## Foreword

This volume contains the final drafts of the papers and posters selected for presentation at the 22<sup>nd</sup> Annual Meeting of the Cognitive Science Society in Philadelphia, PA, August 13-15, 2000. A glance through the Table of Contents shows that this meeting reflects the eclectic and forward-looking character of Cognitive Science as it comes into its own at the turn of the Millennium. “CogSci2000” embodies a set of scholarly contributions that range from psychological and neuroscientific experimentation through computational modeling to philosophical musings about the foundations of the field. In our view, the coherence and range of these contributions characterize the emergence of Cognitive Science from the status of an interdisciplinary field to a full-blown discipline with its own formalisms, methods, techniques, and overarching goals: to find a computational theory of Intelligence.

Having just offered a description of cognitive science that has the smell of a definition, we hasten to back off from that designation: Hardly any scientific discipline, not even speaking of the humanistic ones, succumbs readily to such definition. We offer the phrase as one that suggests and encompasses many of the themes that underlie the specific research questions taken up in this collection and that recur elsewhere in the cognitive science literature.

Coherent as our field seems when described in one grand phrase, it is not easy to subdivide it into proper parts. Categorization is itself one of the most vexed unsolved issues in our field (and thus the topic of several sessions at this meeting). Yet as a matter of practicality, as the hosts of this conference, we were forced to try, if only to cobble together paper and poster sessions that would have maximum organization and minimal overlap, allowing the conference attendees to choose among parallel sessions with a minimum of handwringing and regret. We hope that the attendees will be satisfied that the sessions are productive, lively, informative, and, in general, a lot of fun.

We turn now to acknowledging and thanking the many people, groups, and institutions that made this conference as successful as it was.

The COGNITIVE SCIENCE SOCIETY BOARD, for inviting us to host CogSci2000 and for providing the framework, backup and advice from prior conference organizers.

The PROGRAM COMMITTEE that stewarded the review process, farming out the papers, personally reviewing many of them, nagging the reviewers until they sent their reports, and finally making their recommendations to us. There were 319 submissions requiring about 1000 reviews. 95 paper submissions (out of 248) and 130 posters were accepted. The poster presentations include those paper submissions that were converted to posters based on the recommendations of the program committee.

The VOLUNTEER REVIEWERS from the cogsci community who carried out the difficult task of reviewing quite wonderfully. This allowed us to provide at least two, in most cases three, reviews to each author whether or not the submission was accepted for presentation. Although these reviews were perforce short and sometimes there were partial mismatches between reviewer and reviewee, our impression is that the process – compressed into a few short weeks – worked very well. There were a few complaints, to be sure, so when appropriate we obtained yet more reviews at the last minute. We also received very many gratifying letters from authors both successful and unsuccessful expressing their overall satisfaction with the process.

Our POSTDOCTORAL FELLOWS and ADVANCED GRADUATE STUDENTS who were repeatedly pressed into service for a host of tasks.

TOBY MINTZ and IONE FINE for organizing the Tutorials, BONNIE WEBBER for the solicitation and selection of symposia, and MARK STEEDMAN for assembling the Panel on Education.

Our PROVOST ROBERT BARCHI for his useful opening welcome and remarks.

Our PLENARY SPEAKERS, JAMES ALLEN and RANDY GALLISTEL, for their talks which in addition to the scientific content set the intellectual tone for these meetings.

Our very special thanks go to TRISHA YANNUZZI who in essence “is” CogSci2000 from the beginning to the end in all administrative aspects including the automation of the very efficient and smoothly run submission and review process. We wish we had the wordsmithery to express our gratitude to her, but we must settle for a resounding and heartfelt THANK YOU to TRISHA and to her small, but incredibly efficient staff, ANN BIES, LAUREL SWEENEY, JENNIFER MACDOUGALL, NICOLE BOLDEN and LEE LEIBER (IRCS Technical Staff).

For financial support: NATIONAL INSTITUTES OF HEALTH, MICROSOFT CORPORATION, the COGNITIVE SCIENCE SOCIETY, and the INSTITUTE FOR RESEARCH IN COGNITIVE SCIENCE at the UNIVERSITY OF PENNSYLVANIA.

And, of course, the AUTHORS of paper and poster submissions without whom there would be no CogSci2000. We thank them and applaud them for their efforts in the preparation of these submissions and placing them before their peers, thereby furthering knowledge in the field of Cognitive Science and inspiring its practitioners – certainly including us.

Welcome to CogSci2000!

Lila Gleitman and Aravind Joshi

## Table of Contents

Foreword from the Conference Co-Chairs.....	iii
Conference Page.....	xvi
Cognitive Science Society.....	xvii
Tutorial Program.....	xviii
Symposia.....	xix
Special Session on Undergraduate Education in Cognitive Science.....	xx
Reviewers for the Twenty-Second Annual Conference.....	xxi

### Invited Speakers

<i>Spoken Language Systems and Human Communication</i>	
James F. Allen.....	1
<i>The Symbolic Foundations of Conditioned Behavior</i>	
Randy Gallistel.....	1

### Education Panel

<i>Special Session on Undergraduate Education in Cognitive Science</i>	
Mark Steedman.....	2

### Symposia

<i>Perspectives on Conceptual Change</i>	
David Kaufman.....	5
<i>The Role of the Cerebellum in Cognition and Affect</i>	
Natika Newton.....	10
<i>Bayesian Approaches to Cognitive Modeling</i>	
Michael C. Mozer and Joshua Tenenbaum.....	16
<i>The Nature of Human Errors: An Emerging Interdisciplinary Perspective</i>	
Jiajie Zhang.....	17

### Papers

<i>Induction of Causal Chains</i>	
Woo-kyoung Ahn and Martin J. Dennis.....	19
<i>Evaluating the Effectiveness of a Cognitive Tutor for Fundamental Physics Concepts</i>	
Patricia L. Albacete and Kurt A. VanLehn.....	25
<i>Memory in Chains: Modeling Primacy and Recency Effects in Memory for Order</i>	
Erik M. Altmann.....	31
<i>Computational Explorations of the Irrelevant Sound Effect in Serial Short-Term Memory</i>	
C. Philip Beaman.....	37
<i>Sex, Syntax, and Semantics</i>	
Lera Boroditsky and Lauren A. Schmidt.....	42
<i>In Search of the Minority Default: The Case of Arabic Plurals</i>	
Sami Boudelaa and M. Gareth Gaskell.....	48
<i>Representing Categories in Artificial Neural Networks Using Perceptually-Derived Feature Networks</i>	
Robert B. Branstrom.....	54
<i>A Sensorimotor Map of Visual Space</i>	
Bruce Bridgeman.....	60

<i>Unity of Consciousness: What it is and Where it is Found</i>	
Andrew Brook.....	65
<i>Are Retrievals from Long-Term Memory Interruptible?</i>	
Michael D. Byrne.....	71
<i>Hemispheric Specialization During Episodic Memory Encoding in the Human Hippocampus and MTL</i>	
Daniel J. Casasanto, William D. S. Killgore, Guila Glosser, Joseph A. Maldjian, and John A. Detre.....	77
<i>A Connectionist Single-Mechanism Account of Rule-Like Behavior in Infancy</i>	
Morten H. Christiansen, Christopher M. Conway, and Suzanne Curtin.....	83
<i>Committing to an Ontology: A Connectionist Account</i>	
Eliana Colunga and Linda B. Smith.....	89
<i>An Exemplar Model of Classification in Single and Combined Categories</i>	
Fintan Costello.....	95
<i>A Six-Unit Network is All You Need to Discover Happiness</i>	
Matthew N. Dailey, Garrison W. Cottrell, and Ralph Adolphs.....	101
<i>Addressing the Learnability of Verb Subcategorizations with Bayesian Inference</i>	
Mike Dowman.....	107
<i>Hidden Markov Models for Coding Story Recall Data</i>	
Michael A. Durbin, Jason Earwood, and Richard M. Golden.....	113
<i>A Rarity Heuristic for Hypothesis Testing</i>	
Aidan Feeney, Jonathan St. B. T. Evans, and Simon Venn.....	119
<i>Modeling Orientation Effects in Symmetry Detection: The Role of Visual Structure</i>	
Ronald W. Ferguson.....	125
<i>Visual Learning for a Mid Level Pattern Discrimination Task</i>	
I. Fine and Robert A. Jacobs.....	131
<i>Decoding Syntactic Parameters: The Superparser as Oracle</i>	
Janet Dean Fodor and Virginia Teller.....	136
<i>Lexical Contact During Speech Perception: A Connectionist Model</i>	
Eric Forbell and Eric Chown.....	142
<i>The Resemblance of One-Year-Old Infants to their Fathers: Refuting Christenfeld &amp; Hill (1995)</i>	
Robert M. French, Serge Brédart, Johanne Huart, and Christophe Labiouse.....	148
<i>Memory versus Perceptual-Motor Tradeoffs in a Blocks World Task</i>	
Wai-Tat Fu and Wayne D. Gray.....	154
<i>Babies, Variables, and Relational Correlations</i>	
Michael Gasser and Eliana Colunga.....	160
<i>Resource-Adaptive Selection of Strategies in Learning from Worked-Out Examples</i>	
Peter Gerjets, Katharina Scheiter, and Werner H. Tack.....	166

# Twenty-Second Annual Conference of the Cognitive Science Society

August 13-15, 2000

Institute for Research in Cognitive Science

University of Pennsylvania

Philadelphia, PA

## Conference Co-Chairs

Lila Gleitman, University of Pennsylvania

Aravind Joshi, University of Pennsylvania

## Conference Program Committee

Norm Badler, University of Pennsylvania  
Mark Baker, Rutgers University  
Gene Buckley, University of Pennsylvania  
Paul G. Chapin, National Science Foundation  
Robin Clark, University of Pennsylvania  
Veronica Dahl, Simon Fraser University  
Kostas Daniilidis, University of Pennsylvania  
Susan Epstein, Hunter College and the City  
University of New York  
Martha Farah, University of Pennsylvania  
Gilles Fauconnier, University of California, San  
Diego  
Kenneth D. Forbus, Northwestern University  
Bob Frank, Johns Hopkins University  
Randy Gallistel, University of California, Los  
Angeles  
Rochel Gelman, University of California, Los  
Angeles  
Dedre Gentner, Northwestern University  
Geoff Hall, University of British Columbia  
Gary Hatfield, University of Pennsylvania  
Frank Keil, Yale University  
Phil Kellman, University of California, Los  
Angeles  
Michael Kelly, University of Pennsylvania  
David Knill, University of Rochester  
Tony Kroch, University of Pennsylvania  
Barbara Landau, University of Delaware

David Lebeaux, NEC Research Institute  
Mitch Marcus, University of Pennsylvania  
Dimitris Metaxas, University of Pennsylvania  
Johanna Moore, University of Pittsburgh  
Rolf Noyer, University of Pennsylvania  
Martha Palmer, University of Pennsylvania  
Ellen F. Prince, University of Pennsylvania  
Zenon Pylyshyn, Rutgers University  
Owen Rambow, ATT Labs - Research  
Daniel Reisberg, Reed College  
Virginia Richards, University of Pennsylvania  
Whitman Richards, Massachusetts Institute of  
Technology  
Don Ringe, University of Pennsylvania  
Maria-Isabel Romero, University of  
Pennsylvania  
Paul Smolensky, Johns Hopkins University  
Matthew Stone, Rutgers University  
Gary Strong, NSF and DARPA  
Michael K. Tanenhaus, University of Rochester  
Paul Thagard, University of Waterloo  
Sharon L. Thompson-Schill, University of  
Pennsylvania  
John Trueswell, University of Pennsylvania  
Sandra R. Waxman, Northwestern University  
Bonnie Webber, University of Edinburgh  
Janet Werker, University of British Columbia  
Fei Xu, Northeastern University

## Conference Staff

Ann Bies, Nicole Bolden, Lee Leiber, Jennifer MacDougall, Laurel Sweeney, Trisha Yannuzzi

## 2000 Marr Prize

Eliana Colunga and Linda B. Smith, Indiana University  
*Committing to an Ontology: A Connectionist Account*

This conference was supported by the Cognitive Science Society, the National Institutes of Health, Microsoft Corporation, and the Institute for Research in Cognitive Science at the University of Pennsylvania.

# **The Cognitive Science Society**

## **Governing Board**

Jeffrey Elman, University of California at San Diego, La Jolla  
Vimla Patel, McGill University  
Susan L. Epstein, Hunter College and the City University of New York  
Kim Plunkett, Oxford University  
Martha Farah, Univ. of Pennsylvania  
Lawrence W. Barsalou, Emory University  
Paul Thagard, University of Waterloo  
Alan Lesgold, University of Pittsburgh  
Kenneth D. Forbus, Northwestern University  
Dedre Gentner, Northwestern University  
Douglas L. Medin, Northwestern University  
Michael Mozer, University of Colorado, Boulder  
Keith Stenning, Edinburgh University

## **Chair of the Governing Board**

Jeffrey Elman, University of California at San Diego, La Jolla

## **Chair Elect**

Lawrence W. Barsalou, Emory University

## **Journal Editor**

James G. Greeno, Stanford University

## **Executive Officer**

Colleen Seifert, University of Michigan

The Cognitive Science Society, Inc., was founded in 1979 to promote interchange across traditional disciplinary lines among researchers investigating the human mind. The Society sponsors an annual meeting, and publishes the journal *Cognitive Science*. Membership in the Society requires a doctoral degree in a related discipline (or equivalent research experience); graduate and undergraduate students are eligible for a reduced rate membership; and all are welcome to join the society as affiliate members. For more information, please contact the society office or see their web page at <http://www.umich.edu/~cogsci>

Cognitive Science Society, Univ. of Michigan, 525 East University, Ann Arbor, MI, 48109-1109; [cogsci@umich.edu](mailto:cogsci@umich.edu); phone and fax: (734) 429-4286.

# **Tutorial Program**

August 11-12, 2000

## **The Two Visual Systems and their Interactions**

Bruce Bridgeman, University of California, Santa Cruz

## **An introduction to the COGENT Cognitive Modelling Environment**

Dr. Richard Cooper, Birkbeck College, England

## **Cognitive Modeling and Simulation in Real-Time/Multi-tasking Domains Using the COGNET Framework**

Wayne Zachary, CHI Systems

## **Cognitive Neuroscience for Cognitive Scientists**

Martha Farah, University of Pennsylvania

## **Cognitive Science and Education: Creating, Implementing, and Funding Collaborations to Build a Cognitive Science Foundation for Teaching and Learning**

Christine Massey, IRCS, University of Pennsylvania

## **Tutorial Program Committee Co-Chairs**

Toben Mintz, University of Southern California

Ione Fine, Salk Institute for Biological Studies

## **Symposia**

### **Perspectives on Conceptual Change**

David Kaufman, University of California, Berkeley

### **The Nature of Human Errors**

Jiajie Zhang, University of Texas, Houston

### **The Role of the Cerebellum in Cognition and Affect**

Natika Newton, Nassau Community College

### **Bayesian Approaches to Cognitive Modeling**

Michael C. Mozer, University of Colorado at Boulder and  
Joshua Tenenbaum, Stanford University

### **Symposia Chair**

Bonnie Webber, University of Edinburgh

## **Special Session on Undergraduate Education in Cognitive Science**

Cognitive Science presents unique opportunities and problems as a component of the undergraduate curriculum. The opportunity is to provide a view of natural and artificial minds that is relevant to a wide range of careers in research, technology and the professions. The problem is to present this material in a form that coheres as a subject, and to ensure sufficient background to teach it in sufficient depth. The symposium presents a series of short lectures by distinguished educators and researchers from Europe and North America who will explore recent developments and future directions for the subject.

Among those participating are:

Andrew Brook, Carleton University  
Nils Dahlback, Linköping University  
Randy Jones, Colby College  
Keith Stenning, University of Edinburgh  
John C. Trueswell, University of Pennsylvania

### **Special Session Chair**

Mark Steedman, University of Edinburgh

## Reviewers for the Twenty-Second Annual Conference of the Cognitive Science Society

Agnar Aamodt	Mei Chen	Wayne D. Gray
Adele Abrahamsen	Sonu Chopra-Khullar	Prahlad Gupta
Woo-Kyoung Ahn	James Chumbley	Karl Haberlandt
Isabel Albers	Timothy C. Clausner	Udo Hahn
Martha W. Alibali	Catherine A. Clement	Koichiro Hajiri
Jan Allbeck	Charles Clifton	James Hampton
Amit Almor	Marc Cohen	Mary L. Hare
Erik M. Altmann	Phil Cohen	Trevor A. Harley
Jorge Alvoeiro	Fred Conrad	Catherine L. Harris
Mike Anderson	Andrew Conway	Nancy Hedberg

## **Invited Speakers**

### **Spoken Language Systems and Human Communication**

James F. Allen, University of Rochester

A conversational agent is a system that can engage in natural language conversation in order to further its goals. Such a system requires a concerted effort to bring work in natural language understanding, dialog modeling, knowledge representation and reasoning into a single coherent system. The TRIPS system is a specific agent that can support unconstrained dialogue in order to assist the user in problem solving tasks. Significant effort has been made to make the system robust, so that it can perform well even in the face of inevitable speech recognition errors, and can continue the dialogue in a natural way under any circumstances. This talk will discuss the overall project and its accomplishments so far, and then focus on a few specific mechanisms that enable robust interaction. It will also review some recent evidence on the nature of human language comprehension and discuss the implications of this work for future dialogue systems.

### **The Symbolic Foundations of Conditioned Behavior**

Randy Gallistel, University of California, Los Angeles

The concept of associative learning has been central to psychology for more than a century. In the 60s and 70s, the associative conception of mind was challenged by the rise of the information processing approach, which emphasizes the construction of a symbolic representation of experience by means of computational operations. This latter conception has come to dominate thinking about sensory processing and perception at both the psychophysical and the neurobiological levels of analysis, but it has remained largely alien to our thinking about learning and memory. Conditioning paradigms – Pavlovian and operant conditioning protocols – were created in order to establish the laws of association formation, and it is widely assumed that the results of conditioning studies are in fact explainable on associative grounds. However, long neglected quantitative features of the data from conditioning experiments pose strong challenges to fundamental assumptions, such as that temporal pairing is a sine qua non for association formation or that reinforcement strengthens and non-reinforcement weakens associations. These assumptions are central not only to associative theories of conditioned behavior but also to connectionist models of behavioral processes and to efforts by neuroscientists to determine the cellular and molecular bases of learning and memory. The findings that challenge associative assumptions are readily explained by information processing theories of conditioning in which subjects measure and record intervals, estimate conditional rates of occurrence, and make decisions based on noisy decision variables computed from these remembered estimates. The success of information processing models on the home ground of associative models suggests that the brain is truly a symbol processing organ, whose operation must be understood in information processing terms.

## **Special Session on Undergraduate Education in Cognitive Science**

Cognitive Science presents unique opportunities and problems as a component of the undergraduate curriculum. The opportunity is to provide a view of natural and artificial minds that is relevant to a wide range of careers in research, technology and the professions. The problem is to present this material in a form that coheres as a subject, and to ensure sufficient background to teach it in sufficient depth. The symposium presents a series of short lectures by distinguished educators and researchers from Europe and North America who will explore recent developments and future directions for the subject.

### **Chair**

Mark Steedman, University of Edinburgh

### **Abstracts**

#### **The Cognitive Science Programme at Carleton University**

Andrew Brook, Carleton University

Carleton University in Ottawa offers free-standing, fully-integrated Cognitive Science programmes at both the undergraduate and the doctoral level. The undergraduate programme was recently reviewed by two senior Canadian cognitive researchers. Some of their findings and recommendations might be of interest to other cognitive science educators. In this presentation, I will describe some of the strengths and weaknesses of both our programmes, summarize some of the key findings and recommendations about the undergraduate programme, and discuss the implications of the latter.

#### **The Three Cultures of Cognitive Science**

Nils Dahlback, Linköping University

When designing an educational program for cognitive science, it is important to base this on some coherent view of the field. If not, there is a risk that the students are presented with a haphazard selection of courses that is more a reflection of the interests of the current available faculty than anything else. Lacking an integrative framework, it will be difficult for the students to relate the different topics and perspectives presented to each other, and it will be difficult for prospective employers in both industry and academia to know which competence the students bring with them. In this talk, an alternative view of cognitive science as neither one unified cognitive science nor just a multidisciplinary field of a number of sciences (psychology, AI, linguistics, philosophy, neuroscience, etc.) is presented. It is argued that cognitive science is best described as a matrix of two dimensions, a content or domain dimension (e.g., language, problem solving etc., and subsets of these) and a methods dimension, comprising three basic approaches to research: empirical, formal, and model building. The latter are seen not only as methods per se, but rather as scientific 'cultures,' carriers of differing explicit and implicit views of what constitutes 'good research.' Since cultural knowledge to a large extent can be acquired only by 'living' in the culture, the Linköping Cognitive Science Master's program is built on the assumption that the students should early in their studies learn all three scientific traditions, both the theoretical and methodological aspects, on an equal footing, before specializing in a particular sub-field. The talk presents the 'three cultures' view of cognitive science, how this has influenced the general design of the program, and describes theoretical and applied courses which illustrate our approach to supporting the students acquiring their own perspective of a multicultural but still unified field of cognitive science.

## **Using Project Work in Teaching Cognitive Science**

Randy Jones, Colby College

In recent years I have developed and taught introductory undergraduate courses in cognitive science and artificial intelligence, as well as one graduate-level course on cognitive science. In developing my courses, I have strongly subscribed to a proposition that I assume most of us (as teachers and cognitive scientists) believe: an effective form of education requires students to participate actively in constructive projects that exercise the material they are learning in class. This presentation describes a set of class projects I have developed, in the hopes that others will find them useful in teaching courses on cognitive science. Some of the projects are directly applicable to a cognitive science course. Others I have developed for a course on artificial intelligence, but would also be appropriate for cognitive science, depending on the emphasis of the course. Among other topics, the projects include study of knowledge representation, learning, production systems, cognitive modeling, and interactive systems. Project descriptions and executable code are available on-line at <http://www.cs.colby.edu/~rjones/courses/cs397/projects/> and <http://www.cs.colby.edu/~rjones/courses/cs353/projects/>.

## **Teaching Multiple Disciplinary Perspectives: A First Year Course in Cognitive Science**

Keith Stenning, University of Edinburgh

First year Edinburgh undergraduate students arrive knowing little of AI, computer science, linguistics, logic, philosophy, psychology – the component disciplines of cognitive science. They don't even know whether these component disciplines are of interest to them. For the last four years we have been teaching a half-year course on Human Communication which is designed to give students from all departments in the university a grasp of what cognitive science is, and how the component disciplines contribute to it. This talk will describe some of our experiences. Are we best teaching single disciplines first, and integrating only after? Or is it better to start by treating disciplines as merely perspectives on a common subject matter?

## **Cognitive Science Education at Penn and the Undergraduate Summer Workshop**

John C. Trueswell

In this talk, I will try to convey the flavor of cognitive science education from the perspective of the group at the University of Pennsylvania. Over the years, Penn has maintained a loose federation approach to cognitive science, in the sense that the departments that make up the participating subdisciplines of cognitive science have used the Institute for Research in Cognitive Science (IRCS) as a gathering place and intellectual-exchange center, but also as a catalyst for interdisciplinary course offerings at the undergraduate and graduate level. I'll discuss the pros and cons of such an educational system, and emphasize how it leaves open the definition of cognitive science, recognizing the current dynamics of the field. As an illustration of this, I will focus on a recent educational initiative stemming from IRCS: The Undergraduate Summer Workshop in Cognitive Science and Cognitive Neuroscience. Each year, IRCS brings together a select group of undergraduate students from around the world who are interested in pursuing graduate work within some area of cognitive science or cognitive neuroscience. The workshop provides students with an intense two-week introduction to Penn's perspective on these emerging disciplines. Penn faculty offer day-long seminars and labs in their area of specialization, permitting in depth discussion of a particular research topic. Each week ends with a panel discussion by the faculty, relating the topics of that week, and providing spontaneous discussion of where the field of cognitive science might be headed in the coming years. By acknowledging and educating students that cognitive science is still an ill-defined rapidly changing field, we stimulate students to learn more about cognitive science, and entice them to contribute to its development and definition.

## **Paul Thagard**

Philosophy Department  
University of Waterloo: Waterloo, Ontario, N2L 3G1  
email: pthagard@watarts.uwaterloo.ca

## **Introduction**

Humans possess remarkably rich and adaptive conceptual knowledge systems that enable them to form relatively stable representations about the world, perceive coherence amidst noise and chaos, and communicate elaborate explanations to others who see the world in strikingly similar ways. On the other hand, knowledge can sometimes be surprisingly brittle and context-bound, coherence may be more illusory than real, and individuals (e.g., teachers and students) may repeatedly fail to achieve common ground during routine discourse. How can we account for such apparent contradictions? Conceptual change names a family of theories, methodological approaches, and research traditions concerned with the origin, ontogenesis, and evolution of knowledge systems as a result of formal and informal learning. Conceptual change is the subject of considerable research across all of the cognitive sciences. In particular, it is central to investigations in the philosophy of science, cognitive development, and science education.

The speakers in this symposium will address issues in conceptual changes as they pertain to children, students learning science, lay adults, and practicing scientists. They will consider philosophical, developmental, computational, and instructional issues related to the characterization of systematicity and coherence in scientific explanation. The participants will offer distinct and sometimes divergent points of view on conceptual change with particular

attention to the reasons and mechanisms that produce systematicity and coherence (and alternatively incoherence) within and across individuals in generating scientific explanations. The speakers will address a range of related questions, including the following:

1. How can we characterize the state of knowledge structures prior to formal learning? What happens to students' knowledge when it makes contact with formal learning?
2. What are the knowledge elements that undergo change in conceptual change (e.g., beliefs, theories, schemata, propositions, and coordination classes)? What constitutes evidence for such changes?
3. What are "common" or "typical" trajectories in conceptual development (e.g., from atheoretical to theoretical, incoherent to increasingly coherent)? How can we account for periods of stability and instability in the generation of scientific explanations?
4. What are the mechanisms of change (e.g., differentiation, belief revision, enrichment, conceptual combination, re-organization and reprioritization of knowledge elements)?

5. What factors or criteria contribute to the acceptability, plausibility, and overall appraisal of scientific explanations in children, lay people, and scientists?
6. How can we expand the scope of conceptual change research to incorporate emotional and motivational variables?

Research in the philosophy of science, cognitive development, and science learning has several interesting points of convergence, despite the fact that they constitute different research programs. Philosophy of science is a discipline devoted to analyzing the character of scientific investigations (Bechtel, 1988). It endeavors to answer questions such as what constitutes a valid scientific explanation and how do scientific theories change over time. Conceptual development research is devoted to the study of age-related transitions in domain-specific (e.g., physics, biology) understandings. Conceptual change investigations in science education focus on a) characterizing transformations in learners that (with varying success) result in transformations in understanding of scientific phenomena and b) promoting instructional situations that increase the likelihood of robust and generative understanding.

Each of these disciplines is focally concerned with changes in knowledge systems that go well beyond mere knowledge accretion or belief revision. There is general agreement that conceptual change necessitates a substantial reorganization of knowledge. The history and philosophy of science (HPS) has had an enormous influence on both cognitive development and science education research (Brewer, Chinn, & Samarapungavan, 1998). HPS has provided an explanatory vocabulary for characterizing changes in scientific understanding and criteria for evaluating the quality of explanations. It has also served to highlight the fundamental commonalities underlying the conceptual change process and has led to some strong claims about the deep structural similarities between children (or naïve students) and practicing scientists. Clearly, not every theorist views the “scientist as child” metaphor as equally illuminating. In fact, each of the participants in this symposium has been critical of this perspective. Nevertheless, this point of view serves to introduce some important distinctions about the “theoretical character” of conceptual learning.

Theory theory proponents claim that there are deep similarities between scientists and children in the formation of theories (e.g., Gopnik & Wellman, 1994). Children’s naïve theories embody causal notions, enable distinct types of interpretations, explanations, and predictions, and are similarly subject to processes of modification and revision as the evidence dictates. The process of conceptual change in children is very similar in character to the process of theory revision in science. Vosniadou (1994) views conceptual

change in children and science students as differing substantially in character from scientific theory change in that children lack systematicity, abstractness, and metaconceptual awareness (i.e., understanding the hypothetical nature of their beliefs). She proposes the notion of framework theories, which consists of basic presuppositions about the way the world works and serves to constrain the acquisition of science concepts. These framework theories guide children’s interpretation of scientific phenomena and enable them to generate scientific explanations and predictions in a reasonably consistent fashion (Ioannides & Vosniadou, submitted). These “theories” are continuously enriched, differentiated, and revised as children encounter new information. However, when framework theories come into contact with formal science instruction, fragmentation, incoherencies, and misconceptions are often the result.

diSessa (1993) begins with the premise that naïve understandings of the physical world constitute a rich, complex, and diverse knowledge system. However, the system as a whole is only weakly organized and students’ intuitive scientific understandings are often a fragmented, loosely connected, collection of ideas, having none of the commitment or systematicity attributable to theories. The elements of knowledge called “p-prims” reflect minimal abstractions from common experience. Through learning and instruction, p-prims get tuned to newer contexts, refined, and reprioritized as the knowledge system is reorganized. They become supplanted in many contexts by more complex explicit knowledge structures that include physical laws. However, p-prims continue to exert substantial influence even in the reasoning of experts. Growth in scientific understanding involves a major structural change toward systematicity. Recently, diSessa and Sherin (1998) introduced the notion of coordination class, which involve systematically connected ways of gaining information from the world. Coordination classes include strategies of selective attention and systematic integration of observations.

In characterizing the nature of change in the history of science, Thagard (1992) identifies degrees of conceptual reorganization, ranging from belief revision to wholesale changes in the organizing principles underlying a conceptual system. For example, Darwin’s theory of natural selection redefined the classification of organisms according to historical lineage rather than feature similarity. The theory of explanatory coherence (instantiated in a connectionist model, ECHO) is integral to understanding the differential evaluation of competing hypotheses for best explanation and more generally, the process of conceptual change/theory adoption in science. The theory provides a set of principles (e.g., symmetry, simplicity, and data priority) that establish relations of coherence and incoherence between propositions. Thagard has used the theory of explanatory coherence, as instantiated in ECHO, to model numerous theoretical

disputes in the history of science. Thagard (1992) also considered whether conceptual change is similar in scientists and children. His analysis of the kinds of epistemic changes and process of “theory revision” reported in the developmental literature suggests that they are not typically characteristic of the kinds of dramatic changes evidenced in scientific conceptual revolutions. Thagard has also considered how other forms of coherence such as analogical, deliberative, and most recently, emotional coherence affect argumentation and theory change (in press).

## **Conceptual Change in Science Learning: From Coherence to Fragmentation**

Stella Vosniadou

Accounts of the knowledge acquisition process have customarily assumed that knowledge acquisition proceeds in a continuous manner enriching initially fragmented conceptual structures and making them increasingly more systematic, and more coherent. In this paper I will try to develop a different point of view based on a series of empirical studies investigating the development of science concepts. More specifically, the following arguments will be made with respect to a) the nature of children’s initial conceptual structures and b) the process of conceptual change.

*Initial conceptual structures:* There is considerable agreement in the cognitive science and science education literature that by the time children go to school they have acquired considerable knowledge about the physical world (an intuitive physics) that exerts considerable influence on subsequent learning and particularly on learning science. Researchers disagree, however, on the exact nature of such an intuitive physics. One view, expressed by diSessa (1988) is that initial knowledge structures about the physical world consist of an unstructured collection of small knowledge elements, which he calls phenomenological primitives (p-prims). These pieces of knowledge are generated as abstractions of common phenomena and are activated in certain characteristic cases. According to this view the process of conceptual change is one of collecting and systematizing the fragments of knowledge into consistent wholes. This happens as p-prims change their function in order to be integrated into the scientific framework.

Unlike the above view of knowledge acquisition, a number of empirical studies investigating the process of knowledge acquisition in science conducted in our lab, show that preschool children answer questions about force, matter, heat, the earth, etc., in a relatively consistent way, revealing the operation of a common explanatory framework

(Vosniadou & Brewer, 1992; 1994; Ioannides & Vosniadou, 1991; submitted). These results are consistent with research on conceptual development in infancy showing that the process of knowledge acquisition starts immediately after birth and proceeds in an orderly fashion towards the construction of an initial framework theory of physics that allows children to function adequately in the physical environment. The term theory is used here to denote a causal, relational explanatory structure and not an explicit, well formed and socially shared scientific theory. In other words, the empirical results support the hypothesis that children’s initial conceptual structures are not as fragmented as initially thought, but rather, children start the knowledge acquisition process by forming rather narrow but nevertheless internally consistent explanatory frameworks.

*The process of conceptual change:* The results of the empirical studies mentioned above show that the process of conceptual change is a slow and gradual affair that happens over a long period of time. During this process, we do not observe a change from fragmentation to increased coherence. Rather, the initial explanatory structures become more fragmented as aspects of the scientific theory are assimilated into the framework theory either creating synthetic models (which are internally consistent but scientifically wrong) or internally inconsistent structures.

In order to better understand the debate regarding coherence vs. fragmentation we should take into consideration the fact that most of the studies that support the argument that knowledge of physics’ concepts consists of “disconnected knowledge fragments” (see also Reif & Allen, 1989), are studies of older students (either college students or late high school students). On the contrary the arguments that support the coherence to fragmentation view (e.g., Vosniadou, 1994) are based on experimental evidence coming from younger children. The argument advanced here is that both of the experimental findings are correct, but that the fragmentation observed in older children and naïve adults represents a change from initial coherence to fragmentation. This is the case because a) initial conceptual structures are much more cohesive than originally thought, and b) because science instruction proceeds by fragmenting initial explanatory frameworks without succeeding in building an alternative cohesive scientific explanatory framework. Although increased fragmentation appears to be the common result of much science instruction, the process of knowledge acquisition does not stop there. The students that proceed to become experts acquire increasingly less fragmented and more cohesive science concepts.

## A Complex Adaptive Systems View of Conceptual Change

Andrea A. diSessa

Although it seems largely unacknowledged in the conceptual change community, there is a huge diversity of views about basic issues in conceptual change. Even the seemingly innocuous question “what changes in conceptual change (and what does not)?” leads to a plethora of views invoking not obviously commensurable explanatory constructs such as concepts, beliefs, models, ontologies, ontological commitments, nodes and links, schemata, and so on. One of the major fault lines in the community concerns whether conceptual change is *localizable* (e.g., in a few discrete entities, such as concepts), or whether, in contrast, it is more appropriate to think of conceptual change as emergent within a *complex system*, implicating many types of mental entities and many possible configurations. Localizability will be the focal issue of this talk.

I propose to explain and advocate the “complex adaptive systems view” (CASV) of conceptual change beginning by motivating the CASV approach methodologically. If we are to settle issues such as the localizability of conceptual change, it is imperative that we announce and debate standards for explanation within this research area. I put forward a beginning set of standards:

- Theoretical accountability — Accounts of conceptual change should employ technically well-developed explanatory constructs (e.g., concept, ontology, etc.). Dictionary definitions don’t come close to the level of specificity one needs in scientific accounts of cognitive development. At a minimum, an appropriately developed explanatory construct should allow distinguishing, in principle, between instances and non-instances of such a construct. One should expect, sooner or later, that accounts of such constructs include specification of the processes of normal deployment the construct and processes of change.
- Empirical accountability — Although a wide range of empirical methods are appropriate for studying conceptual change, we may still hold some general principles. In particular: (a) we should expect empirical work to include, in some measure, process data that can confirm or disconfirm assumptions about theoretical entities and processes hypothesized to be involved in conceptual use and conceptual change; (b) we should expect sufficient breadth of experimentation to allow limits of contextual dependence of both the construct involved and particular instances of the construct. Both (a) and (b) are plausible general accountabilities. The

vast majority of conceptual change studies collect no process data, and (b), *contextuality*, is particularly important in settling localizability questions.

I will exemplify these principles in two ways: First, I will introduce some particulars of my own CASV approach, including (a) two claimed-to-be well-rationalized explanatory constructs, *p-prims* (diSessa, 1993) and *coordination classes* (diSessa & Sherin, 1998), and (b) examples of process and other data that support theoretical claims and entailments. P-prims constitute a large class of simple “intuitive” schemata, and most directly limit claims of localizability in conceptual change. A coordination class is a model of a large-scale knowledge system constituting (a step toward) a technically precise and cogent definition of a particular class of concepts. Coordination classes define a number of obvious partial constructions of a full “concept,” which, once again, provides opportunities to examine localizability of conceptual development empirically.

Finally, I will enter into an abbreviated “competitive argumentation” comparing the success of this version of CASV with excellent recent work by Vosniadou and Ioannides (Ioannides & Vosniadou, submitted) studying the same conceptual terrain, mechanics—work that is, however, open to criticisms on the basis of the above principles. In particular, we have recently begun to gather and analyze data to bridge age-of-subjects and other methodological differences that has, so far, kept comparisons from being as compelling as they might be. We are gathering data over the same age ranges as Vosniadou and Ioannides, using similar methods, but with a slightly more open protocol to allow better contextuality analysis and some relevant process data. By the time of the conference, we should have preliminary results that bear directly on the cogency of Vosniadou’s theoretical frame, and, in particular, on the localizability of conceptual change concerning the concept “force.”

## Emotional Coherence in Scientific Explanation and Conceptual Change

Paul Thagard

Scientists are supposed to be dispassionately rational, but they are as emotional as other people. Theories are not only accepted or rejected: sometimes they are loved or hated. Good theories are often praised for their beauty and elegance, while bad theories are sometimes derided as ugly or crazy. This talk will interpret the cognitive-emotional judgments of scientists in terms of a recently developed theory of emotional coherence (Thagard, in press). My earlier work used a computational model of explanatory coherence to explain the acceptance and rejection of hypotheses on the

basis of the degree to which they satisfy a set of constraints defined in terms of explanation and evidence (Thagard, 1992). In line with much recent research in psychology and neuroscience on the ubiquity of emotions in cognition, my new model incorporates emotion into coherence computations and shows how emotional judgments can emerge from explanatory and other kinds of inference. The diversity and intensity of reactions to controversial theories such as evolution by natural selection can be explained by the theory of emotional coherence. Theory change is in part a matter of emotional change, as scientists shift their emotional attitudes toward hypotheses from positive to negative and vice versa. For example, in recent years most gastroenterologists have shifted their attitudes concerning the bacterial theory of ulcers from feeling it was ridiculous to viewing it as powerful and exciting (Thagard, 1999).

Conceptual change is also an emotional as well as a cognitive process. Concepts are mental representations corresponding to words, whereas propositions are mental representations corresponding to sentences. Both kinds of mental representations usually have emotional valences attached to them. For example, the valence of "baby" is typically positive, and the valence of "garbage" is typically negative. Conceptual change is emotional change when it involves a shift in valence from positive to negative or vice versa. In the Darwinian revolution, for example, many people shifted the valence attached to "evolution" from negative to positive. I will describe how the theory of emotional coherence can account for this aspect of conceptual change.

# THE FUNCTION OF THE CEREBELLUM IN COGNITION, AFFECT AND CONSCIOUSNESS: EMPIRICAL SUPPORT FOR THE EMBODIED MIND

## Introduction

Natika Newton (nnewton@suffolk.lib.ny.us)

Department of Philosophy  
Nassau Community College  
Garden City, NY 11530

A growing movement in cognitive science views consciousness and cognition as self-organizing systems involving emotion and sensory-motor agency (e.g. Damasio 1994, 1999; Clark 1996; Glenberg, 1997; Hurley 1998). The view that cognition is best understood as *embodied* is replacing models involving amodal symbol systems like the arbitrary, intrinsically meaningless symbols of computer programs, which notoriously fail to explain common-sense reasoning and consciousness. The embodied-cognition approach sees such behavior as extensions of the animal's value-laden interaction with its environment.

How can abstract reasoning (e.g. logic and mathematics) make use of bodily action abilities? Briefly: sensorimotor imagery, conscious or semiconscious activated memory traces of the experiences of performing basic actions, functions not only in action contemplation and planning but also in the mental manipulation of objects in abstract reasoning. Abstract thought builds on basic action schemas: bodies interacting with objects in space (e.g. Huttenlocher 1968). To those claiming to lack such imagery, it can be argued that such images are not necessarily fully conscious, and brain imaging studies are now available that can decide such matters.

Actions require motivation. Even covert attention shifts depend on emotional interests of the organism; subcortical structures such as the amygdala, hippocampus and the hypothalamus influence voluntary attention mechanisms in the anterior cingulate. Actions imagined but not performed are both activated and inhibited in the frontal lobes and motor cortex; inhibition, controlled in large part by the hypothalamus, allows action images to be consciously experienced (Jeannerod 1998) along with the emotional values associated with the actions.

The combination of the above approach with recent work on emotion is powerful, allowing the formation of a global theory of brain function in which dynamic interactions among brain areas and brain events can be mapped at many levels of organization. An important prediction of the approach is that brain mechanisms once thought devoted to motor activity are also active in emotional and cognitive activities. Our example is the cerebellum. As we shall see, it appears that the cerebellum is not only a coordinator of motor actions, but also of reasoning and, most recently discovered, of emotional with cognitive states. If reasoning and other cognitive activities make use of motor schemas, this is exactly what one would expect. The cerebellum appears to be not just an organ for the coordination of actual motor activities, but also for coordinating the output of both cortical and subcortical structures involved in affect-laden cognitive activity at all levels.

## The Role of the Cerebellum in Cognition and Affect

Jeremy Schmahmann (schmahmann@helix.mgh.harvard.edu)

Associate Prof. of Neurology  
Harvard Medical School, Mass. General Hospital  
Boston, MA 02114

Many studies suggest that the cerebellum is essential to the neural circuitry subserving cognition and emotion. It connects with the reticular system (arousal), hypothalamus (autonomic function and emotional expression), limbic system (experience and expression of emotion), and paralimbic and neocortical association areas critical for higher order function (cognitive dimensions of affect). Behavioral changes in adults and children with focal cerebellar lesions provide clinical support for the relationship between the cerebellum and cognition. A cerebellar cognitive affective syndrome in adults and children is defined by impairments in executive, visual spatial, and linguistic function and dysregulation of affect. A cerebellar role in the modulation of aggression and mood appears in children with the posterior fossa syndrome following surgery involving the vermis, and during clinical and experimental neurosurgical manipulation. Functional imaging studies reveal cerebellar involvement in nociception, autonomic behaviors, affective experiences, and multiple cognitive paradigms. These suggest topographic organization in the human cerebellum with the somatosensory homunculus in the anterior lobe, cognitive operations in the neocerebellum in lobules VI and VII, and emotion particularly influenced by the vermis. We have extended the hypothesis that the phylogenetically older fastigial nucleus, vermis and flocculonodular lobe constitute the "limbic cerebellum" to include these structures in the Papez circuit.

The cerebrocerebellar system appears to consist of discretely organized parallel anatomic subsystems that serve as substrates for differentially organized functional subsystems. We have proposed that there is a universal cerebellar transform (UCT), possibly error detection, prevention, and correction utilizing an internal model that facilitates the production of harmonious motor, cognitive, and affective/autonomic behaviors: the cerebellum detects, prevents, and corrects mismatches between intended and perceived outcome of interactions with the environment. Disruption of circuitry linking the cerebellum with the cerebral hemispheres prevents cerebellar modulation of functions subserved by the affected subsystems, and produces dysmetria, the universal cerebellar impairment (UCI). Dysmetria of movement, or ataxia, is matched by "dysmetria of thought", the proposed fundamental mechanism underlying disorders of intellect and emotion resulting from cerebellar dysfunction, including the cerebellar cognitive affective syndrome, abnormalities of affect, and psychotic thinking.

### **The Integrative Role of the Cerebellar Vermis in Cognition and Emotion**

**Carl Anderson (carl\_anderson@hms.harvard.edu)**

Developmental Biopsychiatry Research  
Program, and Brain Imaging Center,  
McLean Hospital, Belmont, Mass. 02178

The cerebellar vermis and the fastigial nucleus are treated here as the "the cerebellar vermis-fastigial nucleus" (VFN) complex. The fastigial nucleus, phylogenetically the oldest of the four cerebellar nuclei, influences eye movements, posture, equilibrium and autonomic activity (Beitz, 1982). The role of VFN complex in cognitive/emotional synergy is supported by imaging studies and by observations of its focal and myriad interconnections among key brainstem nuclei and bi-hemispheric networks of motor and limbic system structures. The neocerebellar hemispheres, lateral extensions of the VFN, are activated during mental imagery, tactile learning and language and sensory-processing. Although motoric aspects of articulation, balance and bimanual coordination may involve more medial areas of the cerebellum or VFN, this region is also nonspecifically activated during many of the same functional imaging studies of neocerebellar activation. This apparent lack of specificity hints at the role of the VFN in consciousness.

As it bridges the hemispheres, pathology of the VFN appears to connect many apparently unconnected psychiatric disorders. Although the cerebellum occupies only 10% of the human brain, it contains more than half of its neurons (except in the psychiatric disorders detailed below where the VFN is significantly smaller). Among mammals, *Homo Erectus* relies most heavily on the VFN for integrating visual, vestibular and proprioceptive cues. Bipedal standing robustly activates anterior and posterior vermal regions (Ouchi et al., 1999). Destruction of the vermal cortex (Sullivan et al., 2000), a result of chronic alcoholism, produces out-of-balance staggering gait ataxia through inflexible coordination of visual, vestibular and proprioceptive feedback. Childhood trauma appears to result in pervasive cerebellar damage. This may be due to the protracted postnatal ontogeny of the cerebellum rendering it sensitive to early corticosteroid exposure (Lauder, 1983). In this case VFN pathology is associated with the development of limbic seizures (Heath, 1976; Strain et al., 1979; Cooper et al., 1974, 1985; Riklan et al., 1976). An association between the VFN and limbic seizures was first observed in electrical recordings from the hippocampus and fastigial nucleus of violent adult Harlow monkeys (Heath, 1972). Aggressive behavior in these animals resulted from the stress of total maternal deprivation (Harlow, 1971). Bremer (1997) found that lesions of the vermis, but not the cerebellar hemispheres, tamed their aggression, suggesting that deprivation disordered the developing vermal cortex. Heath accordingly used electrical stimulation of the vermis (which inhibits cortex and disinhibits the fastigial nucleus) to relieve psychotic symptoms in humans (Heath, 1980). Interestingly, research by Mason and Harlow (1975) has shown that rocking during early life, which stimulates the VFN, mitigates the adverse effects of maternal deprivation. Child abuse is also associated with dissociation, increased prevalence of abnormal EEG=s (Ito, 1998), and symptoms suggestive of limbic seizures (Teicher et al., 1993). It seems to cause a limbic "kindling" that produces epilepsy in experimental animals. Repeated electrical stimulation of the limbic system in experimental animals can lead to seizures. Repeated abuse in humans may also result in limbic electrical abnormalities associated with epileptic-like behavioral experiences. Electrical stimulation of the VFN in humans suppresses the spread of epileptic seizures (Cooper et al., 1974; Cooper and Upton, 1985). We used fMRI to assess the relationship between behavioral measures of limbic kindling and blood volume in the VFN of young adults with a history of childhood abuse and found a strong correlation between VFN blood flow and kindling (Anderson et al., 1999; Teicher et al., 1993); early abuse seems associated with a functional deficit in limbic-VFN networks. Converging data suggest involvement of VFN abnormalities in various disorders including depression (Fischler et al., 1996; Lauterbach, 1996; Beauregard et al., 1998), schizophrenia (Loeber et al., 1999; Jacobsen et al., 1997),

autism (Courchesne et al., 1991) and ADHD (Berquin et al., 1998). The VFN innervates the locus coeruleus (LC), ventral tegmental area (VTA), substantia nigra (SN), and midline raphe, cell body regions of the dopaminergic, noradrenergic and serotonergic pathways (Reis & Golanov, 1997; Snider & Maiti, 1976; Snider et al., 1976). We also found a strong dose-dependent effect of methylphenidate on blood flow in the VFN of ADHD children (Anderson et al., 2000).

Pettigrew (1998) shows that binocular rivalry occurs between, not within, cerebral hemispheres, and that the rate of perceptual rivalry is slow in bipolar disorder. Pettigrew's interhemispheric "sticky switch" in manic depression could be due to VFN pathology observed in bipolars (Lauterbach, 1996). The VFN complex projects to pons and reticular formation sites where network cascades are easily activated. Fastigial electrical stimulation desynchronizes EEG, characteristic of the behavioral states of REM sleep and attention orienting. Snider (1976) demonstrated direct and indirect projections from the VFN to the LC (Ruggiero et al., 1997) and paraventricular nucleus (Astier et al., 1990) and parabrachial nuclei (Supple & Kapp, 1994). All regions that could contribute to desynchronized EEG and facilitate cortical binding. Usher (1999) proposes that electrotonic coupling within the LC plays a role in attentional modulation and regulation of goal-directed versus exploratory behaviors. This electrotonic syncytium structure may represent the fingerprint of dynamical internal models in the cerebellum (Imamizu et al., 2000). Makarenk (1998) demonstrates that synchrony of inferior olive neurons arises from chaotic subthreshold oscillations. These neurons, while having maximum functional permissiveness, can also transform rapidly into robustly determined functional patterns of multicellular coherence. Along with a hypothesis of how pontine organization may be controlled by the cerebellum for binding assemblies of cortical-striatal-thalamic loops into coherent motor strategies (Schwarz & Theier, 1999), these findings suggest that consciousness (in terms of motor patterns) may develop in the spatial-temporal chaos of phase synchronized pontine olive ensembles.

Drug addiction is also associated with early child abuse, ADHD and bipolar disorder. A potent anti-addiction drug, ibogaine, causes hallucinations, cerebellar tremor, transient ataxia, and vermal lesions in rats. Ibogaine strongly activates climbing fiber activity in VFN Purkinje cells (O'Hearn & Molliver, 1997). Hallucinations associated with ibogaine treatment indicate impairment of the cerebellar efferent copy mechanism. Subjects may then sleep for 24 hrs and awaken free from addiction (Kovera et al, 1999), suggesting a connection between ibogaine action and changes in the fractal organization of REM sleep (Anderson, 1998). The cerebellar vermis is most active during REM, especially in human infants (Chugani, 1998). Schlesinger et al. (1998) found that REM deprivation implicated VFN function in postural control and attention. Interpreted in the context of vertically convergent fractal time processes, early stress appears to disrupt organization of fractal REM patterns, leading to alteration of patterns of nuchal atonia occurring during REM sleep in fetuses and neonates (Anderson, 1995; Anderson et al., 1998); suggesting a connection between REM sleep, the VFM and cognitive/emotional synergy. Our hypothesis is that early stress results in pathological fastigial regulation of chaotic spatial-temporal patterns of pontine olive ensembles. As the VFM appears to influence the architecture of REM sleep, abnormal spatial-temporal patterns lock into a negative feedback loop, with further disorganization of pontine olive ensembles. Ibogaine, by overdriving VFM climbing fiber activity, breaks these cycles, resulting in REM rebound and the flooding of abuse memories as efferent copy mechanisms are reset during the treatment. Thus the VFN may represent a key node in the interface of limbic-brainstem network oscillations and self-organized attentional/orienting mechanisms with dynamic internal motor schemas during our ongoing emotion-laden experience of consciousness.

