This note compares published theoretical expressions¹⁻⁴ for the elastic moduli of two-phase systems with experimental results obtained for a sodium borosilicate glass containing dispersions of spherical tungsten particles. The glass used was of the same composition as the D-glass (16% Na₂O, 14% B₂O₃, 70% SiO₂) used in previous investigations.^{5,6} The techniques of specimen preparation and measurement of Young's modulus were identical to those employed for the D-glass containing angular dispersions of alumina.^{6*} Tungsten particle size was approximately 30 μ . Figure 1 shows the microstructure of a glass-tungsten composite containing 40 volume percent tungsten. Table I gives the experimental and theoretical results, which are also illustrated in Fig. 2. For the theoretical calculation, glass property values were taken as Young's modulus = 805 kilobars⁶ and Poisson's ratio = 0.197.⁵ Tungsten elastic properties were taken as Young's modulus = 3550 kilobars⁷ and shear modulus = 1481 kilobars.⁷ Young's modulus for the predictions of Kerner,¹ Hashin and Shtrikman,³ and Hashin² were calculated from the

corresponding equations for the bulk and shear modulus. Kerner's predictions coincided with Hashin's approximate equation for spherical phase geometry and Hashin and Shtrikman's lower bound for arbitrary phase geometry. Experimental results fall between Hashin's upper bound for spherical phase geometry and Hashin and Shtrikman's lower bound for arbitrary phase geometry, in agreement with theory. It is of interest to note here that similar results were obtained for the same glass containing angular dispersions of sapphire.⁶ It, therefore, appears that for this type of two-phase system, composed of a matrix containing random dispersions with Young's modulus higher than the matrix, dispersion shape, at least macroscopically, plays little or no role.
