, we assume that the camera motes are placed in a particular direction so that the full-body of people passing-by can be captured, which facilitates the HOG-based human detection algorithm we used. We have not evaluated the cases when the cameras have different viewing angels. For example, the cameras can be placed on the ceiling to have the top-down view of passing-by pedestrians. In this case, other human detection or background subtraction techniques can be used to extract human features.

In the human matching process, we define a time window with two thresholds $[th_{min}, th_{max}]$ in order to reduce the number of matching candidates. With small fixed value of th_{max} , our algorithm is not able to handle some cases where people stop to chat in the hallways. Our model will regard this case as two different subjects instead of one on the same path, but breaking in the middle. As the time spent on chatting is uncontrollable, if we want to consider this special case in our model, there will be many more matching candidates to choose from for each detected subject. While exponential distribution is most suitable for modeling traveling times, it is defined on the interval $[0, \infty)$. So using another model such as Beta distribution or some other bounded interval probability distribution may be a good option.

We assume that only a few subjects may appear in the scene at any time, thereby facilitating the matching process per frame. Our future work will consider cases where a crowd of people moving together with more advanced vision algorithms (to detect humans under occlusion) and additional prior knowledge.

Currently, the developed framework has not been deployed for real-time applica-

tions. Our future work will focus on the engineering issues including code optimization, sensor placement, bandwidth and data storage.

The dataset we use now contains relatively small number of subjects and sequences. With larger dataset, our estimated model parameters should be more accurate and reflect the real traffic pattern in the smart building. As a future work, we plan to carry out largescale experiments, e.g., analyzing the traffic patterns using the data collected throughout one day or one week.

Chapter 5

Conclusion

In this thesis, we propose a general framework for traffic modeling and prediction with Bayesian inference, where the transit probabilities between each pair of entry and exit points (states) are modeled by a multinomial distribution, and the traveling time durations between states are modeled by an exponential distribution. Subjects appearing in different pose are detected and matched via images acquired at different cameras, thereby facilitating estimation of the parameters in our model. We derive a maximum-likelihood estimator to the object association based on the observations. The proposed framework is validated with a camera sensor network in a smart building. With five cameras placed at intersection of stairways, elevators, and hallways, our experiments with more than 4,000 images show that the traffic patterns of dwellers can be modeled and predicted well with our model.