**Consciousness and the Cerebellum**  
**Ralph D. Ellis (ralphellis@mindspring.com)**  
Department of Philosophy  
Clark-Atlanta University  
Atlanta, GA 30314

If the cerebellum plays a coordinating and synchronizing role in the brain, this role must be an important determinant of the structure of conscious processing, because conscious processing is a whole brain activity of a self-organizing system. That consciousness does not result from passive stimulation is clear since occipital activity alone does not yield perceptual consciousness (Aurell 1989; Posner & Rothbart 1995; perceptual studies by Mack & Rock 1998 also entail this). Moreover, cerebellar activity is similar for abstract thought, physical movement, or imagination of physical movement (Ito 1993); this suggests that the cerebellum

subserves intellectual operations, and that intellectual understanding is an extension of manipulation of action affordances (Newton 1996).

Wakefulness results from synchronization of wave patterns in diverse regions, especially between the thalamus and the cortex (Asimov 1965). Since the cerebellum controls widely distributed synchronizations, it is crucial for the difference between sleep and wakefulness; hence again, for consciousness. Equally important, coordination between hippocampus and other subcortical regions, and the effect of this coordination on the extended reticular thalamic activating system (ERTAS), which attunes the thalamus to select for incoming stimuli with emotionally important action affordances, is also needed for *perceptual* consciousness. Occipital processing alone is not conscious; other areas, including anterior areas such as anterior cingulate and frontal and parietal lobes; must be activated in response to input from emotional brain areas; since this activity involves widespread synchronization, the cerebellum also plays a part. If consciousness begins with action affordances, or Damasio's (1999) "as if body loop," then the cerebellum is pivotal for consciousness.

The hippocampus shows an event related potential within 20 ms. of a perceptual stimulus (Coles 1990), indicating subcortical activation with wave synchronization phenomena, this implies cerebellar involvement as well: the first occipital ERP does not begin until around 100 ms. Rather than anterior and subcortical activation's being a *response* to an *occipital stimulus*, this activation must *already* have taken place prior to consciousness. ERTAS, guided by emotional subcortical purposes, *determines* registration of perceptual input in consciousness.

When a visual stimulus is unexpected, there is a 1/4 second delay from occipital processing to the other brain processes needed for perceptual consciousness (Srebro 1985) — too long to be explained by the speed of spreading activation. The delay allows emotional areas to activate thalamus, frontal and parietal areas in response to hippocampal and cerebellar tuning toward relevant action affordances; this "looking for" activity has already begun *prior to* occipital effects on perceptual consciousness (since the occipital P200 has not yet occurred). Even in *involuntary* attention and in cases of frontal lobectomy, the limbic system selectively gates incoming stimuli according to general motivational purposes *via* subcortical control of neurotransmitters, tuning the thalamus (Damasio 1999; Faw forthcoming) and allowing consciousness rather than blindsight. Persons with no anterior cingulate are in vegetative states (Damasio 1999), so even involuntary attention is impossible without it.

This reverses traditional thought about the causal ordering of brain events: perception was thought to drive emotion, which in turn drove action. Instead, the organism must first be geared up to seek important data, the most fundamental of which involve action and thus cerebellar functions. Subcortical tuning activates frontal and limbic regions to form preconscious image schemas associated with important perceptual categories, prior to processing of the stimulus. If the stimulus resonates with this self-generated activity, a more vivid image is formed, and one that is felt as the image of a present perceptual object rather than as an image (Aurell, 1989).

In tracking a soccer ball, expectation is at each moment motivated by categories of utility and retention of the ball's previous location. When the ball suddenly turns up where we are not looking, we do not see it, but have a vivid image of where it *should have been*. It then takes a fourth of a second to find the ball. It catches attention by presenting affordances to the motivated organism. Self-organization must be holistically coordinated, requiring cerebellar synchronizations. Since perception is motivated by utility (Newton 1996) and frontal and parietal areas are tuned by emotional areas (hypothalamus, hippocampus, cerebellum, amygdala), we see the sinister smile without noticing its sinister details; we note a room's disorder but not the crooked picture frame that makes it disorderly (Merleau-Ponty, 1942, p. 173).

Emotion is not sufficient for consciousness. Plants and low animal species have organismic purposes, but little consciousness. Consciousness occurs only when emotion combines with representation, occurring not passively but as an activity of the organism. Emotional agnosics can't represent what emotions are "about." We are conscious of emotions through representation. Even unconscious emotions still drive the representational processes in which we do engage, and even pure curiosity is an emotion that motivates us to explore our environment and represent what is there (Panksepp 1998).

# Bayesian Approaches to Cognitive Modeling

**Joshua Tenenbaum**

*Department of Psychology  
Stanford University  
Stanford, CA 94305*

**Michael C. Mozer**

*Department of Computer Science  
University of Colorado  
Boulder, CO 80309–0430*

Many, if not all, aspects of human cognition depend fundamentally on inductive inference: evaluating degrees of belief in hypotheses given weak constraints imposed by observed data. In logic-based models of cognition, the currency of belief is a binary truth value. In connectionist models of cognition, the currency of belief is an activation level. In Bayesian models of cognition, the currency of belief is a probability. The term “Bayesian” comes from Thomas Bayes, an 18th century minister who introduced a key theorem which serves as the mathematical basis of probabilistic inference. Under the single assumption that degrees of belief be represented as probability distributions, Bayes’ theorem describes how the degree of belief in a hypothesis,  $h$ , should be updated as a result of some new evidence,  $e$ :

$$P(h|e) = P(e|h)P(h) / \sum_{h' \in H} P(e|h')P(h')$$

where  $P(h|e)$  denotes the conditional (*posterior*) probability that  $h$  is true given that  $e$  is true,  $P(h)$  denotes the unconditional (*prior*) probability that  $h$  is true, and  $P(e|h)$  denotes the *likelihood* of observing  $e$  given that  $h$  is true.  $H$  denotes a set of mutually exclusive and exhaustive alternative hypotheses that could be invoked to explain  $e$ . A Bayesian’s belief in  $h$  given  $e$  is thus a measure of how well  $h$  explains  $e$  relative to how well alternative hypotheses  $h' \in H$  explain  $e$ .

As a normative theory of inductive inference, the Bayesian paradigm provides a principled, general-purpose framework for constructing rational models of cognition across a wide range of domains (Anderson, 1990; Knill & Richards, 1996; Oaksford & Chater, 1998). This symposium will provide a forum for representatives of Bayesian approaches from various areas of cognitive science—perception, learning, reasoning, memory, and language acquisition—to discuss both the successful aspects and the open challenges of the Bayesian paradigm. Questions to be addressed include:

- How does a Bayesian analysis provide a rational explanation for phenomena that have previously been addressed by mechanistic models? When and why does Bayes predict new phenomena that mechanistic models fail to predict? When do Bayesian analyses result in emergent predictions that are not intuitively obvious from the model’s design?
- How does Bayes support the integration of disparate sources of information into a single coherent inference?
- How does Bayes allow the unification of two or more apparently distinct modes of processing into a single compu-

tational framework?

- Where does a Bayesian agent’s hypothesis space come from? What kind of extra-Bayesian assumptions are needed in deriving the probabilistic generative model (prior probabilities and likelihoods) that is the foundation of a Bayesian analysis?
- The Bayesian paradigm conceives of perception and cognition as being adapted to the structure and statistics of the environment, but the mechanisms of this adaptation may vary across domains. What are the roles of evolution, learning, and habituation in adapting a Bayesian agent to the structure of a particular domain?
- There are typically many different ways to give a Bayesian analysis of a particular task. Is there always one “correct” Bayesian model? What are the criteria for deciding that one is correct?
- How can Bayesian models be tested empirically? Is the Bayesian approach falsifiable? Should it be?
- How can we reconcile the success of Bayesian models of cognition with the well-known findings from the heuristics and biases literature that “people are not Bayesian”? Could these discrepancies reflect different ways of formulating Bayesian analyses of the same tasks?
- Bayesian models, when fully implemented, are often computationally intractable. What are the implications of this intractability for a model’s psychological or neural plausibility? What are the possibilities for principled approximations that might preserve the rigor of the approach in a more tractable setting? How might familiar, cognitively plausible heuristics be viewed as approximations to the full Bayesian competence?
- “Probability is not really about numbers; it is about the structure of reasoning” (G. Shafer, as quoted in Pearl, 1988). How might the structural aspects of Bayesian inference, as captured in Bayes nets and other graphical models, be important for understanding human cognition?

Speakers at the symposium will include: Michael Brent (*Bayesian modeling of segmentation and word discovery*), Evan Heit (*A Bayesian account of category-based induction*), Michael Mozer (*Temporal dynamics of information transmission in a Bayesian cognitive architecture*), and Joshua Tenenbaum (*Rules and similarity in concept learning*).

## The Nature of Human Errors: An Emerging Interdisciplinary Perspective

### Introduction

In light of a growing awareness of the role of human errors in widely publicized incidents such as airline accidents and complications of medical procedures, now is the right time for cognitive science to make a contribution to the study and prevention of human errors. As shown in Figure 1, human errors account for more than half of accidents in most industries. In air traffic control, the rate is over 90%. Human errors occur primarily due to inadequate information processing. As an interdisciplinary field for the study of information processing in humans and machines, cognitive science can make a significant contribution to human error studies.

In this symposium, the four presentations will address human errors from four different perspectives.

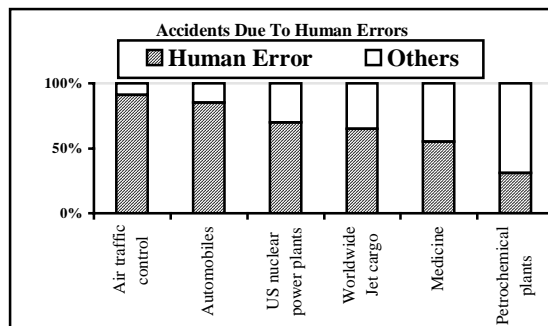

Figure 1. Accidents due to human errors

### Human Errors: Cognitive Theory & Interface Design

*Jiajie Zhang*

There are two major types of human errors (Reason, 1990): planning and execution errors. Slips are errors of execution in which the correct action does not proceed as intended. Mistakes are errors of planning in which the original intended action is not correct. This presentation will focus on four types of slips (Norman, 1981). Caption slips result from automatic activation of a well-learned routine that overrides the current intended activity (e.g., driving home directly instead of picking up a prescription on the home way). Description slips are due to incomplete or ambiguous specification of intention that is similar to a familiar intention (e.g., inserting a Zip disk to a floppy drive). Associative activation slips are due to activation of similar but incorrect schemas (e.g., picking up the desktop phone when the cell phone rings). Loss-of-activation slips are due to loss of the activation of current intention (e.g., forgetting an idea for this symposium proposal after answering an interruptive phone call). The first part of this presentation will describe a

cognitive theory of slips (based on Norman's schema theory) that attempts to explain why slips occur and predict when they occur.

The second part will be about the design of systems that minimize human errors. The cognitive theory of slips points out the causes and predicts what types of slips will happen under what circumstances. With such a theoretical guideline, we can design systems that have properties that can make certain types of slips impossible to occur or minimize the factors that can cause errors (e.g., a good user interface that minimizes mental workload).

### Conceptual and Procedural Errors in Medical Decision Making

*Vimla L. Patel*

Cognitive studies of errors in medical decision making have traditionally focused on biases and faulty heuristics that lead health professionals to fail to attend to, or properly consider, relevant data. The error is sometimes attributed to physicians' lack of competency in probabilistic reasoning. In our view, decision making is an inherently complex cognitive and social process and errors can have multiple etiologies. It is convenient to partition sources of error into three categories: 1) individual/cognitive, 2) social/communicative and 3) systemic/institutional. Errors can arise due to actions (or neglect) of a single individual. Decision making critically depends on the availability of current information, a level of understanding, and the use of appropriate decision strategies.

The most serious cognitive errors are those that arise for reasons other than simple neglect or oversight (e.g., unintended slips). Possible causes include procedural errors and faulty conceptual knowledge. In addition, several studies have documented errors due to dissociations between subjects' conceptual understanding and their application of knowledge in solving patient problems. For example, a subject may understand that certain levels of serum cholesterol coupled with other symptoms necessitate pharmaceutical intervention, but may fail to incorporate this knowledge into an action plan. Similarly, an individual may know how to carry out an effective procedure, but lack the prerequisite conceptual knowledge required to determine its suitability or to cope with problems that arise when it is being performed. This can lead to errors of over-generalization or contribute to use of an overly narrow perspective (violation of constraints).

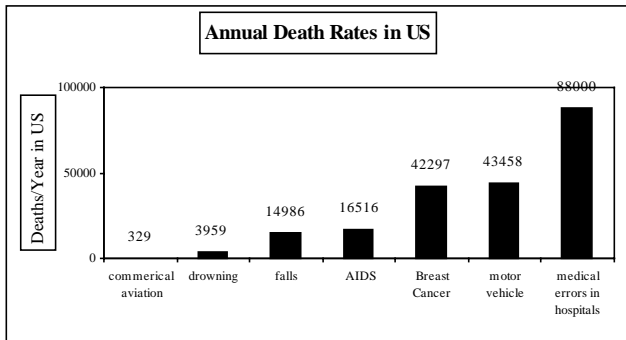

High velocity decision-making environments, such as intensive care settings, are vulnerable to multiple sources of social and communicative errors. These errors can emerge from disruptions in the flow of information such as the failure of coordination and communication between an overnight and daytime nurse who must achieve mutual understanding about the state of a patient for whom they both care. Systemic and institutional errors are caused by problems that are not due to any individual or team of individuals, but rather are caused by some fault in a system. This category may include problems with technological systems, the physical design of the workspace, or the use of institutionally sanctioned, but faulty protocols.

This presentation will consider a range of medical decision making errors, drawing on both laboratory and naturalistic studies, and will attempt to relate these errors of reasoning to issues of education and training.

**Information Technology’s Role in the Prevention of Human Errors in Clinical Medicine**

*Edward H. Shortliffe*

A recent report from the Institute of Medicine (IOM, December 1999) indicates that 44,000 to 98,000 patients die from medical errors every year in US hospitals. The study suggests that more people die from medical errors in hospitalization than from motor vehicle accidents, breast cancer, or AIDS (see Figure 2). When deaths from ambulatory settings are considered, the estimate can go much higher.

**Figure 2.** Annual death rates in US

Several industries (e.g., aviation and nuclear power plants) have been very successful in preventing human errors, perhaps because their accidents, when they do occur, make bigger headlines than medical incidents due to their catastrophic nature. For example, 329 people die a year from commercial aviation in US. In contrast, the death rate due to medical errors in the US is equivalent to one jumbo-jet crash every day. The IOM report has increased the public’s awareness of the frequency and significance of medical errors, and the Clinton Administration has authorized the creation of a Center for Patient Safety with initial funding of \$35 million a year, setting a goal of reducing medical errors by 50% in five years.

This presentation argues that there is much that the health-care industry can do to prevent the kinds of errors described in the IOM report. Many of the problems are re-

lated to inadequacies in process rather than to incompetence in health workers, and information technology can play a particularly important role in dealing with such errors. Examples include the computer-based verification of dosing information at the time that a drug regimen is ordered, or improved access to (and legibility of) pertinent clinical information that may prevent decision-making errors before they occur. Challenges in implementing and integrating such facilities into clinical environments will be discussed, along with examples of systems currently in use to address these kinds of human errors in clinical settings. The role of computer-based clinical decision-support systems will be emphasized.

**Human Error Modeling in Aviation**

*Mike Freed and Roger Remington*

In commercial aviation, as in many other demanding tasks, human error is among the most significant sources of cost and risk. One important consequence is a necessary conservatism about introducing new aviation technologies. In particular, new procedures and devices that affect the type, pace, or amount of work of an operator may inadvertently facilitate error. Designers typically assess the human performance impact of new technology by building system prototypes, training users, and then running “human in the loop” studies in which operators are observed carrying out tasks in a variety of scenarios. This tends to be very costly, limiting the amount of testing that can be done and, indirectly, the flexibility of the system to accommodate innovation and adjustment.

One solution is to develop better methods for evaluating at an early stage in design (before a physical prototype), when altering the design is inexpensive. For some domains, methods such as guideline based critiquing and cognitive walkthrough can be used to detect human factors problems in a design at this early stage. For more complex domains, computer simulation is needed to handle the vast amount of situational detail that must be considered as possibly contributing to operator error.

We will describe APEX, a tool for simulating human operators in complex, dynamic environments (so far including TRACON air traffic control and Boeing 757 flight deck). The human performance model used in APEX adapts an AI technology called reactive planning to enable capable behavior in such demanding environments. This technology turns out to be especially suited for simulating human proneness to certain forms of systematic procedural error, especially what Reason calls “frequency gambling errors.” Ultimately APEX is intended to help designers sift through thousands of possible scenarios to identify possibilities for error that might otherwise have been overlooked. To this end, we have used examples of operator error from “human in the loop” simulation studies and from reported incidents in the Aviation Safety Reporting System database to drive development of the model. We are also beginning to study procedural errors empirically in order to test the effect of certain possible causal factors.

# Induction of causal chains

## Abstract

The current study examined one way in which people learn complex causal relations from covariation. When participants were presented with covariation information between X and Y and covariation information between Y and Z only, they were willing to infer a causal relationship between X and Z, although it is not warranted by the evidence. Furthermore, the perceived strength of the terminal relationship was tied to the perceived strength of the intermediate relationships, as manipulated through the order of evidence. These results imply that people do not follow normative, contingency-based theories, but instead carry out a hypothesis-testing process and combine piecemeal relationships into an overarching causal induction.

## Introduction

Learning causal relations between two events is a fundamental cognitive activity. Although there are many ways to acquire causal knowledge (Ahn & Kalish, in press), the current study examines one way of learning causal relations, namely, through covariation.

In a simple case of covariation involving two events, a possible cause is either present (X) or absent ( $\sim X$ ), and the target effect to be explained is either present (Y) or absent ( $\sim Y$ ) as shown in Figure 1. One way to define covariation between two factors is to calculate an index  $\Delta P = P(Y/X) - P(Y/\sim X)$ , the difference between the probability that the effect occurs, given that the cause is present, and the probability that the effect occurs, given that the cause is absent (e.g., Cheng & Novick, 1992; Jenkins & Ward, 1965). In the example shown in Figure 1,  $\Delta P$  is 0.2. Numerous studies have demonstrated positive correlations between objective  $\Delta P$  and the perceived causal strengths between events (e.g., Wasserman, Chatlosh, & Neunaber, 1983).

	Y	$\sim Y$
X	6	4
$\sim X$	4	6

Figure 1. Example contingency between X and Y. Numbers show example frequencies of each evidence type.

In addition to the simple causal relations examined in these previous studies, people have knowledge about com-

plex causal mechanisms (e.g., Ahn, Kalish, Medin, & Gelman, 1995). For instance, in explaining why Kim had a traffic accident, one might refer to a mechanism of drunk driving rather than just the fact that there is a positive covariation between a traffic accident and drunk driving. Most people understand the mechanism underlying the effect of drunk driving on a traffic accident to be that when drunk, a person's motor responses are uncoordinated, in which case a person might not stay in the road, and so on. The question is, how do we acquire understanding of these causal mechanisms?

In answering this question, it is important to understand first how our knowledge about causal mechanisms might be represented. One useful tool is conditional dependencies or Bayesian networks<sup>1</sup>. The idea is that mechanisms can be represented in terms of a complex web of covariation, or more specifically, as a directed graph in which nodes representing variables are connected with arrows indicating causal directions (Glymour, 1998; Glymour & Cheng, 1998; Pearl, 1996; Spirtes, Glymour, & Scheines, 1993; Waldmann & Martignon, 1998). For instance, a mechanism underlying the covariation between drunk driving and a traffic accident might be represented as follows:

drink alcohol  $\rightarrow$  uncoordinated motor responses  $\rightarrow$  traffic accident

Glymour (1998) proposes that B is a mechanism for a correlation between A and C, if, conditional on B, the correlation of A and C goes to zero. In the above example, one observes that as drunk driving increases, the number of

<sup>1</sup> Although we agree that Bayesian networks are a useful tool for representing people's causal mechanism knowledge, we do not endorse the view that conditional dependencies are all there is to that knowledge. Ahn and Kalish (in press) state that conditional dependencies are consistent with causal mechanisms because people's ideas about mechanisms support patterns of association. For instance, if someone believes that getting sneezed on causes illness via the mechanism of the transmission of germs, they should expect that the covariation between sneezing and illness is conditional on the transmission of germs. However, Ahn and Kalish disagree with Glymour (1998), who argues that patterns of covariation *are* mechanisms, and not just evidence for them. That is, a pattern of covariation might be one useful piece of evidence for identifying a relation as causal (i.e., addressing an epistemic question), but they are not what people mean by causation (i.e., addressing a metaphysical question). The current study addresses the epistemic question rather than the metaphysical question. Thus, we do not focus on this debate and instead assume that mechanisms can be represented in terms of conditional dependencies.

	X	~X

	Y	~Y
Z	6	4
~Z	4	6

Figure 2. Example contingency between events X and Y and contingency between events Y and Z.

traffic accidents increases. Conditional on the number of uncoordinated motor responses, however, the covariation between drunk driving and traffic accidents would be greatly reduced. Thus, uncoordinated motor responses serve as a mechanism for this covariation.

Little is known about how people actually learn these complex patterns of covariations. Waldmann and Martignon (1998), who make use of a Bayesian network to represent mechanism knowledge, admit that it is improbable that humans learn such networks bottom-up, as instantiated in some computational models (e.g., Spirtes et al., 1993). For instance, Hashem and Cooper (1996) generated nine sets of relatively simple causal networks (e.g.,  $A \rightarrow B \rightarrow C$ , or  $A \leftarrow B \rightarrow C$ ) instantiated as diseases. Second and third year medical students were instructed to ask for any conditional probabilities among the three variables in each network, and to estimate the causal strength between B and C after receiving answers to their questions. Even from these simple causal networks, their estimates significantly deviated from the normative answers. The results suggest that it is unlikely that people can keep track of all conditional probabilities necessary for acquiring causal networks.

A simpler way of acquiring mechanism knowledge is by combining piecemeal causal relations. In this study, we attempt to show that upon learning that X sometimes causes Y and Y sometimes causes Z, people conclude (albeit erroneously) that X sometimes cause Z. Such inference is non-normative in that even if there is a contingency between X and Y and a contingency between Y and Z, it does not guarantee that there will be a positive contingency between X and Z. A normative conclusion would be that no inference about the relationship between X and Z can be made.

Consider Figure 2 which shows 40 individual cases, 20 of which depict the covariation between X and Y and 20 of which depict the covariation between Y and Z ( $\Delta P = 0.2$  in both cases). Each of these 40 cases represents a different observation. On the left, we know, for instance, that there are six cases in which X and Y co-occurred, but we do not know what might have happened about Z in these six cases. Depending on this unknown information, the contingency

between X and Z can vary widely. To demonstrate this point, the top half of Figure 3 shows three possible distributions of these patterns of co-occurrence within the different levels of X and Y. For instance, in the six cases in Figure 3a. where both X and Y occur (the upper left-hand cell of the first contingency table), in two of the cases Z occurs and in the other four Z does not occur. The resulting co-occurrence patterns between X and Z are shown in the bottom half of the figure. Note that, not only is the pattern of co-occurrence between X and Y identical in each example, but the pattern between Y and Z is also identical (i.e.,  $\Delta P = 0.2$ ). However, the contingency between X and Z varies widely. Thus, a normative answer given covariation information about X and Y and covariation information about Y and Z only is that contingency between X and Z cannot be determined.

We propose that people would not make such normative judgments, and instead they would frequently assume that they can estimate the relationship between X and Z only from the covariation between X and Y (X-Y covariation) and covariation between Y and Z (Y-Z covariation). The reason for this is two-fold. First, as discussed earlier, keeping track of multiple conditional dependencies seems to be beyond the capacity of human cognition, but people have complex causal mechanism knowledge that can be represented in terms of conditional dependencies. Thus, people must have acquired this knowledge through other means. Second, in real-life situations, constituent covariations are oftentimes revealed in different cases. For instance, one might observe that eating a lot of food high in fat increases one's cholesterol level, and one might also observe that *other* people with high cholesterol die of a heart attack (not knowing whether these people had high-fat diets when alive). Therefore, it is adaptive, although non-normative, to make unwarranted inferences about unobserved covariations based on piecemeal covariations.

Specifically, we propose that people carry out a sort of syllogistic reasoning in this situation (Goldvarg & Johnson-Laird, 1999). Given that X causes Y and Y causes Z, people would subsequently conclude that X causes Z. We also propose that the stronger the perceived intermediate

	a. $\Delta P = -0.2$		b. $\Delta P = 0$		c. $\Delta P = 1$	
	X	~X	X	~X	X	~X
Y	6 (2 Z, 4 ~Z)	4 (4 Z)	6 (5 Z, 1 ~Z)	4 (1 Z, 3 ~Z)	6 (6 Z)	4 (4 ~Z)
~Y	4 (2 Z, 2 ~Z)	6 (2 Z, 4 ~Z)	4 (4 ~Z)	6 (4 Z, 2 ~Z)	4 (4 Z)	6 (6 ~Z)
Z	4	6	5	5	10	0
~Z	6	4	5	5	0	10

causal relations are, the stronger the perceived causal relationship between the two terminal events would be. Thus, if causal relations between X and Y, and Y and Z are weak, one would infer a weak causal relation between X and Z. If so, any manipulation that increases the perceived intermediate causal strengths should also increase the perceived causal strength between the terminal events. One such manipulation is presented in Dennis and Ahn (in press) who manipulated the order of evidence supporting a positive causal relationship versus evidence supporting a negative causal relationship. Because the current study utilized the same manipulation, we will first describe this study in detail, and then return to the issue of deducing overarching causal relations from piecemeal covariations.

### Order manipulation

Consider four cells in Figure 1 again. Cells XY and  $\sim X\sim Y$  serve to confirm that a positive causal relationship exists between X and Y. Henceforth, we will call these two cells positive evidence. Cells X $\sim Y$  and  $\sim XY$  serve to confirm that there is a negative causal relationship between X and Y (negative evidence, henceforth). Participants in Dennis and Ahn (in press) observed a sequence of trials, each of which described presence or absence of two events, and judged the causal strength between the two events at the end of the sequence. Participants in one condition observed the bulk of positive evidence followed by the bulk of negative evidence (positive-first condition). In the other condition, participants observed the bulk of negative evidence followed by the bulk of positive evidence (negative-first condition). Although the order was different, all participants observed an identical covariation between X and Y, namely zero, in their experiment. The three possible results from this experiment were; (1) no effect of order, (2) a recency effect in which the negative-first condition leads to more positive causal estimates than the positive-first condition, and (3) a primacy effect in which the positive-first condition leads to more positive causal estimates than the negative-first condition. Existing models of causal induction predict either no effect (Cheng, 1997) or a recency effect (Rescorla & Wagner, 1972; see Dennis & Ahn, in press for more details of this prediction.) However, the results showed a strong primacy effect. This result was obtained even with the prospect of receiving reward for accurate judgments, indicating that the results are unlikely to be due to a fatigue effect.

Dennis and Ahn (in press) proposed that the primacy effect is obtained because causal learning occurs through a process of belief formation and updating. In this view, the information that a person receives at the beginning is used to construct an initial hypothesis about possible causal relationships. This initial belief then helps to provide an anchor point for future adjustments (Hogarth & Einhorn, 1992). However, as shown by Tversky and Kahneman (1974), people do not sufficiently adjust their initial anchor, resulting in the primacy effect.

### Order effect in the two-step causal chain

In addition to showing that people frequently infer unwarranted overarching causal relations from constituent covariations, the second goal of the current study is to examine whether the order effect is obtained when judging X to Z causal strength based on X-Y covariation and Y-Z covariation. In the positive-first condition, participants observed a bulk of positive evidence for X and Y, and for Y and Z, followed by a bulk of negative evidence for X and Y, and for Y and Z. In the negative-first condition, participants observed identical contingencies with the negative evidence preceding the positive evidence. It is hypothesized that compared to the negative-first condition, the positive-first condition will lead to more positive causal estimates for the relationship between X and Z.

## Method

### Overview of Methods

In general, there were four phases: instructions, a learning phase, a test phase, and a follow-up phase. In the learning phase participants observed a series of trials providing X-Y covariation, and Y-Z covariation. The test phase required that participants make judgments about the causal relationship between events X and Z. The main experimental manipulations which occurred during the learning phase were the order in which participants received a bulk of positive or negative evidence for X-Y and Y-Z covariation. This manipulation was a within-subject variable, so that each participant actually saw two sets of learning and test phases. In the follow-up phase, participants described their thought processes. Each phase is explained below.

The Instruction and the learning phases were presented on iMac computers, using Microsoft PowerPoint 98 ®. The test and follow-up phases were presented as a paper-and-pencil task. Participants were 39 undergraduates at Vanderbilt University.

### Procedure

**Instruction phase** In order to make participants get acquainted with the format of events, participants first received ten example learning trials with animations in which a person either does or does not eat a fictional plant called Ablex, and the same person subsequently does or does not exhibit a fictional physical reaction called Burlosis. The face of the person in each trial varied in order to have participants familiarized with the fact that each trial dealt with different cases.

Afterwards, participants were told to estimate "the extent to which Ablex plants cause Burlosis" on a scale from -100 (i.e., Ablex plants may prevent Burlosis) to 100 (i.e., Ablex may be a strong cause of Burlosis). Participants received instructions about the scale and examples of some of the scores. In addition, participants were instructed that

$XY$   $YZ$   $Y \sim Z$   $\sim X \sim Y$   $\sim Y \sim Z$   $XY$   $YZ$   $\sim X \sim Y$   $\sim Y \sim Z$   $X \sim Y$   $XY$   $YZ$   $\sim X \sim Y$   $\sim Y \sim Z$   
 $\sim XY$   $XY$   $YZ$   $\sim Y \sim Z$   $\sim X \sim Y$   $\sim Y \sim Z$   $XY$   $YZ$   $\sim X \sim Y$   $\sim Y \sim Z$  (Block2)  $Y \sim Z$   $X \sim Y$   $\sim XY$   
 $XY$   $YZ$   $Y \sim Z$   $\sim XY$   $\sim Y \sim Z$   $Y \sim Z$   $X \sim Y$   $\sim Y \sim Z$   $\sim XY$   $X \sim Y$   $\sim X \sim Y$   $\sim Y \sim Z$   $\sim Y \sim Z$

Figure 4. The sequence used for the positive-first condition. Note: The sequence should be read from left to right. The trials in outline are negative evidence. (Block 2) indicates where the positive block ends.

"You may also decide that you cannot determine an estimate, given the information presented. In this case, you should give an estimate of 'NA.'" Participants wrote down their estimate from the practice trials on the sheet provided.

**Learning Phase** Upon completing the practice trials, participants were told that in the actual experimental trials, they would see descriptions of three events; the possible application of a fictitious fertilizer, the possible increase in the level of a fictitious chemical in the soil, and the possible blooming of a fictitious flower. During each learning phase, they were told what these three events were; they were presented with animations that would accompany each event. (See the material section.)

Participants were specifically told that they will have only two pieces of information available during learning (e.g., "whether it [i.e., the plot] had increased levels of the chemical compound alizene and whether the plant Lanya subsequently bloomed on it, or whether it received the fertilizer Yerban and whether it subsequently had increased levels of alizene"). They were also explicitly told that they would never receive information about both the fertilizer and the plant. This instruction was added to prevent any false memory of having observed the covariation between the fertilizer and the plant. That is, if participants did not select "NA" in estimating the causal strength between the fertilizer and the plant, it cannot be due to the fact that they misremembered what covariation information they had seen. In addition, we attempted to reduce participants' cognitive load during the learning phase by instructing them what their task is in advance. Thus, participants were told that their task was, for instance, "to judge the causal relationship between Yerban and Lanya." After these instructions, participants were presented with 40 learning trials. (See the material section for more detail.)

**Test Phase** After observing the entire sequence of trials in a learning phase, participants provided causal strength ratings for the effect of the fertilizer on the plant's blooming. Following Wasserman, Elek, Chatlosh, and Baker (1993), participants were asked, for instance: "To what extent does the fertilizer Yerban cause the plant Lanya to bloom?" Participants wrote a number between -100 and 100. They were also reminded to write "NA" if they "cannot determine an answer from the evidence given."

**Follow-up Phase** When participants were done with the learning and test phases for two sets of materials, they were asked to rate how much thought they put into each judgment on a 5-point scale where 1 indicated "no" and 5 indi-

cated "very much." Finally, they were asked to write about their "thought process in performing the experimental task" such as "Were there any strategies in particular you used while observing the experimental trial? How did you interpret each type of evidence?"

## Design and Materials

During the learning phase, participants received 40 trials, in which 20 provided X-Y covariation information and 20 provided Y-Z covariation information. For both,  $\Delta P$  was 0.2 as in Figure 2.

Two experimental conditions were defined by the order in which covariation information was presented during the learning phase. In order to construct the experimental sequences, two different blocks (positive and negative blocks) were created. The positive block had 24 trials, 20 of which were positive evidence (i.e.,  $XY$ ,  $YZ$ ,  $\sim X \sim Y$ , or  $\sim Y \sim Z$ ). The negative block had 16 trials, 12 of which were negative evidence (i.e.,  $X \sim Y$ ,  $\sim X Y$ ,  $Y \sim Z$ , or  $\sim Y Z$ ). Within each block (positive or negative), the trials were randomly ordered except that  $XY$  was always followed by  $YZ$ , and  $\sim X \sim Y$  was always followed by  $\sim Y \sim Z$ <sup>2</sup>. This random order was fixed across participants.

The two different experimental conditions were constructed by manipulating the order of these two blocks, so that, in the positive-first order condition, the positive block came before the negative block. This pattern is shown in Figure 4 where the positive and the negative blocks are separated (Block 2). Although lines separate the positive and the negative blocks in this figure, the entire sequence was presented to the participants without any indication of blocks. In the negative-first order condition, the negative block came before the positive block, which can be seen by switching the two blocks in Figure 4. Each participant went through both experimental conditions; the order of conditions was counterbalanced across participants.

The actual events used for X was the application of a fertilizer called Yerban or Zertax, Y was a change in level of a chemical called Alizene or Banizon, and Z was the blooming of a plant called Lanya or Hyaeth. We used animations to show spraying of fertilizer, increasing chemical level, and blooming plant. These animations were intended to keep participants' attention and to reduce their cognitive load by visualizing the events, so that participants would not make NA responses simply because they were over-

<sup>2</sup> This constraint could not have limited our interpretation of the effect of order because the same constraint was used for both order conditions. In another experiment where this constraint was not imposed, the number of NA responses was approximately the same as in the current experiment.

whelmed with too many combinations of presence and absence of events. Finally, each trial had a unique plot number displayed at the top of the screen, so that it was clear that each observation was separate.

To summarize, after receiving general instructions, each participant observed a series of trials about covariation between X and Y, and covariation between Y and Z in either the positive-first or the negative-first order, and made a causal strength judgment about X and Z. Afterwards, they observed another series of trials about three new events in the other condition, and then made a second judgment. Finally, they wrote about their thought processes.

## Results

We first examined the number of NA responses. In order to be truly valid NA responses, a participant should have given NA responses in both the positive-first and the negative-first conditions. Only one out of 39 participants did so. This participant's explanation also agreed with the true justification for doing so, "It was very difficult to reason without seeing all three factors together..."

Overall, 20.5% of responses across the two conditions were NA responses. There are a number of reasons to believe that these NA responses were unlikely to indicate a response of "indeterminate," but rather were a way to indicate a lack of causal relation between the two events. First, as reported earlier, only one of these subjects gave NA responses in both conditions. Second, the other participants' reasons for giving an NA response are consistent with this interpretation. For instance, one participant stated, "... no causal relationship, or lack thereof, could be estimated because every relationship that was shown had another that contradicted it..."; another participant stated, "...There seemed to be no relationship between any..." Third, most interestingly, there were more NA responses from the negative-first condition (35.9% of participants) than from the positive-first condition (7.7% of participants),  $\chi^2(1, N=39) = 8.1, p < .01$ , McNemar's test (McNemar, 1947). As we shall see below, those who did not give NA responses gave lower estimates in the negative-first condition than in the positive-first condition. Thus, more NA responses in the negative-first condition seemed to reflect participants' belief in weaker causal strengths.

Finally, we examined the mean estimates for each condition. The mean rating in the positive-first condition were 32.5 whereas that in the negative-first condition was only 5.8. For a statistical analysis, we excluded data of those who gave at least one NA response in either condition. With the remaining 23 participants, a dependent *t*-test showed that the mean rating in the positive-first condition (22.6) was reliably higher than that in the negative-first condition (4.1),  $t(22) = 3.71, p = .001$ . Thus, although participants saw identical contingencies between X and Y, and between Y and Z, their estimated causal strength between X and Z was stronger when they first saw positive evidence

for these two contingencies than when they first saw negative evidence.

## Discussion

The experiment reported here suggests that people are willing to make overarching causal inductions from constituent covariations. The bulk of participants in our experiment were willing to infer a causal relationship between the two terminal events in a proposed causal chain, even though they did not see the actual covariation between the two events. Of those people who were not so willing to make that inference, the majority seemed not to understand the normatively correct reason for a response of "indeterminate," instead using such a response as a proxy for a perceived lack of causal relationship. This willingness to make overarching inductions seems to be a sensible thing to do, given that people rarely have the luxury in the real world of observing a complete set of covariation patterns between multiple events.

When people make these overarching inductions, they seem to first infer that X causes Y and Y causes Z. Based on these inferences, they conclude that X causes Z. Some participants' explanations for their responses supports this. For example, one participant wrote, "I tried to find the patterns; for example, that A caused B, and B caused C, so A probably causes C" Another wrote, "I tried to see the relationship between the plant and the compound, and compound and fertilizer separately first. From there I tried to determine whether or not the presence or absence of fertilizer yielded the presence or absence of plant..." In other words, it appears that people may try to integrate the relative strengths of the intermediate relationships to estimate the strength of the relationship between the terminal events.

In this study, we used three events that may have reflected prior knowledge about the function of chemical fertilizers. Participants could have judged the strength of the causal relationships based solely on this prior knowledge. But such an interpretation is unlikely, given that the events we used were fictitious ones (and thus, there could not have been prior knowledge about causal strengths among these events), and furthermore, people's causal strength estimates were susceptible to manipulation of the order of evidence. Finally, preliminary results from a new study show that the same effects occur using very abstract events (e.g. squares changing shape or triangles changing color).

Extending Dennis and Ahn (in press), we found an order effect in situations involving three events. As we suggested, we think this order effect occurs because of an anchoring-and-adjustment process. One participant's description precisely illustrates this process: "If a particular pattern kept coming, but one or two trials deviated from the pattern, I would excuse them as flukes." In this case, the adjustments to the initial anchor was not strong enough, leading to biased final estimates of causal strength.

These results also have implications for current, nor-

mative theories of causal learning (Cheng, 1997; Glymour, 1998; Glymour & Cheng, 1998). These theories propose that people's estimates of causal power match those predicted by contingency indices calculated from observed conditional probabilities. However, in the current experiment no such index can be calculated, given the lack of observed co-occurrence between the terminal events. Yet people still were willing to provide judgments of causal strength, suggesting that the normative contingency-based theories are inadequate descriptions of human causal learning.

In contrast, the results are consistent with a causal power view of causal learning. According to this view, people infer causal relationships based on the proposed transfer of some sort of causal force or energy between one object and another. Specifically, the mechanism by which one event brings about another is proposed to be the main focus of causal reasoning (Ahn, et al., 1995; Bullock, Gelman, & Baillargeon, 1982; Harré, 1988). In the case of our experimental results, the presence of a putative mechanism (i.e. the change in soil chemistry) seems to outweigh the absence of the covariation information necessary to draw accurate causal inferences. Furthermore, the perceived strength of the target relationship was tied to the perceived strength of the mechanism, as evidenced by the primacy effect obtained. That is, the current results demonstrate people's reliance on mechanism information in the acquisition of new causal learning.

## Abstract

In this article we describe and analyze the evaluation of the Conceptual Helper, an intelligent tutoring system that uses a unique cognitive approach to teaching qualitative physics. The results of the evaluation are encouraging and suggest that the proposed methodology can be effective in performing its task.

## Introduction

Several studies (e.g. Hake, 1998; Halloun & Hestenes, 1985a, 1985b) have revealed that solving physics problems of a qualitative nature, such as the one presented in figure 1, pose a great cognitive challenge for most students taking elementary mechanics classes. They uncover naïve conceptions that are seldom removed or modified while completing their courses. Several attempts have been made to improve this situation though none has met with great success (Hake, 1998). Given that mechanics is a required course for most science majors, there is a clear need to improve its instruction. Toward this end we developed an intelligent tutoring system called the Conceptual Helper that follows a cognitive teaching strategy which is deployed emulating effective human tutoring techniques as well as successful pedagogical techniques and less cognitive demanding methods (Albacete, 1999; Albacete & VanLehn, 2000). In this article we describe the evaluation of the system and discuss its implications.

Two steel balls, one of which weights twice as much as the other, roll off of a horizontal table with the same speeds. In this situation:

- both balls impact the floor at approximately the same horizontal distance from the base of the table.
- the heavier ball impacts the floor closer to the base of the table than does the lighter.
- the lighter ball impacts the floor closer to the base of the table than does the heavier.

Figure 1. Example of a qualitative problem

## Brief description of the Conceptual Helper

The Conceptual Helper is an intelligent tutoring system (ITS) designed to coach students through physics homework problem solving of a qualitative nature, i.e., those problems that do not require the use algebraic manipulation to be solved but so require the application of conceptual knowledge. The tutor is basically a model-tracing ITS enhanced by the use of probabilistic assessment to guide the remediation. As a model-tracing ITS it contains a cognitive model that is capable of correctly solving any problem assigned to the student. Model tracing consists of matching every problem-solving action taken by the student with the steps of the expert's solution model of the problem being solved. This matching is used as the basis for providing immediate feedback to students as they progress through the problem. The system also has a student model which is represented by a Bayesian network. Each node in the network represents a piece of conceptual knowledge that the student is expected to learn or a misconception that the tutor can help remedy. Each node has a number attached to it that indicates the probability that the student will apply the piece of knowledge when it is applicable. As the student solves a problem, the probabilities are updated according to the actions taken by the student.

The challenge for the tutor is to decide when to intervene and what to say when it does so. This task is particularly challenging in this domain because tutoring of qualitative knowledge usually takes the form of verbal discussions, which given the state of the art of natural language processing is not an option for the computer tutor. To take care of the issue of when to intervene, we emulated human tutors in two ways: first, by giving immediate feedback (red for incorrect; green for correct) on each student entry (Merrill et al., 1992) and second, by helping the student with post-problem reflection (Katz & Lesgold, 1994; Katz et al., 1996). However, most of our work went into the second issue—deciding what to say when intervening. Novel approaches were developed in three areas: 1) the teaching strategy, 2) the manner in which the knowledge is deployed, and 3) the way in which misconceptions are handled.

## The Conceptual Helper's teaching strategy

Several studies (e.g. Van Heuvelen, 1991) have characterized students' knowledge of conceptual physics as a collection of ill-structured, unconnected facts and concepts which remain almost the same after completion of their physics classes. In contrast, cognitive science theory describes experts' knowledge bases as being well structured and *highly connected* (e.g. Chi & Koeske, 1983). Based on these findings, the teaching strategy embedded in the Conceptual Helper tries to make students' knowledge bases akin to the experts' by concentrating on teaching students the *links* that connect the domain's concepts of interest rather than the concepts in themselves.

The word "links" has been traditionally used in Semantic Networks to describe two-place predicates such as "is-a" or "part-of". However, we use the word "links" to describe rich qualitative rules that integrate pieces of knowledge. The links that the Conceptual Helper focuses can be inferred from the principles or from the definitions of the concepts of the domain. For example, one of the target links is "the direction of the net force applied to an object is the same as the direction of the object's acceleration." This connection between the concept of acceleration and the concept of net force can be inferred from Newton's second law. Likewise, the link "if the acceleration of an object is zero, then the object's velocity is constant" can be inferred from the definition of the concept of acceleration. These types of links are not evident to the students, in the sense that, even if students can repeat without hesitation the definition of acceleration and Newton's second law, by and large, they are generally not able to assert the links between concepts that follow from those definitions (Reif, 1995). However, these types of links are essential for reasoning qualitatively about the motion of objects and for solving the qualitative problems.

## How is the target knowledge taught?

The knowledge presented by the teaching strategy is deployed using a combination of: a) effective tutoring techniques, such as hinting through dialogues (Fox, 1993; Lepper et al., 1990), b) successful pedagogical techniques, like the use of molecular view of matter (Murray et al., 1990), and c) less cognitive demanding methods, such as using anthropomorphism (diSessa, 1993; Roschelle, 1992) and objects belonging to the material ontology (Chi, 1992) to reify abstract physics concepts. Figure 2 describes a mini-lesson that the tutor would present to the student when explaining the link "if (in a linear motion) the velocity of an object is decreasing, then the object's velocity and its acceleration have opposite directions." It exemplifies some of the techniques used by the tutor.

## The manner in which misconceptions are handled

To help students replace their misconceptions with scientifically correct knowledge, the Conceptual Helper presents students with the basic line of reasoning underlying the correct interpretation of the phenomena that are the base of the misconception. This is as opposed to using discovery environments or computer-simulated experiments, which

are two common ways in which teachers have tried to correct misconceptions (Hake, 1998). We believe that it is not setting up the (simulated) equipment, making the runs, recording the data, and inducing a pattern that convinces a student of a certain piece of knowledge, but rather the line of argument itself. Knowing the correct line of reasoning enables the student to self-explain the phenomenon, which has been argued (Chi, 1996) to be an effective means for learning.

## Evaluation of the Conceptual Helper

Forty-two students taking Introductory Mechanics classes were recruited and randomly divided into a Control group and an Experimental group. Both groups took a paper-and-pencil pre-test that consisted of 29 qualitative problems, 15 of which belonged to the Force Concept Inventory test<sup>1</sup>. Then they solved some problems with the Andes system receiving appropriate feedback according to the group they belonged to. The students in the Control Group had their input turned green or red depending on the correctness of the entry. Then, in the case of an incorrect action, the students could ask for help by making a choice from a help menu. The kind of help they received consisted of simple hints such as "the direction of the vector is incorrect." If the student asked for more help, they would just be told the correct answer. On the other hand the students in the experimental group received the green/red feedback depending on whether their action was correct but when the input was incorrect the Conceptual Helper intervened as explained above. After the students finished solving the problems with the system they took a post-test which was the same as the pre-test with the exception of a few changes in the cover stories of some problems. Among the problems included in the pre-test, post-test, and Andes there were multiple-choice questions and problems that required an explicit solution. Finally the students were asked to complete a questionnaire expressing their evaluation of the system.

## Results and their interpretation

The data gathered in such a way was analyzed in different ways.

### 1. T-test using the gain scores from pre-test to post-test as the dependent measure

Before comparing the gains of the two groups, we first checked whether their initial competencies were equivalent. The mean pretest score of the control group was 33.7 with standard deviation of 7.47. The mean pretest score of the experimental group was 31.36 with a standard deviation of 8.14. No reliable difference was found between the two groups ( $t(40)=0.965$ ,  $p=0.34$ ). Next, the gain scores from pre-test to post-test were compared. The mean of the control group was 4.12 with a standard deviation of 5.33.

---

<sup>1</sup> The Force Concept Inventory Test has become the standard test across the US to measure conceptual understanding of elementary mechanics (Hakes, 1998).

General definition of acceleration which constitutes the theoretical basis for the link (Reif and Allen, 1992)

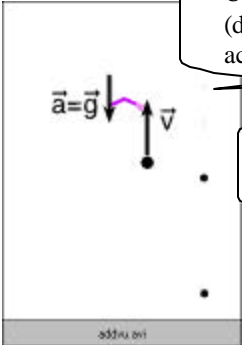

Anthropomorphizing the acceleration

General definition of the link (VanLehn et al., 1998)

Acceleration is a vector defined as the rate of change in velocity with time. You can think of the acceleration vector as what changes the velocity vector. Acceleration can change the velocity's magnitude, its direction, or both.

In this case, the magnitude of the velocity of the coin, i.e., its speed, is decreasing. The acceleration is making it shorter. For that to happen in a linear motion, the velocity vector and the acceleration, have to have opposite directions.

In the animation below, you can see the acceleration vector, with an imaginary arm, making the velocity vector shorter. Notice that the velocity and the acceleration have opposite directions.

Use of anthropomorphism to reduce cognitive demands (diSessa, 1993; Roschelle, 1992). Imaginary acceleration's arm shortening the velocity.

Use of vectors as the material representation of abstract concepts (Chi, 1992)

Why is the speed of the coin decreasing?

Figure 2: example of a mini-lessons

The mean of the experimental group was 7.47 with a standard deviation of 5.03. A reliable difference was found ( $t(40)=2.094$ ,  $p=0.043$ , two-tailed). This statistically significant difference suggests that the intervention of the Conceptual Helper had a positive impact on the students' understanding of the concepts as well as on their ability to abandon common misconceptions.

## 2. Effect size

Effect size is a standard way to compare the results of one pedagogical experiment to another. One way to calculate effect size, used in Bloom (1984) and many other studies, is to subtract the mean of the gain scores of the control group from the mean of the gain scores of the experimental group, and divide by the standard deviation of the gain scores of the control condition. That calculation yields  $(7.47 - 4.12) / 5.33 = 0.63$ . This result was comparable with peer and cross-age remedial tutoring (effect size of 0.4 according to Cohen, Kulik and Kulik, 1982). Some better results have been obtained with interventions that lasted a whole semester or academic year. For example, Bloom (1984) found an effect size of 2.0 for adult tutoring in replacement of classroom instruction and Anderson et al. (1995) reported an effect size of 1.0 for their tutoring systems. However,

our results were achieved with only two hours of instruction.

## 3. The fraction of the maximum possible gain realized (G)

Another measure that is used in the literature to compare the results of the FCI test is  $G = (S_f - S_i) / (100 - S_i)$ , where  $S_i$  and  $S_f$  are the pre- and post-test scores in percent (Hake, 1998). The nationwide score on the FCI test for traditionally taught classes is  $G = 0.25$ . For classes that are taught in a more interactive manner,  $G$  is between 0.36 and 0.68 (Mazur, 1997). The results obtained considering all the problems were the following: The mean of the control group was 0.26 with a standard deviation of 0.36. The mean of the experimental group was 0.43 with a standard deviation of 0.25<sup>2</sup>. The mean  $G$  for the control group matches that for traditionally taught classes. However, the  $G$  for the experimental group, 0.43, places it with the classes that are taught in a more interactive manner.

<sup>2</sup> Even though in the literature  $G$  is reported for each particular classroom in which a teaching method is applied and no statistical comparisons are made, we performed a two-tailed t-test to compare the  $G$  of the control and experimental group. The results were  $t(40)=1.84$ ,  $p=0.073$ .

#### 4. Existence of an aptitude-treatment interaction (ATI)

Innovative interventions sometimes cause higher gains for students with higher pre-test scores. What we want to find, of course, is that students with lower pre-test scores improved more, as they are the students who need more help. In order to see whether there was an aptitude-treatment interaction (ATI) and which way it would go, the experimental group was divided into two groups according to whether the student's pre-test score was above or below the median. The mean gain of the low pre-test score group was 10.68 with a standard deviation of 5.00. The mean gain of the high pre-test score group was 4.27 with a standard deviation of 2.39. A statistically significant difference between the gain scores was found ( $t(20)=3.83$ ,  $p=0.002$ , two-tailed).

A similar analysis was done with the control group. The results obtained were as follows: The mean gain of the low pre-test score group was 5.90 with a standard deviation of 5.87. The mean gain of the high pre-test score group was 2.35 with a standard deviation of 4.31. No statistically significant difference between the mean of the gain scores was found ( $t(18)=1.54$ ,  $p=0.14$ , two-tailed). Figure 3 illustrates the results for the experimental and control groups.

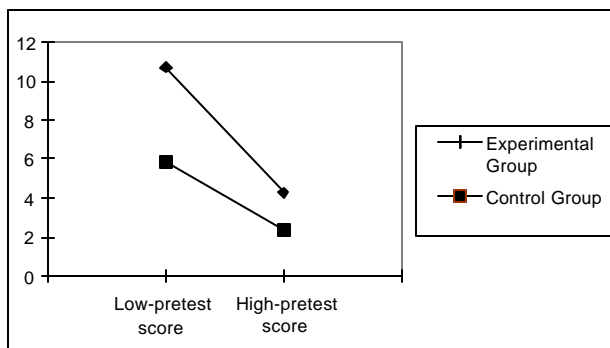

Figure 3. Mean gain of the low- and high- pretest score groups in the experimental and control groups.

It was encouraging to find that in the experimental group the poorer subjects' knowledge gains were significantly higher than those of good students, revealing that there was a desirable ATI. Additionally, it should be noted that the lower gain score in the high pre-test score group was not a consequence of a ceiling effect. The mean pre-test score of the high-pretest group was 38.04 with a standard deviation of 4.32. Since the maximum score is 49 there was an opportunity for this group to have a gain score very close to that achieved by the group of poorer students. Moreover, one student got a post-test score of 49, which indicates that the post-test did not require unlearnable knowledge.

#### 5. Detailed analysis of the individual pieces of knowledge and the effectiveness of each mini-lesson

A more detailed analysis was performed with the objective of determining the effectiveness of each mini-lesson in conveying the appropriate pieces of knowledge and in fostering their transfer. The method used basically consisted

of comparing whether receiving a mini-lesson had an effect on gaining versus not gaining the knowledge. Gaining the knowledge means giving an incorrect answer in the pre-test and a correct one in the post-test. Not gaining the knowledge means giving an incorrect answer in both pre- and post- tests. In the case where the target knowledge was addressed during explicit problem solving (e.g. for the rule "if an object's velocity is constant then its acceleration is zero") only students from the experimental group were considered, because only they could receive the mini-lessons. In the case where the target knowledge was addressed only through multiple-choice questions (e.g. the rule "heavier/lighter objects fall faster"), we compared the gains of the experimental group to the gains of the control group. The reason for doing this is that all the students in the experimental group received these mini-lessons, which were presented whenever the student answered a multiple-choice question (whether correctly or incorrectly). In the cases where the knowledge was addressed in both explicit and multiple-choice questions (e.g. the rule "force that continues to act after no contact"), we investigated whether receiving a mini-lesson during explicit problem solving would have any effect on gaining the rule. Hence only students from the experimental group were considered.

Statistical power problems prevented the analysis of most of the 18 target rules from showing a reliable relationship between receiving a mini-lesson and gaining the piece of knowledge. For some rules, almost all students received the corresponding mini-lesson, whereas for other rules, too few students received the mini-lesson. Nonetheless, there were a few rules where the relationship between mini-lessons and gain could be tested. They are described in Table 1. In all cases a Fisher's exact test (Hayes, 1994) was performed.

In most cases shown in Table 1 the number of students in each group was not large enough to provide statistical power, even if all those who received the mini-lesson gained and all those who did not receive the mini-lesson failed to gain (see third row of Table 1). Nonetheless, the data suggest a positive relationship between receiving a mini-lesson and gaining the corresponding knowledge.

#### 6. Summary of students' comments about the system

Students were asked to fill out a short questionnaire to express their opinion about the system. The rating of the different aspects of the system was done on a scale ranging from 1 to 5 where 5 was the best possible score. Students gave a score of 4 or above to all different aspects of the system (e.g., explanations that are clear to understand) which show a favorable acceptance of the system as well as a fairly high degree of liking of the mini-lessons.

## Discussion

The evaluation of the tutor suggests that the teaching strategy followed by the Conceptual Helper along with its methodology for deploying the target knowledge and handling misconceptions, is effective in accomplishing the task it was designed to perform. The experimental group surpassed the control group in every statistical test performed. Moreover, a detailed examination of the

Table 1. Relationship between receiving a mini-lesson and gaining knowledge for selected rules

Rule name	Group	Gainers	Non-gainers	Total	P	P for most extreme cases
Influence of weight on horizontal motion	<b>Experimental</b>	12 (.44)	2 (.07)	14 (.52)	0.005	<0.005

	<b>Total</b>	6 (.5)	6 (.5)	12 (1)		

The numbers in parenthesis represent the proportions with respect to the grand population

effectiveness of each individual mini-lesson showed a trend in favor of using the lesson.

Several studies (e.g. Halloun & Hestenes, 1985a) suggest that practice on solving quantitative problems does not transfer to conceptual problem solving. For instance, student who get full marks in their physics course still score poorly on the FCI test. On the other hand, elaborate confrontation-based, interactive instruction (e.g. see Hake, 1998) does raise scores on the FCI test, and by approximately the same amount as the Conceptual Helper. We believe that both forms of instruction are successful, at least in part, for the same reasons.

First, both handle misconceptions and errors with a form of confrontation. Both present students with situations (problems) and ask them to express their reasoning while solving them. In the Conceptual Helper, they do that by either taking an action, such as drawing a force, in an explicit solution problem or by choosing an answer in a multiple-choice question. If the action taken is incorrect, they are confronted with their erroneous knowledge by getting a mini-lesson. In interactive instruction the confrontations are quite elaborate and often involve doing experiments (e.g., Hake, 1992, McDermott, Shaffer & Somers, 1994, or White, 1993). What is interesting is that the evaluation of our system suggests that, in the case of misconceptions, confrontation based on *simply showing the*

*correct line of reasoning* to describe the phenomena under consideration can be just as effective in remediating misconceptions as the more elaborate, time-consuming kinds traditionally used to teach conceptual physics. Additionally, the evaluation suggests that, for correcting conceptual errors (or lack of knowledge), confrontation based on teaching the links that connect the concepts of the domain in the manner presented by the Conceptual Helper, may help the students build a more organized and better connected knowledge base, which in turn may facilitate qualitative reasoning.

A second factor underlying the success of both forms of instruction is that they both use conceptual problems instead of quantitative problems. This facilitates transfer, but it does not make it trivial. In particular, the Conceptual Helper does not “teach to the test” i.e., it does not teach exactly what the students are tested on. For example, the last rule in Table 1, which corresponds to the common misconception that there exists a force in the direction of the motion that continues to act after an object has been set in motion, shows a trend in favor of receiving a mini-lesson. The mini-lesson was received by students when they made a mistake in solving a problem that dealt with describing the motion of a box sliding on a frictionless surface after it has been pushed. On the other hand, the post-test problem analyzed in Table 1 involved describing the forces acting on

a ball thrown up in the air. Hence the situations presented in both problems were quite different even if the underlying misconception involved was the same.

In summary, it seems that the Conceptual Helper is just as effective but more efficient than other forms of qualitative physics instruction, in part, possibly because both forms of instruction use conceptual problems and confrontation. The next step in this line of research is to develop efficient and effective methods for *integrating* conceptual and quantitative learning.

# Memory in Chains: Modeling Primacy and Recency Effects in Memory for Order

Erik M. Altmann (altmann@gmu.edu)  
Human Factors & Applied Cognition  
George Mason University  
Fairfax, VA 22030

## Abstract

Memory for order is fundamental in everyday cognition, supporting basic processes like causal inference. However, theories of order memory are narrower, if anything, than theories of memory generally. The memory-in-chains (MIC) model improves on existing theories by explaining a family of order memory effects, by explaining more processes, and by making strong predictions. This paper examines the MIC model's explanation of primacy and recency effects, and the prediction that primacy should dominate recency. This prediction is supported by existing data sets, suggesting that Estes's (1997) perturbation model, dominant among theories of order memory, is incorrect. Fits to data are presented and compared with fits of other models.

## Introduction

When EgyptAir Flight 990 crashed off the coast of Massachusetts last year, the co-pilot had been recorded commending his life to God shortly before the plane went down. Did he do this because he had decided to crash the plane? Or did he do this because the plane was already crashing? The correct causal inference depends on knowing more than the key events — it also depends on knowing the *order* in which they occurred. If there were a living eyewitness, that person's memory for order would be immensely valuable, assuming it were correct. A theory that would help to predict the accuracy of order memory would thus be important in many applied domains.

Despite the importance of order memory, current theories are, if anything, narrower than is typical of memory theories generally. For one thing, they are only descriptive, in that they reproduce empirical phenomena once the analyst has encoded the appropriate underlying memory representation. For example, a widely cited model of order memory is the perturbation model (Estes, 1997). This model takes as input an array of items indexed by the dimension along which order confusion can occur (in the example above, time). Every so often, two cells in this array have some chance of swapping with one another. Over time, elements drift away from their original position, producing an "uncertainty gradient". However, the assumption that memory is organized as an array suggests that memory is an immense multi-dimensional array, with a dimension for each different kind of confusion. A representation this complex would place a heavy burden on the encoding process that creates it, and yet the perturbation model fails to address encoding at all. Two other models of order memory, the primacy model (Henson, Norris, Page, & Baddeley, 1996; Page & Norris, 1998) and the partial matching model (Anderson & Matessa, 1997), fail to address the encoding question, as well.

This paper presents a model of order memory that not only explains the underlying encoding processes, but also fits existing data better than the other models cited above.<sup>1</sup> The memory-in-chains (MIC) model accounts for a family of effects, but the focus here is on the theoretical prediction that primacy should dominate recency in memory for order.

## Encoding Memory for Order

The model presented here is built on the ACT-R/PM cognitive theory, which combines perceptual-motor constraints (Byrne, 1998) with an analysis of memory as adapted to the structure of the environment (Anderson, 1990). The three theoretical mechanisms underlying the MIC model are a dual-code representation of attended objects, associative learning, and noisy communication between cognition and attention.

## Dual-Code Representation

The main assumption shaping the representation of items in the MIC model is that cognition and attention are different processes that must communicate.<sup>2</sup> This assumption is fleshed out by what we know about the functional roles of the two processes. For example, we know that cognition can program attention in a top-down manner, and we know that attention communicates relatively low-level information to cognition for complex processing.

This analytical framework allows us to specify generic processes involved in processing sequential stimuli. For a given stimulus, cognition must first tell attention to attend to the stimulus. Then, attention must send the attended object back to cognition for further task-related processing. Thus, processing one stimulus requires two acts of communication — one to direct attention and one to receive the contents of the attended location.

In terms of representation, this communication model implies that processing a single stimulus involves two codes. One code, representing the item's location or position, is passed from cognition to attention. Another code representing the item's semantic or post-categorical identity, is passed back from attention. This need for two codes per item converges with broad support in the literature for dual-

---

<sup>1</sup> Executable and documented code for the model is available at <http://hfac.gmu.edu/people/altmann/nairne-rpm.txt>

<sup>2</sup> I use "attention" here to mean attention to external stimuli, and will use "the focus of mental attention" to refer to ACT-R's internal goal focus. The latter maps roughly to the task-related contents of the central executive (reviewed in Baddeley, 1992).

code representations (e.g., Logan, 1996; Paivio, 1971; Whiteman, Nairne, & Serra, 1994).

The communication model is illustrated in Figure 1A, which shows codes for three hypothetical items (X, Y, and Z). Time moves from left to right, and arrows mark the sequence in which codes appear in the focus of mental attention within cognition. (This interpretation of the arrows is elaborated below.) To process stimulus X, cognition sends a location code ( $X_L$ ) to attention, from which it receives an object code ( $X_O$ ). This is followed by whatever further task-related processing (not shown in the figure) might be required of the stimulus. The cycle then repeats for the next stimulus, Y.

An additional constraint on the model is that the channel through which cognition and attention communicate is the memory system itself. That is, when cognition sends a message to attention, it places a location code in memory for attention to retrieve. Similarly, attention sends a message back by placing an object code in memory for cognition to retrieve. This implementation of the communication channel is specified by the underlying theory, ACT-R/PM, but the tight functional integration of communication and memory can be traced to the earliest information-processing models of the cognitive system (e.g., Broadbent, 1958). The general implication is that functional descriptions of memory can also serve as functional descriptions of communication within the cognitive system as a whole. Two specific implications for the MIC model, concerning associative learning and noisy communication, are addressed in the next two subsections.

### Associative Learning

Evidence suggests that associative links between temporally proximal codes are acquired incidentally by the cognitive system (e.g., Altmann & John, 1999; Crowder, 1976; Hasher & Zacks, 1979; Mandler & Mandler, 1964; Nairne, 1983). Like other unified cognitive theories, ACT-R contains an *associative learning* mechanism to explain and predict the corresponding behavioral phenomena (Anderson & Lebiere, 1998). Associative learning in ACT-R creates a link between two codes if one (the target) is retrieved from memory while the other (the cue) is already in the focus of mental attention within the cognitive system. As in Soar (Newell, 1990), this association is a new, permanent element of long-term memory. In the future, if the cue again enters the focus of mental attention it will prime (spread activation to) the target, increasing the chance that the target will be the next item retrieved to the focus of attention. Associative links therefore allow chained retrieval, in which each retrieved item cues retrieval of the next item.

Applied to the memory-based communication protocol described above, associative learning produces a linked structure in which location codes are interleaved with object codes. Figure 1A illustrates such a structure after the model has studied and encoded the three hypothetical items (X, Y, and Z) introduced earlier. An important assumption in the model, based on standard associationist principles, is that each code remains in the focus of attention long enough to still be there when the next code is retrieved. The consequence is that the first code becomes the cue for the

**Figure 1:** Memory representations encoded by the MIC model after studying items X, Y, and Z. An item has a location code (subscript L) and an object code (subscript O). Panel A: Error-free representation. Panel B: Representation with two branches (incorrect links), in dashed ink, caused by noisy processing at study time.

second code, and the associative-learning mechanism links the two codes permanently in memory. In Figure 1 (and later figures), links created by associative learning are represented by arrows.

### Noisy Communication

If communication between cognition and attention were free of noise, then, subject to associative learning, it would produce a memory structure that allowed perfect sequential retrieval of items (Figure 1A). However, a memory system without noise would be unrealistic, and indeed sub-optimal (Anderson & Lebiere, 1998). In ACT-R as in other theories, items in memory have activation levels that determine their availability — items high in activation are less vulnerable to interference from other items. Noise in the memory system is expressed as transient fluctuations in individual activation levels, introducing the possibility of memory-retrieval error.

In the MIC model, noise can critically affect communication between attention and cognition at study time and produce incorrect links between codes. For each item processed, two memory retrievals are involved, one of a location code and one of an object code. Both retrievals are subject to activation noise. Specifically, when attention attempts to retrieve the location code most recently placed in memory, it may retrieve an old location code instead. Similarly, when cognition attempts to retrieve the object code most recently placed in memory, it may retrieve an old object code instead.<sup>3</sup> In terms of an everyday example, suppose that a newcomer is being introduced to a number of people, one at a time but perhaps too rapidly. While looking at the current person, the newcomer might “fall behind” and retrieve a previous, incorrect name. The result of such an

<sup>3</sup> I assume that errors occur within a code type only, and that a retrieval attempt always produces an item. These assumptions imply, for example, that an attempt to retrieve a location code will always produce a location code, though it may produce the wrong location code.

error would be that the newcomer might associate the wrong name with the wrong face. This kind of associative error is what the MIC model can encode at study time when there is noisy communication between attention and cognition.

Associative learning implies that a retrieval error during encoding produces an incorrect link in memory. I will refer to an incorrect link as a *branch*, because it branches off the correct temporal path through the codes of the list. The creation of a branch is illustrated in Figure 1B. There, a retrieval error occurs as  $Y_L$  is in the focus of mental attention and cognition tries to retrieve  $Y_O$ . This code was just placed in memory by attention, but due to noise in activation levels,  $X_O$  is transiently more active and hence is retrieved instead. This incorrect retrieval causes an association to be encoded between  $Y_L$  and  $X_O$ . This branch, shown as a dashed arrow, means that X could be mistakenly placed in Y's position at test time, producing an order error. This possibility is explored below in a discussion of the model's order-reconstruction process.

A second branch is also created in the scenario in Figure 3. When the model is presented with Z, it correctly retrieves  $Z_L$ , but  $X_O$  is still in the focus of mental attention (because of the retrieval error that occurred while processing Y). Therefore, associative learning creates a branch from  $X_O$  to  $Z_L$ , bypassing  $Y_O$ . This branch, however, need not produce an order error at test time, a possibility I also explore below.

A critical constraint on the communication model is the *near-miss* constraint, which is that incorrect codes temporally proximal to the correct code are more likely to intrude (and cause a branch). This constraint follows directly from the dynamics of activation in ACT-R. A code's activation depends on the lag since it was last retrieved — the longer the lag, the lower the activation. Therefore, a presented item will be more active than its predecessor (more precisely, the item's codes will be more active than its predecessor's codes), because the lag since presentation is smaller. The implication is that most branches created at study will be like those in Figure 1B — near misses, rather than far misses. This explains the uncertainty gradient, as I describe next.

## Reconstructing Memory for Order

In order-memory experiments, items themselves are usually shown at test as well as at study — participants are asked simply to reconstruct their original order. Because items and positions are available at test, an assumption I represent in the model is that people randomly choose an initial item or position to start the reconstruction process. This assumption means that the model can take many paths through the representation in Figure 1B. In particular, one of these paths produces a positional swap of the kind that underlies uncertainty gradients (Nairne, 1992), and a second path produces a correct reconstruction.

The model will make an order error if the first cue it uses is location code  $Y_L$ . This code was linked incorrectly to  $X_O$  at encoding time, because of a retrieval error then. The result now is that the model will infer that  $X_O$  was the object that originally appeared in location  $Y_L$ , producing an order error. Next, the model might use  $X_O$  as a cue for which location to focus on next, in which case it would focus on

location  $Z_L$ . Using  $Z_L$  as a cue, the model would most likely retrieve  $Z_O$ , which is correct. Thus, of two items placed, one was placed incorrectly and one correctly. The environment now indicates one remaining position and one remaining item. (Participants are typically instructed in the one-to-one nature of the reconstruction task, namely that every item maps to one position, with no items or positions left over.) The model will therefore infer that object  $Y_O$  occurred at location  $X_L$ . That is, the model will have swapped the order of the neighboring items X and Y. This is precisely the swap assumed (but not explained) by the perturbation model (Estes, 1997; Nairne, 1992).

Despite the encoding error, the structure in Figure 1B can also produce a correct reconstruction. If the model begins with location code  $X_L$ , for example, then it will most likely retrieve  $X_O$ , which is correct. Used as a cue,  $X_O$  will then prime two location codes,  $Y_L$  and  $Z_L$ . Suppose, first, that  $Z_L$  is retrieved. Used as a cue,  $Z_L$  will likely retrieve  $Z_O$ , which is correct. At this point, because only one item and one position remain, the model can place  $Y_O$  at  $Y_L$ , and the reconstruction will be correct. Suppose, instead, that when  $X_O$  is the cue,  $Y_L$  is retrieved. Used as a cue,  $Y_L$  will likely retrieve  $X_O$ , but this is now a dead end —  $X_O$  has been placed already. The model might now decide to place  $X_O$  elsewhere, but it might also decide simply to abandon  $Y_L$  as a cue and use  $Z_L$  instead. This would also produce a correct reconstruction.

## How Primacy and Recency Arise

A standard empirical finding is that items at either end of a list are remembered more accurately than items in the middle. To explain these primacy and recency effects in order memory, we first need to revisit how the model generates order errors from an incorrect representation like the one in Figure 1B. Suppose, again, that the model initially focuses on  $Y_L$  at test time (essentially asking itself, "What item was in the second location?"). This cue will prime retrieval of  $X_O$ , causing the model to place X second instead of first. In contrast, given the correct representation of Figure 1A,  $Y_L$  would correctly prime  $Y_O$ . Thus, the frequency of branches, in aggregate data, is an important factor in determining the frequency of order errors. This relationship between branches and order errors means that we can examine branching patterns in the representation created at study time to predict error patterns at test time.

Primacy and recency effects arise in the MIC model because branch frequency is higher for middle items than for end items. Support for this claim comes from analyzing the interaction of branch frequency, branch *length*, and the distribution of branch lengths across a list. The notion of branch length is illustrated in Figure 2. Panel A shows two branches out of  $Y_L$ . Each branch is of length 1, meaning that the code at the head of the branch is temporally off by one from the correct code. Panel B shows two branches out of  $Z_L$ . One branch is of length 1, but the other is of length 2 because the code at the head of the branch is off by two from the correct code.

Two important points are illustrated in Figure 2. First, branch frequency varies inversely with branch length. That is, in aggregate data, branches to nearby codes are more

**Figure 2:** Middle codes have greater branch frequency than end codes. Panel A: A middle code with two short branches. Panel B: An end code with one short branch (bigger F) and one long branch (smaller F).

frequent than branches to far-away codes. This relationship follows directly from the near-miss constraint at encoding time: Temporally near codes are more likely than temporally remote codes to intrude on communications between cognition and attention and thereby cause branches. In Figure 2, branch frequency is indicated by the size of the “F” label. The branch of length 2 has a smaller F, meaning that it occurs less frequently in aggregate data.

The second point is that branch lengths are distributed unevenly across a list: Middle items have more short branches than end items. This distribution is also illustrated in Figure 2. Panel A shows all possible branches out of a middle code, where by “all possible” I mean that there is one branch to each possible incorrect code in the list. Similarly, Panel B shows all possible branches out of an end code. The middle code in Panel A has two short branches, whereas the end code in Panel B has only one. Because short branches are more frequent in aggregate data, the middle code will produce more order errors at test time.

In sum, primacy and recency effects in the MIC model reflect error patterns during encoding, in that middle items suffer branches more frequently than end items. At test, these extra branches produce more order errors.

### Prediction: Primacy Dominates Recency

Models of order memory make conflicting predictions about the relationship between primacy and recency. The perturbation model, for example, predicts that primacy and recency should be symmetrical. In contrast, the primacy model was constructed to account for the common result that primacy is greater than recency (Henson et al., 1996).

The MIC model predicts that primacy should be greater than recency, an effect I refer to as *primacy dominance*. This prediction is a logical consequence of interactions between the task and constraints on the cognitive system (as specified by ACT-R/PM). In contrast, the primacy model (Henson et al., 1996; Page & Norris, 1998) accounts for primacy dominance with ad hoc mechanisms that are not constrained by task structure or independent theory.

Primacy dominance in the MIC model is a consequence of three interacting constraints. The first constraint is sequential processing at study — participants see one item at a time. The second constraint is related to branch *direction*. Every branch has a direction in that it points either forward or backward in time. A forward branch points to a code newer than the correct one (in Figure 3, from  $X_L$  to  $Y_O$ ). A backward branch points to a code older than the correct one (in Figure 3, from  $X_O$  to  $X_L$  instead of to  $Y_L$ ). As I elaborate below, branch direction interacts with sequential processing to make forward branches less likely to be taken at test time as the model is reconstructing order. The third constraint is the distribution of branch directions across a list. The early (not-recent) end of the list systematically involves more forward branches than the late (recent) end. Because forward branches are less likely to be taken at test time, early items suffer fewer order errors.

To see why forward branches are less likely to be taken at test time than backward branches, we need to consider the contingent nature in which forward branches are encoded at study. The encoding of forward and backward branches is illustrated in Figure 3. In that scenario, the model correctly processes  $X_L$  and transitions to  $X_O$  (creating link 1). A retrieval error then occurs — with  $X_O$  still in the focus of attention, the model retrieves  $X_L$  instead of  $Y_L$ . This creates a backward branch from  $X_O$  to  $X_L$  (link 2). The next step (assuming no further retrieval errors) creates a forward branch from  $X_L$  to  $Y_O$  (link 3). Thus, one retrieval error has produced two branches, one backward and one forward.

Two important points are illustrated in Figure 3. First, link 3 (the forward branch) is *contingent* on link 1 (the correct link). That is, a forward branch can only occur if a correct link out of the same code already exists. This contingency simply reflects sequential processing — X is already linked into the chain when Y is processed. The effect of this contingency is that at test time, if the model uses  $X_L$  as a cue, link 3 and link 1 prime competing targets. Thus the potential for taking a forward branch (link 3) is mitigated by the existence of the correct alternative (link 1). (By “taking a branch” I mean that the code at the tail end successfully primes the code at the head end, causing the latter code to be retrieved next.) The second important point in Figure 3 is that no such contingency accompanies a backward branch. Link 2 is the only link leading from  $X_O$ . At test time, if the model uses  $X_O$  as a cue, the backward branch will prime only  $X_L$ , with no correct alternative. Thus,

**Figure 3:** Forward branches are contingent on correct links, but backward branches are not. (1) Cognition retrieves  $X_O$ , creating a correct link. (2) Cognition retrieves  $X_L$  instead of  $Y_L$ , creating a backward branch. (3) Cognition retrieves  $Y_O$ , creating a forward branch.

backward branches are more likely than forward branches to be taken at test time, in the sense that they prime only incorrect target codes. Put another way, backward branches have a higher *effective* branch frequency than forward branches. If a given forward branch and a given backward branch have the same frequency over multiple trials, the backward branch will be taken more often, making it effectively more frequent.

The third constraint leading to primacy dominance is that forward and backward branches are distributed unevenly across a list. Both kinds of branch occur with equal frequency overall, because a single retrieval error at study produces one branch in each direction. However, earlier items have more forward branches than later items. In the extreme cases, the first item can have only forward branches, and the last item can have only backward branches. Thus, earlier items have a lower effective branch frequency. That is, branches from earlier items, though as frequent as branches from late items, are effectively less frequent because they are less likely to be taken during order reconstruction.<sup>4</sup>

In sum, primacy dominates recency as a natural consequence of task structure interacting with cognitive constraints. Sequential processing makes forward branches contingent on correct links, and because forward branches are more frequent for early items, these items suffer fewer order errors. In graphical terms, the serial position curve in order memory is rotated slightly clockwise.

### Comparing Model to Data

To test whether the model reproduces the serial position effects predicted by the analysis above, I simulated data from Nairne (1992). In that study, memory for order was tested implicitly. Participants were asked to give pleasantness ratings of words, with words presented in lists of five for three seconds a word. In a between-subjects manipulation, participants were given a surprise order-reconstruction test after 30 seconds of distraction, after 4 hours, or after 24 hours.

**Figure 4:** Accuracy data for order memory (Nairne, 1992) and fits of the MIC model.

<sup>4</sup> Specifically, the first item has a lower effective branch frequency than the last item, the second item has a lower one than the second-last, and so on.

**Figure 5:** Accuracy data for order memory (Nairne, 1992) and fits of the partial-matching (PM) model.

Data from Nairne (1992) are shown in Figure 4, fit to data from the MIC model. In all three conditions, primacy appears to dominate recency, and the model captures this pattern, accounting for 93% of the variance over 15 data points (RMSE = 4.2%). The close fit of the MIC model to complex data is strong support for its assumptions.

Moreover, the fit of the MIC model improves slightly on that of the perturbation and partial-matching models of the same data. The partial matching model, which fits better than the perturbation model (Anderson & Matessa, 1997), accounts for 90% of the variance over the same 15 data points (RMSE = 5.0%).<sup>5</sup> These fits are close, but Figure 5 shows that in all three conditions the model under-predicts primacy and over-predicts recency. This mis-alignment is systematic, according to the MIC model, because the partial matching model (like the perturbation model) mistakenly predicts that primacy and recency should be the same.

Many important details about the MIC model are omitted here. For example, only 15 data points, or those for correct responses, are shown in Figure 4; the total number of points fit by the model is 75. In addition, I have not described the time parameter that causes the model's serial position curve to shift downwards with longer retention intervals. These issues will be addressed in a subsequent report.

### Discussion

The MIC model explains a family of phenomena in memory for order. This paper has described how the model explains primacy and recency effects — why they occur, and how they are related. Primacy and recency effects occur because middle items suffer more branches (incorrect links) than end items and thus are more vulnerable to order errors. In addition, primacy should dominate recency because early items suffer fewer backward branches than early items. Backward branches cause more order errors than forward branches, offsetting the benefits of recency and rotating the

<sup>5</sup> The 15 data points given here are a subset of the 75 data points found in Nairne (1992). Fits of the perturbation and partial matching models to the complete data set are given in Anderson and Matessa (1997). The fit of the partial matching model to the 15 data points used here was determined by running the model available on the Web at <http://act.psy.cmu.edu>.

bowed serial-position curve slightly clockwise. In addition to these serial position effects, the MIC model also explains positional uncertainty (Altmann, 2000), and thus is a step toward an integrated and executable theory of memory for serial order.

The MIC model is important for several reasons. First, it extends an existing cognitive theory to incorporate an additional set of effects. The model inherits a representation, a learning mechanism, and a communication channel from ACT-R/PM. The model's explanations follow directly from the integration of these mechanisms, illustrating (again) the explanatory power of unified theories (Newell, 1973; 1990).

Second, the MIC model goes beyond existing models of order memory to explain study-time processes as well as test-time processes. Of existing models, the perturbation model is the best known, and has been advanced as a generalized model of memory loss and distortion (Estes, 1997). However, the perturbation model has nothing to say about how memory for order is encoded at study time, begging the question of how the information-rich, array-like memory representation input to the perturbation model comes about in the first place.

Third, the MIC model is behaviorally distinguishable from the perturbation and partial-matching models. Both models predict that primacy and recency should be symmetrical, but several data sets suggest otherwise. The primacy model (Henson et al., 1996; Page & Norris, 1998) accommodates this primacy dominance, but like the others fails to explain how order information is encoded in the first place. The MIC model, in which primacy dominance is a logical consequence of the underlying memory theory, may also be the most accurate and complete explanation, as well.

Rigorously testing the prediction of primacy dominance will be the next important step in this research. Because this prediction flows from architecture-level premises (about representation, learning, and cognitive noise), primacy dominance should be found pervasively in empirical studies. A second important step will be to extend the model to account for the "sawtooth" pattern arising when confusable and non-confusable items are interleaved (Henson et al., 1996). Finally, order memory is a strong constraint on memory theory generally. As we build toward unified theories of cognition, it will be important to integrate order memory with related models (e.g., Anderson & Matessa, 1997; Burgess & Hitch, 1999) and with the rich theoretical history of serial learning (see, for example, Crowder, 1976).

# Computational Explorations of the Irrelevant Sound Effect in Serial Short-Term Memory.

C. Philip Beaman (c.p.beaman@reading.ac.uk)

Department of Psychology  
University of Reading  
Earley Gate, Whiteknights  
Reading RG6 6AL

## Abstract

Although a number of current models of immediate serial recall exist, only one published model (Neath, 1999, 2000) incorporates simulations of the disruption of immediate serial recall by irrelevant background sound. This paper explores a possible model of irrelevant sound effects derived from Neath (1999) and applies the results of the model to previously unconsidered data sets. Studies by Neath (1999, 2000) apply the feature model, a mathematical model of short-term memory (Nairne, 1990), to some basic data regarding the irrelevant sound effect but this approach is ultimately limited by implicit assumptions regarding the nature of interference in short-term memory. Relaxing these assumptions allows for a wider application of a model of the irrelevant sound effect derived from that of Neath but not tied to the implementational detail of the feature model. The new model fits not only the original data considered by Neath (1999, 2000) but also empirical results concerning the effects of word-dose (Bridges & Jones, 1996) and token set size (Tremblay & Jones, 1998). It is concluded that the principles underlying the model provide a promising basis for further theoretical work.

## Introduction

Theories of verbal short-term memory have frequently made use of the irrelevant sound effect, the disruption to serial recall of visually-presented verbal lists by background noise, to inform the proposed architecture of short-term memory (e.g., Salamé & Baddeley, 1982; Jones & Macken, 1993). Briefly, sound played to a participant during or immediately following the visual presentation of a to-be-recalled list impairs recall of the list even though the participant was explicitly told to ignore anything they might hear and participants are never tested on the contents of the "irrelevant" or "unattended" sound. It is well established that, although there are individual differences in the level of susceptibility to irrelevant sound disruption (Ellermeier & Zimmer, 1997), most participants show the effect.

There has been a paucity of formal simulations of irrelevant sound disruption, even though it has been claimed that a number of models of immediate serial recall can, in principle, account for the effect (Burgess & Hitch, 1999; Norris, Page & Baddeley, 1995). One model that has been applied to the effect is the feature model of Nairne (Nairne, 1990; Neath & Nairne, 1995), a mathematical model of

short-term memory based around the idea that the items most likely to be recalled from a list are those items which are most distinctive (Nairne, 1988). The model has been applied to a number of short-term memory phenomena including modality differences, interference from concurrent articulation and from post-list stimulus suffixes (Nairne, 1990), the word-length effect (Neath & Nairne, 1995), and latterly the irrelevant sound effect (Neath, 1999, 2000).

## The Feature Model

The feature model assumes that interference rather than decay accounts for loss from short-term or *primary* memory. Representations of items in the feature model are vectors that code for the "features" of an item using a binary system allowing features to assume the values of +1 or -1. Features may be modality dependent, coding information available only in a specific sensory modality, or modality independent, coding information that can be conveyed equally by two or more modalities. Interference occurs in the model through overwriting. If a feature takes the same value as its counterpart in the immediately preceding vector, the earlier feature value is overwritten. This is implemented by setting the value of the feature to 0 so that it is informationally uninformative. To give an example, if feature  $x$  of item  $n+1$  is the same as feature  $x$  of item  $n$ , then feature  $x$  of item  $n$  is overwritten and can play no part in determining whether or not item  $n$  is accurately recalled (see Figure 1). Feature values are generated randomly and independently for each feature vector.

**Figure 1.** Degradation of the representation of a list item in primary memory when a successive item shares some of the same feature values.

Retrieval consists of finding the best match to a degraded cue amongst a set of undegraded feature vectors assumed to reside in what is termed *secondary memory*. Two memory systems coding the same information is in many ways an unsatisfactory situation if retrieval depends on the degraded representation. Nevertheless, it is useful from the point of view of modelling the irrelevant sound effect since accurate recall of the degraded memory trace can be viewed as recall of the correct item in the correct order. In immediate serial recall the to-be-recalled stimuli are typically overlearned, lists of digits or consonants for example, so the task is essentially one of identifying which (known) item appeared in which serial position. As argued elsewhere (Beaman & Jones, 1997, 1998) the irrelevant sound effect consists primarily of a disruption of order information. The distance between the degraded item and its undegraded secondary memory representation is calculated by summing the number of mismatched features,  $M$ , and dividing by the total number of compared features,  $N$ , as described in Equation 1.

$$d_{ij} = a \sum \frac{b_k M_k}{N} \quad (1)$$

The value  $M_k$  is the number of times feature position  $x_{jk}$  does not equal feature position  $x_{ik}$ . The parameter  $a$  is a scaling parameter that is assumed to correspond to the overall level of attention, and  $b_k$  is used to weight particular comparisons if the task makes them more important than other comparisons. Distance,  $d$ , is then used to calculate the similarity between the degraded vector and the undegraded secondary memory representation according to Equation 2.

$$s(i, j) = e^{-d_{ij}} \quad (2)$$

The probability that a particular secondary memory trace,  $SM_j$  will be sampled as a potential recall response for a particular degraded memory vector  $PM_i$  is then given by Equation 3, where  $w_{ij}$  and  $w_{ik}$  are possible response bias weights.

$$P_s(SM_j | PM_i) = \frac{w_{ij}s(i, j)}{\sum_{k=1}^N w_{ik}s(i, k)} \quad (3)$$

This basic overwriting model was supplemented by Neath (1999, 2000) with two additional assumptions to account for the irrelevant sound effect<sup>1</sup>. The first assumption was that

<sup>1</sup> In fact, the full version of the feature model also includes a further recovery equation that produces the characteristic bow-shaped serial position curve. However here we are specifically concerned with the results of overwriting. Since there has been never been any suggestion that interactions between irrelevant sound and serial position might be of theoretical significance the recovery equation has been omitted here and performance averaged over serial position, a procedure also followed by Neath (Neath, 1999, 2000).

irrelevant sound will act like a concurrent articulation task, already accounted for by the model (Nairne, 1990) and overwrite a certain proportion of the modality independent features. The second assumption was that irrelevant sound and concurrent articulation manipulations differ in that effort is required to actively produce irrelevant noises in the concurrent articulation manipulation, which is not true of the irrelevant sound manipulation. Neath therefore proposed varying the attentional parameter  $a$  by a greater amount in simulations of concurrent articulation than in simulations of irrelevant sound.

With these amendments the feature model shows the correct qualitative pattern of results across a number of experimental studies altering only those parameters associated with the particular psychological process implicated (Neath, 1999, 2000). For example, the model shows correctly that the irrelevant sound manipulation impairs memory for lists of words, but less so than concurrent articulation. However, as with all simulation studies, there is experimental evidence not addressed by the model. Some of this evidence is directly relevant to the way in which irrelevant sound interferes with memory representations and cannot be accounted for by the feature model as it is currently formulated.

Two inconsistencies exist in the feature model account. Firstly, as described earlier, within-list interference results only in a lack of information about the overwritten item, not misinformation. Equation 1 ensures that these effects will be functionally identical, since only mismatches between the degraded vector and the undegraded secondary memory representation influence the similarity calculation (Equation 2) and both lack of information and misinformation are counted as mismatches. Nevertheless, the theory would be more parsimonious if all overwriting was implemented in an identical manner. The second inconsistency is more serious and concerns the difference between overwriting by irrelevant sound and overwriting by concurrent articulation. Concurrent articulation is implemented as setting half of the modality independent features to a constant value because participants are required to repeated the same utterance over and over "so the same information will overwrite the to-be-remembered items" (Neath, 2000). However in a simulation showing how varied speech (referred to in the literature as "changing-state" irrelevant sound) impairs recall performance more than repeated speech ("steady-state" irrelevant sound) (Jones, Madden & Miles, 1992) this logic was not used. Instead a variation in the attentional parameter is invoked, with variable speech assumed to attract more attentional resources.

The alteration in the attention parameter  $a$  is necessary as demonstrated by Figure 2, which shows the average sampling probabilities of a 9-item list in steady state, changing state and quiet control conditions across 200 simulations. The steady state condition comprised of setting half of the modality independent features to a constant value as described in previous simulation studies (Nairne, 1990). The changing-state condition comprised of overwriting half the modality dependent features with different random combinations of +1 and -1. The attentional parameter,  $a$ , was set to an identical value for all conditions. All other

weights were set to 1.0. Note that, provided all the other parameters remain unaltered, the same patterns of performance can be obtained at different overall recall levels by simple manipulation of the attentional parameter,  $\alpha$ . However, this would simply be an exercise in data-fitting and not of psychological interest. The important point to note is that without the adjustment of the attentional parameter no changing-state effect is observed. Parameter adjustment of this type is also perilously close to data-fitting.

**Figure 2.** Sampling probabilities of items in the feature model under steady state and changing state irrelevant sound conditions when the attentional parameter is kept constant.

### A Revised Model: The Changing-State & Token Set Size Effects

The problem of the changing-state effect can be viewed as a special case of what Tremblay and Jones (1998) termed "token set size". These authors argued that the essential cause of disruption by irrelevant sound was the presence of change in the irrelevant speech stream (Tremblay & Jones, 1998). The number of different changes, they argued, was irrelevant: disruption should markedly increase from one token (steady-state) to two tokens (changing-state) and there should be little or no further disruption beyond this token set size.

To give a concrete example, repetition of the utterance "A" in the irrelevant sound stream constitutes steady-state irrelevant sound and a token set size of one. According to Tremblay and Jones this should not cause discernible disruption to immediate recall. Repetition of the utterance "A-B" however, has a token set size of two and introduces change into the irrelevant sound stream and should therefore disrupt immediate recall. Repetition of the utterance "A-B-C" is also a changing-state stimulus (with a token set size of three) and should therefore also disrupt recall, but not necessarily to any greater degree than a token-set size of two since it is the number of changes, not the nature of the changes, which is important. Thus, changes from A to B then back to A are functionally equivalent to changes from A to B to C. Jones and Tremblay (Jones & Tremblay, 2000) argued that the increment in the attention parameter necessary to account for the changing-state effect did not

have a principled basis. If the increase in the attention parameter was necessary to account for increased attentional demands of changing-state stimuli, they argued, it should be increased in linearly as token set size increases, which would result in a linear increase in disruption not present in the experimental data.

A more realistic simulation than that attempted by Neath (Neath, 1999, 2000), and one that is not subject to these criticisms can be attempted by dropping the overwriting inconsistencies within the feature model. Closer examination of the experimental procedure employed in the Tremblay and Jones study reveals that over a 19 second presentation and retention interval Tremblay and Jones presented large numbers of repetitions of the same tokens. 38 separate occurrences of the same token in set size 1 condition, 19 repetitions each of 2 tokens in set size 2 condition, 13 repetitions of 3 tokens in set size 3, 8 repetitions of 5 tokens in set size 5 and 5 repetitions of 7 tokens in set size 7. If a conservative estimate of a covert rehearsal rate no faster than the slowest overt rehearsal rate of 2 items per second is assumed there could have been 38 rehearsals of a single item in this time period. The feature model has to assume that interference with the representations can occur at rehearsal as well as encoding since the experimental data demonstrate that the irrelevant sound effect can occur in an unfilled retention interval, after list presentation but before recall (Beaman & Jones, 1998). Therefore there will have been multiple opportunities for interference in this time period and the feature model's assumptions that changing-state irrelevant sound randomly overwrites half of each item's feature values once begins to look implausible.

Instead assume that each item was rehearsed once as it is presented- this is a standard assumption common to many models of immediate serial recall (e.g., Page & Norris, 1998). This leaves a 10 second retention interval which, with a slow rehearsal rate of 2 items per second and a 9 item list to rehearse gives time for only 2 complete rehearsals of the entire list. Thus altogether there is sufficient time for at least 3 rehearsals of the whole to-be-recalled list. During this time overwriting can occur. If, instead of the rather arbitrary random overwriting in Neath's version of the feature model, feature vectors are generated to represent the irrelevant sound utterances overwriting can then proceed according to the within-list overwriting principles specified by Nairne (1990). To simulate the token set size, the number of feature vectors representing the irrelevant sound was varied. Unlike the previous reported simulation, there was no adjustment of the attention parameter between set size 1 (steady-state) and set size 2 or above (changing-state).

The data regarding the token set size effect are shown in Figure 3, together with a simulation study using the same procedure described here. The number of overwrites was set to 3 per item, and the items chosen to overwrite were randomly sampled from a set size of 2, 3, 5, or 7 randomly generated feature vectors. As Figure 3 clearly shows, this procedure produces a very good match between the performance of the model and the data from the experiment. Notably, the model actually provides a closer fit to the data than the predictions of Tremblay and Jones (1998).

**Figure 3.** The effects of token set size of irrelevant sound on sampling probabilities in the revised model. The crucial difference between steady state and changing state conditions is represented by the difference between set sizes 1 and 2, and unlike in the feature model, is here reproduced accurately.

### The Word-Dose Effect

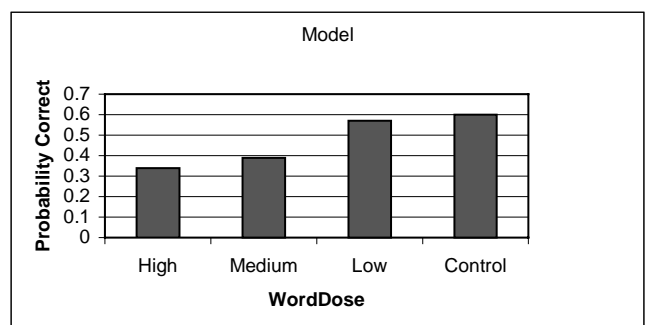

Further evidence not specifically considered by Neath (2000) which is impossible to fit into his account without amendment includes the so-called "dose" effect (Bridges & Jones, 1996). This refers to the finding that increasing the absolute number of words in the irrelevant sound stream increases the size of the effect. Dose differs from token set size in that, for example, "A-B-A-B" has a set size of two but a dose of four. The word dose manipulation introduced by Bridges and Jones (1996, Experiment 1) shows strongly linear effects (see Figure 4) when recall performance is collapsed across presentation position of the to-be-recalled lists. An attempt to fit a linear trend line to these data yielded an  $R^2$  value of .9978. The original feature model cannot account for these data because there is no mechanism within the model for relating probability of overwriting to number of irrelevant items presented. In the absence of this the model simply implements irrelevant sound interference of any type, regardless of the number of times each irrelevant item is presented as a single overwriting of each to-be-recalled item by a random combination of +1s and -1s. The problem presented by token set size effects is thus repeated, and the model cannot produce word dose effects.

**Figure 4.** Moderating effects of word dose on disruption of serial recall by irrelevant sound.

However, as before, reconsideration of the word dose data suggests an alternative modelling formulation. Bridges and Jones presented 5 different speech items repeatedly over the 9 second period of presentation of the to-be-recalled lists, a 10 second retention interval and a 15 second response time (Bridges & Jones, 1996). If the simplifying assumption is made to exclude the response time from the analysis then in the high dose condition participants heard 57 separate utterances, in the medium dose, 29 utterances, and in the low dose 19 utterances.

It is not clear how the timing of the rehearsal coincides with the presentation of the irrelevant sound material, however the data indicate that a linear relationship exists across high, medium and low word "dose". In the next simulation therefore I assume one overwrite per item for the low dose condition, and increment the number of overwrites by one for the medium-dose and two for the high-dose conditions. The item chosen to overwrite each time will be chosen at random from a set of 5 vectors representing the 5 irrelevant sound items generated in the same manner as the vectors representing the to-be-recalled list. Overwriting will then proceed in the same manner as within-list overwriting. It is clear that this procedure ensures not only that overwriting becomes internally more consistent but also allows for simulation studies of such effects as word dose that are more directly motivated by the experimental procedure and do not resort to altering free parameters. The results of the word dose simulation are shown in Figure 5. Comparison of this figure to the data displayed in Figure 4 reveals that a reasonable qualitative fit to the data has been obtained. There is a discernible effect of word dose, to which a linear trend line can be fit with  $R^2 = .9198$ , mirroring the linear trend observed in the experimental data.

**Figure 5.** Effects of word-dose on sampling probabilities of the revised model.

### General Discussion

Although the basic structure of the feature model was appropriated for this series of demonstrations, the intention was not to produce a simulation of irrelevant sound effects specific to the feature model. Instead, the intention was to investigate how some of the basic data regarding the irrelevant sound effect can emerge from an architecture in which items are represented in a distributed fashion and

presentation of irrelevant sound reduces the signal-to-noise ratio when recall of the order of those items is necessary. This investigation has succeeded in showing that increasing the noise in a distributed representation will reproduce many of the main findings in the irrelevant sound effect literature with relatively few assumptions. As such, there are three important points to note about this exercise.

The first point is to note that many of the feature model's assumptions, although implemented here, did not play any role in determining the outcome of the simulations. For example, although the assumption that overwriting occurs across features sharing the same value was implemented here, it is not necessary to make this assumption in order to obtain these results. Since each vector was constructed using random selections of binary values, the same result would be expected even if overwriting occurred across features with different values. It is possible to state with some confidence that reducing the signal-to-noise ratio by addition of noise to a distributed representation of the to-be-recalled item will therefore reproduce at least some of the key phenomena of irrelevant sound. The second point of note is that the simulations presented here reproduce many of the key characteristics predicted by Jones' changing-state hypothesis (Jones, Madden & Miles, 1992). These include: the changing-state effect itself, the specific disruption of order information, the word dose effect, and the lack of any great effect of token set size above 2 tokens. The simulations produce these effects, however, without the explicit representation of order cues assumed to be necessary by Jones.

The final point in favour of the current set of simulations is their relative parsimony and close correspondence to experimental procedure. Neath (2000) was criticized by Baddeley (2000) and Jones and Tremblay (2000) for the number of free parameters required in his simulations of irrelevant sound effects. The current set of simulations show that incrementing the attentional parameter is not necessary if the original (within-list) overwriting principles of the feature model are followed. This procedure provides a better fit to the data than the addition of the extra parameter. By explicitly matching the possibilities of overwriting to the rehearsal process it also proves possible to account for the word dose effect, which cannot otherwise be accounted for by the feature model. What is envisaged is an interference effect of discrete irrelevant sound elements on a continuous, serial, mental rehearsal process.

### Abstract

Many languages have a grammatical gender system whereby all nouns are assigned a gender (most commonly feminine, masculine, or neuter). Two studies examined whether (1) the assignment of genders to nouns is truly arbitrary (as has been claimed), and (2) whether the grammatical genders assigned to nouns have semantic consequences. In the first study, English speakers' intuitions about the genders of animals (but not artifacts) were found to correlate with the grammatical genders assigned to the names of these objects in Spanish and German. These findings suggest that the assignment of genders to nouns is not entirely arbitrary but may to some extent reflect the perceived masculine or feminine properties of the nouns' referents. Results of the second study suggested that people's ideas about the genders of objects are strongly influenced by the grammatical genders assigned to these objects in their native language. Spanish and German speakers' memory for object-name pairs (e.g., apple--Patricia) was better for pairs where the gender of the proper name was congruent with the grammatical gender of the object name (in their native language), than when the two genders were incongruent. This was true even though both groups performed the task in English. These results suggest that grammatical gender may not be as arbitrary or as purely grammatical as was previously thought.

### Introduction

Does the language you speak shape the way you understand the world? Linguists, philosophers, anthropologists, and psychologists have long been interested in this question. This interest has been fueled in large part by the observation that different languages talk about the world differently. However, despite the interest and controversy, definitive answers are scarce. This paper briefly reviews the empirical history of this question and describes two new studies that demonstrate both the role of semantic constraints in shaping language, and the role of language in shaping habitual thought.

The doctrine of Linguistic Determinism—the idea that thought is determined by language—is most commonly associated with the writings of Benjamin Lee Whorf. Whorf proposed that in so far as languages differ, their speakers too may differ in how they perceive and act in objectively similar situations (Whorf, 1956). What has been called the strong Whorfian view—the idea that thought and action are *entirely* determined by language—has long been abandoned in the field. Particularly effective in undermining the strong

view was work showing striking similarity in color memory despite wide variation in color language (Heider, 1972; but see Lucy & Shweder, 1979; Kay & Kempton, 1984).

Although the strong linguistic determinism view seems untenable, many weaker but still interesting formulations can be entertained. Several lines of research that have looked at domains other than color, have found cross-linguistic differences in thought. Unlike English speakers, speakers of classifier languages like Yucatec Mayan and Japanese were found to attend to the substance of an object more so than to its shape, and were also more likely to extend novel labels based on the substance than on the shape of a given example (e.g., Imai & Gentner, 1997; Lucy, 1992). When asked to reconstruct an array of objects, speakers of Tzeltal (a Mayan language that relies primarily on an absolute framework for describing spatial relations) were likely to preserve the positions of objects with respect to cardinal directions (so that the Northern-most object was still the Northern-most), while English speakers (who rely heavily on relative spatial descriptions) tended to preserve the objects' positions relative to themselves (so that the left-most object was still left-most) (Levinson, 1996).

Studies of conceptions of time have also revealed cross-linguistic differences (Boroditsky, 1999). English and Mandarin speakers talk about time differently—English speakers predominantly talk about time as if it were horizontal, while Mandarin speakers commonly use both horizontal and vertical metaphors to talk about time. This difference between the two languages is reflected in the way their speakers think about time. A collection of studies showed that Mandarin speakers tend to think about time vertically even when they are thinking for English (Mandarin speakers were faster to confirm that March comes earlier than April if they had just seen a vertical array of objects than if they had just seen a horizontal array, and the reverse was true for English speakers). Another study showed that the extent to which Mandarin-English bilinguals think about time vertically is related to how old they were when they first began to learn English. In another experiment native English speakers were taught to talk about time using vertical spatial terms in a way similar to Mandarin. On a subsequent test, this group of English speakers showed the same bias to think about time vertically as was observed with Mandarin speakers. This last result suggests two things: (1) language is a powerful tool in shaping thought, and (2) one's native language plays a role in shaping habitual

thought (how we tend to think about time, for example) but does not completely determine thought in the strong Whorfian sense.

There is an interesting discrepancy between these later findings, and those on color perception. Why would there be such strong evidence for universality in color perception, but quite the opposite for spatial relations or thinking about time? One possibility is that language is most powerful in influencing thought for more abstract domains, that is, ones not so reliant on sensory experience (Boroditsky, 1999). This paper considers an extreme point along this concrete-abstract continuum—the influence of grammatical gender on the way people think about inanimate objects. We will first characterize the ways in which people’s ideas about the genders of objects may be similar across cultures, and then go on to explore whether there may also be systematic language-driven differences in how people conceive of objects.

## Grammatical Gender

Forks and frying pans do not (by virtue of being inanimate) have a biological gender. The perceptual information available for most objects does not provide conclusive evidence as to their gender—conclusive gender information is only available in language (and only in those languages that have grammatical gender). The present paper examines whether (1) there are any correspondences in the assignment of grammatical gender between languages, (2) whether people include gender in their conceptual representations of objects (despite the fact that objects don’t actually have gender), and (3) whether people’s ideas about the genders of objects (if they have any at all) are influenced by the grammatical genders assigned to these objects in their native language.

Unlike English, many languages have a grammatical gender system whereby all objects (e.g., penguins, pockets, and toasters) are assigned a gender. Many languages only have masculine and feminine genders, but some also assign neuter, vegetative, and other more obscure genders. It has long been claimed that the assignment of grammatical gender to object names is semantically arbitrary, and has nothing to do with the conceptual properties of the referent (e.g., Bowers, Vigliocco, Stadthagen-Gonzalez & Vinson 1999). At first glance, this does appear to be the case. As Mark Twain noted, “In German, a young lady has no sex, while a turnip has, ....a tree is male, its buds are female, its leaves are neuter; horses are sexless, dogs are male, cats are female—tomcats included.” Further, the grammatical genders assigned to names of particular objects vary greatly across languages (Braine, 1987). For example, the sun is feminine in German, but masculine in Spanish, and neuter in Russian. The moon, on the other hand, is feminine in Spanish and Russian, but masculine in German.

Despite wide variation in the assignment of grammatical genders, speakers across languages do share some common beliefs about the genders of objects. For example, when asked to classify names or pictures of objects into masculine and feminine, English and Spanish speakers tend judge natural objects as feminine and artifacts as masculine (Mullen, 1990; Sera et al., 1994). It is also interesting that English speakers make consistent judgments about the genders

of objects, despite the lack of a grammatical gender system in English (Sera et al., 1994).

So are people’s shared beliefs about the genders of objects reflected in the assignment of grammatical gender, or is grammatical gender entirely arbitrary? If the assignment of grammatical gender is not entirely arbitrary, then there may be some correspondences across languages. For example, animals or things that are easy to anthropomorphize may have stereotypically feminine or masculine qualities and so may be more likely to have consistent grammatical genders across languages. The names of animals that are beautiful and graceful may tend to be grammatically feminine, while those of aggressive and strong animals may tend to be masculine. It is possible then, that the grammatical genders of nouns may correspond across languages. Further, we should see more correspondence for nouns whose referents are easy to anthropomorphize (and are likely to have stereotypically masculine or feminine properties) than for nouns whose referents are more abstract or less human-like.

To test these predictions, we compared the grammatical genders assigned to objects in Spanish and German to the intuitions of English speakers regarding the gender of the same objects. Since English does not use grammatical gender, English speakers’ untrained intuitions about the genders of objects provide a nice comparison group. If the assignment of grammatical gender is truly arbitrary, then we should see no correspondence between the intuitions of English speakers about the genders of objects and the genders assigned to those objects in Spanish and German. If, on the other hand, the grammatical genders of nouns do in part reflect the properties of their referents, then we should see a correspondence in the assignment of genders across languages, and also a correspondence between Spanish and German genders and English speakers’ naive intuitions.

## Experiment 1

### Methods

#### Participants

Fifteen native English speakers (none of whom were familiar with either Spanish or German) participated in this study in exchange for payment.

#### Materials

We constructed a list of 50 animal names and 85 names of artifacts (including vehicles, articles of clothing, and household items). Only words that had a single dominant translation (as determined by two native Spanish and two native German speakers) into both Spanish and German were included on the list.

#### Procedure

English speakers were asked to classify each object and animal on our list as either masculine or feminine. Participants were required to provide a single answer for each item.

## Results

Overall, there was appreciable agreement on the assignment of grammatical genders between Spanish and German ( $r=.21$ ,  $p<.05$ ). As we predicted, the two languages agreed more on the genders of animals ( $r=.39$ ,  $p<.01$ ), then on the genders of artifacts ( $r=.10$ ,  $p=.35$ ). Interestingly, English speakers' ratings of these objects showed the same pattern of correspondence. Spanish and German grammatical genders corresponded well with English speakers' intuitions about the genders of animals ( $r=.29$ ,  $p<.05$ , and  $r=.43$ ,  $p<.01$  respectively), but not the genders of artifacts ( $r=.04$ ,  $p=.73$ , and  $r=.11$ ,  $p=.32$  respectively). It is striking that despite a lack of grammatical gender in English, English speakers intuitions about the genders of animals corresponded well with the grammatical genders assigned to those animals in Spanish and German. These findings suggest that the grammatical genders assigned to animals may not have been entirely arbitrary, but rather may have reflected people's perceptions of the particular animals as having stereotypically masculine or feminine properties.

It appears that the assignment of grammatical genders to nouns (or at least to animal names) may not be entirely arbitrary, and may have been influenced in part by people's perceptions of the nouns' referents. But what happens once grammatical genders are assigned? Could they in turn influence people's mental representations of objects? If so, then there may be striking cross-linguistic differences in how people think about objects.

How might people's representations of objects be affected by the grammatical gender of their labels? One possibility is that in order to efficiently learn the grammatical gender of a noun to begin with, people focus on some property of that noun's referent that may pick it out as masculine or feminine. For example, if the word for "sun" is masculine in one's language, one might try to remember this by conceiving of the sun in terms of what are perceived as stereotypically masculine properties like powerful and threatening. If the word for "sun" is feminine, on the other hand, one might focus on its warming and nourishing qualities.

Even after the grammatical genders of nouns are learned, language may influence thought during "thinking for speaking" (Slobin, 1996). Languages can force their speakers to attend to the genders associated with objects by making them grammatically obligatory. When speaking a language with grammatical gender, speakers often need to mark objects as gendered through definite articles (e.g., "le" and "la" in French), refer to objects using gendered pronouns (e.g., if the word for "fork" is masculine, a speaker might say, "he is sharp"), and alter adjectives or even verbs to agree in gender with the nouns (e.g., in Russian, verbs in the past tense must agree in gender with their subject nouns). Needing to refer to an object as masculine or feminine may lead people to selectively attend to that object's masculine or feminine qualities thus making them more salient in the representation.

So, does talking about inanimate objects as if they were masculine or feminine lead people to think of inanimate objects as masculine or feminine? Some preliminary evidence suggests that it may (Jakobson, 1966; Konishi, 1993; Sera, Berge, & del Castillo, 1994). In one early study, Rus-

sian speakers were asked to personify days of the week (reported in Jakobson, 1966). Subjects consistently personified the grammatically masculine days of the week (Monday, Tuesday, and Thursday) as males, and the grammatically feminine days of the week (Wednesday, Friday, and Saturday) as females, though they could not explicitly say why they did so.

In another study, German and Spanish speakers rated a set of nouns on the dimension of potency (a dimension highly associated with masculinity) (Konishi, 1993). Half of the nouns were grammatically masculine in German and feminine in Spanish, and the other half were masculine in Spanish and feminine in German. Both German and Spanish speakers judged the word "man" to be more potent than "woman". Interestingly, they also judged nouns that were grammatically masculine in their native language to be more potent than nouns that were grammatically feminine. This was true even though all of the test nouns referred to objects or entities that had no biological gender (including names of inanimate objects, places, events, and abstract entities).

Converging evidence comes from a series of studies in which Spanish speakers were asked to rate pictures of objects as masculine or feminine (Sera et al., 1994). Spanish speakers consistently classified objects in accordance with their grammatical gender in Spanish. The effect was more pronounced when the pictures were accompanied by their Spanish labels. The grammatical gender consistency effect also showed up when subjects were asked to attribute a man's or a woman's voice to each picture. Finally, Sera et al. found that by about second grade, Spanish speaking children assigned voices to objects in accordance with the grammatical gender of their labels.

Although results of these studies are suggestive, there are serious limitations common to these and most other studies of linguistic determinism. First, speakers of different languages are usually tested only in their native language. Any differences in these comparisons can only show the effect of a language on thinking for that particular language. These studies cannot tell us whether experience with a language affects language-independent thought such as thought for other languages, or thought in non-linguistic tasks.

Second, comparing studies conducted in different languages poses a deeper problem: there is simply no way to be certain that the stimuli and instructions are truly the same in both languages. This problem remains even if the verbal instructions are minimal. For example, even if the task is non-linguistic, and the instructions are simply "which one is the same?", one cannot be sure that the words used for "same" mean the same thing in both languages. If in one language the word for "same" is closer in meaning to "identical," while in the other language it's closer to "relationally similar", speakers of different languages may behave differently, but due only to the difference in instructions, not because of any interesting differences in thought. There is no sure way to guard against this possibility when tasks are translated into different languages. Since there is no way to know that participants in different languages are performing the same task, it is difficult to deem the comparisons meaningful.

Finally, in all of the tasks so far, participants were asked to provide some subjective judgment (there were no right or wrong answers). Providing such a judgment requires participants to decide on a strategy for completing the task. When figuring out how to perform the task, participants may simply make a conscious decision to follow the grammatical gender divisions in their language. Evidence collected from such subjective judgments cannot tell us whether gender is actually part of a person's conceptual representation of an object, or if (left with no other criterion for making the subjective judgment) the person just explicitly decided to use grammatical gender in answering the experimenter's questions.

The present study improves on the previous studies in two important ways. First, both Spanish and German speakers were tested in English. This allows us to test whether experience with a language affects language-independent thought (here, thinking for other languages). Second, participants were tested in a memory task and at test were asked to provide the right answer (not a subjective judgment). The present study examined the ways in which previous knowledge (experience with Spanish or German) interfered with participants' ability to correctly perform the task.

In this study, participants were taught proper names for objects (e.g., an apple may have been called "Patrick") and were tested on their memory for these object—name pairs later in the experiment. First, we were interested in whether English speakers would be better at remembering female names for objects that another group of English speakers had rated as more feminine (and male names for objects rated more masculine). Second, we were interested in whether Spanish and German speakers would be better able to remember a proper name for an object if the proper name was consistent with the grammatical gender of the object name in their native language. All objects were chosen to have opposite grammatical genders in Spanish and German (e.g., the word for "apple" is feminine in Spanish, but masculine in German). So, we predicted that German speakers would be better at remembering a proper name for "apple" if the name was "Patrick" than if it was "Patricia". The opposite should be true for Spanish speakers. Since the experiment was conducted entirely in English, this is a particularly conservative test of whether grammatical gender influences the way people think about objects.

## Experiment 2

### Methods

#### Participants

Twenty-five native Spanish speakers, sixteen native German speakers, and twenty English speakers participated in the study in exchange for payment.

#### Materials and Design

A set of 24 object names (e.g., apple, arrow) and 24 proper names (e.g., Patricia, Patrick) was constructed (see Appendix A). The object names were chosen such that half

were grammatically masculine and half were grammatically feminine and the grammatical gender in Spanish and German was opposite for each object name (if an object name was grammatically masculine in Spanish, it was grammatically feminine in German and vice versa). A separate group of 30 English speakers rated the 24 objects chosen for this experiment as masculine or feminine.

Half of the proper names were male and half were female; male and female proper names were chosen to be similar to one another (e.g., Alexander, Alexandra). This was done to increase the difficulty of the memory task. All of the materials used including the instructions were in English. For each participant, the computer randomly arranged the object names and proper names into object—name pairs, and presented them in a random order.

Spanish, German, and English speakers completed the same experimental task. Participants read the following instructions "For this experiment, we have given names to a bunch of objects. For example, we may have decided to call a chair 'Mary'. You will see objects and their names appear on the screen (e.g., chair—Mary), and your task is to try to memorize the name we have given to each object as well as you can. Your memory for these names will be tested later in the experiment."

#### Procedure

Participants were tested individually. A computer presented the experimental materials and recorded the participants' responses.

**Learning:** Participants learned 24 object—name pairs presented to them on a computer screen in a random order. Each object—name pair was presented on the screen for five seconds, and was automatically followed by the next pair. Each pair was presented only once.

After the learning, participants completed a five-minute distraction task unrelated to this study which was inserted to promote forgetting.

**Test:** Object names from the learning set were presented on the computer screen one at a time and participants were instructed to indicate the gender of the proper name that had been associated with that object name in the learning set by pressing one of two keys on the keyboard.

### Results

As predicted, English speakers remembered object—name pairs better when the gender of the proper name was consistent with the object's rated gender (86% correct) than when the two genders were inconsistent (78% correct),  $t=2.17$ ,  $p<.05$ . The results suggest that people do include gender in their conceptual representations of inanimate objects. Further, Spanish and German speakers showed language-specific biases in memory. Both groups remembered object—name pairs better when the gender of the proper name given to an object was consistent with the grammatical gender of the object name in their native language (82% correct) than when the two genders were inconsistent (74% correct),  $t=2.55$ ,  $p<.01$ . Since the object names used in this study had opposite grammatical genders in Spanish and German, Spanish and German speakers showed opposite

memory biases—for those objects that Spanish speakers were most likely to remember female names, German speakers were most likely to remember male names (and vice versa),  $F(1, 39)=6.21$ ,  $p<.05$ . These findings suggest that people's ideas about the genders of objects are strongly influenced by the grammatical genders assigned to those objects in their native language.

### Summary

Two studies examined whether (1) the assignment of genders to nouns is truly arbitrary (as has been claimed), and (2) whether the grammatical genders assigned to nouns have semantic consequences. In the first study, English speakers' intuitions about the genders of animals (but not artifacts) were found to correlate with the grammatical genders assigned to the names of these objects in Spanish and German. These findings suggest that the assignment of genders to nouns is not entirely arbitrary but may to some extent reflect the perceived masculine or feminine properties of the nouns' referents. Results of the second study suggested that (1) people do include gender in their conceptual representations of inanimate objects, and (2) people's ideas about the genders of objects are strongly influenced by the grammatical genders assigned to these objects in their native language. Spanish and German speakers' memory for object-name pairs (e.g., apple-Patricia) was better for pairs where the gender of the proper name was congruent with the grammatical gender of the object name (in their native language), than when the two genders were incongruent. Since both groups performed the task in English, it appears that the semantic representation of gender (once it has been established) is not language-specific. These results suggest that grammatical gender may not be as arbitrary or as purely grammatical as was previously thought.

### Acknowledgments

This research was funded by an NSF Graduate Research Fellowship to the first author. Partial support was also provided by NIMH research grant MH-47575 to Gordon Bower. The authors would like to thank Michael Ramscar, Herbert H. Clark, Barbara Tversky, and Gordon Bower for many insightful discussions of this research, and Jill M. Schmidt who was indispensable in assembling the stimuli.

## Abstract

A Minority-default inflectional system is one in which a regular affixational process (e.g., the plural morpheme ~s in English) applies to fewer forms in the language than the irregular stem modifying process (e.g. the umlauting in “foot-feet”-like pairs). Following the work of McCarthy & Prince (1990), the plural system of Modern Standard Arabic has been cited as an archetype of a minority-default system with the regular sound plural involving fewer nominal forms than the irregular broken plural. On the basis of linguistic, statistical and distributional evidence, we argue that this assertion is wrong. We point out that while both broken and sound plural have qualitatively limited productivity, the latter is quantitatively the more productive process. Furthermore, the diversity of regularly inflected phonological forms ensures that they will be treated as the default by a connectionist model. In the light of these findings we argue that a good model of morphological processing should motivate the observation that so few of the world’s languages use minority defaults.

## Introduction

A major debate in psycholinguistics revolves around the question of how human language users employ finite means to produce large numbers of words and utterances. In order to deal with this generic question, several more specific questions need to be spelt out. One such specific question is whether or not the structural properties of regularly and irregularly inflected words correspond to their representational and processing properties. Focusing on the representational format would lead one to tackle the question of whether morphologically complex words are represented as full forms or as decomposed morphemes (Marslen-Wilson et al., 1994). Focussing on the processing aspect of the equation would lead one to raise the same question from a different standpoint, namely whether morphologically complex words are formed via a symbolic rule-based mechanism operating on grammatical categories or via a memory-based associative network that extracts probabilistic contingencies between them (Rumelhart & McClelland, 1986; Pinker & Prince 1988; Marslen-Wilson & Tyler, 1998).

The acquisition of the English past tense has been extensively studied in an attempt to decide between the different approaches to this problem. The literature on the subject provides at least three different models. The first, and most traditional assumes that the regular past forms in English like “walk-walked” are formed by a rule, whereas irregular past tenses like “eat-ate, give-gave” are learned individually

by rote (Berko, 1958). Because it fails to explain the sub-regularities among the irregular verbs and the expansion of irregular inflection to phonologically similar nonce forms, this view has largely been superseded by a second model which claims that a rule-governed process inflects all the regular forms while an associative memory takes care of all the irregular forms. The associative memory identifies the irregular forms and blocks the default process from applying to them (Pinker, 1991; Pinker & Prince, 1988). The third model is a connectionist one, which dispenses with explicit rules and assumes that language learning is better accounted for using a single mechanism, namely a network of interconnected units (Rumelhart & McClelland, 1986). Both regular and irregular forms are inflected by this network, with responses to novel forms depending on their phonological similarity to familiar patterns (Plunkett & Marchman, 1991).

Both dual-route models and connectionist networks are able to handle an inflectional system like English because of its distributional characteristics. The English system is one in which about 95% of the forms are regularly inflected. This is an unproblematic situation for a dual-route model, which deals with the small number of irregulars via associative memory and the rest via a default rule. A connectionist network would also exhibit relative ease handling such cases. The network would store information about all forms and the preponderance of regular forms would trigger a regularisation process, by virtue of the fact that any novel form is more likely to resemble a regular form than an irregular one. Proponents of the dual-route model have argued that a dual mechanism can also deal satisfactorily with linguistic systems where the default is a minority, such as the inflection system in German (Clahsen, 1999). This is because rule-like behavior does not need to be contingent on the default pattern applying to a majority of the forms in the language. Rather, a default can be defined, the argument goes, even in terms of the least frequent patterns, because this process depends on applying the same procedure to different items bearing the same symbol (Clahsen, 1999). Conversely, a connectionist network was predicted to be unable to simulate people’s regularisation of novel forms in a minority-default system like German.

The Arabic plural is perhaps the most widely cited example of a minority default system (McCarthy & Prince, 1990; Hare, Daugherty & Seidenberg, 1992; Ravid & Farah, 1999). For this reason it was used as a litmus test by Plun-

kett and Nakisa (1997) who found that a connectionist network can model generalisation behaviour to both regular and irregular patterns, despite the absence of a default rule. One of our aims here is to take issue with the position that Arabic has a minority default plural system, and show that it hinges on an inaccurate description of the language. In order to come to grips with this claim we will begin by laying out the morphological system of Modern Standard Arabic and argue that this language does not exhibit a minority-default, using linguistic and corpus analyses. Second, we will examine the phonological distribution of Arabic nominal forms using a more representative sample than the one used by Plunkett and Nakisa (1997). All these sources of evidence converge on the idea that the Arabic plural system has a majority default of the type learnable by a connectionist model. We conclude by considering why minority default systems seem scarce across world languages.

## The Morphological System of Arabic

Traditionally Arabic surface forms are analysed as consisting of two abstract morphemes a root and a word pattern<sup>1</sup>. The root usually comprises three consonants and carries semantic meaning, while the word pattern contains vowels and conveys syntactic information. According to this approach, the representation of a surface form such as [nuqil] “*be moved*” will consist of the root {nql}, and the word pattern {fuil} where the letters “f, l, i” indicate the slots into which the root consonants map.

The morphology of Arabic falls into two relatively distinct parts (Bohas & Guillaume, 1984). The first consists of primitive nouns that are thought to be unrelated to verbs, although verbs can be derived from them. For example, from the primitive noun [kalbun] “*dog*” the verb [kaliba] “*get infected with rabies*” can be formed. The second part relates to verb morphology and subsumes verbs proper and deverbal nouns. Verb morphology can be further divided into unaugmented and augmented verb forms. There are three unaugmented forms and 14 augmented forms of which only 9 are frequently used in Modern Arabic. As for deverbal nouns, there are about 10 types such as the active participle, passive participle, instance noun, manner noun, “*assimilated noun*”, and the “*masdar*” (Holes, 1995).

## Verb Morphology

Verb morphology with its two components is the most productive part of the language in the sense of being the main source of most of the *transparent derivatives*<sup>2</sup>. For example, combining the root {xrʒ} “*go out*” with the pattern {faʕal}, produces the form [xaraʒ] “*go out*”. The same root can be further combined with as many as 5 augmented patterns yielding the following surface forms: [xarraʒ] “*move out*”

<sup>1</sup> Within the framework of multilinear phonology the word pattern is further broken down into a vocalic morpheme and a skeletal morpheme (McCarthy, 1981).

<sup>2</sup> Some authors claim that “as many as 400 different surface word forms can be derived from some trilateral verbs” (Xasaara, 1994, p. 134)

[ʔaxraʒa] “*take out*”, [taxarraʒ] “*graduate*” [taxaaraʒ] “*disengage*”, [ʔistaxraʒ] “*extract*”. From each of these forms a host of deverbal nouns can be derived. For example, the masculine active participle [xaariʒun] can be derived from the unaugmented surface form [xaraʒ]. Also, the following active participles can be derived respectively from each of the augmented verb forms above: [muxarriʒ], [muxriʒ], [mutaxarriʒ], [mutaxaariʒ], [mustaxriʒ]. Passive participles can also be formed from these verb forms. In addition to this, an “*instance noun*”, a noun denoting that the action takes place only once, [xarʒatun] “*one departure*” can be obtained from the verb [xaraʒ], the noun [taxaaruʒ] can be derived from the verb [taxaaraʒ], the noun [ʔistixraaʒ] can be derived from the verb [ʔistaxraʒ] and so on. This pattern of productivity holds even for verbs that are originally derived from primitives. Thus from the primitive noun [kalb] “*dog*” the verb [takaalab] “*to rave*” is derived and from the latter an active participle [mutakaalib] “*someone who raves*” and a noun [takaalub] “*raving*” are formed. Similarly, loan words like [talifuun] “*telephone*” can be used to derive verbs such as [talfan] “*to telephone*”, and an active participle like [mutalfin] “*phone-caller*”.

## Nominal Morphology

Arabic nouns undergo various morphological alterations of which the most frequent is perhaps pluralization. This is achieved either via suffixation or via pattern modification. In the first case, known as sound pluralization, the suffix ~uun is added to masculine nouns (e.g. [naazihun-naazihuun] “*successful*” male) while ~aat is appended to feminine nouns (e.g. [naazihatun-naazihaat] “*successful*” female). In the second, often referred to as broken pluralization, the pattern of the singular noun is dramatically altered and in some cases some of its consonants are lost (e.g. [ʃunquud-ʃanaqiid] “*cluster*” [ʃandaliib-ʃanaadil] “*nightingale*” (Murtonen, 1964; Xasaara, 1994; Holes, 1995). Sound pluralization is considered as regular inflection because it involves little or no allomorphy while broken pluralization is irregular because it is rich with allomorphic variations.

McCarthy & Prince’s (1990) work on the broken plural in Modern Standard Arabic has promulgated the idea of Arabic having a minority default system of pluralization. According to them the sound plural is “*systematically found only with the following short list: proper names; transparently derived nouns or adjectives such as participles, deverbals and diminutives; non-canonical or unassimilated loans and the names of the letters of the alphabet*” (McCarthy & Prince, 1990: p. 212). Phrased as such, the above claim is misleading because it fails to distinguish between qualitative and quantitative productivity. The distinction between these two aspects of productivity rests on the difference between the number and/or the strength of the constraints weighing on a particular morphological process (Aronoff & Anshen, 1998). Perhaps an English example will help to bring our point home. The suffix ~ity is qualitatively productive but quantitatively unproductive. This is because it tends to be appended preferentially to adjectives ending in suffixes like ~ible, ~able, ~ic, ~id etc. Conversely the suffix ~ness, is quantitatively productive because it is subject to fewer constraints and is not restricted to follow a

limited set of suffixes (Aronoff & Anshen, 1998). Arabic sound and broken pluralization processes lend themselves readily to a description in terms of a distinction between qualitative and quantitative productivity. Both are subject to few constraints. Sound pluralization is restricted to a set of nominal forms that must meet formal (e.g., length in syllables) and syntactic criteria (e.g. being preferably adjectives). But broken pluralization is subject to even more rigid and more numerous formal (e.g. length and syllabic structure) and syntactic criteria (e.g. being preferably a substantive). Quantitatively, however sound pluralization would not be a minority case even if it were found *only* with transparent derivatives. Transparent derivatives, as we will shortly show, correspond to the most productive part of the language. Additionally, sound pluralization affects systematically all recent loan words comprising more than three letters like [dimuqraat<sup>5</sup>iyun] “*democracy*”, [tafazatun] “*television*”.

### Type Frequency of Broken and Sound Plurals

A given trilateral root in Arabic can be productively mounted on some combination of the 9 frequent augmented word patterns to create new words. For instance, the trilateral unaugmented surface form [katab] “*write*” can be combined with as many as 7 augmented forms. Conversely, the unaugmented trilateral [ʔabaθ] “*fool around*” gives rise only to one augmented form [ʔaabaθ] “*banter*”. Although no systematic statistical work on the number of augmented and unaugmented verb forms is available in Arabic, one may safely hypothesise that trilateral roots can yield on average at least three surface forms. Confining our analysis to active and passive participles in the masculine and feminine forms, we can plausibly say that each of the augmented forms gives rise to at least 4 deverbal forms. There are 11978 roots of which 7597 are trilaterals, 4081 are quadrilaterals and 300 are quinquilaterals (Moussa, 1996). Assuming that the derivation of four masculine and four feminine deverbal surface forms from each root is not an overestimate, the trilateral roots alone will yield as many as 91164 surface forms that take a sound plural. If we consider the derivatives from quadrilateral and quinquilaterals, this estimate will increase greatly.

It is true that some transparent derivatives like “assimilated nouns” and lexicalized active participles often pluralize in the broken way. This does not mean that nouns taking a broken plural will outnumber those pluralizing regularly because for almost every assimilated noun or indeed for any other noun that has a broken plural, there is either a diminutive form, a feminine form or both, and these take a sound plural. Thus the assimilated noun [ʔaaqir] “*barren*” has the broken plural [ʔawaaqir], whereas its diminutive [ʔuwaiqir] has the sound feminine plural [ʔuwaiqiraat]. Likewise, the primitive noun [qird] “*monkey*” has a broken plural [quruud] but its feminine form [qirdatun] “*female monkey*” has a sound plural form [qirdaatun].

The type of pluralization taken by a particular nominal form may be driven by semantic considerations as well. Many active participles, derived from roots mounted on the unaugmented pattern, like [kaatib] may pluralize regularly

or irregularly depending on whether they function as a substantive or as an adjective. Used as a substantive to denote a permanent activity or quality, they form a broken plural. Thus when the token [kaatib] is used in the sense of “*author*”, it has the broken plural [kuttaab]. By contrast, when it is used in the sense of “*someone who writes*”, it pluralizes regularly as [kaatibuuna].

In order to support our claim statistically, we analysed all nouns listed in the “Basic Lexicon of Modern Standard Arabic” (henceforth BLMSA), which consists of the 3000 most frequent words in the language (Khoulooghli, 1992). The BLMSA is based on a statistical analysis of more than 200,000 words drawn from newspapers and literary work throughout the Arab world. The author reports a total of 1670 nominal forms (i.e. nouns and adjectives).<sup>4</sup> Of these, 666 tokens are explicitly listed as taking a broken plural and 610 as taking a sound plural (215 masculine and 395 feminine). For the remaining 394 words, the author lists either the plural form (sound or broken) with no mention of the singular or vice versa. The 394 words divide into 357 singular forms for which the corresponding sound plural is not listed, 11 sound plural forms without their relevant singular forms, 20 singular forms without their corresponding broken plurals, and 6 broken plurals for which the corresponding singulars are not listed. Possibly the author lists only the singular or the plural of these forms because the other is not one of the 3000 most frequent words of the language. However, this does not mean that they would be *hapax legomena* in a larger database if this were available. Indeed many of the unlisted words like [murabbaʔaat] “*squares*” and [ʔaaliha] “*gods*” the respective sound and broken plural forms of the listed singular forms [murabbaʔ] “*square*” and [ʔilaah] “*god*” are part of the familiar repertoire of words that can be encountered even in children’s books.

In sum, of the 1670 most frequent nominal forms of the language almost two thirds, 978 nouns, pluralize via suffix addition and the remaining forms take a broken plural. This is important for two reasons. First, testing a few random samples taken from the BLMSA shows that it has an average coverage of 75 to 95% of any Modern Arabic text. So if the BLMSA is representative, we can infer that about 56% of Arabic words are nouns (i.e. lexical nouns and adjectives) and most critically that about 59% of all nouns of the language take a sound plural while only 41% take a broken plural. Because BLMSA is a sample of the most frequent words, it is likely that lower frequency nouns are even more skewed towards the regular plural.

In view of this, it seems untenable to consider Modern Standard Arabic as an example of a minority-default system. Just why this stance has come to be held is an offshoot of Arabic lexicographers’ work that lists only the broken plural forms because they are unpredictable.

In this section, we have laid out linguistic and corpus-based evidence that the Arabic plural system is not a minority-default. The affixational process involves far more words than the templatic processes, although the proportion

<sup>4</sup> The remaining 1330 items listed in the BLMSA comprise verbs and the closed classes of particles, prepositions and conjunctions.

is still not as high as the English past tense system, with 95% regulars (Daugherty & Seidenberg, 1992).

### The Phonological Distribution of Sound and Broken Plurals

The supposed status of the Arabic plural as a minority default system has resulted in claims that it cannot be accommodated by a connectionist model. Plunkett and Nakisa (1997) examined this claim using statistical analyses and connectionist simulations. They noted that a minority default is not necessarily a problem for a connectionist account provided there is an even distribution of regulars and relatively tight clustering of irregulars in the phonological space spanned by the uninflected forms (cf. Hare, Elman & Daugherty, 1995). In cases where irregulars share strong phonological resemblances, but the minority of regulars vary widely in their phonological form, a multi-layered connectionist network can develop “distributional default” behaviour. Although the irregulars may be dominant in number, they are concentrated in relatively small pockets of the network’s input space, and so are unlikely to be similar to novel items. Instead, most novel inputs will be more similar to a regular item, and so will be inflected in the same way leading to default behaviour.

Plunkett and Nakisa (1997) examined the phonological distribution of Arabic singulars in this respect using a set of nouns drawn from the Wehr Arabic Dictionary (Wehr, 1976). On the basis of statistical analyses of the distribution of singulars in phonological space, they argued that the Arabic plural system does not provide a basis for developing a distributional default. Instead of evenly spanning the phonological space, the sound plurals appeared to be even more phonologically coherent than many of the broken plural sets. A connectionist network trained on the singular to plural mapping for these items would therefore be unlikely to develop behaviour resembling a default rule.

Plunkett and Nakisa (1997) also showed that despite the absence of the conditions necessary for developing default behaviour, a connectionist model was able to learn and generalise the pluralization task rather well. In fact generalisation (i.e., performance on untrained patterns) in the network was superior to a dual-route model irrespective of the division of labour between the two routes. In effect, the network was performing adequately with neither a majority nor a minority default.

The work of Plunkett and Nakisa (1997) is important because it marks out the conditions necessary for default-like behaviour in a connectionist model of morphological processing. The behaviour of a connectionist system does not just depend on the numbers of regular and irregular items. It also depends on the distribution of these items in phonological space. However, with respect to the specific case of Arabic, there are still many unanswered questions. Since the data-source used by Plunkett and Nakisa (1997) has, as we have argued, a bias in the proportions of sound and broken plurals, the detailed predictions made in their paper may be unfounded. We have already argued that sound plurals are in the majority in Arabic, but this is not enough to demonstrate that a connectionist system will learn

to treat them in a default-like way. The phonological properties of a representative sample of the language must also be examined in order to assess the basis for a distributional default. If it turns out that both sound and broken plural classes are phonologically well defined and compact, then a “no default” system would be predicted on the basis of Plunkett and Nakisa (1997).

The 1670 nominal forms were classified by plural type, and the 16 categories that contained 10 or more members were used in the analyses and these amounted to 1491 items. Of these, 972 took the sound plural (273 masculine forms and 699 feminine forms). The remaining 519 items were members of 14 broken plural subtypes, containing between 13 and 121 nouns). In order to examine the phonological similarities between the members of these groups, each singular form was translated into a featural code based on a slight modification of the template system of Plunkett and Nakisa (1997). First, the phonemic transcriptions for the singular forms were aligned to an 18-slot template consisting of alternating consonants and vowels. The slots were filled from left to right, with consonants placed in consonant slots and vowels in vowel slots. When a word contained two consonants or vowels in a row, this procedure led to an empty slot between them, but it also ensured that as far as possible the representations reflected similarities between words by comparing like with like. For example, the representation of /jurʔhun/ “scar” in the template was jur-HUn----- . The slot-based phoneme representations were then translated into featural representations in order to capture similarities between different phonemes. The outcome of this transformation was an 18 slot x 20 features (360 dimensional) vector for each singular form. Taking the dataset as a whole, the vectors span a 360 dimensional space, in which each word form is a point. The issue we address is how the different plural classes are distributed in this multidimensional space.

Principal components analysis takes a set of points in a high dimensional space and determines a smaller set of orthogonal vectors within this space that captures the greatest variation between the points. The original points can be projected on to these principal components to extract a low dimensional plot preserving the most important information from the high dimensional space and eliminating redundant dimensions. Figure 1 plots the positions of the different plural subtypes in the space defined by the first three principal components. For the sample used by Plunkett and Nakisa (1997), the sound plurals occupied relatively restricted positions in the space. For our sample, the sound plurals are fairly ubiquitous. There are many completely empty regions of the space, corresponding to phoneme combinations that are in some way badly formed, but most of the occupied regions are occupied by sound plurals, whereas the broken plurals sets are generally more coherent. Plunkett and Nakisa (1997) quantified their observations by calculating a coherence measure for each plural subtype. However, this measure is less valuable for our dataset (containing plural types of greatly varying size) because it is confounded with set size, such that larger sets will be rated as more coherent purely because of their size.

**Figure 1:** Phonological distribution of Arabic singulars across a plane through the first three principal component. Pluses mark broken plurals, dots mark sound plurals.

Instead, we looked at the relative isolation of the regular and irregular groups as a whole. Put simply, for the regulars to act as the distributional default in a connectionist model there should be a high chance that a randomly chosen non-word will be most similar to one of the existing regulars, and therefore will be processed in the same way. Each word in the language will have its own “sphere” of influence in the phonological space—if any novel form falls in this area, it will be closest to that point and will tend to be inflected in the same way.

The most influential items in the language will be the ones with the largest area of influence. We can analyse these areas by calculating, for each word in the language, the distance from the nearest neighbour (both of the same class and of any class). The class that exerts the most influence will be the one that has the most isolated members, because these words will have the greatest influence in terms of generalisation to novel forms. This analysis shows that not only are there more sound plurals in Arabic, but they are more spread out in the phonological space, and so have a greater sphere of influence. Sound plurals differ from their nearest neighbour by 4.9 features on average, whereas broken plurals differ by 3.7. This advantage is independent of the number of items in each plural class. When nearest neighbour distances are broken down by overall class, the combined effect of numerical dominance and greater area of influence becomes clear, sound plurals differ from their nearest broken plural by 12.2 features on average, whereas broken plurals differ from their nearest sound plural by 6.0 features on average. This statistic implies that it is easy to find sound plurals that are unlike any broken plural but difficult to find broken plurals that are unlike any sound plural. This finding is confirmed in Figure 2, which plots only the singular forms that are 8 or more features different from their nearest neighbour of the opposite class (68% of the sound plurals, and 25% of the broken plurals). The broken plurals are quite closely packed in tight pockets of the space, whereas the sound plurals are more spread out. This is exactly the state of affairs required for distributional default behaviour to develop in a connectionist model.

**Figure 2:** Distribution of “isolated” Arabic singulars. Pluses mark broken plurals, dots mark sound plurals.

## General Discussion

Much of the evidence relating to the debate between symbolic and connectionist accounts has stemmed from the study of the English past tense, in which regulars are numerically dominant. Proponents of the symbolic account have challenged the ability of connectionist models to deal with inflectional systems in which the default inflection is a minority. Modern Standard Arabic and German were taken as instances of languages that do not depend on the regular pattern involving the majority of forms. Connectionist simulations of minority default behavior (Hare et al., 1995; Plunkett & Nakisa, 1997) have refined the debate, by showing that minority default systems are not necessarily problematic for a connectionist model. If the distribution of regulars is sufficiently broad, then a connectionist model can develop default-like behavior (Hare et al., 1995). Even in the case where regulars are more tightly clustered, a connectionist model can learn the mapping, and perform generalization, although the regular will not become a true default (Plunkett & Nakisa, 1997). These studies emphasize the importance of phonological distribution in the analysis of linguistic systems, alongside the numerical information.

Our main point in this paper was to argue that the Arabic plural system is not a minority default, with regular sound plural applying to fewer forms than the idiosyncratic broken plural. Three sets of arguments were brought to bear on our claim. First, we have shown that while both broken and sound plural are qualitatively productive, only the latter reflects quantitative productivity. Second, the empirical investigation of the most frequent nominal forms collected from BLMSA demonstrates that sound pluralization involves almost twice as many word forms as broken pluralization. The sound plural does not have a low type frequency. Third, analyses of similarities in phonological space showed that the distribution of Arabic nominal forms follow much the same pattern as that of English verbs.

Our analysis raises a set of problems relative to current models of human language productivity. Symbolic models are perfectly compatible with languages exhibiting a minority default inflectional system, but do not provide a princi-

pled explanation for the scarcity of these cases. This follows from the assumption that the human cognitive processor manipulates symbols and does not need a majority of forms to show a rule-based behavior. So far as we know only German and Arabic are cited as current examples of such systems. As it is demonstrated above Arabic is not and Bybee (1995) offered an account that questioned the claim that German is a minority default. Note however, that from the perspective of language change we do not exclude the possibility of a linguistic system passing through a minority default inflectional system. Rather, our point is: if minority default systems are as natural and as easy to handle as symbolic models would have it, then why do they seem to be scarce?

Connectionist models, meanwhile, have responded to the challenge of the minority default. These systems are less at ease with a minority default system, since they require the regulars to have sufficient variety in their phonological form if they are to be treated as the default case. But more critically, they also offer an explanation for the lack of minority defaults in most modern languages. Hare and Elman (1995) used connectionist networks to model the diachronic changes in the verb system of Old English, which at some stage is likely to have been a minority default system. Developments in the structure of language were assumed to be the product of imperfect learning from generation to generation, modeled by generations of connectionist networks. In essence, the development of the language was one of regularization, with regulars becoming more and more dominant in each successive generation. Thus, minority defaults can be learned by a connectionist network as long as certain distributional conditions are met. Even when those conditions are met, however, the state of the language is somewhat unstable, with a diachronic movement towards majority default likely in the long term. This fits in with the observation that the vast majority of linguistic systems—including the Arabic plural—do not employ a minority default.

# Representing Categories in Artificial Neural Networks Using Perceptually Derived Feature Networks

**Robert B. Branstrom (branstrm@socrates.berkeley.edu)**

Department of Psychology; 3210 Tolman Hall  
University of California  
Berkeley, CA 94720

## Abstract

How might categories be represented in artificial neural networks while satisfying biological constraints? This article proposes using feature networks, an architecture based on two types of neural organization in perceptual systems, receptive fields and topographic representation. Using these two organizing principles, category features are represented in distributed networks that allow precise, graded or probabilistic interpretations. Simulations are illustrated that show these networks have characteristics consistent with human behaviors of assimilation, contrast, and chunking. A brief discussion and simulation show how these feature networks can be combined associatively to form complex multiple-feature categories. Implications of the architecture for representation and the nature of symbol processing are discussed.

## Introduction

Regardless of the nature of the representation (i.e., visual image, verbal, etc.), categories are a foundational aspect of higher level cognition. The nature of categories remains a topic of considerable debate. The classical, or Aristotelian, view is that characteristics or traits define categories: things which have those characteristics are in the category and those which do not are not. This is simplistic, because sometimes something is in a category but does not have all necessary characteristics. For example, a three-legged animal that chases cats and cars would still be classified as a dog, even if it doesn't have the requisite four legs. Two approaches, both dealing with uncertain information, have evolved to address this problem. The first approach is probabilistic, asserting that something may be in a category if its characteristics are likely, rather than necessary. Thus the three-legged dog is still a dog because dogs usually, but not always, have four legs. The second approach applies the concept of graded structure (Rosch, 1973), asserting that membership in the category is a matter of degree, not an all-or-nothing feature. Thus a three-legged dog would still be a dog, albeit not as good an example as a four-legged dog. The condition "has four legs" is only partly satisfied, so the animal is not as good an example of a dog.

What approach might be taken to model categories? The classical view can be represented by formal set theory. Modifications to this view have been made to accommodate the probabilistic view and the graded structure view. In the probabilistic view, something is in the category if it has, say, eight of the necessary 10 conditions (Medin & Smith, 1984). The graded structure view has been approximated by fuzzy set theory (Zadeh, 1965). However, these views were developed for their formal properties, not their biological realism, so they don't offer plausible mechanisms that might underlie categorization processes.

An approach that steps closer to the biological structures of the brain is connectionism. Loosely, connectionist (or artificial neural network) models, assert that the brain is composed of many highly interconnected neurons, and that the processing power of the brain comes from these many connections. Network models of categorization typically represent categorical structure as a set of nodes representing characteristics (cf., Anderson, 1995). The characteristic may be absent or present (valued at 0 and 1, respectively). This vector of characteristics can also have graded values between 0 and 1. These values could represent either the probability or degree of the characteristic being present.

While these network models of categorization have useful functional characteristics, it's generally accepted that they still do not represent an approach that is close to the brain's actual organization. Among other things, real brains are expected to have more distributed representations for high level concepts. Anderson (1995, p. 345-6) proposed a number of principles to guide the development of "natural data representations," based on what is known about vertebrate nervous systems. These are worth summarizing here:

1. Similar events should give rise to similar representations.
2. Things should have separate representations if they need to be separated, thus categories could be separated by their features.
3. If something is important it should be represented by multiple elements.
4. Preprocess information as much as possible in the hardware.

5. Make the representation flexible so it is not problem specific.

Anderson also asserts (p. 346) that it would be easy to use "rather crude spatial means--say, spatially organized excitation and inhibition--to emphasize or deemphasize one or another aspect of the computation." Following Anderson's guidelines, this article proposes a network model of categorical and conceptual representation in which each feature is represented by a set of spatially organized nodes. The model accommodates both probabilistic and graded structure theories. The paper is organized as follows. First, two key structures of brain organization in perceptual systems are introduced and adapted for representation of category features. Then a number of simulations are provided to illustrate key behavioral characteristics of the features model. A proposal is then made for how these feature networks could be interconnected to provide an aggregate model of a category or concept. Finally, some implications of the model for cognitive science are discussed.

### Representing single attributes

There are two common characteristics of perceptual systems that are spatially based. The first is the organization of sensory inputs using receptive fields. Receptive fields are sets of input cells that are interconnected such that closer cells have a common effect (excitatory or inhibitory) on the next level of processing. More distant cells have the opposite effect. In two dimensions, these are described as center-on, surround-off if the closer cells are excitatory, or center-off, surround-on if the closer cells are inhibitory. The second characteristic of perceptual systems is analogical representation of the physical world in neural structure. In visual and haptic systems this is spatially based topographic representation, and in the auditory system it is frequency based tonographic representation. In both cases, the principle is the same: values close to each other in the physical world are close to each other in the neural structure.

Sometimes these structures are combined, with rows of interconnected receptive fields. In the visual system, this architecture is responsible for the well-known effect of Mach bands, in which differences in contrast in input data are enhanced at edges to increase contrast sensitivity. This effect is illustrated in Figure 1. The lower graph of the figure shows the specific inputs to each cell. The upper graph shows the output pattern across many cells, including the enhanced contrast where the input pattern changes.

This model applies the same architecture (rows of interconnected receptive fields) to features of categories and concepts. Two important observations are important here. First, features are usually scalar in nature, i.e., they carry ordinal (and sometimes higher level) information.

Figure 1: Edge contrast--Interconnected receptive fields enhance differences in input values at the edge where the difference occurs.

For example, dogs typically have fur. This can be represented on a scale from no-fur (Mexican hairless) to heavily furred (St. Bernard). Second, characteristics may be precise (24 inches tall) or vague (about 24 inches tall). This model allows for both of these characteristics. The ordered nature of a feature (i.e., the degree to which it holds) is mapped topographically onto the ordered organization of the nodes in the network. Precise values are represented as single nodes and vague values are represented as a cluster of adjacent nodes.

Several comments are in order before describing the model more specifically. First, the use of conceptual topographic mappings (as compared to physical or spatial topographic mappings) shouldn't be surprising if we take seriously the claim of evolutionary biologists, who argue that the easiest way to create a new structure is to borrow an old one. Second, representations of number are assumed to be at the level of an interval scale, so that both the order and distance between nodes is relevant to the representation. Third, nodes in the model's feature network are not suggested to be at the level of neurons, nor are they intended to be physically adjacent to each other. The *organization* of the nodes is the important factor; if this architecture holds in real brains it is expected that each node would be made up of many neurons and that connections would be distributed over wide areas. Finally, it should be noted that the idea of distributing features over multiple nodes was used by Shultz and Lepper (1996) to model cognitive dissonance. They distributed features across two-node polarized pairs.

Figure 2: Point-valued representation--Input to a single node results in a characteristic "Mexican hat" output pattern.

Figure 3: Vague-valued representation--Input to several adjacent nodes results in the same output pattern, but one that is more dispersed.

## The model

The model was created on a spreadsheet. Specifically, a one-dimensional row of nodes (cells) was used to represent a feature. Each node's activation was calculated as the sum of its input and the weighted-sum of the inputs of the six nearest nodes. Neighboring node inputs were all weighted at 0.2 of their actual value, and were positive for adjacent nodes and negative otherwise. In other words, the neural representation was a set of one-dimensional, overlapping, center-on/surround-off receptive fields. Inputs are modeled as values from 0 to 1, and outputs can be either positive or negative. (Although this latter effect is neurally unrealistic--neurons don't have negative activations--it is assumed this is reasonable given the usual positive base activation rate, which may be reduced. The zero base rate is used for simplicity of exposition.)

## Point-valued vs. vague-valued representations

Representations may be either point-valued or vague. This is modeled as either a single input or input spread across several nodes. Figure 2 shows a point-valued representation and Figure 3 shows a vague-valued representation. In both cases, the effects are similar: from the center of input the activation spreads slightly to neighboring cells, with closer cells being less activated than the central point and further cells being inhibited to negative values.

Vague representations may be interpreted as either probabilistic or graded. Thus, in Figure 3, the input value for 7 may be interpreted as a 40% probability of 7 occurring or as 7 to degree 0.4. When interpreted as probabilities, it isn't required that these values sum to 1.

This is consistent with empirical findings on subjective estimates of probabilities (Edwards, 1961).

## Assimilation and contrast effects

In addition to probabilities, judgments of similarity are also subjective. Sherif, Taub, and Hovland (1958) found that, when comparing two weights, subjects' estimates of the weight of one item depended on the similarity of the comparison weight. When the two weights were very similar, subjects shifted their weight judgments of the test weight (relative to when there was no comparison weight) towards the value of the comparison weight. This effect (or bias) they labeled assimilation. As the difference between weights increased, subjects shifted their estimates of the test weight more than the actual changes. This effect (or bias) was labeled contrast. In short, when two items were compared, the subjective judgment of difference depended upon the amount of the actual difference. Small initial differences were reduced so the two items appeared more similar than they actually were, while larger initial differences were enhanced so the two items appeared more different than they actually were.

The feature model yields the same effects. Figure 4 illustrates two point-valued inputs that are close to each other, yet still separated by another node. Their output, however, is merged into a single lump. (In this case, the output is two-peaked. The actual shape depends upon several factors, including the number of cells between inputs, the size of the receptive fields and the value used to weight neighboring cell inputs.)

A contrast effect, which occurs when the distance between the initial inputs is increased, is illustrated in Figure 5. The contrast occurs in two ways. First, the

Figure 4: Assimilation effect--When two inputs are close to each other, the outputs from the feature network are merged into a single output.

activation value of the most intermediate node between the input values is inhibited below its normal base rate of zero, heightening the vertical contrast with the activation values of the nodes where the input actually occurs. Second, the "center of mass" of the output activations is shifted horizontally, slightly away from the actual value where the input occurs. This is seen in the actual output activation values. For example, input occurs at node 5, which has the highest output (activation value equal to 1). But node 4's activation is .2 and node 6's activation is 0. This asymmetry, in effect, shifts the mean activation of the representation for that input slightly away from its actual value.

Several observations are in order here. First, the effects are a result of the size of the receptive field. The assimilation effect occurs when the center (excitatory) parts of the receptive fields overlap and the contrast effect occurs when the surround (inhibitory) parts of the receptive fields overlap. Second, the assimilation effect could put a lower bound on what differences can be perceived; in effect they represent a just noticeable difference (Gregory, 1987, p. 405) for whatever is represented in the network. Third, if learning features from environmental inputs has created appropriately sized receptive fields, these effects are functionally adaptive. Essentially, assimilation allows for very small (and likely irrelevant) differences to be ignored, because they are merged and treated as one. Slightly larger (and likely more important) differences, which might not otherwise be noticeable, have their differences enhanced. (Even larger differences, which presumably would be easier to notice, aren't enhanced at all because the receptive fields of nodes receiving inputs don't overlap at all.) Fourth, these effects occur with vague representations as well as

Figure 5: Contrast effects--When two inputs are slightly further apart, the outputs enhance the difference, both horizontally and vertically

the illustrated point-valued representations. Finally, this contrast effect is similar to the peak shift found in stimulus learning (Hanson, 1959). Peak shifts occur when a correctly learned stimulus (which generalizes over a symmetric gradient) must be discriminated from a new, closely related stimulus. The original stimulus gradient shifts slightly, creating an asymmetric gradient, but one that enhances discrimination. Because peak shifts are learned, they occur over time, whereas contrast effects occur immediately in real time. But both are adaptive mechanisms that enhance contrast.

### Chunking

One of the best known effects in cognitive science is chunking, the combination of several smaller bits of information into a single larger piece (Miller, 1956). When multiple pieces of information are represented as inputs in the feature network, assimilation and contrast effects provide a type of chunking. Figure 6 illustrates this, with seven inputs in two clusters of five and two, separated by one node with no input. The resulting output is two distinct "chunks," which could be called "low" and "high" on the particular feature in question.

### Multiple features

Typically, categories are made up of items with complex combinations of multiple features. This section begins an exploration of this issue by considering how feature networks might be combined to represent more complex concepts and categories. Due to the dynamic complexities of interconnected features, this section provides only a sketch of how multiple attributes might be represented.

Because each feature is represented as a network of

Figure 6: Chunking--When many input nodes are activated, their outputs are clustered into related groupings, such as "high" and "low."

ordered values, these networks can be related based on correlations between features. For example, the ability to fly is correlated with the presence of wings. Both are characteristics of birds and other flying species. Thus positive connections can be made between corresponding nodes in the two different attributes, such as good flying ability and good wings. Similarly, negative correlations can be made between opposite ends of the network. Figure 7 illustrates how these connections would be made from two nodes in a "flying ability" feature network to two nodes in a "wings" feature network. The straight-across connections are positive (shown as solid lines) representing positive correlations, and the diagonal connections are negative (shown as dashed lines), representing negative correlations. The double arrows on all connections represent that the connections are bilateral, that is they are mutually excitatory or inhibitory. This allows a dynamic interplay between the features, such that each node includes among its inputs the activations of the other feature's nodes from the previous iteration. These recurrent connections require a more complex formulation of the node activation functions, particularly the use of decay to dampen each node's activations over time. In the simulations presented here, correlative connections were weighted  $\pm 0.2$  and each node's activation value was decayed 80% from the prior period before computing the net input values.

When interconnected in this way, activation spreads from one feature to another. Figure 8 shows the spread of activation from an activated feature (flies well) in one period to a secondary feature (has good wings) in the following period. Two interesting characteristic of the

Figure 7: Multiple feature networks can be connected based on the correlations of features. Solid lines represent positive correlations and dashed lines represent negative correlations. Here, good flying ability (node 13) is positively correlated with good wings (node 13) and negatively correlated with poor wings (node 1). Double arrowheads indicate that the connections are bilateral.

secondary feature's output are the weaker level of activation relative to the activated feature and the drop in activation on the poor side of the scale, creating a contrast with the activated end of the feature network. The first characteristic is due to the weight of the correlation connections being less than one. The second characteristic results from the inhibitory connections that cross over to the opposite end of the secondary feature. The net effect of these two characteristics is that the activation level is lowered, but this is offset by an induced contrast effect.

### Categories

Treating categories as features can extend the use of interconnected feature networks to categories. For example, "birdness" is descriptive of a category, but can also be treated as a feature that is correlated with features like flight, wings, feathers, and egg laying. Because they are correlated, all the features of the category would be connected to the category network. Thus, networks for features like flying ability, wings, feathers, lays eggs, etc. would all connect to a bird feature network. When some of the features of being a bird are activated, the activation spreads to other features, including the bird feature.

Levels of categories (superordinate, basic, and subordinate) also appear to be easily computed in this structure, because the assimilation and contrast effects of the feature networks allow for generalization to higher category levels via chunking, and discrimination between lower level categories via contrast effects. Further simulations are needed to explore these dynamics.

Figure 8: Activation of a correlated feature--Input (bottom graph) characterized vaguely as "good flyer" causes a similarly vague output of the "flying ability" feature network (middle graph). Both positive and negative correlations with the "wings" feature network (top graph) result in a slight contrast effect.

### Conclusions

If categories provide the foundation of higher level thought, then their representation in neural structures is an important nut to crack. The proposed method of representing categories via their features in ordered feature networks is promising because it is simple and based on known patterns of neural organization. These networks allow for crisp, vague, and probabilistic representations. Perhaps most unusual, they provide a natural way to dynamically generalize and bifurcate concepts because of their assimilation and contrast effects. While further research about the characteristics of these networks (especially more complex interconnected feature networks) is needed, their ability to perform these

basic tasks is intriguing.

Because these networks provide a means of representing symbolic information, they may shed light on the nature of symbolic thought. Those who view the mind as a symbolic processor and those who view the mind as a vast connectionist network have reached an uneasy truce. While not held universally, the view promoted by Smolensky (1988) is common: The mind is a symbol processor that runs on top of a neural network computing platform. The feature network model presented here suggests that this simple dichotomy may be unrealistic because the nature of the symbol processing itself may be important. In particular, dynamic grouping and splitting of fuzzy neural representations (i.e., generalizing and discriminating) and associations between correlated features may characterize thought more than logical operations.

# A Sensorimotor Map of Visual Space

**Bruce Bridgeman (bruceb@cats.ucsc.edu)**

Department of Psychology; U.of Ca. Santa Cruz  
Santa Cruz, Ca. 95064 USA

## Abstract

The brain holds two representations of visual space: a cognitive representation that drives perception, and a sensorimotor representation that controls visually guided behavior. We separate spatial values in the two with the Roelofs effect: a target within an off-center frame appears biased in a direction opposite the offset of the frame. The effect appears for a verbal measure (cognitive) but not for a jab at the target (sensorimotor). Subjects might perform the jab by fixating the target during an exposure period, and jabbing where their eyes are aimed after the offset of target and frame. We show that normal humans use a context-free sensorimotor map even when they do not fixate the target: the motor map is a true 2-dimensional representation, not a 0-dimensional matching process.

## Two Visual Systems

Common sense tells us that one must accurately perceive an object's location and properties to interact effectively with it. This intuition is in error, however: several experimental designs now show that humans can engage in accurate motor behavior despite inadequate or erroneous perceptual information. Accurate perception is not required to visually guide an action.

Early experiments on separation of cognitive and sensorimotor systems showed that normal subjects could not perceive jumps of targets that take place during saccadic eye movements (a cognitive-system function). But they could still point accurately to the new locations of the same targets (a sensorimotor-system function), even if their pointing movements were controlled open-loop (Bridgeman, Lewis, Heit & Nagle, 1979). This showed that information about the new location of the target was accurate. But it was not available to perception, defined here as sensory information that is experienced, or more operationally information that can be described and remembered. If a visual stimulus is masked so that an observer denies seeing it, according to this definition the stimulus is not perceived even if it can affect later perceptual judgments or actions.

If each pathway can be probed without affecting the representation in the other, then they must be coding spatial information independently. A more rigorous way to separate cognitive and sensorimotor systems, then, is by double dissociation, introducing a signal only into the sensorimotor pathway in one condition and only into the cognitive pathway in another (Bridgeman, Kirsh & Sperling, 1981). A fixed target was projected in front of a subject, with a frame surrounding it. When the frame was displaced left or right, subjects saw illusory induced motion -- the target appeared to jump in the opposite direction. After target and frame

were extinguished, the subjects pointed to the last target position. They pointed to the same location despite the stroboscopic induced motion. But the illusion did not affect pointing, showing that the displacement signal was present only in the cognitive system.

In another condition we inserted displacement information selectively into the sensorimotor system by nulling the cognitive signal. Each subject adjusted the real target jumps until the target appeared stationary, with a real displacement in phase with the background jump equaling the induced displacement out of phase with the background. Thus, the cognitive pathway specified a stable target. Nevertheless, subjects pointed in different directions when the target was extinguished in the left or the right positions, showing that the difference in real target positions was still represented in the sensorimotor pathway. This is a double dissociation because in the first condition the apparent target displacement affected only the cognitive measure, while in the second condition the real displacement affected only the sensorimotor measure.

## A position-motion confound?

If a moving stimulus is sampled at different times for different functions, apparent dissociations might appear even though a unified visual representation underlies each function. Recently, methods have been developed, using static illusions, that can test dissociations of cognitive and sensorimotor function without possible confounding effects of motion. One method is based on the Ebbinghaus illusion, also called the Titchner circles illusion. A circle appears to be larger if it is surrounded by smaller circles than if it is surrounded by larger circles.

Aglioti, DeSouza and Goodale (1995) exploited this illusion by making the center circle into a 3-dimensional poker chip-like object and asking subjects either to judge the size of the circle or to grasp it. The grasp was adjusted closer to the real size of the circle than to its illusory size. Subjects were able to see their hands, however, so it is possible that subjects adjusted their grasp not to the non-illusory true size of the circle, but to the visible error between the grasp and the edge of the circle. The adjustments did not occur until just before the movement was completed, nearly 2 sec after it started.

Recognizing this problem, Aglioti et al. (1995) noted that calibration of grip aperture is largely refractory to visual information available during a movement, relying instead on motor programming that occurs before the movement begins. The experimental support cited for this open-loop

property, however, concerns movements to targets without illusory size modifications, so that visual recognition of grasp error and subsequent correction would not occur. The movements can be controlled open-loop because no correction is necessary. In a subsequent experiment that avoids the feedback confound, Haffenden and Goodale (1998) measured the illusion either by asking subjects to indicate the apparent size of a circle or to pick it up, in both cases without vision of hand or target. The illusion appeared for both estimations but was much smaller for grasp, indicating that the sensorimotor system was relatively insensitive to the illusion.

Another experiment contrasting grasp and perception, using the Müller-Lyer illusion, showed that while the illusion is significantly smaller when measured with grasp than with perception, there is some illusion under both conditions (Daprati & Gentilucci, 1997). Again, relatively slow grasp movements may be responsible, and vision of both hand and stimulus was allowed.

In summary, in normal subjects there is behavioral evidence for a distinction between processing in two visual streams, but we still know very little about processing in the sensorimotor pathway. With the exception of saccadic suppression and induced motion methods, all of the methods address the properties of objects rather than their locations.

A new method has produced large and consistent contrasts between cognitive and sensorimotor systems, differentiated by response measure. The dissociation is based on another perceptual illusion, the Roelofs effect: if a rectangular frame is presented off-center, so that one of its edges is directly in front of the subject, that edge will appear to be offset in the direction opposite the rest of the frame. A rectangle presented on the left side of the visual field, for example, with its right edge in the center, will appear less eccentric than it is, and the right edge will appear to the right of the subject's center (Roelofs, 1935).

We have extended and generalized this phenomenon to apply it to the study of the two-visual-systems theory. First, the frame need not have one edge centered in front of the subject; illusions occur whenever the frame is presented asymmetrically in the visual field. Second, if a target is presented within the offset rectangle, its location tends to be misperceived in the direction opposite the offset of the frame. Misperception of frame position induces illusions of target position; this is an induced Roelofs effect, but will be called simply a Roelofs effect here.

Roelofs effects can be observed reliably if subjects describe the target's position verbally, a task that addresses the cognitive system. If their task is to point to the target as soon as it disappears from view, however, they are not affected by the frame's position. This task addresses the sensorimotor system. Motor behavior for many subjects remains accurate despite the perceptual mislocalization (Bridgeman, Peery & Anand, 1997).

Though the motor task in our case is isomorphic with stimulus position, it is a communicatory act, and might be closely linked to cognitive representations. An alternative is to require an instrumental act, in which a subject must do something to the world rather than simply indicate a position

to another person. Behavior with a purely instrumental goal might be different from behavior with a communicatory goal, even if both the stimuli and the motor movements themselves are identical. Thus in our first experiment subjects jabbed a 3-dimensional target object, pushing it backward and making a clicking noise. Their intention was not to communicate anything, but only to do something to the world. With this improvement in our technique we achieve a cleaner separation of cognitive and motor systems. For a quick jab at a 3-dimensional target, rather than a pointing motion, almost all subjects show independence from Roelofs effects in immediate action, along with the previously observed robust Roelofs effects in verbal estimation of position.

Because this series of experiments follows up on earlier studies (Bridgeman et al., 1997), we were able to take advantage of the results of those studies to improve our experimental design. In the earlier data nearly all of the variance in responses as a function of target position was accounted for by a linear regression, so in the current experiments we did not need to present 5 target positions: two target positions would give us the same information, and allow us to increase the number of trials per condition.

## Experiment 1

Using these improved techniques, we begin the job of characterizing the psychophysics of the sensorimotor system.

### Method

**Subjects** Nine University of California undergraduates participated in the experiment, all right-handed with normal or corrected-to-normal visual acuity. Four were male and 5 female.

**Apparatus** Subjects sat with heads stabilized before a white hemicylindrical screen that provided a homogeneous visual field 180° wide x 50° high. A lever box located in front of the screen presented 5 white levers, each 1.8° wide, spaced 2.5° apart center-to-center (Figure 1). The center lever, marked with a black stripe, functioned as the target. Each lever was hinged at its base and spring-loaded. It activated a microswitch when pushed backward by 5mm. A long black baffle hid the microswitch assembly without revealing the position of the lever array. In the motor condition, the task was to jab the black target stripe rapidly with the right forefinger. The remaining levers served to record the locations of inaccurate responses.

A rectangular frame 38° wide x 1° in line width was projected, via a galvanic mirror under computer control, either centered on the subject's midline, 6° left, or 6° right of center. Inside the frame, the lever box occupied one of two positions, 3.5° left of center or 3.5° right of center. On each trial the frame and target were positioned in darkness during the intertrial interval. Then a computer-controlled shutter opened for one second. Stray light from the projected frame made the screen and the levers visible as well. As soon as

the shutter closed, the subject could jab the target or verbally indicate its position in complete darkness. Responses were recorded by the computer on an absolute scale (lever 1, 2, 3, 4, or 5).

**Procedure** Cognitive Measure: For the cognitive system the subject verbally estimated the position of the target spot on the center lever. The choices were 'far left', 'left', 'center', 'right', or 'far right', so that the response was a 5-alternative forced choice. Choices were identified with the five lever positions, which were centered before the subject during the instruction period, when the screen was illuminated by general room lighting and the frame was not projected. The five levers, and nothing else, were visible when the five alternatives were defined. By equating the responses with the visible levers in the apparatus, we could assign estimations in degrees of angle to the qualitative verbal responses. Interpretation of the data depends upon presence or absence of Roelofs effects, however, not on absolute calibrations of the cognitive measure. In the present series of experiments the cognitive measure serves as a control to assure that a cognitive illusion is present, differentiating the cognitive and sensorimotor systems. All quantitative results are based on the motor measure.

Subject instructions in the verbal condition emphasized egocentric calibration. Quoting from the instructions that were read to each subject, "In this condition you will be telling the experimenter where you think the target is in relation to straight ahead." Further, "If the target looks like it's directly in front of you, you will indicate this by saying 'center'." Thus center was defined in terms of the subject's body rather than the apparatus or the frame.

Sensorimotor measure: the subject rested the right forefinger on a foam pad mounted on the centerline of the apparatus just in front of the chin rest, then jabbed the target with the forefinger as soon as the target disappeared. Thus both cognitive and sensorimotor measures were open-loop, without error feedback. Before the experimental trials began, subjects practiced jabbing the target -- some were reluctant to respond vigorously at first for fear of damaging the apparatus. Subjects then received at least 10 practice trials in the jab condition and 10 the verbal condition.

Trial Execution: A computer program randomly selected target and frame positions, with the exception that an identical set of positions could not occur on two successive trials. For verbal trials, the experimenter recorded the subject's response by typing a number (1-5) on the computer's keyboard corresponding to the subject's verbal estimate. The computer recorded motor responses automatically.

In each trial one of the two target positions and one of the three frame positions was presented, exposed for one second, and extinguished. Since the projected frame provided all of the illumination, target and frame exposure were simultaneous. A computer-generated tone told the subject to respond. For no-delay trials the tone sounded as the shutter extinguished the frame, while on other trials the tone began after a 1-sec or 2-sec delay. During the delay the subject sat in darkness.

Two target positions x three frame positions x two response modes x three delays resulted in 36 trial types. Each trial type was repeated 10 times for each subject, resulting in a data base of 360 trials/subject. There was a brief rest and a chance to light adapt after each block of 60 trials.

Data were collated on-line and analyzed statistically off-line. Two-way ANOVAs were run for each subject, each response mode, and each delay condition. Factors were frame position and target position. Summary statistics were analyzed between subjects.

## Results

**Cognitive** The Roelofs effect, measured as a main effect of frame position, was significant under all delay conditions. Subjects tended to judge the target to be further to the left than its actual position when the frame was on the right, and vice versa. Six of 7 individual subjects showed a significant Roelofs effect ( $F(2,5) > 8.43$ ,  $p < 0.05$ ), and the magnitude of the Roelofs effect averaged across subjects was 2.23 deg (s.e. 0.86 deg).

Figure 1. Motor responses, immediate action.

**Sensorimotor** The results can best be summarized with the generalization that subjects hardly ever missed the target, regardless of target position or frame position (Figure 1). Seven of 8 subjects showed no significant Roelofs effect (frame effect  $p > 0.094$ ). Averaged across subjects, the magnitude of the Roelofs effect was 20 min. arc (s. e. 22 min. arc).

**Comparing the two measures** Overall, ANOVA showed a significant difference between cognitive and motor measures ( $F_{1,43} = 12.45$ ,  $p = 0.001$ ), as expected from the robustness of Roelofs effects with the cognitive measure and the absence of Roelofs effects at short delays with the motor measure.

The sizes of the Roelofs effects under various conditions can be compared by measuring the difference between average response with the target on the right and with the target on the left. The cognitive measure shows a large and

consistent deviation, replicating Bridgeman et al. (1997), while the sensorimotor measure shows no deviation.

## Discussion

This experiment showed that the sensorimotor pathway can maintain veridical information about target position, unaffected by visual context, even when perception shows an illusion of position. The rules are different for the two systems. Cognition is conscious and must use context, even when that leads to errors of localization. The sensorimotor system does not use context, and its spatial values are held unconsciously. Conflicting spatial values can exist in the two systems simultaneously.

A possible mechanism of the sensorimotor store is that subjects might fixate the target visually when it is visible, then point where they are looking when the target is extinguished. This would mean a 0-dimensional storage of information of spatial information limited to the location of a single point, held in gaze position rather than in an internal register. If this interpretation is correct, subjects will be unable to perform the motor task if they are prevented from ever fixating the target. In the next experiment, extending the Roelofs effect paradigm, we seek to control for possible attention and fixation effects by preventing our subjects from fixating the target.

## Experiment 2

We hypothesize that if subjects cannot fixate the target, the motor system cannot use spatial information from gaze position and will be forced to call upon the cognitive system for spatial location information. Further, we prevent covert orienting to the target by requiring subjects to perform a continuous oculomotor task throughout the exposure period.

## Method

**Subjects** Seven University of California undergraduates participated in the cognitive condition, and 7 in the motor condition, all right-handed with normal or corrected-to-normal visual acuity. Each subject was run in only one condition, cognitive or motor.

For this experiment we need fixation points that define eye movements, but give the subject no information about target or frame positions. A pair of fixation points is added to the display, in positions statistically uncorrelated with target or frame positions, to elicit horizontal saccades.

**Apparatus** In order to present the target, frame and fixation points simultaneously, and also to improve the accuracy of our jab recordings, we move to an electronic apparatus with all stimuli displayed on a CRT screen. The screen is mounted with its face down and is viewed through a mirror mounted at 45 deg in front of the eyes, so that the display appears to be directly in front of the subject. A touch pad mounted vertically in the apparent plane of the display records jab responses made with a stylus. The frame's width is 24 deg, and the saccade targets are 23 deg apart, displayed above the frame. As before, targets are at 6 deg. left, center, and 6 deg. right.

## Results

Results were analyzed in the same manner as experiment 1. The cognitive subjects showed an effect of target position, frame position and fixation point position, all significant at  $p < 0.0001$ .

The motor subjects, in contrast, showed no Roelofs effect (no significant frame effect), but had a target significant at  $p < 0.0001$  and a fixation point effect significant at  $p < 0.0011$ . There were no significant interactions in either set of results.

## Discussion

Since the subjects in the motor condition showed no Roelofs effect, while those in the cognitive condition did, we can conclude that the sensorimotor representation was controlling the jab for the motor subjects. The representation is at least 2-dimensional, a true map and not a simple matching of gaze and jab positions. The single most important finding of the experiments reported here is that preventing direct fixation on the target, even when multiple targets must be discriminated, does not cause a Roelofs effect. These experiments show that oculomotor fixation and spatially selective attention are not responsible for accurate pointing behavior in an illusory visual context.

## Conclusions

Once again, the evidence can be interpreted in terms of two visual systems, one based on egocentric coordinates to govern motor behavior and another that uses information from visual context to represent spatial relationships in perception. Also, these experiments lend support to the claim that the price in performance the cognitive system must pay in order to take advantage of visual context information is a susceptibility to illusions of spatial context. While it has been shown that direct fixation driven by attentional selection is not the mechanism responsible for accurate pointing behavior in a visual context that creates illusory perceptions in the cognitive system, this shows only that fixation is not responsible. Other aspects of attention may be responsible for the continued accuracy of motor behavior in these experiments.

The visual mechanism by which motor behavior is governed has been shown to be extremely robust, both by these and previous studies. Indeed, the reappearance of a Roelofs effect for motor responses after a delay (Bridgeman et. al., 1997) shows that the cognitive system can provide information to the motor system when necessary, and this so far appears to be the only form of communication between the two systems. To date there is no evidence that the cognitive system can access spatial location information in the motor system, supporting the inference that spatial information can flow in only one direction, from cognitive to motor. In normal visual conditions, however (motor interactions with still-visible targets), spatial information in the two systems remains segregated.

# Unity of Consciousness: What It Is and Where It Is Found

Andrew Brook

Philosophy and Interdisciplinary Studies

## Abstract

The unity of consciousness is our capacity to be conscious of a number of items all at once, in what could be called a single conscious act. Such unity is found in at least three places: consciousness of the world in general, consciousness of self in general, and paying focal attention to aspects of either. In all three, unified consciousness has both a synchronic and a diachronic dimension. That is to say, consciousness is unified both at a given moment and over time. Unified consciousness can be breached in two ways: by splitting (into two unified centres of consciousness, as in brain bisection operations) and by shattering (as in some severe schizophrenias and dysexecutive disorder). Studying it in its breakdown conditions is a good way to throw light on it. In this paper, we will delineate the unity of consciousness, explore some situations in which it breaks down, and relate it to some other mental unities.

**1. Introduction** One of the most striking features of consciousness is that what is presented to us in it is usually highly unified. This unity takes the following general form. We are conscious not just of individual objects but of a multitude of objects related to other objects in a multitude of ways. I am aware not just of A and, separately, of B and, separately, of C, but of A-and-B-and-C, all at the same time – or better, as all parts of a single complex object of a single conscious state. Since at least the time of Kant (1781/7), this unity has been called the *unity of consciousness*.

There has been a huge resurgence of interest in consciousness in cognitive science in the past decade or two. Here is how the philosopher Daniel Dennett summarized the attitude of the nonphilosophical part of the cognitive community two decades ago:

Consciousness appears to be the last bastion of occult properties, epiphenomena, immeasurable subjective states – in short, the one area of mind best left to the philosophers. Let them make fools of themselves trying to corral the quicksilver of “phenomenology” into a respectable theory. [1978, p. 149]

He could have added that this was pretty much true of most philosophers, too.

This situation began to change in the mid to late 1980s, due to the work of psychologist, Bernard Baars (especially 1988) and many others. (Baars developed the methodology called contrastive analysis, in which we compare the difference made by performing a task consciously and without consciousness. This method gave researchers a method to study consciousness much better than the

traditional appeal to introspection.) Consciousness studies quickly became a major player in cognitive research. At least a hundred new books and thousands of articles written from both an experimental and a philosophical point of view have now appeared. Interestingly, even though one of the things that immediately strikes almost everybody about consciousness is its unity, relatively little attention has been paid to it in this burgeoning literature. Neither philosophers nor experimentalists have had much to say about it.

Here we need to make a distinction. Under the name, the binding problem, one phenomenon related to the unity of consciousness has received a lot of attention – our ability (better, the ability of our visual cortex) to ‘bind’ diverse features of objects sensed by diverse parts of the visual or other sensible cortices into representations of three-dimensional objects. Binding of this sort is not unity of consciousness, not as I am discussed the latter. First, the representations that result from binding need not even be conscious. Many perfectly good representations of three dimensional objects affect behaviour and even enter memory without us ever becoming conscious of them. Second, the unity that I am exploring in this paper concerns multiple objects, related to one another in such a way that one is aware of many of them together, not individual objects by themselves. Contrary to the situation with binding, unified consciousness of multiple objects has received little attention.

## 2. Breaches of Unified Consciousness

This lack of attention to the unity of consciousness notwithstanding, some clinical and experimental phenomena in which this unity in fact plays a central role have received a lot of attention, especially situations in which there is some drastic change in unified consciousness.

There are at least two ways in which the unity of consciousness can be breached without unity being destroyed altogether. First, there are the “brain bisection” operations (commissurotomies) much beloved by philosophers, in which it appears that one “centre of consciousness” becomes two under certain conditions (Nagel 1971; Marks 1981). Since the two centres coexist and are both active at the same time, this breach of unity occurs at a single time.

Much ink has been spilled on the question of what is

going on in the phenomenology of these patients. Some theorists have even claimed that there is no whole number of 'centres of consciousness' in these subjects: there is too much unity to say that they are two, yet too much splitting to say that they are one. Some reason work by Sergent (1990) might seem to support this conclusion. She found, for example, that when a sign '6' was sent to one lobe and a sign '7' was sent to the other in these subjects (in such a way that no crossover could occur), they could say that 6 is a smaller number than 7 but could not say whether the signs were the same or different. However, the interpretation of these data is controversial. In particular, there does seem to be a clear answer to any precise 'one or two?' question we could ask, so it is not clear that Nagel's no whole number view receives any support from them. ('Unified consciousness of the two signs with respect to numerical size?' Yes. 'Unified consciousness of the visible structure of the signs?' No).

At any rate, since there continues to be unified consciousness, whether in what are unambiguously two centres or in something less well delineated, we do not have the complete destruction of unity here, though it is a breach of some kind. Then there is the more controversial phenomenon that used to be called Multiple Personality Disorder, now called, more neutrally, Dissociative Identity Disorder. In the most common variety, the units (whatever we want to call them: persons, personalities, sides of a single personality) "take turns" and when one is active, the other(s) usually are not. This is another breach in unity without unity being destroyed, in this case across time.

Then there are phenomenon in which unity does seem to be destroyed. In both brain bisection and dissociative identity cases, we have at most one unified consciousness splitting into two or more – two or more at a time or two or more across time. It is, of course, a matter of debate whether we have even that, especially in the case of dissociative identity disorder, but we clearly do not have more than that. In particular, unity itself does not disappear. The unity may split but it does not shatter. There are at least two kinds of case in which unity does appear to shatter.

One is a certain particularly severe variety of schizophrenia in which the victim seems to lose the ability to form an integrated, interrelated representation of his or her world and his or her self at all. The person speaks in "word salads" that never get anywhere, indeed that sometimes never even reach the level of complete sentences. The person is unable to put together integrated plans of actions even at the level necessary to obtain sustenance or escape irritants. And so on. Here, unity of consciousness appears simply to have shattered.

In schizophrenia of this sort, the shattering of unified consciousness is part of a general breakdown or deformation of mental functioning: affect, desire, belief, even memory all suffer massive distortion. In another kind of case, the normal

unity of consciousness is just as absent but there does not seem to be a general disturbance of the mind. This kind of case has been called dysexecutive syndrome (Dawson 1998, p. 215). What characterizes the breakdown in the unity of consciousness here is that subjects are unable to consider two things together, even things that are clearly related to one another. For example, such people cannot figure out whether a piece of a puzzle fits into a certain place even when the piece obviously fits. They cannot crack an egg into a hot pan. And so on. The reason seems to be that they cannot focus on two items simultaneously and so cannot fit the two together.

The ability to unify the contents of consciousness, as these last examples show, is central to all cognitive functioning, certainly functioning of any complexity. Moreover, the phenomenon once received a lot of attention. For example, it is the centrepiece of Kant's model of the mind (Brook 1994). These facts notwithstanding, the phenomenon has received, as I said, relatively little attention in recent work on consciousness.

### 3. Two Kinds of Consciousness

Before we can draw out the morals for the nature of unified consciousness contained in breaches of unity of the kinds we have just sketched, we first need to say a bit about consciousness in general. In particular, we need to make a crucial distinction.

Current work on consciousness labours under a huge and confusing terminology. Different theorists talk about access consciousness, phenomenal consciousness, self-consciousness, simple consciousness, creature consciousness, state consciousness, monitoring consciousness, awareness taken to be coextensive with consciousness, awareness distinguished from consciousness, higher order thought, higher order experience, qualia, the felt qualities of representations, consciousness as displaced perception, memes, virtual captives .... and on and on and on. A terminology this florid, confused and overlapping is a good sign that consciousness research is still very immature science. For purposes of this article, we need to make just one distinction: between what we will call simple consciousness, on the one hand, and consciousness of self, on the other.

Simple consciousness is closely related to sentience and to being awake. It is (perhaps among other things) being in a certain informationally and behaviourally responsive state to one's immediate environment. It is the ability, for example, to process and act responsively to information about food, friends, foes, and other items of relevance. One finds simple consciousness a long way down the evolutionary ladder.

Consciousness of self is the ability to process and respond in a similar fashion to oneself, more specifically, to one's own psychological states and to oneself as oneself, as the

thing whose states they are. The latter form of consciousness of self, the ability to identify oneself as oneself, probably requires the use of indexicals and may therefore be restricted to human beings and perhaps a few other species of primate.

The importance of this distinction between simple consciousness and consciousness of self is that the literature tends not to distinguish them and even to run them together. Everyday English does so, too. We speak of someone regaining consciousness – where we mean simple consciousness of the world. Yet we also say things like, “She wasn’t conscious of what motivated her to say that” – where we do not mean that she lacked simple consciousness of the world but rather that she was not conscious of something about herself. Some theorists make this distinction but others treat consciousness as either synonymous or at least coextensive with consciousness of the second sort, what we are calling consciousness of self. A few even occupy a middle ground, those philosophers who talk about the felt qualities of things as central to consciousness, for example. They do not seem to hold that we must be *conscious of* these felt qualities for them to exist as conscious states – but they do not view them as objects of simple consciousness of the world either.<sup>1</sup> To understand the unity of consciousness, we need to make the distinction. We need to treat consciousness of self and simple consciousness of the world as distinct. Why? Because even though the distinctive unity associated with consciousness is found in both, it takes somewhat different forms.

#### 4. Unity of Consciousness

Indeed, we find unity of consciousness in at least three places. We might call them *unity of simple consciousness*, *unified consciousness of self*, and *unity of focus*.

Unity of consciousness in general starts from the intuitive idea laid out above that we are aware of a great many things at once. Here is a more informative definition:

The unity of consciousness =*df.* a consciousness of objects in which a number of representations of objects and sometimes also the representation themselves are combined in such a way that to be conscious of any of these objects and/or representations of them is also to be conscious of other objects and/or representations as connected to it/them and of the group together as a single complex whole of objects and/or representations.

*i. Unity of simple consciousness* Unity of simple consciousness is the consciousness that we have of the world around us (including, it should be noted, one’s own body and perhaps even psychological states) as a single world, of the various items in it as linked to other items in it. That is to say, it is simply unity of consciousness as found in the conscious representation of one’s environment.

*ii. Unified consciousness of self* Here one is aware of

oneself as not just the subject but, as Kant put it (A350), the “single common subject” of unified fields of representation (and the single common agent of unified activities of deliberation and action). Unified consciousness of self has been argued to have some very special properties, in particular that the reference to oneself as oneself that generates it is achieved without “identification” – that is to say, not via attribution of identifying properties or attributes to oneself (Castañeda 1966; Shoemaker 1968; Perry 1979) but we do not have room to go into that interesting issue here.

*iii. Unity of focus* Unity of focus refers to our ability to pay unified attention to objects and one’s own self. It may be part of unified consciousness in general. Whether it is or not, it is certainly not the same thing. In the two situations of unified consciousness just explored, consciousness ranges over many objects (or, in the case of unified consciousness of self, many occurrences of becoming aware of an object). Unity of focus is a matter of focussing on one such item. What I have in mind is Wundt’s old distinction between the field of consciousness (*Blickfeld*) and the focus of consciousness (*Blickpunkt*). The consciousness of an item on which one is focussing is just as unified as the consciousness of many such items at the same time. If so, we find an occurrence of unified consciousness *within* each of the two sites of unified consciousness laid out in (i) and (ii). We are talking, of course, about focal attention.

Note that, in addition to paying focal attention to individual objects, we can also unite a number of considerations in focal attention at the same time – desires, beliefs, alternatives, probabilities, and so on – and integrate them with, for example, available alternatives to reach decisions and choose courses of action. We can then go on to do the same with behaviour and resources, focussing on carrying out the choice in the face of obstacles, conflicting desires, and so forth. Moreover, there are costs attached to not having fully functioning focal attention, as the dysexecutive syndrome mentioned above makes painfully apparent. These remarks suggest that unified consciousness is not the only form of mental unity, a suggestion to which we will return briefly below.

Though this has often been overlooked, the unity found in unified consciousness comes in two very different forms, no matter which site we have in mind. The unity can consist entirely in phenomena occurring at the same time and it can consist in links of certain kinds among phenomena occurring at different times. In its synchronic form, it consists in such things as our ability to compare two items to one another, to see how two items fit or do not fit into one another, etc. Diachronically, it consists in the ability to retain a representation of an earlier object in the right way and for long enough to relate the earlier object to some currently represented object.

## 5. The Situations in which Unity is Breached

Let us now return to the four breaches of unified consciousness discussed earlier. We can see that in every case, at least one feature of unified consciousness as we defined it is absent.

In brain bisection cases, there are, notoriously, all sorts of situations in which a being in the body in question who is aware of some represented objects is not aware of others. Thus, for example, if the right hemisphere is asked to do arithmetic in a way that does not penetrate to the left hemisphere and the hands are shielded from the eyes, it is easy to set up a situation in which the left hand will be doing arithmetic while whatever controls the mouth insists that it is not doing arithmetic, indeed has not even thought of arithmetic today. And so on.

In DID cases, a central feature of the case is reciprocal amnesia (with all sorts of variations). Again, this is a situation in which a being aware of some represented objects is not aware of others.

The same pattern is even more clear in the cases of severe schizophrenia and dysexecutive disorder sketched. In both cases, awareness of some conscious states goes with lack of awareness of others. There is nothing aware of all the relevant conscious states together.

In short, our definition seems to illuminate the situations in which unity of consciousness is breached quite nicely.

## 6. Other Unities in Cognition

The unity of consciousness is far from being the only kind of mental unity as our remarks about what can be integrated in focal attention might indicate. There is unity in the early stages of cognition, unity that consists of integration of motivating factors, cognitive capacities, etc., and also unity in the outputs, unity that consists of integration of behaviour. First, the early stages of cognition.

One of the more striking things about human beings as cognitive systems is that we can bring an extremely wide range of factors to bear on a cognitive task, e.g., when we seek to characterize something or reach a decision about what to do about something. We can bring to bear: what we want; what we believe; our attitudes to self, situation, and context; input from each of our various senses; information about the situation, other people, others' beliefs, desires, attitudes, etc.; the resources of however many languages we have available to us; the various kinds of memory; bodily sensations; various problem-solving skills that we have acquired; and so on. Not only can we bring all these elements to bear, we can integrate them in a way that is highly structured and ingeniously appropriate to our goals and the situation(s) before us. This form of mental unity could appropriately be called *cognitive unity*.

At the other end of the cognitive process, we find an equally interesting form of unity, what we might call *unity of*

*behaviour*. To act, we need to coordinate our limbs, eyes, bodily attitude, etc., indeed in ways the precision and complexity of which would be difficult to exaggerate. Think of a concert pianist performing a complicated work.

And between the two is the unified consciousness laid out in the previous section.

## 7. The Unity of Consciousness as Evidence

It would seem that anything as central to human cognition as unified consciousness would have to play a role in any serious attempt to understand cognition. This, of course, has not been the case for a while. As has often been remarked, until about fifteen years ago, as cognition was modelled in cognitive science, it could just as well have been entirely nonconscious.

Historically, the unity of consciousness played a large role. Indeed, it is central to one of the most famous arguments in philosophy, Kant's "deduction" of the categories. In this argument, boiled down to its bare essentials, Kant argued that in order to tie various items together into a single unified conscious representation, we must be able to apply certain concepts to the items in question, in particular qualitative, quantitative, relational and what he called 'modal' concepts. (Modal concepts are the concepts we use when we decide whether something merely could exist, actually does exist, or [if this is ever the case] must exist.) By far the most important relational concept for Kant was the concept of cause and effect. Indeed, Kant thought that he could tease a complete defence of physics as a body of genuine knowledge out of the fact (as he saw it) that we have to be able to apply the concept of cause and effect to items in our experience if we are to have a unified consciousness of them.

It also played a role in arguments for dualism. Theorists otherwise as different as Descartes and Reid argued that unified consciousness could never be achieved by any system of components acting in concert. Give each of these components a part of a thought or perception divided up as finely as you please; the result will never be a unified thought or perception. As James famously put it,

Take a sentence of a dozen words, take twelve men, and to each one word. Then stand the men in a row or jam them in a bunch, and let each think of his word as intently as he will; nowhere will there be a consciousness of the whole sentence. [James, 1890, Vol. 1, p. 160]

The inference from this argument was that the human mind could not be any system of components. Now, anything material will be a system of components. If so, then the mind is not made out of matter.

Remarkably enough, some version of this argument impressed practically all theorists until well into the twentieth century, despite the complete absence of anything

like an alternative account and even though no less a figure than Kant poked a huge hole in it as early as 1781. (He noted that unified consciousness being achieved by a system of components acting together would be no more mysterious than it be achieved by something that has no parts or components.)

Nonetheless and whatever the merits of this argument for the simplicity and immateriality of the mind, the unity of consciousness did receive a lot of attention. And rightly so; cognition of any complexity must be unified in the way that consciousness is. Without the ability to retain representations of earlier objects and unite them with current represented objects, for example, the only language that we would be able to understand would be single words. The simplest of sentences is something spread over time. Now, unification *in consciousness* might not be the only way of achieving this unity but it is clearly a central way. If so, consciousness being unified is central to cognitive life as we know it.

In some circles, the idea that consciousness has a special kind of unity has fallen into disfavour lately. Davidson, Fodor, Dennett, Pylyshyn and the Churchlands come immediately to mind. The mind, they say, is modular (Fodor 1983) and most modules work out of the sight and control of consciousness. Moreover, we often do things that we don't intend, act for reasons of which we are not aware, and so on. Does any of this entail that consciousness is not unified? Not at all. The most these observations do is to shrink the range over which the unity extends. If something is out of the sight and/or the control of the conscious mind, we should ask: out of the sight or control of what? Unified consciousness. And we still need to understand the nature of this unity. Practically anything that could be said about the unity of consciousness when consciousness was conceived in the pre-twentieth century way as ranging over most everything mental can still be said about the unity of consciousness conceived in the twentieth-century way with a range that has shrunk dramatically.

Yet few recent philosophers and even fewer other cognitive researchers even raise the question of what the unity of consciousness is like. This is strange; it hardly seems controversial to say that we have unified consciousness, though how far this unity extends and over what can be debated. Indeed, without knowing what the unity of consciousness is, it is hard to see how we can even talk coherently about the situations so prominent at the moment where unity is absent or breached.

## 8. Background: Theories of Consciousness

We will close with a different question: Does the unity of consciousness have implications for the big debates about the general nature of consciousness currently raging? There are currently at least three camps. There are those who see consciousness as something quite unique, the “felt quality”

of representations or whatever. On this picture, representations could function much as they do even if, in Nagel's (1974) phrase, it was not like anything to have them. They would merely not be conscious. If such a split is possible, then the next question is whether consciousness plays any important cognitive role at all, its unity included. Maybe it is a free rider (Jackson 1986; Chalmers 1996).

Then there is a second camp. It holds, to the contrary, that consciousness is simply a special kind of representation: a representation of a representation, for example (Rosenthal 1991; Dretske 1995; Tye 1995).

Finally, there are those who hold that what we call consciousness is really something else. On this view, consciousness will in the end be “analysed away” – what we misleadingly label ‘consciousness’ is something very different from what we take consciousness to be like. Perhaps it is competing information-parcels in a Pandemonium architecture that have gained temporary dominance in the struggle for cognitive resources (Dennett 1991). Perhaps it is self-monitoring transformations of some sort in a multidimensional phase-space (Churchland 1995). Whatever, consciousness is not anything like the unified system of representations that both common sense and the Kantian model of the mind take it to be like.

No matter what one's view of the nature of consciousness, and the three views sketched above probably do not exhaust the possibilities, one will have to provide an account of the unity found in it. Indeed, even if one holds that this unity has been overrated and consciousness is much less unified than theorists have thought, one will still have to provide an account of this unity in those situations in which it does occur. The kind of integration of properties and objects into more complex objects of experience that we sketched above is too central to be ignored.

On the other hand, the unity of consciousness as we have defined it might not have much by way of implications for which of the three views is right. If it is as genuine and undeniable as I've urged, it may cut a bit against the third, eliminativist position. But adherents of this position have increasingly been treating consciousness as something real, i.e., nothing to be eliminated, in any case. The unity of consciousness seems neutral with respect to the other two positions. If so, curiously enough, which view of consciousness we start from may not matter much when we set out to understand the unity of consciousness.

<sup>1</sup> A full set of relevant distinctions here would distinguish among consciousness of self, consciousness of one's psychological states, one's conscious states themselves, and so on. We do not need to go into the differences among these things here. For purposes of understanding the unity of consciousness, it is enough to distinguish between consciousness of self, on the one hand, and simple consciousness of the "world", on the other.

# Are Retrievals from Long-Term Memory Interruptible?

Michael D. Byrne

Department of Psychology  
Rice University  
Houston, TX 77251

## Abstract

Many simple performance parameters about human memory are not well-understood. One such parameter is how the cognitive system handles interruption at a relatively low level. This research is an attempt to determine if simple, well-practiced retrievals from long-term memory can be interrupted by a higher-priority task. An experimental paradigm referred to as a “reverse PRP” paradigm is introduced, and the results of one experiment in this paradigm reported. The results suggest that retrievals can indeed be interrupted, but that there is an interruption cost.

## Introduction

There are numerous situations in which people are interrupted in doing simple tasks by higher priority tasks and must drop what they are working on the new task. In most situations, this is merely an inconvenience. However, in high-performance tasks such as air traffic control, even a small delay in responding to the interrupting task can have more serious consequences. In many cases, the interruption may place demands on perceptual or motor performance, but in other cases it is a cognitive operation that is interrupted. Generally speaking, cognitive theories have little to say about what should happen in such situations. However, this does not mean that these phenomena cannot be understood in the context of, and do not have implications for, theories of cognition.

ACT-R/PM (Byrne & Anderson, 1998) provides a set of perceptual-motor extensions to the ACT-R cognitive architecture (Anderson & Lebiere, 1998). Communication between central cognition (the ACT-R production system) and the perceptual-motor modules takes two forms: [1] the left-hand, or THEN, side of productions can request activity from the perceptual-motor modules (e.g. shift visual attention, press a key), and [2] perceptual-motor modules deliver results (e.g. representations of percepts) to ACT-R’s declarative memory in the form of chunks.

Declarative memory chunks in ACT-R are accessed via retrieval, which is a time-consuming process. That is, retrievals take time, which is part of the process of matching the IF side of productions in ACT-R. Because perceptual-motor modules operate in parallel with the production system, it is possible for one or more of the perceptual-motor modules to change the contents of declarative memory while a retrieval is in progress. The fundamental question this research is attempting to address is what happens in this situation: Do retrievals always complete or can they be

interrupted? Rather than attempt to answer this question on theoretical or computational grounds, this research approaches this as an empirical question.

## Reverse PRP Paradigm

Consider this simple dual task: two digits appear on a display, and the product of those digit should be spoken aloud. On some trials, the digits are replaced a short time after they appear by a colored block. When the block appears, the task is to make a choice response based on the color of the block as rapidly as possible. Because the delay is short, the appearance of the color block may be interrupting the retrieval of the product of the two digits. Can the single, simple retrieval be interrupted?

This task shares a number of important properties with the psychological refractory period (PRP) paradigm, which is perhaps the simplest dual-task experimental paradigm. The PRP has a long history in psychology (see Pashler, 1994 for a review). In this paradigm, subjects are asked to do two tasks, usually referred to as T1 and T2, in rapid succession. The stimulus for T1 appears, then after some delay (called the stimulus onset asynchrony or SOA), the stimulus for T2 appears. Subjects are instructed to give T1 maximum priority and the typical results are that responses to T2 are slowed,

Figure 1. Predictions of the ballistic retrieval hypothesis

and more so at shorter SOAs. Results of such experiments have been taken as evidence that central cognition is effectively serial (again, see Pashler 1994 for a review).

The basic experimental paradigm used in this research inverts the priority instruction given to the subjects. That is, subjects are instructed to give T2 maximum priority; when the T2 stimulus onsets, subjects are to immediately give that stimulus highest priority. If T1 involves retrieval from declarative memory, the interruptibility of that retrieval will have a large impact on response time for T2. If the T1 retrieval is not interruptible (this will be termed “ballistic”), then, assuming serial cognition, cognitive processing of the T2 stimulus will be forced to wait for the completion of the retrieval and will thus be slowed. In particular, it should be slowed more at shorter SOAs. This situation is depicted in Figure 1. In Figure 1 and the following figures, time moves from left to right, and each stage of processing is represented by a box. Arrows represent dependencies. T1 stages are the upper set of boxes, T2 stages the lower set.

Panel (a) of Figure 1 shows the situation at short SOAs, which will result in a long T2 response time. Cognition for T2 must wait for the T1 retrieval to complete, which causes an elevated T2 response time. As SOA increases, T2 response time should decrease (Figure 1, panel b) until at long enough SOAs T2 should no longer be slowed at all (Figure 1, panel c). The slope of T2 response time as a function of SOA should thus be -1 until the “long enough” SOA is reached and the slope drops to zero. At this point, the response time for T2 should be the same as when T2 is not an interrupting task, that is, the single task time.

Figure 2. Difficulty effect under the ballistic retrieval hypothesis

A secondary prediction made by the ballistic retrieval hypothesis is that the duration of the T1 retrieval should directly impact the T2 response time. If processing for T2 must wait for the completion of T1 retrieval, extending the duration of that retrieval (e.g. by making the retrieval more difficult) should directly impact T2 response time. If processing for T2 must wait for the completion of the T1 retrieval, extending the duration of that retrieval should

result in a time cost for T2 identical in size to the increase in retrieval difficulty. This is depicted in Figure 2: panel (a) depicts a short T1 retrieval, panel (b) depicts a long T1 retrieval.

If, on the other hand, retrievals are interruptible, T2 response should be insensitive to the state of the T1 retrieval. That is, there should be no effect of either SOA or T1 difficulty. This situation is depicted in Figure 3.

Figure 3. Interruptible retrieval hypothesis

There is a potential complication, which is interruption cost. The shift from T1 to T2 may have a cognitive cost. If such a cost exists, and it is fixed, then the T2 response time in the interruption situation should be elevated when compared to the T2 response time when T2 is performed in isolation (the single-task case). This should hold regardless of T1 difficulty or SOA. Figure 4 represents the situation in which retrievals are interruptible but with an interruption cost.

Figure 4. Interruptible retrieval with switch cost

To summarize, the ballistic retrieval hypothesis predicts that T2 response time should have a -1 slope as a function of SOA, and that adding difficulty to retrieval should generate a parallel function of SOA, with the distance between the RT functions equivalent to the single-task difficulty effect of T1. On the other hand, interruptible retrieval hypothesis predicts that T2 should be insensitive to either SOA or T1 retrieval difficulty.

## Methods

### Participants

The participants were 39 Rice University undergraduates who participated for credit in a psychology class.

## Stimuli and Design

There were three kinds of trials: multiplication only, color identification, and interruption. Single-digit multiplication was used as T1 in this paradigm. Participants saw two digits presented visually (e.g. “6 8”) and responded with the product of the two digits vocally (e.g. “forty-eight”). Retrieval difficulty was manipulated by varying the size of the digits used. This manipulation has been shown to be effective in previous work (Byrne & Anderson, 1999). “Easy” retrieval used the digits from 1 to 4, while “hard” retrieval used the digits 6 through 9. Squares (e.g. “7 7”) were not used.

A simple color identification task served as T2 in this paradigm. This was a choice reaction time task with two alternatives. A rectangular block of color appeared on the display. If the color block was blue, participants pressed one key on the keyboard; if the block was red, another key was pressed.

For interruption trials, the color block appeared and covered the digits on the screen. The SOA was the time between the onset of the digits and the onset of the color block, measured in milliseconds. SOAs of 200, 375, 550, and 725 ms were used. Participants were instructed that when an interruption occurred, they were to respond to T2 as rapidly as possible and that completion of T1 was not necessary. These instructions were given to maximize the priority given to T2; participants should have no reason to continue with T1 and thus should switch to T2 as rapidly as possible.

The design was also blocked, each block consisted of five sets of 40 trials. One set in each block consisted of only color identification trials, to provide an estimate of single-task response time. The remaining four sets were a mixture of multiplication-only trials and interruption trials, with interruptions occurring 20% of the time. Thus, for interruption trials, there were three factors, all within-subjects: block, from one to three, four levels of SOA, and two levels of difficulty. Which trials contained interruptions and the order of sets within a block were randomized.

## Procedures

Participants were first trained on the color identification task until they performed two consecutive sets of 40 trials with 95% or better accuracy. Participants were then given 40 trials of practice with multiplication-only trials, followed by a 40-trial set of multiplication trials, 20% of which contained interruptions.

## Apparatus

Stimulus presentation and data collection were done on Apple iMac personal computers. Vocal responses were timed with an Apple PlainTalk microphone by monitoring the microphone level and stopping the timer when a threshold level of input was exceeded. Keypress responses were timed by actively polling the state of the keyboard. Both measures should be accurate to approximately 5 ms.

Figure 5. Color identification response time as a function of block

## Results

Due to the excellent power of the repeated-measures design and the large number of subjects and trials, an alpha level of 0.01 will be used for all statistical tests.

The color identification task is fairly simple and participants were forced to practice to a relatively stringent criterion, so performance was expected to be rapid but there was still the possibility that subjects may have been speeding up with practice. Figure 5 presents single-task color identification response time as a function of block. Clearly, there was no practice-related speedup in this case, in fact, the absolute response times actually went down slightly with practice, though this is probably coincidental. Overall, the effect of block was not reliable,  $F(2, 70) = 1.83, p = 0.17$ . The lack of learning on this task suggests that performance on this task is limited primarily by fixed architectural properties such as perceptual-motor limitations; the cognitive demands of this task are fairly minimal.

Multiplication-only trials demonstrated a much more complex pattern. Response time for multiplication-only trials is shown in Figure 6. As expected, there was an effect of difficulty,  $F(1, 35) = 81.74, p < 0.001$  with hard problems clearly slower than easy ones, on average, about 350 ms slower. There was also a main effect of block,  $F(2, 70) = 10.30, p < 0.001$ ,<sup>1</sup> and a block by difficulty interaction,  $F(2, 70) = 12.14, p < 0.001$ , both primarily a function of improvement on hard problems. If retrievals are ballistic, all of these effects should show up in T2 response time in the interruption trials, since T2 cognition should be forced to wait for the completion of the retrieval.

<sup>1</sup> To control for sphericity problems, repeated-measures factors with more than two levels were adjusted with either Huynh-Feldt epsilon or Greenhouse-Geisser epsilon where appropriate.

Figure 6. Multiplication-only response time for easy and hard problems as a function of block

Figure 7. T2 interruption response time as a function of SOA for hard and easy T1 retrievals

The interruptible retrieval hypothesis, given the lack of practice effects on color identification in isolation, should predict no effect of difficulty or block on T2 interruption performance.

The data of primary interest, of course, are the data for the interruption trials. These data, as a function of SOA, are presented in Figure 7. The results are generally consistent with the interruptibility hypothesis. Most importantly, there was no effect of SOA,  $F(3, 105) = 0.90, p = 0.40$ . There is clearly a potential problem of accepting the null hypothesis here. However, the prediction made by the ballistic hypothesis is specific: there should be a -1 slope with SOA. This can be tested with a linear contrast on SOA, which was not reliable,  $t(35) = -0.51, p = 0.61$ . A -1 slope would be a large effect in this context, and power to detect a large effect in this situation was estimated to be 0.99 (see Cohen, 1988 for details on this procedure). Thus, accepting the null hypothesis in this case is statistically justifiable.

All other effects and interactions were also not reliable, save one: the effect of T1 difficulty (the difference between the easy and hard conditions) was reliable,  $F(1, 35) = 8.29, p = 0.007$ . The absolute magnitude of this difference is small, however, at just under 40 ms. The two difficulty effects, one in multiplication-only trials, and one in interruption trials, is presented for each block in Figure 8. These effects are obviously different, and indeed a repeated-measures ANOVA on the difficulty reveals a very reliable effect of multiplication-only vs. interruption,  $F(1, 35) = 65.46, p < 0.001$ . This suggests that while the difficulty effect did manifest itself in the T2 response time, this effect is probably not due to retrieval difficulty in T1, since that difficulty effect was roughly nine times larger.

There was also a reliable effect of block,  $F(2, 70) = 6.73, p = 0.004$ , and an interaction,  $F(2, 70) = 10.68, p < 0.001$  on the difficulty effect. This seems to be driven primarily by the previously-mentioned improvement in “hard” multiplication problems over time, which results in a reduction in difficulty effect for the multiplication-only trials; in contrast, the small

Figure 8. Difficulty effect as a function of block for multiplication-only trials and interruption trials

difficulty effect seen in T2 interruptions is fairly stable over blocks.

Of course, the lack of SOA effect may be due to subjects adopting a strategy of delaying response to T1 until they could be confident that an interruption would not occur. The multiplication-only response times are fairly rapid, suggesting this is unlikely, but there is a more direct test. Subjects often responded to T1 even when the interruption occurred, but they did so more often for long SOAs than for short SOAs and more often for easy problems than hard problems. This is shown in Figure 9. Effects of block, SOA, and their interaction were reliable, [for SOA,  $F(3, 105) = 108.70, p < 0.001$ ; for difficulty,  $F(1, 35) = 152.24, p < 0.001$ ; for the interaction,  $F(3, 105) = 11.42, p < 0.001$ ] but there were no reliable effects or interactions involving block. This sensitivity to SOA and difficulty suggests that participants did indeed attempt to respond as rapidly as possible to T1 and did not uniformly postpone T1 in anticipation of an interruption.

Figure 9. Proportion of interruption trials on which a T1 response was emitted

The final effect to consider is the interruption cost, that is, the difference between color identification response time when it was in isolation vs. when it was the interrupting task. Figure 10 presents the results. Clearly, there was an interruption cost,  $F(1, 35) = 235.58, p < 0.001$ . The absolute magnitude of this difference is large relative to the single-task color identification response time. Single-task response time for color identification averaged just under 450 ms, but with interruptions it was close to 700 ms, a 250 ms penalty.

Figure 10. Color identification response time as a function of block when it was in isolation (single-task or ST) vs. as the interrupting T2

There is no real evidence that this cost was reduced with practice as there was no reliable effect of block,  $F(2, 70) = 0.80, p = 0.45$ , or an interaction of task condition and block,  $F(2, 70) = 0.81, p = 0.45$ .

## Discussion

These data are clearly more consistent with the interruptibility hypothesis. The lack of SOA effect on T2 response time is most telling. However, the data are not entirely equivocal. There was a reliable effect of T1 retrieval difficulty on T2 response time, though this effect was small and clearly of a different magnitude than the difficulty effect present in T1. The source of this effect is unclear. One possible explanation is that perceptual processing of T1 is more difficult for larger digits but this is purely speculative.

For the purposes of setting architectural policy in ACT-R/PM, these results certainly suggest that retrievals should be interruptible. However, whether retrievals should always be interrupted by any change in declarative memory or whether they should only be interrupted under certain conditions is unclear. In this experiment, the retrieval is interrupted by a higher-priority change that is both presented foveally and displaces the T1 stimulus in the visual array. These conditions at least appear to favor interruption. The frequency of interruption in this experiment, 20%, may also play a role.

At a more general level, the interruption cost itself is quite intriguing. The source of this cost is not clear, though something of its nature was revealed; it appears not to change with practice (blocks) and appears not to be affected

by SOA. Whether this cost is sensitive to factors such as interruption frequency, modality match with the T1 stimulus, and T2 difficulty, is unknown. Follow-up research certainly appears appropriate.

However, in some sense, the change from T2 to T1 processing can be thought of as a task-switch (e.g. Rogers & Monsell, 1995). While a great deal is known about task-switching (Altmann & Gray, 1999 provides an excellent account), it is not clear whether or not this is a special case of task-switching phenomenon. In traditional task-switching experiments, one type of task follows the completion of another, but the two tasks do not temporally overlap, that is, one does not interrupt the other. The ramifications of this difference in experimental paradigm are not entirely clear; the interruption cost may be related to the cost associated with task-switching or it may be an independent effect. Again, further research will be required to better understand the interruption cost.

### **Acknowledgements**

I would like to thank Michael Fleetwood and Bryan Blauvelt for their assistance in data collection, and to Erik Altmann for comments on an earlier draft.

## Abstract

Hemispheric specialization during episodic memory encoding was examined using three functional magnetic resonance imaging (fMRI) tasks. Stimuli for the three tasks differed in the degree to which they elicited subjects' use of verbal and image-based encoding strategies. Intentional encoding of visually presented scenes, sentences, and faces was associated with neural activity in the hippocampus and surrounding mesial Temporal Lobe (mTL) structures. Across tasks, material-specific lateralization of neural activity was observed in the posterior mTL. In contrast, hippocampal activation did not lateralize according to material type for two of the three tasks. These results suggest a functional dissociation between the hippocampus and other mTL subcomponents, and indicate that material-specificity may not fully explain hemispheric specialization in the mTL memory system.

## Introduction

The human hippocampus and adjacent mesial temporal lobe (mTL) structures are believed to subservise encoding of new information into episodic memory: the form of long-term memory that supports conscious recollection of ongoing experiences (Squire and Zola-Morgan, 1991; Tulving, 1998). The role of the mTL in long-term memory processing has been investigated extensively ever since Scoville and Milner (1957) reported profound global anterograde amnesia in patient HM following bilateral resection of the hippocampus, uncus, and amygdala. Numerous studies of unilateral mTL resection have documented that in left-language dominant patients, resection of the left anterior temporal lobe consistently produces verbal memory impairment, and although the findings are less robust, that resection of the right, non-language-dominant anterior temporal lobe produces visuospatial memory impairment (Milner, 1958; Blakemore and Falconer, 1967; Milner, 1968; Jones-Gotman, 1986). Such findings gave rise to the ipsilateral deficit model, or *material-specific model*, which asserts that memory function lateralizes with cerebral function: in left-language dominant individuals, the left hemisphere mediates verbal memory, and the right hemisphere visuospatial memory (Saykin, et al., 1992).

Neuroimaging results have not been entirely consistent with lesion data regarding material-specificity during memory processing. Although several studies have demonstrated material-specific laterality in the frontal lobes (Wagner, et al., 1998; McDermott, et al., 1999) and in the mTL (Grady, et al., 1995; Stern, et al., 1996; Nyberg, et al., 1996a; Kelly, et al., 1998; Detre, et al., 1998), numerous studies suggest that hemispheric effects depend upon the memory process being instantiated (encoding vs. retrieval), rather than the type of stimulus material (Tulving, et al., 1994; Schacter, et al., 1995; Nyberg, et al., 1996b). Other studies suggest that the right and left medial temporal regions respond differentially to novel and familiar stimuli (Tulving, et al., 1996; Fujii, et al., 1997), or that laterality of activation varies with depth of encoding (Nyberg, et al., 1996a; Martin, et al., 1997), success of encoding (Casasanto, et al., 2000), or with task parameters such as the stimulus presentation rate (Kelly, et al., 1998).

The present study examined fMRI activation during intentional encoding of unfamiliar faces, complex visual scenes, and four-word declarative sentences. The goal of the study was to determine whether activation in the mTL lateralizes according to the type of stimulus material presented. Other variables that may affect hemispheric laterality, such as stimulus novelty, task instructions, and stimulus presentation parameters, were held constant across the three tasks. It was hypothesized that encoding of unfamiliar faces would be associated with preferential activation of right-hemisphere mTL structures, encoding of sentences with preferential activation of left-hemisphere mTL structures, and encoding of complex visual scenes, which are amenable to both verbal and visuospatial encoding, would be associated with bilateral mTL activation.

## Materials and Methods

### Subjects

Healthy, normal volunteers between the ages of 18 and 30 were consecutively recruited from the University of Pennsylvania community, and paid \$20 for their

participation (Scenes task: N=19, 6 male; Sentence Task: N=15, 6 male; Face task: N=6, 2 male). All subjects were right-handed by self-report, and all of the sentence task participants were native speakers of English.

### **Cognitive Task Design**

For each encoding task, subjects viewed a total of 60 stimuli, presented over six 40-second blocks (10 stimuli per block, 3500 ms presentation, 500 ms ISI) while lying supine in the bore of the MRI scanner. Stimulus blocks alternated with blocks of control images, matched with target stimuli for size, color, luminosity, and presentation rate. Scene stimuli were obtained from a commercial library of digitized images (PhotoDisc, Inc., 1995, Seattle, WA). (See figure 1a.) Face stimuli were constructed from University of Pennsylvania ID card photographs. Consent for use of the photographs was solicited via an e-mail advertisement to approximately 3000 members of the University community, and only photographs from those providing consent were used. The face photographs were equated for size and image quality, and were cropped so as to include the brow, eyes, nose, and mouth, but exclude ears, hair, and any extraneous objects such as eyeglasses or jewelry. (See figure 1b.) Sentence stimuli were four-word, active, declarative sentences culled from children's books estimated to be at the fifth-grade reading level, and presented in Chicago 24-point font. Simple sentences were chosen so that this task could be administered to neurologically impaired patients with cognitive deficits, although all data reported presently pertain to healthy subjects. (See figure 1c.) For the faces and scenes tasks, the control images were visual noise patterns, created by transforming a stimulus image with a random retiling algorithm iterated 10,000 times. For the sentence task, the control image was a set of four strings, composed of asterisks, of the same mean length as the stimulus words. Stimulus presentation routines were developed on a Macintosh Powerbook (Apple Computer, Cupertino, CA), using Psyscope software (Cohen, et al., 1993). Stimuli were back-projected using an Epson LCD projector (model ELP-5000) onto a viewing screen positioned approximately 7 feet from the subject's eyes, which was easily visible via a mirror mounted in the scanner head coil. Subjects were instructed to remember the stimuli for a recognition test immediately following each encoding task, and to attend to the control images, but not to memorize them. The sequence of cognitive tasks was pseudorandomly varied across subjects.

For each recognition test, subjects viewed all sixty of the stimuli presented during the preceding encoding task, randomly intermixed with an equal number of novel distractors. While still lying in the scanner bore, subjects were required to distinguish studied stimuli from unstudied distractors, and to respond using a two-button box interfaced with the Macintosh computer via fiberoptic cable. The forced-choice recognition test was self-paced, and subjects were informed that both the speed and accuracy of their responses was of interest. Functional

imaging data were collected during encoding, but not during recognition testing.

### **Image Acquisition**

Imaging data were collected on a 1.5 Tesla GE Signa MRI scanner equipped with a fast gradient system for echo-planar imaging, using a standard quadrature radiofrequency (RF) whole-head coil. Foam padding was used to comfortably restrict head motion. Sagittal and axial T1-weighted structural images were obtained for each subject. Prior to functional activation, data were acquired for correction of image distortion due to static susceptibility effects (Alsop, 1995). T2\*-sensitive, gradient echo, echoplanar functional images were then obtained with BOLD contrast (TR = 2000 ms, TE<sub>eff</sub> = 50 ms) in 18 to 20 contiguous 5-mm-thick axial slices, in a 24-cm field of view with a 64x64 acquisition matrix, resulting in a nominal pixel resolution of 3.75 x 3.75 x 5 mm. For each encoding task, functional activation was measured over a single 240-scan run consisting of six 80-second task/control cycles. Raw imaging data were extracted onto digital audiotape (DAT) for subsequent analysis.

### **Image Processing and Data Analysis**

Imaging data were reconstructed offline on SUN UltraSparc workstations, (SUN Microsystems, Mountain View, CA) using software developed in Interactive Data Language (Research Systems, Boulder, CO). Raw data were corrected for static susceptibility-induced distortions, and a motion-compensation algorithm targeting translational artifacts occurring along three orthogonal vectors was applied to each data set. Data were convolved in space using a three-dimensional nonisotropic gaussian kernel (full width half-maximum [FWHM] = 8 X 8 X 10 mm). Using SPM97 software (Wellcome Laboratories, London, UK), a linear model for temporally autocorrelated observations was applied voxelwise to each data set. FMRI signal at each voxel was correlated to a reference function obtained by convolving the square wave describing the task/control alternation with an estimate of the subject's hemodynamic response function (Friston, et al., 1994). Statistical parametric maps (SPMs) were generated for each subject's encoding runs. Multisubject SPMs were then constructed for each task using the random effects model, with SPMt maps as input. Normalized group maps were viewed in Talairach atlas space, with across-subject averaged functional images superimposed on a standard pseudosubject structural image. Cognitive subtraction (task condition – control condition) produced a difference image showing activation associated stimulus encoding for each task.

Anatomical regions were defined using the SPL anatomy browser (Kikinis, et al., 1996), interfaced with IDL and SPM98 software. Based on these anatomical regions, an mTL region of interest (ROI) was defined comprising the hippocampus, parahippocampus, and

fusiform gyrus. Although whole-brain data were collected, secondary analysis was restricted to this a-priori defined region of interest. Only activation exceeding a mapwise statistical threshold ( $\alpha = .05$ ) was considered. Suprathreshold activation was quantified for each lateralized anatomical structure within the mTL ROI, by counting the number of active suprathreshold voxels. The hemispheric asymmetry of activation correlating with each cognitive task was determined by calculating an asymmetry ratio for each search region ( $AR = \text{Voxels}_R - \text{Voxels}_L / \text{Voxels}_R + \text{Voxels}_L$ ). The significance of activation asymmetry was assessed by comparing the proportion of active suprathreshold voxels in each lateralized search region, using a standard test for the independence of two proportions (Hinkle, et al., 1988).

Recognition test performance was assessed by computing a discriminability index for each subject (Discriminability = (% hits) – (% false positives)).

## Results

### Behavioral Results

Performance on the post-scan recognition tests confirmed that subjects were able to encode target stimuli satisfactorily. Results show that all subjects performed significantly above chance on all tasks. Subjects' mean discriminability score for the face task was 0.50 (SD +/- .20,  $t = 6.13$ ,  $p = .0008$ ), for the scene task 0.80 (SD +/- .17,  $t = 19.18$ ,  $p = .0001$ ), and for the sentence task 0.70 (SD +/- .17,  $t = 13.97$ ,  $p = .0001$ ).

### Imaging Results

Suprathreshold activation associated with encoding was found in the mTL region of interest across all three tasks. Table 1 presents the Talairach locations of peak activation during encoding for each anatomical structure within the ROI. Figure 2 presents selected slices of the multisubject functional activation maps for each encoding task. It was observed, for the face and scene tasks, that active suprathreshold voxels in the parahippocampus were contiguous with those in the fusiform gyrus, constituting a "cluster" of active voxels. Hippocampal activations formed separate clusters. Therefore, for analysis of hemispheric effects, the region of interest was divided into two subregions: a hippocampal ROI comprising the hippocampus proper (horn of Ammon, subiculum, and dentate gyrus), and a posterior mTL ROI comprising the parahippocampus (perirhinal and entorhinal cortices) and the fusiform gyrus. Figure 3 shows the hemispheric asymmetry of activation across tasks, as indicated by the asymmetry ratio computed for each search region. For the face task, bilateral activation was found in the hippocampus, nonsignificantly greater left than right ( $AR = -0.27$ ,  $ns$ ), and in the posterior mTL, significantly greater right than left ( $AR = 0.33$ ,  $p < .05$ ). For the scene task, unilateral activation was found in the left hippocampus ( $AR = -1.0$ ,  $p < .001$ ), and bilateral activation was found in the posterior mTL ( $AR = -0.03$ ,

$ns$ ). For the sentence task, unilateral left hemisphere activation was found both in the hippocampus ( $AR = -1.0$ ,  $p < .001$ ) and in the posterior mTL ( $AR = -1.0$ ,  $p < .05$ ).

## Discussion

Across encoding tasks, the pattern of activation in the posterior mTL is consistent with the material-specific hypothesis. Greater right than left hemisphere activation was found during face encoding, nearly symmetrical bilateral activation during scene encoding, and exclusively left-sided activation during sentence encoding. The hemispheric laterality of activation can be interpreted as "code-specific" (McDermott, et al., 1999): that is, varying with the extent to which the stimuli can be processed using verbal and nonverbal *representational codes* (Paivio, 1991), the neural substrates of which have been shown to be differentially lateralized (Kounios and Holcomb, 1994; Kelly, et al., 1998).

Surprisingly, we observed that within task, the laterality of activation in the posterior mTL was not always consistent with the laterality of activation in the hippocampus. Hippocampal activation was bilateral during face encoding, and exclusively left-sided during scene and sentence encoding. In contrast to the material-specific activation observed in the posterior mTL, activation in the hippocampus during face and scene encoding did not lateralize according to the material-specific hypothesis. Previous studies have reported activation of left mTL structures during intentional encoding across all material types (Martin, 1997; Kelly, et al., 1998). However, the dissociation we observe between the laterality of activation in the hippocampus and posterior mTL structures during face and scene encoding has not been reported previously. It may be possible to account for our findings in terms of the neural connectivity of the mTL and surrounding structures. Hemispheric specialization for verbal and nonverbal materials has been well established in the neocortex. Because the parahippocampus receives direct input from the cortical sensory association areas, whereas the hippocampus receives the majority of its cortical input indirectly, via the parahippocampus (Eichenbaum and Bunsey, 1995), material-specific hemispheric effects may be observed more readily in parahippocampus than in the hippocampus. Furthermore, hemispheric specialization in the hippocampus may be masked due to integration of the right and left hippocampi, which are reciprocally connected via the hippocampal commissure.

Our findings are compatible with the two-component model of mTL memory processing developed by Eichenbaum and colleagues (1994), which suggests a functional dissociation between the hippocampus and posterior mTL structures. Specifically, the model implicates the parahippocampal region in the intermediate-term storage and maintenance of *individual mental representations*, and the hippocampus in the formation of *relations among mental representations*.

Right Fusiform Gyrus	--	--	--	134	0	--	--

Note. Mean Z score indicates the average of all suprathreshold voxels within the ROI. Active volume represents the number of voxels within the ROI exceeding the significance threshold ( $\alpha = .05$ ).

Figure 2: Multisubject statistical parametric maps (SPMs) of functional activation within the mTL region of interest correlating with each encoding task (top row: face encoding; middle row: scene encoding; bottom row: sentence encoding). The left side of each image corresponds to the left side of the brain. Regions demonstrating suprathreshold activation ( $p < .05$ ) during the task - control conditions are displayed in the red-to-yellow color scale.

Figure 3: Hemispheric asymmetry of activation across encoding tasks in the hippocampus and posterior mTL. The horizontal axis indicates the Asymmetry Ratio (AR) calculated to show the hemispheric distribution of active suprathreshold voxels ( $p < .05$ ) within each search region ( $AR = \text{Voxels}_R - \text{Voxels}_L / \text{Voxels}_R + \text{Voxels}_L$ ).

This model, based primarily on lesion studies in humans and animals, is supported by recent human electrophysiological data that show a temporal dissociation between parahippocampal and hippocampal activation during encoding (Fernandez, et al., 1999), and by PET data that show increased hippocampal activation during relational vs. non-relational memory processing (Henke, et al., 1999). *Individual* mental representations may be either verbal or nonverbal, whereas *relational* representations may combine verbal and nonverbal codes. Although the Eichenbaum model makes no explicit predictions regarding material-specificity, it provides a theoretical framework in which to consider our finding that the posterior mTL shows greater sensitivity to material type than the hippocampus.

## Conclusions

Whereas hemispheric laterality during memory encoding in the posterior mTL appears to be strongly code-dependent, laterality in the hippocampus may depend upon other variables, as well. Within the frontal lobes, hemispheric effects have been shown to depend upon material type for certain anatomical structures, and upon cognitive set (encoding vs. retrieval) for other nearby structures (McDermott, et al., 1999). This pattern may be extensible to the mesial temporal lobes. Future studies may identify variables affecting the laterality of activation in specific mTL subcomponents, and may help to reconcile neuropsychological findings that suggest material-specific hippocampal involvement in memory processing with conflicting neuroimaging results.

This report was supported in part by NIH grant NS37488.

## Abstract

One of the most controversial issues in cognitive science pertains to whether rules are necessary to explain complex behavior. Nowhere has the debate over rules been more heated than within the field of language acquisition. Most researchers agree on the need for statistical learning mechanisms in language acquisition, but disagree on whether rule-learning components are also needed. Marcus, Vijayan, Rao, & Vishton (1999) have provided evidence of rule-like behavior which they claim can only be explained by a dual-mechanism account. In this paper, we show that a connectionist single-mechanism approach provides a more parsimonious account of rule-like behavior in infancy than the dual-mechanism approach. Specifically, we present simulation results from an existing connectionist model of infant speech segmentation, fitting the behavioral data under naturalistic circumstances without invoking rules. We further investigate diverging predictions from the single- and dual-mechanism accounts through additional simulations and artificial language learning experiments. The results support a connectionist single-mechanism account, while undermining the dual-mechanism account.

## Introduction

The nature of the learning mechanisms that infants bring to the task of language acquisition is a major focus of research in cognitive science. With the rise of connectionism, much of the scientific debate surrounding this research has focused on whether rules are necessary to explain language acquisition. All parties in the debate acknowledge that statistical learning mechanisms form a necessary part of the language acquisition process (e.g., Christiansen & Curtin, 1999; Marcus, Vijayan, Rao, & Vishton, 1999; Pinker, 1991). However, there is much disagreement over whether a statistical learning mechanism is sufficient to account for complex rule-like behavior, or whether additional rule-learning mechanisms are needed. In the past this debate has primarily taken place within specific areas of language acquisition, such as inflectional morphology (e.g., Pinker, 1991; Plunkett & Marchman, 1993) and visual word recognition (e.g., Coltheart, Curtis, Atkins & Haller, 1993; Seidenberg & McClelland, 1989). More recently, Marcus et al. (1999) have presented results from experiments with 7-month-olds, apparently showing that infants acquire abstract algebraic rules after two minutes of exposure to habituation stimuli. The algebraic rules are construed as representing an open-ended relationship between variables for which one can substitute arbitrary values, “such as ‘the first item X is the same as the third item Y,’ or more generally, that ‘item I is the same as item J’” (Marcus et al., 1999, p. 79). Marcus et al. further claim that a connectionist single-mechanism approach based on statistical learning is unable to

fit their experimental data. In this paper, we build on earlier work (Christiansen & Curtin, 1999) and present a detailed connectionist model of these infant data, and provide new experimental data that support a statistically-based single-mechanism approach while undermining the dual-mechanism account.

In the remainder of this paper, we first show that knowledge acquired in the service of learning to segment the speech stream can be recruited to carry out the kind of classification task used in the experiments by Marcus et al. For this purpose we took an existing model of early infant speech segmentation (Christiansen, Allen & Seidenberg, 1998) and used it to simulate the results obtained by Marcus et al. The simulations demonstrate that no rules are needed to account for the data; rather, statistical knowledge related to word segmentation can explain the rule-like behavior of the infants in the Marcus et al. study. We then explore the issue of timing in stimuli presentation and present additional simulations from which empirical predictions are derived that diverge from those of the rule-based account. These predictions are tested in experiments with adults. Experiment 1 replicated the results from Marcus et al. using adult subjects. Experiment 2 confirmed the predictions from our single-mechanism approach, whereas the dual-mechanism approach cannot account for these results without adding extra machinery to complement the statistical and rule-based components. Together, the simulations and the experiments thus suggest that a single-mechanism model provides the most parsimonious account of the empirical data presented here and in Marcus et al., thus obviating the need for a separate rule-based component.

## Simulation 1: Rule-Like Behavior without Rules

Marcus et al. (1999) used an artificial language learning paradigm to test their claim that the infant has two mechanisms for learning language, one that uses statistical information and another which uses algebraic rules. They conducted three experiments which tested infants’ ability to generalize to items not presented in the familiarization phase of the experiment. We focus here on their third experiment because it was controlled for possible confounds found in the first two experiments: differences in phonetic features (Experiment 1) and reduplication<sup>1</sup> (Experiment 2). Marcus et al. claim that

<sup>1</sup>Though the control for reduplication was not entirely complete (see Elman, 1999).

because none of the test items appeared in the habituation part of the experiment the infants would not be able to use statistical information in this task.

The subjects in Experiment 3 of Marcus et al. (1999) were 16 7-month-old infants randomly placed in an AAB or an ABB condition. During a two-minute long familiarization phase the infants were exposed to three repetitions of each of 16 three-word sentences. Each word in the sentence frame AAB or ABB consisted of a consonant-vowel sequence (e.g., “le le we” or “le we we”). The test phase consisted of 12 sentences made up of words to which the infants had not previously been exposed (e.g., “ko ko ga” vs. “ko ga ga”). The test items were broken into two groups for both habituation conditions: consistent (items constructed with the same sentence frame as the familiarization phase) and inconsistent (constructed from the sentence frame the infants were not habituated on). The results showed that the infants preferred the inconsistent test items to the consistent ones (that is, they listened longer to the inconsistent items).

The conclusion drawn by Marcus et al. (1999) was that a single mechanism which relied on statistical information alone could not account for the results. Instead they suggested that a dual mechanism was needed, comprising a statistical learning component and an algebraic rule learning component. In addition, they claimed that a Simple Recurrent Network (SRN; Elman, 1990) would not be able to accommodate their data because of the lack of phonological overlap between habituation and test items. Specifically, they state,

Such networks can simulate knowledge of grammatical rules only by being trained on all items to which they apply; consequently, such mechanisms cannot account for how humans generalize rules to new items that do not overlap with the items that appeared in training (p. 79).

In the first simulation, we demonstrate that SRNs can indeed fit the data from Marcus et al. Other researchers have constructed neural network models specifically to simulate the Marcus et al. results (Altmann & Dienes, 1999; Elman, 1999; Shastri & Chang, 1999; Shultz, 1999). In contrast, we do *not* build a new model to accommodate the results, but take an existing SRN model of speech segmentation (Christiansen et al., 1998) and show how this model—*without additional modification*—provides an explanation for the results.

### The Christiansen et al. Model

The model by Christiansen et al. (1998) was developed as an account of early word segmentation. An SRN was trained on a *single* pass through a corpus of child directed speech. As input the network was provided with three probabilistic cues to word boundaries: (a) phonology represented in terms of 11 features on the input and 36 phonemes on the output, (b) utterance boundary information represented as an extra feature marking utterance endings, and (c) lexical stress coded over two units as either no stress, secondary or primary stress. Figure 1 provides an illustration of the network.

The network was trained on the task of predicting the next phoneme in a sequence as well as the appropriate values for the utterance boundary and stress units. In learning to perform this task the network learned to integrate the cues such

Figure 1: Illustration of the SRN used in Simulations 1 and 2. Solid lines indicate trainable weights, whereas the dashed line denotes the copy-back weights (which are always 1). U-B refers to the unit coding for the presence of an utterance boundary. The presence of lexical stress is represented in terms of two units, S and P, coding for secondary and primary stress, respectively.

that it could carry out the task of segmenting the input into words. This involved activating the boundary unit not only at utterance boundaries, but also at word boundaries occurring inside utterances. The logic behind the segmentation task is that the end of an utterance is also the end of a word. If the network is able to integrate the provided cues in order to activate the boundary unit at the ends of words occurring at the end of an utterance, it should also be able to generalize this knowledge so as to activate the boundary unit at the ends of words which occur *inside* an utterance (Aslin, Woodward, LaMendola & Bever, 1996).

The Christiansen et al. (1998) model acquired distributional knowledge about sequences of phonemes and the associated stress patterns. This knowledge allowed it to perform well on the task of segmenting the speech stream into words. We suggest that this knowledge can be put to use in secondary tasks not directly related to speech segmentation—including the artificial language task used by Marcus et al. (1999). In fact, the experimental procedure used by Marcus et al. was the same as the procedure used by Saffran, Aslin & Newport (1996) to study how word segmentation in infancy can be facilitated by statistical learning. That is, Marcus et al. sought to demonstrate that the statistically-based learning mechanism, which Saffran, Aslin, et al. found to be involved in word segmentation, could not account for their results. It therefore makes sense to investigate whether the comprehensive speech segmentation model by Christiansen et al. can account for the Marcus et al. infant results.

### Method

**Networks** Corresponding to the 16 infants in the Marcus et al. study, we used 16 SRNs similar to the SRN used in Christiansen et al. (1998) with the exception that the original phonetic feature geometry was replaced by a new representation using 18 features. Each of the 16 SRNs had a different set of initial weights, randomized within the interval [0.25;-0.25]. The learning rate was set to 0.1 and the momentum to 0.95. These training parameters were identical to those used in the original Christiansen et al. model. The networks were trained to predict the correct constellation of cues given the current

input segment.

**Materials** Prior to being habituated and tested on the stimuli from Marcus et al., the networks were first exposed to the training corpus used by Christiansen et al. This corpus consists of 8181 utterances extracted from the Korman (1984) corpus of British English speech directed at pre-verbal infants aged 6-16 weeks (a part of the CHILDES database, MacWhinney, 1991). Christiansen et al. transformed each word in the utterances from its orthographic format into a phonological form with accompanying lexical stress using a dictionary compiled from the MRC Psycholinguistic Database available from the Oxford Text Archive.

The materials from Experiment 3 in Marcus et al. (1999) were transformed into the phoneme representation used by Christiansen et al. Two habituation sets were created in this manner: one for AAB items and one for ABB items. The habituation sets used here, and in Marcus et al., consisted of 3 blocks of 16 sentences in random order, yielding a total of 48 sentences in each habituation set. As in Marcus et al. there were four different test sentences: “ba ba po”, “ko ko ga” (consistent with AAB), “ba po po” and “ko ga ga” (consistent with ABB). The test set consisted of three blocks of randomly ordered test sentences, totaling 12 test items. Both the habituation and test sentences were treated as a single utterance with no explicit word boundaries marked between the individual words. The end of each utterance was marked by activating the utterance boundary unit.

**Procedure** The networks were first trained on a single pass through the Korman (1984) corpus as the original Christiansen et al. model. This corresponds to the fact that the 7-month-olds in the Marcus et al. study already have had a considerable exposure to language, and have begun to develop their speech segmentation abilities. Next, the networks were habituated on a *single* pass through the appropriate habituation corpus—one phoneme at a time—with learning parameters identical to the ones used during the pretraining on the Korman corpus. The networks were then tested on the test set (with the weights “frozen”) and the activation of the utterance boundary unit was recorded for every phoneme input in the test set. Finally, the boundary unit activations for test sentences that were consistent or inconsistent with the habituation pattern were separated into two groups. Furthermore, for the purpose of scoring word segmentation performance on the test items, the activation of the boundary unit was also recorded for each habituation condition across all the habituation items and the mean activation was calculated. The networks were said to have postulated a word boundary whenever the boundary unit activation in a test sentence was above the appropriate habituation mean.

## Results and Discussion

To provide a quantitative measure of performance we used completeness scores (Christiansen et al., 1998) to assess segmentation performance.

$$\text{Completeness} = \frac{\text{Hits}}{\text{Hits} + \text{Misses}} \quad (1)$$

Completeness provides a measure of how many of the words in a test set the net is able to discover. With respect to our in-

Figure 2: Mean completeness scores for the consistent (CON) and inconsistent (INCON) test items from Simulations 1 (left) and 2 (right).

terpretation of the Marcus et al. data, the completeness score indicates how well networks/infants are at segmenting out the individual words in the test sentences. As an example, consider the following hypothetical segmentation of two test sentences:

# b a b # a # p o # k o # g a g # a #

where ‘#’ corresponds to a predicted word boundary. Here the hypothetical learner correctly segmented out two words, *po* and *ko*, but missed the first and the second *ba* and the first and the second *ga*. This results in a completeness score of  $2/(2+4) = 33.3\%$ .

For each of the sixteen networks, completeness scores were computed across all test items, and submitted to the same statistical analyses as used by Marcus et al. for their infant data. The completeness scores were analyzed in a repeated measures ANOVA with condition (AAB vs. ABB) as between network factor and test pattern (consistent vs. inconsistent) as within network factor. The left-hand side of Figure 2 shows the completeness scores for the consistent and inconsistent items pooled across conditions. There was a main effect of test pattern ( $F(1, 14) = 5.76, p < .04$ ), indicating that the networks were significantly better at segmenting out the words in the inconsistent items (35.76%) compared with the consistent items (28.82%). Similarly to the infant data, neither the main effect of condition, nor the condition  $\times$  test pattern interaction were significant ( $F's < 1$ ). The better segmentation of the inconsistent items suggests that they would stand out more clearly in comparison with the consistent items, and thus explain why the infants looked longer towards the speaker playing the inconsistent items in the Marcus et al. study.

Simulation 1 shows that a separate rule-learning component is not necessary to account for the Marcus et al. (1999) data. An existing SRN model of word segmentation can fit these data without invoking explicit, algebraic-like rules. The pretraining allowed the SRNs to learn to integrate the regularities governing the phonological, lexical stress, and utterance boundary information in child-directed speech. During the habituation phase, the networks then developed weak attrac-

tors specific to the habituation pattern *and* the syllables used. The attractor will at the same time both attract a consistent item (because of pattern similarity) and repel it (because of syllable dissimilarity), causing interference with the segmentation task. The inconsistent items, on the other hand, will tend to be repelled by the habituation attractors and therefore do not suffer from the same kind of interference, making them easier for the network to process.

Importantly, the SRN model—as a statistical learning mechanism—can explain both the distinction between consistent and inconsistent items as well as the preference for the inconsistent items. Note that a rule-learning mechanism by itself only can explain how infants may distinguish between items, but not why they prefer inconsistent over consistent items. Extra machinery is needed in addition to the rule-learning mechanism to explain the preference for inconsistent items. Thus, the most parsimonious explanation is that only a statistical learning device is necessary to account for the infant data. The addition of a rule-learning device does not appear to be necessary.

### Simulation 2: It's about Time

Simulation 1 demonstrated that a statistically-based single-mechanism approach can account for the kind of rule-like behavior displayed by the infants in the Marcus et al. study. However, there may be other cases in which a separate rule-learning component would be required. Here we explore one such case in which our model makes a prediction which is different from what would be predicted from a dual-mechanism approach incorporating a rule-learning component.

Recall that algebraic rules were characterized as abstract relationships between variables, such as item X is the same as item Y. Marcus et al. Experiment 3 was designed to demonstrate that rule learning is independent of the physical realization of variables in terms of phonological features. The same rule, AAB, applies to—and can be learned from—“le le we” and “ko ko ga” (with “le” and “ko” filling the same A slot and “we” and “ga” the same B slot). As the abstract relationships that this rule represents only pertains to the value of the three variables, the amount of time between them should not affect the application of the rule. Thus, just as the physical realization of a variable does not matter for the learning or application of a rule, neither should the time between variables. The same rule AAB, applies to—and can be learned from—“le [250ms] le [250ms] we” and “le [1000ms] le [1000ms] we” (the “le”s should still fill the A slots and the “we”s the B slot despite the increased duration of time between the occurrence of these variables). From this property, one can predict that lengthening the time between variables should not affect the preference for inconsistent items. Indeed, the connectionist implementation of the rule-based approach found in the Shastri & Chang (1999) model would appear to make this prediction.

A lengthening of the pauses between words should, however, have a different effect on our model. In the model, the preference for inconsistent items observed by Marcus et al. is explained in terms of differential segmentation performance. Lengthening the pauses between words would in effect solve the segmentation task for the model, and should result in a disappearance of the preference for inconsistent items. Thus,

we predict that the model should show no difference between the segmentation performance on the consistent and inconsistent items if pauses are lengthened as indicated above. To test this prediction, we carried out a new set of simulations.

### Method

**Networks.** Sixteen SRNs as in Simulation 1.

**Materials.** Same as in Simulation 1 except that utterance boundaries were inserted *between* the words in the habituation and test sentences, simulating a lengthening of pauses between words (from 250 msec to 1000 msec) such that they have the same length as the pauses between utterances.

**Procedure.** Same as in Simulation 1.

### Results and Discussion

Completeness scores were computed as in Simulation 1 and submitted to the same statistical analysis. As illustrated by the right-hand side of Figure 2, the segmentation performance on the test items was improved considerably by the inclusion of utterance boundary-length pauses between words. As predicted, there was no difference between the accuracy scores for consistent (70.14%) and inconsistent items (70.49%) ( $F(1, 14) = .02$ ). As before, there was no main effect of condition, neither was there any interaction between condition and test pattern ( $F's < 1$ ).

Simulation 2 thus confirms the predicted effect of lengthening the pauses between words in stimuli presented to the statistical learning model. This results in diverging predictions derived from the rule-based and the statistical learning models concerning the effect of pause lengthening on human performance on the stimuli. Next, we test these diverging predictions in an artificial language learning experiment using adult subjects.

### Experiment 1: Replicating the Marcus et al. Results

Before testing the diverging predictions from the single- and dual-mechanism approaches we need to first establish whether adults in fact exhibit the same pattern of behavior as the infants in the Marcus et al. study. The first experiment therefore seeks to replicate Experiment 3 from Marcus et al. using adult subjects instead of infants.

### Method

**Subjects.** Sixteen undergraduates were recruited from introductory Psychology classes at Southern Illinois University. Subjects earned course credit for their participation.

**Materials.** For this experiment, we used the original stimuli that Marcus et al. (1999) created for their Experiment 3. Each word in a sentence was separated by 250 msec. The 16 habituation sentences for each condition were created by Marcus et al. using the Bell Labs speech synthesizer. The original habituation stimuli were limited to two predetermined sentence orders. To avoid potential order effects, we used the SoundEdit 16 version 2 software for the MacIntosh to isolate each sentence as a separate sound file. This allowed us to present the habituation sentences in a random order for each subject.

For the test phase, we also used the stimuli from Marcus et al.'s Experiment 3, which consisted of four new sentences that were either consistent or inconsistent with the training grammar. Like the habituation stimuli, each word in a sentence was separated by a 250 msec interval. As before, we stored the test stimuli as separate SoundEdit 16 version 2 sound files to allow a random presentation order for each subject.

**Procedure.** Subjects were seated in front of a G3 Power Macintosh computer with a New Micros button box. Subjects were randomly assigned to one of two conditions, AAB or ABB. The experiment was run using the PsyScope presentation software (Cohen, MacWhinney, Flatt, and Provost, 1993) with all stimuli played over stereo loudspeakers at 75dB. The subjects were instructed that they were participating in a pattern recognition experiment. They were told that in the first part of the experiment their task was to listen carefully to sequences of sounds and that their knowledge of these sound sequences would be tested afterwards. Subjects listened to three blocks of the sixteen randomly presented habituation sentences corresponding either to the AAB or the ABB sentence frame. A 1-second interval separated each sentence as was the case in the Marcus et al. experiment.

After habituation, subjects were instructed that they would be presented with new sound patterns that they had not previously heard. They were asked to judge whether a pattern was "similar" or "dissimilar" to what they had been exposed to in the previous phase by pressing an appropriately marked button. The instructions emphasized that because the sounds were novel, the subjects should not base their decision on the sounds themselves but instead on the patterns derived from the sounds. Subjects listened to three blocks of the four randomly presented test sentences. After the presentation of each test sentence, subjects were prompted for their response. Subjects were allowed to take as long as they needed to respond. Each test trial was separated by a 1000-msec interval.

## Results and Discussion

For the purpose of our analyses, the correct response for consistent items is "similar" while the correct response for inconsistent items is "dissimilar". The mean overall score for correct classification of test items was 8.81 out of a perfect score of 12. A single-sample t-test showed that this classification performance was significantly better than the chance level performance of 6 ( $t(15) = 4.44, p < .0005$ ). Subjects' responses were then subject to the same statistical analysis as the infant data in Marcus et al. (and Simulation 1 and 2 above). The left-hand side of Figure 3 shows the ratings as dissimilar for the six consistent and six inconsistent test items pooled across condition. As expected, there was a main effect of test pattern ( $F(1, 14) = 18.98, p < .001$ ), such that significantly more inconsistent items were judged as dissimilar (4.5) than consistent items (1.69). Neither the main effect of condition, nor the condition  $\times$  test pattern interaction were significant ( $F's < 1$ ).

Experiment 1 shows that adults perform similarly to the infants in Marcus et al.'s Experiment 3, thus demonstrating that it is possible to replicate their findings using adult subjects instead of infants. This result is perhaps not surprising given that Saffran and colleagues were able to replicate statistical learning results obtained using adults subjects

Figure 3: The mean proportion of consistent (con) and inconsistent (incon) test items rated as dissimilar to the habituation pattern in Experiments 1 (left) and 2 (right).

(Saffran, Newport & Aslin, 1996) in experiments using 8-month-olds (Saffran, Aslin, et al., 1996). More generally, these results and ours suggest that despite small differences in the experimental methodology used in infant and adult artificial language learning studies, both methodologies appear to tap into the same learning mechanisms. Also from a dual-mechanism approach, one would expect that the same learning mechanisms—statistical and rule-based—would be involved in both infancy and adulthood, and that similar results should be expected in both infant and adult studies of the kind of material used here.

## Experiment 2: Testing the Diverging Predictions

Having replicated the Marcus et al. (Experiment 3) infant data with adult subjects, we now turn our attention to the diverging predictions concerning the effect of pause length on the preference for the inconsistent items.

### Method

**Subjects.** Sixteen additional undergraduates were recruited from introductory Psychology classes at Southern Illinois University. Subjects earned course credit for their participation.

**Materials.** The training and test stimuli were the same as in Experiment 1 except that the 250 msec interval between words in a sentence was replaced by a 1000 msec interval using the SoundEdit 16 version 2 software. The 1000 msec interval between sentences remained the same as before.

**Procedure.** The procedure and instructions were identical to that used for Experiment 1.

### Results and Discussion

The mean overall classification score was 5.75 out of 12. This was not significantly different from the chance level performance of 6, as indicated by a single-sample t-test ( $t < 1$ ). The responses of the subjects were submitted to the same further

analysis as in Experiment 1. The right-hand side of Figure 3 shows the ratings as dissimilar for the consistent and inconsistent test items averaged across condition. As predicted by Simulation 2, there was *no* main effect of test pattern in this experiment ( $F(1, 14) = .56$ ), suggesting that subjects were unable to distinguish between consistent and inconsistent items. As in Experiment 1, both the main effect of condition and the interaction between condition and test pattern interaction were not significant ( $F's = 0$ ).

These results show that preference for inconsistent items disappears when the pauses between words are lengthened. This corroborates the prediction from the statistically-based single-mechanism model, but not the prediction from the rule-learning component of the dual-mechanism account. It may be objected that the rules need to work over specific domains, and that by lengthening the pauses between words the input is no longer chunked into sentences at a pre-specified length (three words). Hence, the rule can no longer be expected to apply. Note, however, that this requires additional machinery to pre-process the input prior to the learning or application of a rule. This would require a separate account of how this pre-processing ability was acquired and how it was applied in the specific case of Marcus et al.'s original experiment. Of course, this makes the rule-based account even less parsimonious in comparison with the statistical learning model. The latter model can account for both the preference for inconsistent items in the Marcus et al. Experiment 3 (and our Experiment 1) as well as the lack of preference in our Experiment 2 *without requiring any extra machinery*. Thus, a language learning device that exploits the statistical properties of language and integrates these multiple cues can account for the Marcus et al. data, thereby removing the need to posit a dual-learning mechanism.

## Conclusion

Infants possess powerful learning mechanisms that allow them to acquire language rapidly. Saffran, Aslin, et al. (1996) showed that infants can use statistical regularities to discover word boundaries in fluent speech. Marcus et al. (1999) found that infants exhibit rule-like behavior. Because both studies used the same experimental paradigm, a plausible null hypothesis is that both types of behavior should rely on the same learning mechanism. Based on unreported SRN simulations, Marcus et al. rejected this null hypothesis. In contrast, Simulation 1 demonstrated that that an existing SRN model of early infant word segmentation (Christiansen et al., 1998) could utilize statistical knowledge acquired in the service of speech segmentation to fit the infant data from Marcus et al. under very naturalistic circumstances. Experiment 2, which investigated the effect of "variable" timing on rule-like behavior, provided additional support for the single-mechanism approach. The results confirmed the predictions from our model (Simulation 2), but do not appear to fit the dual-mechanism approach because the amount of time between variables should not affect their abstract rule-based relationship. We note that the dual-mechanism account could possibly be augmented to account for these data, but that this would require the addition of extra machinery. Our single-mechanism model, on the other hand, can account for the data from Saffran, Aslin, et al. and Marcus et al. as well as

the results from Experiment 2 *without any modifications*, obviating the need for a separate rule-learning component. We therefore conclude that a connectionist single-mechanism approach provides the most parsimonious account of both statistical learning and rule-like behavior in infancy.

## Acknowledgments

We would like to thank Gary Marcus for making his stimuli available to us for our experiments, and Jeff Elman for his comments on an earlier version.

## Abstract

Young children generalize nouns in systematic ways. They generalize names for solid things by shape and names for non-solid things by material. Recent evidence suggests that the source of these biases is in the children's lexicon: the bias becomes apparent only after they know names for things that are solid and have a similar shape and they know names for things that are non-solid and similar in material. In Experiment 1, we train a simple connectionist network with the regularities present in early noun vocabularies and show that this network shows generalization patterns comparable to those of young children. In Experiment 2 we look for other possible biases coming from statistical regularities and find that the network predicts that children will not cross ontological boundaries in their word generalizations. In Experiment 3 we test this prediction in 30-36 month-old children. We explain this finding in terms of the statistical regularities present in young children's noun vocabularies.

## Introduction

Young children are excellent learners of object names. After hearing a noun used once to name one object, they seem to know the scope of the whole category. To explain this proficiency people have proposed several mechanisms in the form of constraints or biases (Landau, Smith & Jones, 1988; Markman, 1989; Soja, Carey & Spelke, 1991). This paper is about the shape and material biases and about a new "bias", what one might call an "ontology bias". In the end, we propose that all these biases and constraints reduce to associative learning and generalization by similarity.

Our starting point is a recent study by Samuelson & Smith (1999). They examined the similarity structure of 300 object categories, the names of which are typically known by 30 month-olds. They found many nouns that name things that are solid and similar in shape and fewer nouns that refer to non-solid substances similar in material. They also showed that children do generalize novel nouns for solids by shape and for non-solids by material, but only after they know many of these words. These results suggest that these biases may be the product of statistical learning. In other words, children's noun generalizations are themselves generalizations over the nouns the child already knows.

In this paper we show that a simple statistical learner, when trained with the regularities present in early noun vo-

cabularies, generalizes novel nouns like children do. In Experiment 1 we train connectionist networks on the regularities found in early vocabulary by Samuelson and Smith (1999) and show that, like children, the networks generalize by shape for solid objects and by material for non-solid substances. In Experiment 2 we examine this early lexicon for other regularities that might create biases in a statistical learner and find that networks trained on this set exhibit what we call an "ontology bias". In Experiment 3 we test for this bias in children.

## Experiment 1

The goal of Experiment 1 is to determine if the regularities present in early noun vocabularies are sufficient to create word learning biases in a simple associative learner. If this is the case, it would support the idea that the biases are learned as part of learning the regularities in the lexicon. To do this we trained simple connectionist networks with a vocabulary organized using the regularities found in early lexicon by Samuelson and Smith (1999) and then we tested the network's performance on an adaptation of the novel noun generalization task.

## Architecture

We used a Hopfield network, which is a simple settling network. The network was trained using Contrastive Hebbian Learning (Movellan, 1990), an algorithm which adjusts weights on the basis of correlations between unit activations. Figure 1. shows the architecture of the network. The network has a Word Layer, in which words are represented locally. That is, each unit corresponds to one word in the network's vocabulary. Individual objects are represented on what we call the Dimension layer. Activation patterns on this layer represent the shape and material of each individual object or substance presented to the network. More specifically, the shape and material of an object (say the roundness of a particular ball and its yellow rubbery material) are represented by an activation pattern along the whole layer, in a distributed fashion. In the Solidity layer one unit stands for Solid and another for Non-Solid. Finally, there is a hidden layer that is connected to all the other layers and recurrently with itself. Note that the Word Layer and the Dimension and Solidity layers are only connected through the hidden layer, there are no direct connections among them.

Figure 1. Architecture of the network used in Experiments 1 and 2.

### Training

The goal of the training phase was to mimic in the network the vocabulary learning that a child brings into a novel noun generalization experiment. We trained the networks on a subset of the nouns studied by Samuelson and Smith (1999). We specifically selected the names for objects and substances, excluding names for people, animals, places and abstract objects (e.g. wind). There were 149 training nouns. For each of these noun categories we used the adult judgments from Samuelson and Smith (199) to construct category exemplars. Importantly, although adults judged most solid things to be categorized by shape, there were exceptions and complications – e.g. muffins are judged to be alike in both shape and material and bubbles are judged to be non-solid but similar in shape. Our training instantiated the structures attributed to these words by adults.

More specifically, the statistical regularities across the noun vocabularies were built into the network’s training set in the following way. First, for each word that the network was to be taught, a pattern was generated to represent its value along the *relevant* dimension -- the dimension on which objects named by that noun were found to be similar. Second, at each presentation of the word, the value along the *irrelevant* dimension was varied randomly. For example, the word “ball” was judged to refer to things that are similar in shape; thus, a particular pattern of activation was randomly chosen and then assigned to represent ball-shape. All balls presented to the network were defined as having this shape, although each ball presented to the network also consisted of a unique and randomly generated pattern defining the material. So, each time the unit representing the word “ball” was turned on during training, the pattern representing ball-shape was presented along the shape dimension and a different, randomly generated pattern was presented along the material dimension.

Solid objects were assumed to have a bigger range of values along the shape dimension. This assumption is in line with the fact that solid things can hold more varied and complex shapes than non-solid things.

### Testing

We tested the networks in an analog of the novel noun generalization task used with children. Our approach is based on our conceptualization of the novel noun generalization task. In that task, the child sees an exemplar and hears its name. If, for example, the child attends exclusively to the shape of the named exemplar, then a test object that matches the exemplar in shape (although different from the exemplar in material) should be perceived as highly similar to the exemplar. Thus, we asked if the network’s internal representations – the patterns of activations on the hidden layer -- of a named exemplar and a test object were similar.

The novel noun generalization task used with children is typically a forced choice task in which the child must choose between an object matching the named exemplar in shape and one matching in material. Accordingly, on each simulated test trial, we measured the similarity of the internal patterns of representation for two test objects –one matching the exemplar in shape and one matching the exemplar in material.

More specifically, on each test trial, we created a novel exemplar object by randomly generating an activation pattern along the shape and material dimensions. Then we combined the exemplar’s shape pattern with a novel randomly generated material pattern to create a novel shape-matching test object. A similarity measure of the exemplar and the shape match was computed using the Euclidean distance between the activation patterns in the Hidden Layer after the exemplar and its shape match had been presented.

Similarly, we generated a novel material-matching test object by combining the exemplar’s material pattern with a new randomly generated shape pattern and then computed the similarity between exemplar and material match. Finally, we used these similarity measures between the emergent patterns of activation on the hidden layer to calculate the probability of choosing the shape and the material matches using Luce’s Forced Choice Rule.

In this way, we trained 10 networks (with 10 different randomly generated initial connection weights) with the object and substance terms young children know. During training, we presented multiple instances of each trained noun until the network stably produced the right noun when presented an instance of each kind. We then tested each of these networks in the novel noun generalization task using 20 novel exemplars. Half of these exemplars were defined by patterns of activation representing solid things and half by patterns representing nonsolid things. If the statistical regularities in early child vocabulary are sufficient to create learning biases then the networks should present a shape bias when the exemplar is solid and a material bias when the exemplar is non-solid.

### Results

Figure 2 shows the networks’ performance in the novel noun generalization task. As is apparent, the connectionist networks prefer the shape match in the solid trials and the material match in the non-solid trials. This supports the idea that the statistical regularities in the lexicon are sufficient to

Figure 2. Network's performance in Experiment 1. The networks show shape and material biases comparable to those of children.

create word-learning biases in a statistical learner. If this is true, then other regularities present in the language should create their own "biases". One ubiquitous regularity that became obvious to us is that things that share a name share their solidity value. In other words, names do not refer to categories that span across ontological boundaries. This is true for all words in children's vocabulary except one – egg, which adults judged to have both solid and non-solid forms. If noun generalizations by the network are generalizations over the structures of already learned noun categories, then the network's generalizations of new names for novel things should adhere to this constraint. Given a solid exemplar, sameness in shape should not count if the test object is non-solid; given a non-solid exemplar, sameness in material should not count if that material is now solid. In Experiment 2 give this tests to the networks.

### Experiment 2

The goal of Experiment 2 is to test the network on the ontology bias. The network architecture and training procedure were the same as in Experiment 1. Ten networks were trained using the same testing procedure as in Experiment 1 except for the kinds of test objects used.

As in Experiment 1, on each test trial, we created a novel exemplar object by randomly generating an activation pattern along the shape and material dimensions and then created shape and material matches combining the exemplar's shape and material patterns with novel randomly generated material and shape patterns. Again, the networks were tested

on 20 novel exemplars; half of them defined as solid and half of them defined as non-solid. However, to make the ontology violating test, the shape match for solid exemplars was defined as non-solid and the material match for non-solid exemplars was defined as solid. So for the solid trials, we computed forced choice probability between a non-solid shape match and a solid material match, while in non-solid trials we compared a non-solid shape match with a solid shape match.

### Results

Figure 3 shows the proportion of shape choices predicted by the networks for solid exemplar trials and for non-solid exemplar trials. As predicted from the regularities in the training set, the networks chose the test item that matches the exemplar in solidity. That is, when the exemplar is solid the network prefers the solid test object, (even though it does not match in shape) and when the exemplar is non-solid the network prefers the non-solid test item (even though it does not match in material). Thus, the pattern of generalization observed in Experiment 1 (and typical in experimental tests of children) is now reversed: the networks exhibit a shape bias in non-solid trials and a material bias in solid trials. In Experiment 3 we look for this effect in children.

Figure 3. Network's performance in Experiment 2. The networks preferences are reversed when the shape match for the solid exemplar is made non-solid and the material match for the non-solid exemplars is made solid.

	Exemplar	Material Match	Shape Match	
			Ontology Violating	Traditional
TEEMA	 red sand paint	red sand paint   	 toothpaste with glitter shaving cream purple hair gel	 metallic blue clay burlap
WAZZLE	 blue cheese cloth	blue cheese cloth   	 toothpaste with glitter shaving cream purple hair gel	 pink felt with bumps purple foam green fur

Figure 4. Stimuli for Experiment 3A..

### Experiment 3

The goal of Experiment 3 is to test the prediction made by the network in Experiment 1. Given a solid object, will children refuse to generalize its name to an object of the same shape if the test object is not solid? Given a non-solid object, will children refuse to generalize its name to a material match if the test object is solid? Experiment 3A tests the first question using solid exemplars and Experiment 3B tests the second question using non-solid exemplars. Constructing stimuli for Experiment 3A (shape matches that differ in solidity) was easy; we can create the same shape out of hardened clay and shaving cream. Constructing stimuli for the second question (material matches that differ in solidity) required more creativity. What we did was use translucent gel and translucent hardened plastic for one set and off-white hand lotion and off-white hardened paint for the other. In both cases the material looked to be the same and was judged by adults to be the non-solid and hardened versions of the same material.

### Method

**Subjects** Twenty-four children between the ages of 30 and 36 months participated in this study. Half of them were ran-

domly assigned to Experiment 3A and half of them were assigned to Experiment 3B.

**Stimuli** The stimuli for Experiment 3A are shown in Figure 4. There were two exemplar objects. The exemplar for one set, the Teema, was a “U” shape covered with red sand-paint. The exemplar for the other set, the Wazzle, was an irregular “M” shape covered with blue cheese-cloth. For each exemplar there were three objects matching in material and two sets of items matching in shape. The Traditional set consisted of three solid objects that matched the exemplar in shape and differed in material (e.g. metallic clay, styrofoam covered with fur). The Ontology Violating set consisted of shape matches made out of non-solid materials (e.g. shaving cream, hair gel).

The stimuli for Experiment 3B are shown in Figure 5. There were two exemplar objects. The exemplar for one set, the Teema, was a “V” shape made out of translucent gel. The exemplar for the other set, the Wazzle, was an irregular “M” shape made out of hand lotion. For each exemplar there was a set of shape matches made out of three different non-solid substances. For the Teema, the shape matches were made out of wax, glitter and noxzema mixed with sand; for the Wazzle, the shape matches were made out of green sand, toothpaste with glitter and shaving cream. For each exemplar there were also two sets of “material” matches: a Traditional set and an Ontology Violating set. For the Teema the

	Exemplar	Material Match		Shape Match
		Ontology Violating	Traditional	
TEEMA	 translucent gel	translucent plastic 	translucent gel 	 noxzema with sand glitter wax crystals
WAZZLE	 hand lotion	hardened paint 	hand lotion 	 toothpaste with glitter fine sand shaving cream

Figure 5. Stimuli for Experiment 3B.

Traditional set consisted of shapes made out of translucent hair gel and the Ontology Violating set consisted of shapes made out of translucent hard plastic. For the Wazzle the Traditional set consisted of shapes made out of off-white hand lotion and the Ontology Violating set consisted of shapes made out of off-white hardened fabric paint.

**Procedure** The procedure used was a forced choice task. The child were shown an exemplar (i.e., the Teema) and told its name (“this is the Teema”). The child was then presented with pairs of objects, a shape match and a material match, and asked “Can you show me the Teema?”. Each child was presented with the Traditional set of one exemplar and the Ontology Violating set of the other. Half of the children were assigned at random to judge the Traditional version of one exemplar and the Ontology Violating version of the other. The two exemplars were presented in separate blocks. Each shape-match/material-match pair was presented twice in random order for a total of 12 trials. The order of the sets was counterbalanced across subjects; the position of the choices was counterbalanced across trials.

### Results

Figure 6 shows the proportion of shape choices for the solid exemplar (Experiment 3A) and for the non-solid exemplar (Experiment 3B) Ontological Violating and Traditional sets respectively. In the Traditional sets, children’s performance replicates previous findings: they present a clear shape bias for the trials with solid exemplars (Experiment 3A) and

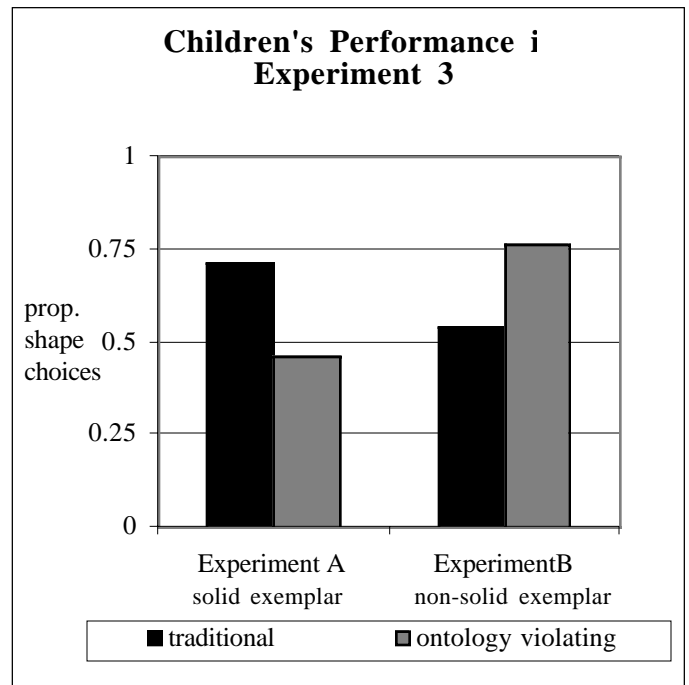

Figure 6. Results of Experiment 3.

show increased attention to the material of non-solid exemplars (Experiment 3B). In the Ontology Violating sets, as

the network simulations predicted, children's shape bias decreased to chance levels in solid trials and increased to above chance in the non-solid trials.

Although these results are consistent with a bias in children to extend category names only within ontological boundaries, there is an alternative explanation. Children's preference for the same-solidity item could be a result of the way the ontological violating choices alter the exemplar-test items' similarity. For example, in the case of the solid exemplar, the material match matches in both material and solidity, while the shape match now only matches in shape (and imperfectly at that, given the change of solidity). While we can't be sure of which explanation is the case in children, we know for a fact that it is more than just similarity for the networks.

## Conclusions

Learning a first language is a hard problem. However, the task appears less daunting when we consider that the kinds of words children know early present an organized structure. A smart learner could learn to exploit this structure to its advantage. In this paper we have shown that a simple statistical learner, with no other mechanisms than associative learning and generalization by similarity, will learn shape and material biases to match the systematic regularities present in its training set. We have also documented a new bias, one which could be taken as evidence of an underlying ontology, but that also makes sense in terms of the statistical regularities present in the language. This suggests that word-learning biases and constraints could be a product of learning. While the evidence presented here is consistent with this account, it does not provide conclusive proof; the regularities found in children's vocabularies could be a product of pre-existing biases. However, the fact that we have demonstrated the computational plausibility of the learning account and simple parsimony suggest that this is not the case.

## Abstract

This paper describes an exemplar-based model of people's classification and typicality judgements in both single and combined categories. This model, called the diagnostic evidence model, explains the observed family resemblance structure of single categories; the productive nature of category combination; the observed overextension of typicality judgments in some combined categories; and the situations in which that overextension occurs. The model also gives a close fit to quantitative results from a representative single-category classification data-set.

Models of categorisation need to explain two basic aspects of human cognition: our ability to classify items as members of single categories such as *fish* or *cat*, and our ability to classify items as members of combinations of categories such as *wild cat* or *pet fish*. A successful model should account for the graded structure of classification in single categories: the fact that people's judgements of membership typicality for items in categories are proportional to the items' family resemblance to members of those categories (Rosch, 1978; Rosch & Mervis, 1975). A successful model should also account for the productivity of category combination: the fact that people are able to understand and judge membership in new combinations of categories, even if no already-existing examples of those combinations are known. This combinatorial productivity is important because it underlies our ability to think new thoughts and understand new expressions. In many currently popular models of categorisation (e.g. the context theory; Medin & Schaffer, 1978), an item's membership in a category is proportional to its similarity to the stored exemplars of that category. While this approach gives a good account for the graded structure of single categories, it has difficulty explaining the productivity of category combination, which involves classification in combinations for which no stored exemplars are available (Rips, 1995). This paper describes an exemplar-based model of classification in single and combined categories which explains the family resemblance structure of single categories, the productivity of category combination, and other specific results in both domains. The model, called the diagnostic evidence model, extends a successful earlier theory (Costello & Keane, 1997, in-pressA, in-pressB).

The first part of the paper presents the diagnostic evidence model of categorisation in single and combined categories, and gives its account for family resemblance and productivity in combination. The second part demonstrates the model by showing how it explains the observed overextension of typicality in some combined categories.

Overextension occurs when people rate an item as a poor member of both constituents of a combination, but as a good member of the combination as a whole; for example, when goldfish are rated as untypical members of the categories *pet* and *fish*, but as typical members of the combination *pet fish* (Hampton, 1988). Overextension has posed problems for a number of theories of category combination. The diagnostic evidence model accounts for results on overextension, and explains why overextension occurs in some combinations but not in others. The third part of the paper demonstrates this model further by showing how it gives a good fit to quantitative results from a representative classification data-set (Nosofsky, Palmeri, & McKinley, 1994); a fit as close as that given by exemplar-similarity models such as the context theory.

## The diagnostic evidence model

The diagnostic evidence model extends an earlier theory of the interpretation of noun-noun combined phrases, called the constraint theory (Costello & Keane, 1997, in-press-A). That theory set out to explain the diversity of interpretations which people produce for noun-noun combinations: the fact that people sometimes interpret combinations by forming conjunctions between the combining categories (as in the interpretation "*pet bird*: a parrot or some other bird which is also a pet"), sometimes by asserting relations between the categories (as in "*jungle bird*: a bird that lives in jungles"), and sometimes by transferring properties from one concept to the other (as in "*skunk bird*: a bird that smells bad"). Constraint theory explains this diversity by describing a combination process that forms mental representations satisfying three constraints of diagnosticity, plausibility and informativeness. Each interpretation type represents a different way of satisfying these constraints. The theory has been tested in a computer program which simulates the interpretation of noun-noun combinations, producing each interpretation type and generating results that agreed with people's interpretations of those combinations (Costello & Keane, in-press-A). Further, Costello & Keane (in-press-B) have provided direct experimental evidence for diagnosticity's role in the formation of combined categories.

Where the Constraint theory gave a qualitative account of noun-noun interpretation, the diagnostic evidence model aims to give a quantitative account of people's classification of items in single and combined categories. The model focuses on the diagnosticity constraint. The model assumes that people represent categories by storing sets of category exemplars in memory. From these sets, diagnostic attributes for categories are computed: these attributes serve to identify category members. An item's membership

typicality in a single or combined category is a function of the diagnosticity of its attributes for that category or for the constituent categories of that combination. An item has high membership typicality in a category if it has attributes that are highly diagnostic for that category. An item has high typicality in a combination if it has some attributes highly diagnostic for one constituent of the combination, and other attributes highly diagnostic for the other. Two novelties in this model are its method for computing attribute diagnosticity, and its logic for combining the diagnosticity of multiple attributes to compute membership in single or combined categories. I describe these below.

### Attribute Diagnosticity

Diagnostic attributes are attributes which occur frequently in stored instances of a category, but rarely in that category’s contrast set (the set of stored instances which are not members of the category). These attributes serve to identify members of a category: a new item possessing a attribute which is highly diagnostic for a given category is likely to be a member of that category. The diagnosticity of attribute  $x$  for category  $C$  is defined in Equation 1. Let  $K$  be the contrast set for  $C$ . Let  $j_x$  be 1 if instance  $j$  possesses attribute  $x$ , and 0 otherwise.  $D(x/C/K)$ , the diagnosticity of  $x$  for  $C$  relative to  $K$ , is equal to the number of instances in  $C$  that possess  $x$ , divided by the total number of instances in  $C$  plus the number of instances in  $K$  that possess  $x$ :

$$D(x/C/K) = \frac{\sum_{j \in C} j_x}{|C| + \sum_{j \in K} j_x} \quad (1)$$

If the attribute  $x$  occurs in all instances in category  $C$ , but no instances in  $C$ ’s contrast set, then  $x$  is fully diagnostic for  $C$  ( $D(x/C/K) = 1$ ). Such an attribute is a perfect guide to membership of  $C$ : every instance possessing  $x$  is a member of  $C$ , every instance not possessing  $x$  is not a member. An attribute which does not occur in all members of  $C$ , or which occurs in some members of  $C$ ’s contrast set, will be less diagnostic for the category. Such an attribute will be a poorer guide to membership of  $C$ : not every instance possessing  $x$  will be a member of  $C$ , not every instance not possessing  $x$  will be a non-member.

An important novelty in the diagnostic evidence model is that the diagnosticity of an attribute for a category can change depending on whether the category occurs singly or as part of a category combination. This change in diagnosticity arises because the contrast set used for computing diagnosticity is different in single and combined categories. For single categories, the contrast set consists of all instances which are not members of the category in question. For combined categories, however, the contrast set consists of instances which are not members of any of the constituents of the combination. The contrast set for a combination is thus a subset of the contrast sets for the single categories which make it up. This change in contrast set means that some attributes which are not diagnostic for a category when it occurs singly (because they occur frequently in that category’s contrast set), will be diagnostic

**Table 1.** An illustrative array of exemplars

Exemplar category labels		Attributes			
		FOUND	KEPT-IN	COLOR	HAS-PART
1	lobster	sea	-----	pink	claws
2	lobster	aquarium tank		pink	claws
3	fish goldfish	house	tank	gold	scales
4	fish guppy	house	tank	silver	skin
5	fish salmon	sea	-----	silver	scales
6	fish shark	sea	-----	silver	skin
7	pet dog spaniel	house	basket	brown	tail
8	pet dog doberman	house	kennel	black	tail
9	pet dog bulldog	house	basket	brown	-----
10	pet terrapin	house	tank	green	skin

for that category when it occurs in a combination (if they occur only rarely in that combination’s contrast set).

The computation of attribute diagnosticity can be demonstrated using an illustrative set of stored exemplars of categories such as *pet*, *fish*, *dog* and *lobster*, shown in Table 1. These exemplars are described in attribute-value pairs on four dimensions: FOUND, KEPT-IN, COLOUR, and HAS-PART. Consider the diagnosticity of the attribute FOUND:HOUSE for the single category *fish*, which has 4 stored exemplars (exemplars 3, 4, 5, 6).  $K_{fish}$ , the contrast set for the category *fish*, contains exemplars 1, 2, 7, 8, 9, 10. FOUND:HOUSE occurs in 2 of the 4 *fish* exemplars in Table 1, and in 4 exemplars in the contrast set  $K_{fish}$ . The diagnosticity of FOUND:HOUSE for the *fish* is thus

$$D(\text{FOUND} : \text{HOUSE}/\text{fish}/K_{fish}) = \frac{2}{4 + 4} = 0.25 \quad (2)$$

This attribute has a low diagnosticity for the single category *fish*: FOUND:HOUSE does not identify members of category *fish* well. In the context of the combination *pet fish*, however, the attribute has a higher degree of diagnosticity for *fish*.  $K_{petfish}$ , the contrast set for the combination *pet fish*, consists of exemplars that are members neither of *pet* nor of *fish* (exemplars 1 and 2). FOUND:HOUSE does not occur in any exemplars in the contrast set  $K_{petfish}$ . The diagnosticity of FOUND:HOUSE for *fish* relative to the contrast set  $K_{petfish}$  is thus

$$D(\text{FOUND} : \text{HOUSE}/\text{fish}/K_{petfish}) = \frac{2}{4 + 0} = 0.5 \quad (3)$$

The attribute thus gives a greater degree of diagnostic evidence for membership in the *fish* constituent of *pet fish*; in other words, the attribute FOUND:HOUSE is more diagnostic in identifying an item as a pet fish than it is identifying an item as a fish. This effect of contrast set on diagnosticity is central to the diagnostic evidence model’s account for overextension in combined categories, and is discussed in the section on overextension, below.

### A Continuous-valued Logic for Evidence

Diagnostic attributes, then, give evidence for an instance’s classification in a category. Instances usually

contain a number of different attributes, however, which may be more or less diagnostic for the category in question, or diagnostic for other categories. How is the diagnostic evidence from an item's attributes combined to produce an overall measure of evidence for category membership? The diagnostic evidence model uses a continuous-valued logic to combine diagnostic evidence from multiple attributes. This logic assumes continuous variables with values between 0 and 1, and uses the following logical operations:

$$NOT A = 1 - A \quad (4)$$

$$A AND B = AB \quad (5)$$

$$A OR B = 1 - (1 - A)(1 - B) \quad (6)$$

These equations derive from standard probability theory, and can be justified by considering the operations *AND*, *OR*, and *NOT* for samples of independently distributed variables. Suppose variables *A* and *B* have 0.75 and 0.5 probability of being true, respectively. Then the probability of *NOT A* being true is 0.25 ( $1 - 0.75$ ). The probability of *A AND B* being true is 0.375 ( $0.75 \times 0.5$ ): of the 75% of cases in which *A* is true, 50% of those are cases in which *B* is also true. Finally, the probability of *A OR B* being true is 0.875 ( $1 - (1 - 0.75) \times (1 - 0.5)$ ): of the 25% of cases in which *A* is false, 50% of those are cases in which *B* is also false; thus *A OR B* is true in 87.5% of cases. Similar (though often more complex) logics have been used in various areas (e.g. in models of evidence-based reasoning; Shafer, 1976). The current model is unique in using this approach to compute the contribution which different attributes make in people's classification of items in single or combined categories.

### Combining Diagnosticity of Multiple Attributes.

To combine the diagnostic evidence from multiple attributes for membership in a category, the diagnostic evidence model uses the equation for *OR*. An instance *i* with a set of attributes  $x_1, x_2, x_3$ , will be a member of category *C* if  $x_1$  or  $x_2$  or  $x_3$  serves to identify the instance as a member of *C* (if  $x_1 OR x_2 OR x_3$  is diagnostic for *C*). This is formalised in Equation 7, which has the form of the equation for *OR* (Equation 6, above). Let *A* be the set of attributes of instance *i* and  $D(x|C/K)$  be the diagnosticity of attribute *x* for *C*. Then  $E(i|C/K)$ , the overall evidence for classifying instance *i* as a member of *C*, is

$$E(i|C|K) = 1 - \prod_{x \in A} (1 - D(x|C|K)) \quad (7)$$

This equation accounts for people's classification in both strictly defined and "family resemblance" categories. If an attribute *x* strictly defines a category *C* (occurs in all instances of *C* and never occurs outside *C*), then *x* is perfectly diagnostic of *C* ( $D(x|C/K) = 1$ ). If any item *i* possesses attribute *x*, then by Equation 7  $E(i|C/K)$  will be 1, and the instance *i* will definitely be a member of *C*. In categories which have no single perfectly diagnostic attribute but rather have a range of attributes of medium diagnosticity, Equation 7 combines evidence from different attributes in computing evidence for category membership: the more diagnostic attributes the instance has, the higher its degree of membership will be. In other words, the more of a family resemblance an instance has to the members of a

category, the higher its membership typicality will be. This relationship between diagnostic attributes and membership has specific support in Rosch & Mervis' (1975) finding that people's judgements of an instance's typicality in a single category rose reliably with the number of diagnostic attributes for that category which the instance possessed.

The combination of diagnostic evidence can be illustrated using the exemplars in Table 1. For example, consider the evidence for exemplar 5 (*salmon*) as a member of the category *fish*. This exemplar has attributes LIVES:SEA, COLOUR:SILVER, and HAS-PART:SCALES. The diagnosticities of these attributes for *fish* are relatively high (0.4, 0.75 and 0.5 respectively, as computed from Equation 1). From Equation 7, these diagnostic evidence values are combined to obtain an overall measure of evidence for exemplar *salmon*'s typicality in category *fish* as follows:

$$E(\text{salmon} | \text{fish} | K_{\text{fish}}) = 1 - (1 - 0.4)(1 - 0.75)(1 - 0.5) = 0.925 \quad (8)$$

The exemplar *salmon* has good evidence for membership in the category *fish* because it possesses highly diagnostic attributes for that category: in other words, *salmon* is a highly typical *fish*. Other exemplars have less diagnostic attributes for the category *fish*, and thus have lesser degrees of evidence and are less typical category members. For example, the exemplar *shark* has the less diagnostic attribute HAS-PART:SKIN and is a less typical member of the category *fish* ( $E(\text{shark} | \text{fish} | K_{\text{fish}}) = 0.91$ , computed as above); the exemplar *goldfish* has two less diagnostic attributes LIVES:HOUSE and COLOUR:GOLD and is less typical again ( $E(\text{goldfish} | \text{fish} | K_{\text{fish}}) = 0.813$ ); the exemplar *spaniel* has no diagnostic attributes and is a poor member of the category ( $E(\text{spaniel} | \text{fish} | K_{\text{fish}}) = 0.25$ ).

### Diagnostic Evidence for Combined Categories

The diagnostic evidence model of classification, then, is consistent with observed patterns of typicality in single categories. The model extends easily to account for classification in category combinations: an item will be a member of a combined category if it gives diagnostic evidence for membership in each constituent in that combination. In computing an item's membership in a combined category, the model uses the continuous-valued *AND* described above (Equation 5) to combine the item's evidence for membership in each constituent of the combination. An instance *i* will be classified as a member of a combined category  $C_1 \dots C_N$  if it gives evidence for membership in  $C_1$  AND evidence for membership in  $C_2$  AND evidence for membership in  $C_3$  and so on. More formally,  $E(i|C_1 \dots C_N | K_{1 \dots N})$ , the evidence for classifying *i* as a member of combination  $C_1 \dots C_N$ , is

$$E(i|C_1 \dots C_N | K_{1 \dots N}) = \prod_{n=1}^N E(i|C_n | K_{1 \dots N}) \quad (9)$$

where the contrast set  $K_{1 \dots N}$  is the set of instances not in any of the categories  $C_1 \dots C_N$ . Note that an instance *i* will give evidence for membership in each constituent of a combination if it has some attributes diagnostic for each constituent: some attributes diagnostic for one constituent, other attributes diagnostic for others.

Because the diagnostic evidence model computes evidence for membership in a combination by combining evidence for membership in its constituent categories, it can explain people’s ability to classify items in new combinations, even if they have no stored exemplars of those combinations. An item is classified as a member of a combination, even one with no stored exemplars, if the item has diagnostic attributes for each constituent category in the combination. For example, in Table 1, there are no stored exemplars of the combination *pet lobster*. However, an item could be classified as a good member of the combination *pet lobster* if it possessed the attribute HAS-PART:CLAWS (perfectly diagnostic for *lobster* in Table 1) and the attribute FOUND:HOUSE (highly diagnostic for *pet*).

In accounting in this way for the productivity of category combination, the model goes beyond theories such as the context theory, in which classification is based on similarity to stored exemplars of a category. Such theories cannot account for classification in new combinations for which there are no stored exemplars. For example, in an exemplar-similarity based model, people would judge membership in *pet lobster* by computing an item’s similarity to stored exemplars of that combination (by comparing the item to previously seen examples of pet lobsters). Since *pet lobster* has no stored exemplars, this computation would be meaningless (see Rips, 1995).

### Accounting for Overextension

Various studies have examined overextension of classification in combined categories. Overextension occurs when people rate an item as a poor member of both constituents of a combination, but as a good member of the combination as a whole. For example, people might rate goldfish as typical members of the combination *pet fish*, but as untypical members of the single categories *pet* and *fish*. Hampton (1988) found that overextension was more likely for some combinations than for others: the lower the degree of overlap between combining categories (the fewer exemplars the categories had in common) the more likely the combinations were to be overextended. For example, the constituents of *pet fish* have low overlap (many fish are not pets; many pets are not fish), and that combination was often overextended. By contrast, combinations of categories with many common members were usually not overextended. For example, the constituents of *pet dog* have high overlap (most dogs are also pets), and that combination was usually not overextended.

Overextension poses a challenge for theories of category combination (Osherson & Smith, 1981). In the diagnostic evidence model, overextension arises because of changes in attribute diagnosticity: because some attributes may have low diagnosticity for a category when it occurs singly, but high diagnosticity for that category when it occurs as part of a combination. As we saw earlier, the attribute FOUND:HOUSE was less diagnostic for the single category *fish*, but was more diagnostic for the category in the context of the combination *pet fish* (because the attribute occurred often in the contrast set for the category *fish*, but not in the contrast set for the combination *pet fish*). This change in

**Table 2.** Overextension of exemplar *goldfish* in *pet fish*

Evidence for membership in	Exemplar	Attribute Diagnosticity			
		FOUND	KEPT-IN	COLOR	HAS-PART
	<i>goldfish</i> :	house	tank	golden	scales
<i>pet</i> singly :	0.714	0.67	0.14	0	0
<i>fish</i> singly:	0.813	0.25	0.33	0.25	0.5
<i>pet fish</i> :	0.89				
<i>pet</i>	1	1.0	0.2	0	0
<i>fish</i>	0.89	0.5	0.4	0.25	0.5

diagnosticity means that an item with that attribute could give good evidence for membership in the combination *pet fish* (and therefore high typicality in that combination), but poor evidence for membership in the single categories *fish* and *pet* (low typicality in those single categories).

Table 2 illustrates this account of overextension, showing computed evidence for the exemplar *goldfish* as a member of the single categories *pet* and *fish*, and the combination *pet fish*. Note that *goldfish* gives higher evidence for membership in *pet fish* (0.89) than in either *pet* (0.714) or *fish* singly (0.813). *Goldfish* would thus be judged a highly typical *pet fish* but a less typical *pet* or *fish*. This is because the exemplar’s attributes have higher diagnosticity for the combination than for the single categories. For example, FOUND:HOUSE has a diagnosticity of 0.67 for the single category *pet* and of 0.25 for the single category *fish*. In the context of *pet fish*, however, FOUND:HOUSE has a higher diagnosticity both for the constituent *pet* (1.0) and the constituent *fish* (0.5). (In Table 2, evidence for membership in the single categories is computed by combining attribute diagnosticity as in Equation 7. Evidence for membership in the combination is obtained by computing evidence for membership in each constituent category as in Equation 7, and combining that evidence as in Equation 9).

In this account, overextension arises from a difference between the contrast sets for single categories and those for a combination, which leads to a difference in diagnostic evidence for membership in the single categories and the combination. If there is little difference between these contrast sets, overextension won’t occur. Table 3 illustrates this for the combination *pet dog*. *Pet dog* is not overextended: the exemplar *spaniel* gives more evidence for membership in the single categories *pet* (0.96) and *dog* (0.98) than in the combination *pet dog* (0.95). Because the categories *pet* and *dog* have a high overlap (in Table 1, all

**Table 3.** Non-overextension of exemplar *spaniel* in *pet dog*

Evidence for membership in	Exemplar	Attribute Diagnosticity			
		FOUND	KEPT-IN	COLOR	HAS-PART
	<i>spaniel</i> :	house	basket	brown	tail
<i>pet</i> singly :	0.96	0.67	0.5	0.5	0.5
<i>dog</i> singly:	0.98	0.5	0.67	0.67	0.67
<i>pet dog</i> :	0.95				
<i>pet</i>	0.96	0.67	0.5	0.5	0.5
<i>dog</i>	0.98	0.6	0.67	0.67	0.67

**Table 4.** Predicted and observed probability of classification of exemplars in Nosofsky, et al., (1994) Experiment 1.

Exemplar labels	Exemplars	Diagnostic evidence ( $C(i/A), W = 8$ )	Predicted classification probability (linear transform of $C(i/A)$ )	Classification probability observed in Experiment
A1	1 1 1 2	0.69	0.77	0.77
A2	1 2 1 2	0.65	0.74	0.78
A3	1 2 1 1	0.75	0.83	0.83
A4	1 1 2 1	0.52	0.6	0.64
A5	2 1 1 1	0.52	0.6	0.61
B1	1 1 2 2	0.37	0.46	0.39
B2	2 1 1 2	0.37	0.46	0.41
B3	2 2 2 1	0.13	0.23	0.21
B4	2 2 2 2	0.07	0.17	0.15
T1	1 2 2 1	0.45	0.54	0.56
T2	1 2 2 2	0.31	0.4	0.41
T3	1 1 1 1	0.78	0.86	0.82
T4	2 2 1 2	0.31	0.4	0.4
T5	2 1 2 1	0.16	0.26	0.32
T6	2 2 1 1	0.45	0.54	0.53
T7	2 1 2 2	0.07	0.17	0.2

dogs are also pets) there is little difference between the contrast sets for the single categories *pet* and *dog* and the contrast set for the combination *pet dog*. There is thus little difference in the diagnosticity of attributes for the single categories and for the combination; hence, there is no overextension.

This account explains Hampton’s (1988) finding that overextension is rare for combinations whose constituent categories have a high degree of overlap. The greater the overlap between the constituent categories of a combination, the less of a difference there is between the contrast sets for those categories occurring singly, and the contrast set for that combination. The less of a difference between contrast sets, the less of a difference between diagnostic evidence for membership in the single categories and in the combination; the less chance of overextension.

### Fitting Classification Data-sets

As described above, the diagnostic evidence model can explain various results in natural-language categorisation and category combination. In this section I fit the model to results obtained in a study of classification in artificial laboratory-learned categories: Nosofsky, Palmeri, & McKinley’s (1994) replication of Medin & Schaffer’s (1978) study. In Nosofsky, Palmeri, & McKinley’s experiment, participants learned to classify drawings of rocketships as coming from planet A (category A) or planet B (category B). The rocketships varied on four dimensions (shape of tail, wings, nose, and porthole) each with two values, represented by 1 and 2. Rockets from planet A had values of 1 on most dimensions, while rockets from planet B had values of 2. An abstract representation of this category structure is shown in Table 2. In an initial training phase, participants learned 9 training items: *A1...A5* from category A and *B1...B4* from category B. In the test phase

participants categorised the 9 training items and 7 new test items *T1...T7*. Test item T3 was the prototype for category A (having a value 1 on all dimensions).

In this experiment participants classified items into one of only two possible categories (A or B). Classification in this two-category task is different from classification in natural-language categories: when only two categories are available, an item’s membership in a category depends both on evidence that the item is a member of the category, and on evidence that the item is not a member of the other category. In applying the diagnostic evidence model to this two-category task, the model was extended (using the continuous-valued logic described above) to take account of both sources of evidence: an item was classified in category A if it gave evidence for membership in A, OR did NOT give evidence for membership in B. Formally,  $C(i/A)$ , the classification score for  $i$  as a member of category A, is

$$C(i/A) = E(i/A/K_A) \text{ OR } (\text{NOT } E(i/B/K_B)) \quad (10)$$

$$= 1 - (1 - E(i/A/K_A))^W (1 - (1 - E(i/B/K_B)))$$

where  $E(i/A/K_A)$  and  $E(i/B/K_B)$  give measures of evidence for membership in A and B respectively (computed according to Equation 7), and where parameter  $W$  represents the relative importance of evidence for membership in A versus evidence for membership in B in classification.

The diagnostic evidence model was applied to the data-set using only the training stimuli (exemplars *A1...A5* and *B1...B4*). These training exemplars were used to compute the diagnosticity of the values 1 and 2 on each dimension for the categories A and B. These diagnosticities were then used to compute the diagnostic evidence score  $C(i/A)$  for both training and test exemplars as members of category A. These scores are shown in the “diagnostic evidence” column in Table 4. These scores are those for the value of  $W$  for which the correlation between predicted and observed

classification was highest ( $W = 8$ ;  $r = .99$ ,  $\%var = 98\%$ ). The model's predicted classification probabilities (shown in the next column in Table 4) were obtained by a linear transformation of the diagnostic evidence scores, mapping the mean diagnostic evidence score onto the mean observed classification probability, and the standard deviation of the diagnostic evidence score onto the standard deviation of observed classification probabilities. (This transformation introduces no extra degrees of freedom into the model's fit to the data; it simply allows direct comparison between computed evidence for classification and the classification probabilities observed in the experiment). The diagnostic evidence model's computed classification scores for items closely follow people's classifications of those items, as comparison of the predicted and observed classification probability columns in Table 4 shows. The model accounts for the qualitative finding that the test exemplar T3 (the prototype for category A) gets a higher classification probability than all other test exemplars. The percentage of variance explained by the diagnostic evidence model (98%) is in the same range as that produced by other models (the context model explains 96% of variance in these results; the Rulx model explains 98%; see Nosofsky, Palmeri, & McKinley, 1994). However, those models used four free parameters to fit the data (varying the selective attention paid to the 4 dimensions on which exemplars were described), as opposed to the single parameter used by the diagnostic evidence model.

### Conclusions and Future work

The diagnostic evidence model of classification described here goes beyond other theories of classification in giving an account for both single and combined categories. The model explains the family resemblance structure of single categories, the productivity of category combination, and the occurrence of overextension in some combined categories. That the model is exemplar-based is significant: a number of results have shown that exemplars are important both for simple and combined categories (e.g. Gray & Smith, 1995). Some argue that exemplar-based models cannot account for the productivity of combination (Rips, 1995); the current model provides evidence against this argument. The model fits a representative classification data set as closely as Medin & Schaffer's (1978) context theory, while using fewer free parameters.

There are, however, various classification results which the diagnostic evidence model cannot currently explain. Because the model does not provide a mechanism for learning, it cannot address the role of learned attribute correlations in classification. A number of studies (e.g. Medin, Altom, Edelson, & Freko, 1982) show that people learn to associate correlated pairs of attributes with categories, and to use those correlated attributes in classification. The diagnostic evidence model as it currently stands cannot account for this result because it treats all attributes independently. Extending the model with a learning mechanism which can recognise attribute correlations and use those correlations to form new "composite" attributes may allow the model to account for

the role of correlation in classification. In an initial test of this approach, in which composite attributes were hard-coded into the representation used, the diagnostic evidence model was able to give a good fit to Medin et al.'s results. In future work I aim to develop the diagnostic evidence model in this direction.

## Abstract

In this paper, we build upon previous results to show that our facial expression recognition system, an extremely simple neural network containing six units, trained by backpropagation, is a surprisingly good computational model that obtains a *natural* fit to human data from experiments that utilize a forced-choice classification paradigm. The model begins by computing a biologically plausible representation of its input, which is a static image of an actor portraying a prototypical expression of either Happiness, Sadness, Fear, Anger, Surprise, Disgust, or Neutrality. This representation of the input is fed to a single-layer neural network containing six units, one for each non-neutral facial expression. Once trained, the network's response to face stimuli can be subjected to a variety of "cognitive" measures and compared to human performance in analogous tasks. In some cases, the fit is even better than one might expect from an impoverished network that has no knowledge of culture or social interaction. The results provide insights into some of the perceptual mechanisms that may underlie human social behavior, and we suggest that the system is a good model for one of the ways in which the brain utilizes information in the early visual system to help guide high-level decisions.

## Introduction

In this paper, we report on recent progress in understanding human facial expression perception via computational modeling. Our research has resulted in a facial expression recognition system that is capable of discriminating prototypical displays of Happiness, Sadness, Fear, Anger, Surprise, and Disgust at roughly the level of an untrained human. We propose that the system provides a good model of the perceptual mechanisms and decision making processes involved in a human's ability to perform forced-choice identification of the same facial expressions. The present series of experiments provides significant evidence for this claim.

One of the ongoing debates in the psychological literature on emotion centers on the structure of emotion space. On one view, there is a set of discrete basic emotions that are fundamentally different in terms of physiology, means of appraisal, typical behavioral response, etc. (Ekman, 1999). Facial expressions, according to this categorical view, are universal signals of these basic emotions. Another prominent view is that emotion concepts are best thought of as prototypes in a continuous, low-dimensional space of possible emotional states, and that facial expressions are mere clues that allow an observer to locate an approximate region in this space (e.g. Russell, 1980; Carroll and Russell, 1996).

One type of evidence sometimes taken as support for categorical theories of emotion involves experiments that

show "categorical perception" of facial expressions (Etcoff and Magee, 1992; Young et al., 1997). Categorical perception is a discontinuity characterized by sharp perceptual category boundaries and better discrimination near those boundaries, as in the bands of color in a rainbow. But as research in the classification literature has shown (e.g. Ellison and Massaro, 1997), seemingly categorical effects naturally arise when an observer is asked to employ a decision criterion based on continuous information. Neural networks also possess this dual nature; many networks trained at classification tasks map continuous input features into a continuous output space, but when we apply a decision criterion (such as "choose the biggest output") we may obtain the *appearance* of sharp category boundaries and high discrimination near those boundaries, as in categorical perception.

Our model, which combines a biologically plausible input representation with a simple form of categorization (a six-unit softmax neural network), is able to account for several types of data from human forced-choice expression recognition experiments. Though we would not actually propose a localist representation of the facial expression category decision (we of course imagine a more distributed representation), the evidence leads us to propose 1) that the model's input representation bears a close relationship to the representation employed by the human visual system for the expression recognition task, and 2) that a dual continuous/categorical model, in which a continuous representation of facial expressions coexists with a discrete decision process (either of which could be tapped by appropriate tasks), may be a more appropriate way to frame human facial expression recognition than either a strictly categorical or strictly continuous model.

## The Expression Classification Model

For an overview of our computational model, refer to Figure 1. The system takes a grayscale image as input, computes responses to a lattice of localized, oriented spatial filters (Gabor filters) and reduces the resulting high dimensional input by unsupervised dimensionality reduction (Principal Components Analysis). The resulting low-dimensional representation is then fed to a single-layer neural network with six softmax units (whose sum is constrained to be 1.0), each corresponding to one expression category. We now describe each of the components of the model in more detail.

## The Training Set: Pictures of Facial Affect

The model's training set is Ekman and Friesen's Pictures of Facial Affect (POFA, 1976). This database is a good

Figure 1: Facial Expression Classification Model.

training set because the face images are reliably identified as expressing the given emotion by human subjects (at least 70% agreement), and the images are commonly used in psychological experiments. We digitized the 110 POFA slides by scanning them at 520x800 pixels, performing a histogram equalization, aligning the eyes and mouths to the same location in every image by a linear transformation, and cropping off most of the background. The result is a set of 110 240x320 grayscale images of 14 actors portraying prototypical expressions of six basic emotions and neutral.

### Feature Extraction: The Gabor Jet Lattice

The system represents input stimuli using a lattice of responses of 2-D Gabor wavelet filters (Daugman, 1985). The Gabor filter, essentially a sinusoidal grating localized by a Gaussian envelope, is a good model of simple cell receptive fields in cat striate cortex (Jones and Palmer, 1987). It provides an excellent basis for recognition of facial identity (Wiskott et al., 1997), individual facial actions (Donato et al., 1999), and facial expressions (Dailey and Cottrell, 1999; Lyons et al., 1999). We use phase-invariant Gabor magnitudes with a parameterization of the filter at five scales ranging from 16–96 pixels in width and eight orientations ranging from 0 to  $\frac{7\pi}{8}$  as described by Donato et al. (1999). Thus, at each point in the lattice (in our representation a  $29 \times 36$  grid of filter locations placed at regular 8-pixel intervals over the face), we extract a 40-element vector of Gabor magnitudes (sometimes called a “jet”) that characterizes a localized region of the face. A few of the filters are displayed graphically in Figure 1. To extract the  $29 \times 36 \times 40 = 41,760$  filter responses, we first convolve the entire image with each filter and take the magnitude of each complex valued response. We then (globally) divisively normalize the vector of responses at each filter scale to unit length. By equalizing the contribution of each filter size to the final representation, we overcome

the problem that most of an image’s power lies in lower spatial frequency ranges, without destroying information possibly present in the relative magnitude of response at each orientation. Since even the smallest filters in our representation overlap with their neighbors, and Gabor magnitudes are mildly invariant to slight translation, we lose very little of the information in the higher spatial frequency ranges, with a small price paid (due to ignoring phase information) in loss of precise feature localization and a larger price paid in that the resulting representation is very high dimensional (41,760 elements).

**Evaluation of the representation** In this section, we examine the representation’s utility and plausibility.

Donato et al. (1999) found that a nearest neighbor classifier with a cosine similarity metric applied directly to a Gabor grid-based representation achieved 95.5% correct classification of image *sequences* containing *individual facial actions* (Ekman and Friesen, 1978), e.g. facial action 1, the inner brow raiser. We evaluated this type of classifier on our task, classification of full-face expressions in static images. Nearest neighbor classification of the 96 expressive faces in POFA using leave-one-actor-out cross validation and a cosine similarity metric achieves an expected generalization accuracy of 74.0%. There are several possible reasons for this sub-par performance: the need to simultaneously integrate information from multiple facial actions, the small size of the POFA database, and/or the lack of information on the dynamics of facial movement. But the simple system’s performance is well above chance (16.7% correct), giving an indication that a more complicated (and more psychologically plausible) model such as a neural network could do much better.

One way of visualizing the effectiveness of a representation, and gaining insight into how an agent might use the representation to support decision-making, is to apply discriminant analysis.<sup>1</sup> For the Gabor magnitude components at a given location and spatial frequency, we find Fisher’s Linear Discriminant (Bishop, 1995), the projection axis  $\vec{w}$  that maximizes the criterion  $J(\vec{w})$ , the ratio of between-class to within-class scatter along  $\vec{w}$ .  $J(\vec{w})$  is a measure (invariant to linear transformations) of the diagnosticity of that portion of the representation for determining the class of the stimulus. That is, we can determine exactly how well (in the linear sense) the representation separates individual facial expressions.

We applied this method to the 85 expressive faces of a 12-actor subset of the POFA database. The results for Fear, the most difficult to recognize expression in POFA (for both humans and machines), are shown in Figure 2. The size of the dots placed over each grid location in the face is proportional to how easy it is to separate Fear from all of the other expressions based on the 8 Gabor filter responses extracted at that position of the grid. There are two interesting aspects to the result. First, the lowest spatial frequency channel (using filters about

<sup>1</sup>We introduced this visualization method for the Gabor representation in a recent technical report (Dailey and Cottrell, 1999), and Lyons et al. (1999) have independently introduced a similar technique.

Figure 2: Diagnosticity of Gabor filter locations for Fear discrimination, separated by filter spatial frequency, from scale 1 (highest SF) to scale 5 (lowest).

96 pixels in width, compared to the total image width of 240) is best for this expression, implying that improvement might be obtained by dropping the smaller scales from the representation and even increasing the filter size. Second, the technique hints at which facial actions are most reliable for distinguishing expressions from one another, readily making predictions for psychological experiments. According to Ekman and Friesen (1978), prototypical displays of Fear include facial action 1 (inner brow raise), 2 (outer brow raise), 4 (scrunching together of the eyebrows), and 5 (upper eyelid raise) in the upper face, along with 25 (lips part) and some combination of 20 (lip stretch), 26 (jaw drop), or 27 (mouth stretch) in the lower face. Although some discriminability can be obtained in the higher spatial frequencies in the region of the mouth (presumably detecting facial action 25), our model finds that the best regions are in the lower spatial frequencies around the eyes, especially around the upper eyelids.

### Principal Components Analysis for Dimensionality Reduction

We use Principal Components Analysis (PCA) as a simple, unsupervised, linear method to reduce the dimensionality of the network’s input patterns by projecting each 41,760-element pattern onto the top  $k$  eigenvectors of the training set’s covariance matrix. This speeds up classifier training and improves generalization. We experimented with various values of  $k$  and achieved the best generalization results with  $k = 35$ , so in all experiments reported here we project training and test patterns onto the top 35 principal component eigenvectors of the training set, then use the standard technique of “z-scoring” each input to a mean of 0 and a standard deviation of 1.0 (Bishop, 1995).

### Classification by a Six Unit Network

The classification portion of the model is a six-unit neural network. Each unit in the network first com-

putes its net input, a weighted sum of the input pattern  $\vec{x}$ :  $a_i = b_i + \sum_j w_{ij}x_j$ . Then the softmax function  $y_i = e^{a_i} / \sum_k e^{a_k}$  is applied to the net inputs to produce a 6-element output vector  $\vec{y}$ . The network is trained with the relative entropy error function (Bishop, 1995). Since the outputs of this network must sum to 1.0, we use a constant target vector of  $(\frac{1}{6}, \frac{1}{6}, \frac{1}{6}, \frac{1}{6}, \frac{1}{6}, \frac{1}{6})^T$  for the neutral training stimuli.

With no hidden layer and just 35 elements in its input, the network is very small, but its number of parameters, 216, is still large compared to the number of training examples (88-99). Therefore, we must avoid overtraining the network; we have found that too-fast optimization techniques lead to poor generalization. We have obtained the best results using stochastic gradient, momentum, weight decay, and early stopping using a hold-out set. For the experiments reported here, we used a learning rate  $\eta = 0.0017$  (the number of units divided by the number of inputs times 0.01), a momentum  $\alpha = 0.9$ , and weight decay rate  $\nu = 0.01$ .

The early stopping technique bears some explanation. We obtain expected generalization results by leave-one-actor-out cross validation. For POFA, this means a network is trained on the images of 13 actors and tested on generalization to the 14th. Rather than training on the full 13 actors, we leave one out as a holdout set to help determine when to stop training. After each epoch of training on the remaining 12 actors’ faces, we test the network’s performance on the 13th actor (the holdout set). If classification accuracy on the holdout set has not improved in 6 epochs, we stop training and restore the weights from the best epoch. Training time under this paradigm varies greatly; it ranges anywhere from 60 to 300 epochs depending on which partition into training, holdout, and test set is used.

### Evaluation of the Network’s Performance

How does the network perform the expression recognition task? An examination of the trained network’s representation provides some insight. The idea is to project each unit’s weight vector back into image space in order to visualize what the network is sensitive to in an image. But this is not a trivial task; though PCA is linear and easily inverted, the Gabor magnitude representation, besides being subsampled, throws away important phase information. Normalization of the power in each spatial frequency channel could also be problematic for inversion. Current techniques for inverting Gabor magnitude representations (C. von der Malsburg, personal communication) are computationally intensive and make several assumptions that do not apply here. So we instead take a simpler approach: learning the function from the 35-element input space into facial image space with linear regression, then using the regression formula to produce an image that visualizes each network unit’s weight vector.

The results for one network trained on an arbitrary 12-actor subset of POFA are shown in Figure 3. In each image, each pixel value is the result of applying the regression formula predicting the value of the pixel at that

Figure 3: Images reconstructed by linear regression from a trained network’s weight vectors.

location as a linear function of the 35-element weight vector for the given network output unit. Dark and bright spots indicate the features that excite or inhibit a given output unit depending on the relative gray values in the region of that feature. Note that the representations are very much like one might predict given the linear discriminant analysis described earlier: each unit combines evidence based upon the presence or absence of a few local features; for Fear, the salient criteria appear to be the eyebrow raise and the eyelid raise, with a smaller contribution of parted lips.

An important factor not shown in Figure 3 is the effect output units have on each other. Due to the divisive normalization of the softmax function, an active output unit can effectively inhibit other units that are only mildly activated. Nevertheless, it seems clear from the reconstructions that the network’s effective strategy is to learn how the combination of facial actions involved in each prototypical expression can be reliably detected in a static image. We hypothesize that, when faced with a forced choice expression recognition task, humans must use similar representations and classification strategies. In the next two sections, we provide some indirect support for this hypothesis with both qualitative and quantitative comparisons between the model’s performance and human performance on the same stimuli.

### Modeling Forced-Choice Classification

Ekman and Friesen (1976) presented subjects with the task of 6-way forced choice classification of the expressive stimuli in POFA and provide the results of their experiment with the dataset. Their criterion for admission into the final database was that at least 70% of subjects should agree on each face’s classification into one of the six POFA expression categories. On average, the proportion of agreement (or chance of correct classification) was 91.7%.

### Classification accuracy comparison

We trained  $14 \times 13 = 182$  networks, one for each of the possible partitions of the database into a training set of 12 actors, a holdout set of one actor, and a test set of one actor. After training using the method described earlier, we tested each network’s classification accuracy on its generalization (test) set and averaged their performance. The 182 networks, on average, obtain a classification accuracy of 85.9% (compared to a human accuracy of 91.7%), and interestingly, the rank order of expression category difficulty, Happy – Disgusted – Surprised – Sad – Angry – Afraid, is *identical to that of the humans*. We also find that the humans and networks

show the same rank order. We have also found that it is possible to boost classifier accuracy on this task if the classifier is given the opportunity to “peek” at the test set (without labels) before actually classifying it. This “batch mode” classification technique is a plausible model for familiarizing subjects with the stimuli in an experiment prior to testing them. It boosts classifier accuracy to up to 95%; details are available in a technical report (Dailey and Cottrell, 1999).

### Visualization with Multidimensional Scaling

Multidimensional Scaling (MDS) is a frequently-used technique for visualizing relationships in high-dimensional data. It aims to embed stimuli in a low dimensional space (usually two or three dimensions) while preserving, as best possible, observed distances or similarities between each pair of stimuli. MDS has long been used as a tool for exploring the psychological structure of emotion. Russell has proposed a “circumplex” model of affect (Russell, 1980) that describes the range of human affective states along two axes, pleasure and arousal. Russell and colleagues have found support for their theory in a wide range of studies for which MDS consistently yields two-dimensional solutions whose axes resemble pleasure and arousal.

A similar technique can be applied to Ekman and Friesen’s forced-choice data. We computed a  $96 \times 96$  Euclidean distance matrix from the 6-dimensional response vectors supplied by Ekman and Friesen and used non-metric MDS<sup>2</sup> to find a 2-dimensional configuration of the 96 stimuli. This configuration, shown in the first graph of Figure 4, yielded a Kruskal stress  $S = 0.205$ . The circumplex embedded in Ekman and Friesen’s data, Happiness – Surprise – Fear – Sadness – Anger – Disgust, or HSFMAD (using M for Maudlin in place of Sadness to distinguish it from Surprise), is different from that typically reported by Russell and colleagues. This is not surprising, however, because a large portion of Russell’s circumplex (affective states that are negative on the arousal dimension and positive or neutral on the pleasure dimension, such as sleepiness, content, and relaxation) is simply not represented in POFA. The HSFMAD circumplex *is* the same, however, reported by Katsikitis (1997), who used the same set of expressions, a similar forced-choice arrangement, but an entirely different set of photographs in which the actors were not instructed on how to portray each expression.

Does the facial expression similarity structure induced by the network resemble the human psychological similarity structure in any way? We have performed MDS analyses at three levels in this network: at the input layer (on the Gabor/PCA representation), at the net inputs to the network’s output units (the units’ un-softmaxed activations  $a_i$ ), and at the softmax output layer. As one might expect, at the input layer, the patterns form

<sup>2</sup>There are many varieties of MDS; we implemented the Guttman-Lingoes SSA-1 algorithm as described in Borg and Lingoes (1987). Put briefly, the algorithm iteratively derives a configuration  $\mathbf{X}$  that minimizes Kruskal’s stress  $S$ , which is the proportion of variance in a monotonic regression unexplained by  $\mathbf{X}$ .

Figure 4: MDS configurations derived from human classification data and the linear activations of the units in the network model. The circumplex (order of stimuli around the graph) is the same: H-S-F-M-A-D (M=Maudlin/Sadness).

a cloud in the plane with little structure. At the network’s output, the responses on the training set tend to be so nearly binary that there is very little similarity structure. But using the net inputs to the softmax units, averaged over all 182 networks, we obtain a solution (stress = 0.231) that orders the expressions in the same way as the human circumplex, as shown in the second graph of Figure 4.

With the caveat that this only occurs in the linear part of the network, the fact that the human and network MDS solutions contain the same ordering is striking. It is very unlikely ( $p = 0.017$  for a single trial and  $p = 0.033$  for two trials) that we would obtain the same ordering if the human and network similarity structure were in fact unrelated.

### Correlation of network and human errors

MDS analysis is useful as a visualization tool, but the correspondence between the human circumplex and network circumplex is not a formal test of the model. Is the correspondence between the human and network MDS solutions simply a fortuitous coincidence? One way to address this concern is with a direct comparison of the confusion matrices for the humans and networks. For the humans and networks, we computed the  $6 \times 6$  confusion matrix whose  $ij$ -th entry gives the probability that when a face from class  $i$  is present, the humans or networks (on the training set) respond with expression  $j$ . Since the network was explicitly trained to produce label  $i$  for members of class  $i$ , we removed the diagonal elements from each confusion matrix and compared the network and human *error patterns*, i.e. the 30 off-diagonal terms of the confusion matrices. Note that it is not “cheating” to use the network’s responses on the training set here; the network was never biased in any way to make errors similar to humans. We found that the correlation between the off-diagonal elements of the confusion matrices for the humans and networks is  $r = 0.567$ . An  $F$ -test ( $F(1, 28) = 13.3; p = 0.0011$ ) confirms the significance of this result. These results lead us to claim that much of the facial expression similarity structure observable in forced-choice experiments is due to direct perceptual similarity, and that our model does an excellent job of capturing that structure.

## Modeling Perception of Morphs

Beyond the forced-choice classification data provided by Ekman and Friesen, the literature on categorical perception of facial expressions transitions is a treasure trove of data for modeling. Previous work (Padgett and Cottrell, 1998) compared a somewhat different facial expression recognition model to human behavior in a large study by Young et al. (1997) (henceforth referred to as “Megamix”). In the Megamix study, the researchers created morph stimuli interpolating each of the 21 possible transitions between six expressive images and one neutral image of POFA actor “JJ.” They then tested subjects on forced-choice identification of the perceived expression in the morphs (they also measured response times, discrimination, and the subjects’ ability to detect mixed-in expressions in the morph stimuli). Padgett and Cottrell (1998) simulated the Megamix morph stimuli with *dissolves*, or linear combinations of each source image and target image. Their linear feature extraction technique (projection of eye and mouth regions onto a Local PCA basis) and neural network classifier applied to the linear dissolves produced good results. However, when we created true morphs and attempted to apply the same techniques, we found that the model no longer fit the human data — there were large intrusions of unrelated expressions along the morph transitions, indicating that linear feature extraction is unable to produce a smooth response to nonlinear changes in the image. One might expect that the Gabor magnitude representation, with its built-in invariance to phase, might better capture the smooth, categorical transitions observed in the Megamix study on nonlinear morphs. In this section, we very briefly show that this is indeed the case: the Gabor/PCA-based model does produce smooth transitions between expression categories without intrusions and a very good fit to the human identification data without any free parameters.

### Network training

We used a slightly different methodology for modeling this data because we wanted to model each human subject with one trained network. This requires as much between-subject variability as possible (although variability is difficult to achieve given POFA’s small size). We trained 50 networks on different random partitions of the 13 non-JJ actors’ images into training and holdout sets. Each network’s training set consisted of 7 examples of each expression plus neutrality, with the remaining data used as a holdout set. As before, neutral stimuli were assigned the uniform target vector  $[\frac{1}{6}, \frac{1}{6}, \frac{1}{6}, \frac{1}{6}, \frac{1}{6}, \frac{1}{6}]^T$  and the expressive faces were assigned binary target vectors.

After training each network until holdout set classification error was minimized, we tested its performance on JJ’s prototypes as well as all morphs between them. We then extracted identification, response time, discrimination, and faint morph detection response variables from the model.

Figure 5: Human and network responses to JJ morphs along the transitions HSFMDA.

### Model fit

Using the same response variable measurements as Padgett and Cottrell (1998), we do find the Megamix pattern of sharp categorical transitions, scallop-shaped response time curves, improved discrimination near category boundaries, and a close correspondence between humans and networks on detection of the secondary expression in morph transitions. Due to space limitations, we cannot report all of the Megamix modeling results here, but we do show the model’s fit to the human responses on one series of morph transitions. Forced-choice identification results for the Happy – Surprised – Afraid – Sad – Disgusted – Angry – Happy transition series are shown in Figure 5. The human data and model prediction are quite similar, but the networks appear to place slightly sharper boundaries between expressions; this is because there is not as much variation in our population of network “subjects” as that occurring in the Megamix data. Nevertheless, the correspondence ( $r^2 = 0.846$ ) is remarkable considering that the networks were never trained on images of JJ or morph stimuli and that there are absolutely no free parameters involved in fitting the model to the data.

### Discussion

We have shown that a simple, mechanistic computational model obtains a natural fit to data from several psychological studies on classification of human facial expressions. Exploring the space of possible expression classification models has led us to reject several alternative models (including local PCA-based input representations and more complicated ensembles of networks containing hidden layers). Since one simple model, despite its lack of culture and social experience, explains so much data without any free parameter fitting, we claim that it is a strong model for how the human visual system perceives facial expressions in static images. To the extent that performance in the controlled forced-choice psychological experiments cited here generalizes to more naturalistic social situations (an admittedly big assump-

tion to make), we suggest that the model captures the essentials of the visual processing used to make many social judgments.

### Acknowledgments

We thank Gary’s Unbelievable Research Unit (GURU) for valuable comments on this research, Curtis Padgett for laying the foundation for the work, and Andrew Young for data obtained in his “Megamix” study. The research was funded by NIH grant MH57075 to GWC.

# Addressing the Learnability of Verb Subcategorizations with Bayesian Inference

**Mike Dowman** (Mike@cs.usyd.edu.au)  
Basser Department of Computer Science, F09,  
University of Sydney, NSW2006, Australia

## Abstract

Elman (1993) has shown that simple syntactic systems can be learned solely on the basis of distributions of words in text presentation. However Pinker (1989) has proposed that children must make use of verbs' semantic representations in order to infer their syntactic subcategorizations (semantic bootstrapping). Results reported here demonstrate how Bayesian statistical inference can provide an alternative, and much simpler, account of how subcategorizations are learned. The acquisition mechanism described here suggests that syntactic acquisition may involve a much larger component of learning, and less innate knowledge, than is presumed within mainstream generative theory.

## Introduction

This paper investigates how children learn their first language, and in particular the syntactic system of that language. It conceives of the problem in the following way: when exposed to utterances in that language, how is it possible to infer the grammatical system which produced those utterances. Further, the learner is assumed not to know the meanings of the words, have access to prosodic cues to structure, or to receive feedback about which sentences are not grammatical.

Currently the major paradigm within which language acquisition is explained is the parameter setting framework (Chomsky, 1995). Within this framework it is proposed that knowledge of language is largely specified innately, and learning consists of identifying word tokens and setting a limited number of parameters according to the syntactic structures to which the child is exposed. Chomsky argues that this position is necessary because 'even the most superficial look reveals the chasm that separates the knowledge of the language user from the data of experience.' (p. 5).

Gold (1967) investigated this problem more formally, and proved that without negative evidence (explicit information about which sentences are ungrammatical) languages are not 'learnable in the limit' unless the class of languages which the learner may consider is restricted *a priori*, for example by innate knowledge. Below I will discuss an alternative result by Feldman, Gips, Horning and Reder (1969) which suggests that Gold's result is not relevant to the circumstances under which children learn languages.

Redington, Chater and Finch (1998) investigated to what extent syntactic categories could be inferred based on distributions alone, without knowing *a priori* what syntactic categories existed in the language. They formed vectors by taking the two preceding and two following context words for each occurrence of each target word in a large corpus of transcribed speech, and recorded how often each context

word occurred in each position. Only the 150 most frequent words were used as context, and so this resulted in 600 dimensional vectors for each word (there being one entry for each of the 150 context words in each of four positions). Clustering those words whose vectors were most similar in terms of Spearman's rank correlation resulted in clusters which corresponded to appropriate word classes for most of the 1,000 target words. While this system was good in that it could be applied to naturally occurring speech, it was necessary to decide at what level of dissimilarity to form separate classes, and so it doesn't completely solve the problem of recovering the syntactic classes used by the original speakers.

Elman (1993) demonstrated that not only word classes, but also syntactic patterns in which words belonging to those classes appeared, could be learned without much innate syntactic knowledge, at least for simple languages. He trained a recurrent neural network to predict the following word in artificially generated sentences conforming to a simple syntactic system containing 23 words, and syntactic features such as number agreement and recursion in relative clauses. Once trained on 50,000 sentences in this simple language, the network performed at near optimum accuracy at predicting the subsequent word at any stage in a sentence, showing that the network had internalized the structural constraints implicit in the data.

While both Redington et al (1998) and Elman (1993) demonstrate that much of syntactic structure can be learned by making statistical inferences based on the distributions of words, Pinker (1989) suggests that some aspects of syntax cannot be learned in this way. He proposes that, in order to determine verbs' subcategorizations in the absence of negative evidence, children must rely on complex innate rules combined with knowledge of the verbs' semantic representations.

Verbs such as *give* can appear in both the prepositional dative construction (1a), and the double object dative construction (1b), but there is a class of verbs such as *donate* which can only appear in the prepositional construction, (1c and 1d). However Gropen et al (1989) observe that, based on the alternation between (1a) and (1b), children generalize this alternation to verbs such as *donate*, and so produce ungrammatical sentences such as (1d). They also demonstrated that when presented with novel, nonce, verbs in the prepositional construction, children will productively use them in the double object construction in appropriate contexts. However, ultimately children do learn which verbs cannot occur in the double object construction, and so we need a theory which can explain why children first make such gen-

eralizations, and then subsequently learn the correct sub-categorizations.

- (1) a. John gave a painting to the museum.
- b. John gave the museum a painting.
- c. John donated a painting to the museum.
- d. \*John donated the museum a painting.

While the main point of Pinker (1989) is that syntax cannot be learned from distributions alone, he acknowledges that the fact that certain syntactic structures do not occur could be used as indirect negative evidence that these structures were ungrammatical. However, he notes that children can neither consider that all sentences which they have not heard are not grammatical, and nor do they rule out all verb argument structure combinations which they haven't heard. He notes that it is necessary to identify 'under exactly what circumstances does a child conclude that a nonwitnessed sentence is ungrammatical?' (p.14). The computational model presented in this paper is able to do just this, and so predict that a verb such as donate cannot occur in the double object construction, while at the same time predicting that a novel verb encountered only in the prepositional construction will follow the regular pattern and also appear in the double object construction.

### Bayesian Grammatical Inference

Most work in syntactic theory assumes that grammars are not statistical, that is that they specify allowable structures, but do not contain information about how frequently particular words and constructions occur. However, if grammars were statistical, it appears that it would be much easier to account for how they were learned. Feldman et al (1969) proved that as long as grammars were statistical, and so utterances were produced with frequencies corresponding to the grammar, then languages are learnable. They note that proofs that language isn't learnable rely on the possibility of an unrepresentative distribution of examples being presented to the learner. While under Feldman et al's learning scheme it is not possible to be certain when a correct grammar has been learned, as more data is observed it becomes more and more likely that the correct grammar will be identified.

Feldman et al's proof uses Bayes' theorem, which relates the probability of a hypothesis given observed data to the *a priori* probability of the hypothesis and the probability of the data given the hypothesis. For a fixed set of data the best hypothesis is that for which the product of the *a priori* probability of the hypothesis and the probability of the data given the hypothesis is greatest. Feldman et al relate the probability of a grammar (seen as a hypothesis about language) to its complexity – more complex grammars are less probable *a priori*. As grammars are statistical, it is also possible to calculate the probability of the data given a grammar. This leads to an evaluation criterion for grammars where the complexity of a grammar is weighed off against how much data it has to account for, and how well it fits that data. A more complex grammar can be justified if it accounts for regularities in the data, but otherwise a simpler grammar will be preferred.

Minimum coding length provides an efficient implementation of Bayesian inference, using information theory (Shannon, 1948), which allows us to quantify the amount of information in a formal description of a grammar. The amount of information conveyed by an event (or symbol in a grammar) is equal to the negative logarithm of its probability. It is conventional to take logarithms to base two, resulting in the units of quantity of information being bits. Within this framework the best grammar is that which, together with a description of a corpus of data in terms of the grammar, can be specified using the least amount of information.

While Feldman et al (1969) showed that, given two or more grammars, it is possible to decide which is the best given a corpus of data, they did not show how these grammars could be created. For any reasonably complex grammar, the number of possible, but incorrect, grammars of equal or simpler complexity is so large that it is not plausible that a child could consider each in turn. However, in the next section, I describe computational models which are able to learn grammars by starting with a simple grammar, and then making small iterative changes which gradually lead towards the correct grammar. This avoids the need to consider every single possible grammar, and so allows grammars to be learned within a reasonable amount of time.

### Computational Models of Syntactic Acquisition

Langley (1995) and Stolcke (1994) used simplicity metrics to learn simple syntactic systems, while Goldsmith (submitted) has applied this approach to the acquisition of morphology. Both Langley and Stolcke's systems produced similar results to those found by Dowman (1998) using the model described in the next section, although Langley's (1995) system did not incorporate considerations of how well the grammar fitted the data. It is shown below how Dowman's (1998) model was used to obtain new results concerning the acquisition of verb subcategorizations.

### Description of Model

Dowman's (1998) model learned grammars for simple subsets of several languages, including the English data given in Table 1, which corresponds to the grammar given in Table 2. The only *a priori* knowledge of the structure of the corpus which was available to the model was implicit in the grammatical formalism with which grammars were specified. This formalism restricted the model to using binary branching or non-branching phrase structure rules, introducing each word with a non-branching rule, and using no more than eight non-terminal symbols. The non-terminal symbols were all equivalent arbitrary symbols, except that each grammar would contain one special symbol, *S*, with which each top down derivation would begin.

The frequency, and hence probability, with which each symbol (including words) appeared in the grammar was specified, and so the amount of information required to specify each symbol in a grammar could be calculated (using Shannon's (1948) information theory). A specification of a grammar would consist of a list of groups of three symbols, one for a rule's left hand side, and two for its right

hand side (a special null symbol being incorporated for use in non-branching rules). As the grammar was statistical, it was also necessary to record how often each rule was used in parsing the corpus. It was assumed that a fixed amount of information could be used to specify these probabilities, and so 5 bits of information was added to the evaluation of the grammar per rule. (The assumption of 5 bits of information is fairly arbitrary, but sufficient for the purposes described here.) The total cost of the grammar was the amount of information needed to specify each symbol in the grammar, and each rule's frequency.

Table 1: Data for English

John hit Mary	Ethel thinks John ran
Mary hit Ethel	John thinks Ethel ran
Ethel ran	Mary ran
John ran	Ethel hit Mary
Mary ran	Mary thinks John hit Ethel
Ethel hit John	John screamed
Noam hit John	Noam hopes John screamed
Ethel screamed	Mary hopes Ethel hit John
Mary kicked Ethel	Noam kicked Mary
John hopes Ethel thinks Mary hit Ethel	

Table 2: Grammar Describing English Data

$S \rightarrow NP VP$	$V_s \rightarrow$ thinks
$VP \rightarrow$ ran	$V_s \rightarrow$ hopes
$VP \rightarrow$ screamed	$NP \rightarrow$ John
$VP \rightarrow V_t NP$	$NP \rightarrow$ Ethel
$VP \rightarrow V_s S$	$NP \rightarrow$ Mary
$V_t \rightarrow$ hit	$NP \rightarrow$ Noam
$V_t \rightarrow$ kicked	

Given such grammars, the data was then parsed left to right, bottom up, with only the first parse found for each sentence being considered, and an ordered list of rules needed to derive the sentence obtained. This list allows us to make a probabilistic encoding of the data in terms of the grammar. Given the probabilities of the rules, and always knowing the current non-terminal symbol being expanded (starting with  $S$ , and always expanding the left most unexpanded non-terminal), it is only necessary to specify which of the possible expansions of that symbol to make at each stage. Hence, if a grammar accounts well for regularities in the data, little information will be required to specify the data. If a symbol can only be expanded by a single rule (such as  $S$  in the grammar above), then no information is necessary to specify that that rule is used.

By summing the amount of information needed to specify the grammar rules, the frequencies of those rules, and the data given that grammar, we obtain an evaluation for each grammar, with lower evaluations corresponding to better grammars. However, in order to complete the model of acquisition, it is necessary to describe the search mechanism that was used for generating and testing grammars.

The model started learning with a simple grammar of the form given in Table 3, with a rule introducing each word. This grammar is very simple, hence having a good evalua-

tion itself, but it does not describe any regularities in the data, and so has a very bad evaluation in that respect, resulting in a poor overall evaluation.

Table 3: Form of Initial Grammars

$S \rightarrow X S$	$S \rightarrow X$
$X \rightarrow$ John	$X \rightarrow$ thinks
$X \rightarrow$ screamed	$X \rightarrow$ Ethel

The model would begin learning by making one of four random changes to the grammar, either adding a new rule (which would be the same as an old rule, but with one of the symbols changed at random), deleting a randomly chosen rule, changing one of the symbols in one of the rules, or the order of the rules, or adding a pair of rules in which one non-terminal symbol occurring on the left hand side of one and the right hand side of another was changed to a different non-terminal symbol. These changes are slightly simpler than those described in Dowman (1998), but further investigations have revealed that this learning system works well, and it was able to reproduce the results obtained with the more complex system, so it was used for deriving the new results presented in this paper.

After each change the evaluation of the new grammar with respect to the data would be calculated. If the change improved the evaluation of the grammar then it would be kept, but if the new grammar was unable to parse the data, it would be rejected. If the change made the evaluation of the grammar worse, then the probability that it would be kept would be inversely proportional to the amount by which it made the evaluation worse, and also throughout learning the probability that changes resulting in worse evaluations would be accepted was gradually reduced. This is an implementation of annealing search, which enables the system to learn despite finding locally optimal grammars in the search space. The program learned in two stages, in the first only taking account of the evaluation of the data in terms of the grammar (making it easier to find the grammatical constructions which best fitted the data), and in the second taking account of the overall evaluation (and so removing any parts of the grammar which could not be justified given the data). After a fixed number of changes had been considered (less than 18,000 in the case of the above data) learning would finish with the current grammar, no improvements usually having been found for a long time. For efficiency reasons, there were also limits placed on how deeply the parser could search for correct parses, and on the maximum number of rules which the grammar could contain at any stage of the search. Because the search strategy is stochastic, it is not guaranteed to always find the optimal grammar every time, so the learning mechanism would run the search several times, and select the grammar with the best overall evaluation.

## Results

When used to learn from the English data in Table 1, the system learned a grammar which corresponded exactly to that in Table 2 in structure. (As linguistic categories are not known *a priori*, the system simply used a different arbitrary

symbol to represent each learned category.) Table 4 shows that this grammar was preferred because, while the grammar itself is more complex than the initial one, and so receives a worse evaluation, it captures regularities in the data, and so improves the evaluation of the data with respect to the grammar by a greater amount. Dowman (1998) used this same learning system (without any modifications except to the maximum number of non-terminal symbols) to learn aspects of French, Japanese, Finnish and Tigak.

Table 4: Evaluations for English Grammar

	Initial state of learning	Learned Grammar
Overall Evaluation	406.5 bits	329.5 bits
Grammar	160.3 bits	199.3 bits
Data	246.2 bits	130.3 bits

### Learning Verb Subcategorizations

Given Dowman's (1998) success in learning simple syntactic systems, it was decided to investigate whether the same model could be used to learn some of the kinds of phenomena which it has been argued are especially problematic for theories of learning. In particular it was investigated whether the distinction between sub-classes of ditransitive verbs such as *gave* and *donated* could be learned.

There were three key results which the model aimed to replicate. Firstly, children eventually learn a distinction between verbs which can appear in both the double object and prepositional dative constructions, and those which do not show this alternation. Secondly, when children encounter a previously unseen verb they use it productively in both constructions. Finally, during learning, before children have seen many examples of an irregular verb which only occurs in a subset of the possible constructions of other verbs, they use that verb productively in constructions in which it is not grammatical.

### Data Used for Learning

The same model was used as in Dowman (1998), but this time the data consisted of two types of sentences, prepositional datives such as (2a) and (2b), containing one of the verbs *gave*, *passed*, *lent*, or *donated*, and double object datives such as (2c), containing *gave*, *passed* or *lent*, but not *donated*. Each of these four verbs occurred with roughly equal frequency, and the alternating verbs were just as likely to appear in either construction. In addition the sentence (2d) was added, containing the only example of the verb *sent*. Noun phrases consisted of either one of two proper nouns, or one of the two determiners *a* or *the*, followed by either *painting* or *museum*. There were no biases as to which noun phrase was most likely to occur in which position, and overall the data consisted of 150 sentences.

No modifications were made to the model of Dowman (1998), except that in order to cope with the more complex data set the maximum number of non-terminals was increased to 14, and the number of iterations in the search was also increased.

- (2) a. John gave a painting to Sam.
- b. Sam donated John to the museum.
- c. The museum lent Sam a painting.
- d. The museum sent a painting to Sam.

### Results

The initial and final evaluations of the grammars are given in Table 5. Again a more complex grammar has been learned which accounts better for regularities in the data than the original grammar. Examination of the learned grammar showed that the verbs had been divided into two classes (they have different symbols on the left hand sides of the rules producing them). *gave*, *passed*, *lent* and *sent* had all been placed in one class, while *donated* appeared in a class of its own. The grammar is able to generate only grammatical sentences, so *gave*, *passed*, *lent* and *sent* may appear in both double object and prepositional constructions, while *donated* may occur only in the prepositional dative construction. This has been learned even though there was no data explicitly indicating that *donated* did not follow the regular pattern, and even though *sent* only occurred once, and in the prepositional structure.

Table 5: Evaluations for Ditransitive Verbs Data

	Initial state of learning	Learned Grammar
Overall Evaluation	3445.6 bits	1703.4 bits
Grammar	190.3 bits	321.0 bits
Data	3255.3 bits	1382.3 bits

The results above account both for eventual learning of the distinction between syntactically distinct verbs such as *gave* and *donated*, and the productive use of novel verbs in regular constructions. The final phenomenon which we aimed to demonstrate was that, at earlier stages of learning, children overgeneralize and use verbs such as *donated* productively in constructions in which they are ungrammatical. In order to investigate this phenomenon, the total amount of data was reduced, to simulate a stage of acquisition where children had not been exposed to so many examples of each kind of verb. When the model learned from this data it failed to maintain a distinction between sub-classes of verbs, allowing all verbs to occur in both constructions. This was because there were not enough examples of *donated* to justify making the grammar more complex by creating a separate syntactic class, and so it was simply placed in the regular class.

### Discussion

These results on the acquisition of regular and irregular verb subcategorizations show that an aspect of syntax is learnable which many other theories would have difficulty accounting for. In particular it is interesting to compare the performance of the model described here to that of connectionist models of syntactic acquisition such as Elman (1993).

Elman's network learned a language containing only 23 words, and yet 50,000 sentences were used to train the net-

work. This means that every word could have been observed in every syntactic position many times over, greatly reducing the need to form generalizations. Christiansen and Chater (1994) investigated to what extent this kind of model was able to generalize to predict that a word observed in one syntactic position would also be grammatical in another position. In order to do this, they trained a similar connectionist network on a more complex language containing 34 words, again using 50,000 sentences. In the training data they did not include *girl* and *girls*, in any genitive contexts, and, *boy* and *boys* in any noun phrase conjunctions. After training they found that the network was able to generalize so that it would allow *boy* and *boys* to appear in noun phrase conjunctions, but it didn't generalize to allow *girl* and *girls* to occur in genitive contexts. Christiansen and Chater considered the learning to have been successful in the case of *boy* and *boys*, but not in the case of *girl* and *girls*.

However, the account of the acquisition of verb subcategorizations presented in this paper relies on statistical properties of the data, and in particular the non-occurrence of certain forms. So, given 50,000 sentences of a language with only 34 words, in which two words did not appear in a given construction, it would seem that a learner would predict that this could not simply be due to chance. Given this perspective, it seems that Christiansen and Chater's network has learned correctly in the case of *girl* and *girls*, but not in the case of *boy* and *boys*.

In order to account for distinctions between *gave* and *donated*, it seems that neural networks must be more sensitive to quantitative information in language. The degree to which recurrent neural networks generalize is partly dependent on the fixed architecture of the network, and in particular on the number of hidden nodes. Bayesian learning methods for neural networks (MacKay, 1995) should be able to solve this problem, by placing a prior probability distribution on network structures and parameter values, although I am not aware of any applications of such networks to models of language acquisition.

Redington et al's (1998) system for learning word classes is capable of making very fine distinctions between subclasses of verbs, but unlike the system described here it is not able to decide when the distributions of two words are dissimilar enough that they should be placed into separate classes, and when the difference in distributions is simply due to chance variation within a class. However Boulton (1975) describes a program which does incorporate a Bayesian based metric into this kind of clustering system, and so demonstrates that it is possible to learn discrete classes automatically.

Certainly evaluation procedures based on simplicity metrics are not new to linguistic theory. Chomsky's (1965) theory of syntactic acquisition relied on such a measure to choose between alternative grammars. However, it is possible to identify some key differences which make Chomsky's theory very different to the Bayesian approach suggested here. Firstly Chomsky considered syntax to be fundamentally non-statistical. He had earlier argued that 'Despite the undeniable interest and importance of semantic and statistical studies of language, they appear to have no direct rele-

vance to the problem of determining or characterizing the set of grammatical utterances....[P]robabilistic models give no particular insight into some of the basic problems of syntactic structure.' (Chomsky, 1957, p17). It seems hard to explain how any system which didn't monitor the frequencies with which verbs such as *donated* and *gave* are used would be able to account for how the different subcategorizations of these verbs could be acquired.

Probably an even more important difference between the kind of simplicity measure proposed in Chomsky (1965) and the kind used here, is that Chomsky did not incorporate a measure of goodness of fit to data into his simplicity metric. Chomsky's metric simply looked for the grammar which was shortest, in terms of the number of symbols which it contained. The theory relied on innate constraints on what forms grammar could take in order that 'significant considerations of complexity and generality are converted into considerations of length, so that real generalizations shorten the grammar and spurious ones do not.' (p42). Ultimately any notion of a simplicity metric was dropped from syntactic theory, because little progress seemed to be being made in understanding grammar selection in this way.

Interestingly however, Chomsky's (1965) theory shows that simplicity metrics are not necessarily incompatible with theories which postulate very strong innate constraints on grammar. It seems that even within a parameter setting model of language acquisition, statistical inferences would make the task of learning much easier, especially given the presence of noise in the data from which people learn (due primarily to grammatical errors, and exposure to data from children who have not mastered certain aspects of grammar). Showing that Bayesian inference can be useful in explaining language acquisition does not necessarily mean that it is actually used. Essentially it allows us to return the degree to which language is determined by innate principles of grammar to an empirical question, allowing the possibility of a much greater degree of learning in the process of syntactic acquisition.

However, postulating that a Bayesian mechanism is used in acquiring syntax results in very different predictions about what form syntactic knowledge will take than if we presume that language is largely determined by universal principles. Chomsky (1995) has argued that the language faculty of the mind should satisfy 'general conditions of conceptual naturalness that have some independent plausibility, namely, simplicity, economy, symmetry, nonredundancy, and the like' (p. 1). While Chomsky notes this is 'a surprising property of a biological system' (p. 5) he argues that this view is justified because throughout the history of syntactic research systems conforming to this kind of principle have turned out to be the right ones. However, if language is learned with a Bayesian system we would not expect it to conform to such principles. Grammars could contain a lot of irregular rules if these accounted well for regularities in observed language. Even the principle of lexical minimization is not so clear cut within a Bayesian based account of learning, as Bayesian metrics will favor grammars which associate a lot of information with individual words if this allows them to account better for regularities in the data. Hence, one prediction of Bayesian theory is that

the most commonly occurring words may be very idiosyncratic and irregular in their behavior, while very rare ones must conform to regular patterns.

It is interesting to compare the Bayesian account of acquisition of subcategorizations presented here to Pinker's (1989) theory. Pinker's theory predicts that universal innate principles relate the meaning of a word to its syntactic subcategorization. Instead of the syntactic subcategorization of a verb being determined empirically by a learner based on observations of patterns of occurrence, it is determined by the meaning of that verb. Certainly Gropen et al (1989) have shown that children are sensitive to correlations between semantic and phonological characteristics of verbs, and which subcategorization frames they are most likely to occur in. However, it is quite possible that these patterns were learned by the child in much the same way as we have proposed that syntactic subcategorizations may be learned. It would be interesting to investigate empirically whether children or adults could be influenced to prefer verbs in one construction or another by controlling the exemplars of these verbs to which they were exposed, perhaps by using artificial language experiments or nonce verbs integrated into natural languages. This kind of experiment should be able to resolve to what extent children make use of innate principles versus learning in determining verbs' subcategorizations.

The main limitation of the computational model described here is that it can only learn from small artificial data sets. There is no reason in principle why it cannot operate on naturally occurring language, it is simply that it would take an extremely long time to run on this kind of corpus. This is clearly a limitation which is shared with connectionist approaches, though Redington et al (1998) demonstrate impressive results learning from real language corpora. Current research is investigating ways in which the search procedure could be made more efficient, so that learning from more realistic corpora is possible, though it seems worth acknowledging that we are modeling a process which takes place over many years, and that the human brain is much more powerful than any computer.

## Conclusion

This paper has shown that Bayesian inference is able to provide a simple and plausible account of how a number of aspects of syntax could be learned. In particular the computational model described here can learn verb subcategorizations where one verb is grammatical in only a subset of the structures in which another can appear, and yet predicts that newly encountered verbs are used productively in regular patterns. The model also accounts for overgeneralization and hence the use of irregular items in regular constructions during early stages of acquisition. While it is not logically necessary that children must make use of Bayesian inference in learning language, it has the potential to be incorporated into theories as diverse as recurrent neural networks and universal grammar.

## Acknowledgments

I would like to thank Jeff Elman, David Powers, Brett Baker, Hong Liang Qiao, Adam Blaxter Paliwala, Cassily Charles, and two anonymous reviewers, for helpful comments on this paper. This research was supported by ARC and IPRS scholarships.

### Abstract

Current methods of coding recall, summarization, talk-aloud, and question-answering data are inherently unreliable and not effectively documented. If the process of coding protocol data could even be partially automated, this would be an important scientific advance in the field of text comprehension. Twenty-four human subjects read and recalled each of four short texts. Half of the human recall data (the "training data") was coded by a human coder and then used to estimate the parameters of a set of Hidden Markov Models (HMMs) where each HMM was associated with a particular complex proposition in the text. The Viterbi algorithm was then used to assign the "most probable" complex proposition to human-coder specified text segments in the remaining half of the human recall data (the "test data"). The HMM algorithm made coding decisions which agreed well with a human coder's decision on the test data indicating that the HMM is indeed capable of formally representing a human coder's "theory" of how text segments should be mapped into complex propositions for simple texts.

### Introduction

Theories and experiments in the field of text comprehension often require mapping recall (e.g., Golden, 1997), summarization (e.g., van den Broek & Trabasso, 1986), talk-aloud (e.g., Trabasso & Magliano, 1996), and question-answering (e.g., Graesser & Franklin, 1990) protocol data into a semantic model of the implicit and explicit information in text clauses. This semantic model of the information in the text clauses has been referred to by Kintsch (1998) as the *textbase microstructure*. Typically this initial *coding procedure* of mapping the protocol data into a textbase microstructure is done using human coders. Inter-coder reliability measures are then used to establish the reliability of the coding procedure.

This widely used coding procedure methodology, however, has several problems. First, such coding procedures

are typically not well documented. Second, the reliability of such procedures is often highly dependent upon "human coders", who despite their best intentions, are prone to inconsistent coding behaviors (especially over very large coding tasks). Third, such coding procedures are typically not readily accessible to other researchers. And fourth, coding procedures across research labs located in different parts of the world are not standardized in any particular manner.

An ideal solution to these problems would be to develop an automated approach to coding human protocol data (as advocated by Ericsson and Simon, 1993). Although important progress in this area has been made (see especially Kintsch, 1998, Chapter 3), additional work is required. It should also be emphasized that the task of coding human protocol data is not nearly as complex as the full-fledged natural language understanding problem. Consider a typical experiment where a group of human subjects are asked to recall the same story from memory. Although the resulting protocol data will be extremely rich and varied, typically the text comprehension researcher is only interested in detecting a relatively small number of complex propositions. This dramatically simplifies the pattern recognition problem.

The main goal of this research is to develop and empirically evaluate a new theoretical framework for reliably mapping protocol data into a textbase microstructure. Specifically, a Hidden Markov Model (HMM) (see Allen, 1995; Charniak, 1993; Jelinek, 1997; for relevant reviews) is constructed for each complex proposition in each of four short stories. The stories, based upon classic fables, each consisted of approximately 10-15 short sentences with each sentence corresponding roughly to a complex proposition (Golden, 1997). Twenty-four human subjects read and recalled each of the four short texts (see Golden, 1997, for additional details). Half of the human recall data (the "training data") was coded by a human coder and then used to estimate the parameters of the HMM associated with each

<sup>1</sup> The order of the authors is arbitrary. Please address all correspondence to Richard M. Golden.

complex proposition. The prior probability that a particular complex proposition was used by the human coder was also recorded. Next, the Viterbi algorithm (Viterbi, 1967; see Allen, 1995; Charniak, 1993; Jelinek, 1997) was used to assign the "most probable" complex proposition to human-coder specified text segments in the remaining half of the human recall data (the "test data"). Measures of agreement between the human coder and AUTOCODER were then computed using only the test data. A high measure of agreement indicates that the HMM is indeed capable of formally representing a human coder's "theory" of how text segments should be mapped into complex propositions.

## Method

### Human Protocol Data

**Texts.** The human protocol data used consisted of recall data associated with four texts collected by Golden (1997). The four texts ("Cuckoo", "Miser", "Eagle", and "Doctor") were especially written to have approximately similar levels of syntactic and semantic complexity. Each sentence in the text was written to conform approximately to: (1) a standard subject-verb-object form, and (2) such that each sentence corresponded roughly to one complex proposition. For example, the "Miser" text read by the human subjects is shown below.

#### The "Miser" Text (Golden, 1997)

A miser bought a lump of gold using all of his money. The miser buried the gold in the ground. The miser looked at the buried gold each day. One of the miser's servants discovered the buried gold . The servant stole the gold . The miser , on his next visit , found the hole empty . The miser was very upset . The miser pulled his hair . A neighbor told the miser not to be upset . The neighbor said , " Go and take a stone , and bury it in the hole . "The neighbor said , " And imagine that the gold is still lying there ." The neighbor said , " The stone will be as useful to you as the gold . " The neighbor said, " When you had the gold , you never used it . "

**Recall Protocol Data.** Twenty-four college students read and verbally recalled each of four texts ("Miser", "Cuckoo", "Doctor", and "Eagle") from memory as described in Golden (1997). The recall data was then transcribed. Text segments in all of the recall protocol data corresponding to complex propositions were then identified by human coders. The recall data from twelve of the college students was designated as *training data*, while the recall data from the remaining twelve college students was designated as *test data*.

To provide some insights into the richness and complexity of the statistical pattern recognition problem considered

in this paper. Here is an example recall protocol extracted from the training data set.

#### Subject 1 recall of "Miser Text" (training data set)

someone that a servant that knew that discovered the money# and took it# and then the miser saw that the money was gone# and he was upset# and complained to a neighbor# and the neighbor said well just get a stone and bury your money# dig a hole and bury the money# because it'll do you just as much good as your real money your gold is doing you#

The symbol # in the above recall protocol associated with subject 1 refers to the marking of text segments by an experienced human coder. Text segments corresponding to complex propositions were marked by experienced human coders for both the training data and test data sets. Here is a representative recall protocol from subject 12 who was assigned to the test data set. The complexity of the recall data (even when a human coder has already identified text segments) is readily apparent (compare recall data of Subject 1, Subject 12 with one another and the original "Miser" text).

#### Subject 12 recall of "Miser Text" (test data set)

and he buried it in the ground # and he went over every day to look at where the money was where the lump of gold was buried# and one day when the miser was- n't there a thief came and dug up the lump of gold# and so the miser goes and he sees the hole in the ground# and he's very upset by that# and a bystander tells the miser to take a rock and bury it in the ground# and the miser says why# and the bystander says well all you ever did was look at the ground anyway# you never did use the gold# so there might as well be a rock there#

### Parameter Estimation (Learning Algorithm)

The learning process involves a specially designed graphical user-interface which is referred to as AUTOCODER. Figure 1 shows a typical AUTOCODER display. A subject's recall data (in this case, the recall data for Subject 12) is displayed. The human coder first segments the text so that each word sequence in each text segment corresponds to a complex proposition. Beneath each word is a pull-down menu consisting of a series of concepts. The human coder decides which words (or word sequences) should be assigned concepts, and then uses the pull-down menu to assign a concept to each selected word within a given text segment. Another pull-down menu is then used to

assign a complex proposition to a given sequence of concepts within a text segment.

**Probabilistic Modeling Assumptions.** Let  $W_1, \dots, W_M$  be the ordered sequence of words (or more generally word phrases) within a particular text segment which an experienced human coder has decided should be assigned concepts. Let  $C_i$  denote the concept assigned to the  $i$ th word,  $W_i$ . Let  $F$  be the complex proposition assigned to the concept sequence  $C_1, \dots, C_M$ .

After the human coder has completed the coding task, AUTOCODER has stored the following items for the human coder. First, a concept dictionary consisting of the concepts created by the human coder. Second, a complex proposition dictionary consisting of the complex propositions created by the human coder. Third, the percentage of times that a particular complex proposition  $F$  has been used (denoted by  $p(F)$ ). Fourth, the percentage of times that a word (or word phrase)  $W_i$  is used to express the concept  $C_i$  (denoted by  $p(W_i | C_i)$ ) is computed (this is referred to as the "emission probability" in the HMM literature). And fifth, the percentage of times that one concept follows another concept given a particular complex proposition  $F$  (denoted by  $p(C_{i+1} | C_i, F)$ ) (this is referred to as the "transition probability" in the HMM literature). Given the usual conditional independence assumptions of an HMM, these statistics in conjunction with the concept and complex proposition dictionaries correspond to a particular type of probabilistic theory of how the human coder codes the recall data.

For example, consider the text segment "*He buried his life savings deeply in the ground*". The human coder might choose to model this text segment as an ordered sequence of word phrases: ( $W_1 = \text{"He"}$ ,  $W_2 = \text{"buried"}$ , \*,  $W_3 = \text{"life savings"}$ , \*, \*, \*, \*) might be associated with the ordered sequence of concepts: ( $C_1 = \text{"MISER"}$ ,  $C_2 = \text{"BURY"}$ , \*,  $C_3 = \text{"GOLD"}$ , \*, \*, \*, \*) where the notation \* is used to refer to a word (or word phrase) which is not assigned a concept for the purposes of coding the protocol data. The complex proposition  $F = \text{"BURY(MISER, GOLD)"}$  would be assigned to the concept sequence ( $C_1 = \text{"MISER"}$ ,  $C_2 = \text{"BURY"}$ , \*,  $C_3 = \text{"GOLD"}$ , \*, \*, \*, \*).

Once the assignments have been made, statistics are computed. Specifically, the probability that one concept follows another given a particular complex proposition (e.g.,  $P(\text{BURY} | \text{MISER, BURY(MISER, GOLD)})$ ) is estimated from the observed relative frequencies. In addition, the probability of a word given a concept is estimated (e.g.,  $P(\text{"life savings"} | \text{GOLD})$ ). The probability that a given complex proposition is used is also estimated from the coder's behavior (e.g.,  $P(\text{BURY(MISER, GOLD)})$ ). Instead of assigning a zero probability to transition and emission probabilities whose corresponding observed relative frequencies were equal to zero, a small "smoothing" probability was used to facilitate processing of novel word sequences. Figure 2 shows a possible HMM representation for the complex proposition **BURY(MISER, GOLD)**.

### Protocol Data Coding Algorithm

The Viterbi algorithm (Viterbi, 1967) as described in Allen (1995, p. 202) was then used to construct the "most probable" concept sequence associated with each possible

complex proposition for a particular text segment. The "information content" in bits (i.e., a normalized log-likelihood measure)  $I$  of a complex proposition  $F$  consisting of  $M$  concepts  $C_1, C_2, \dots, C_M$  and represented by  $M$  word phrases  $W_1, \dots, W_M$  is computed using the formula:

where  $\log[x]$  denotes the logarithm base 2.

$$I = -(1/M) \log \left[ p(F) \prod_{i=1}^M p(C_i | C_{i-1}, F) p(W_i | C_i) \right]$$

Next, the complex proposition which was "most probable" (i.e., had the smallest information content score  $I$ ) was selected. Complex propositions whose information content exceeded some maximum critical value were discarded and those text segments were defined as "incomprehensible" to AUTOCODER. This threshold was set sufficiently high, however, so that the occurrence of "incomprehensible" complex propositions was very rare. Notice that unlike the usual HMM approach to syntactic and semantic parsing, a unique HMM is constructed for each complex proposition rather than trying to construct a general HMM applicable to all possible complex propositions which could occur in the text.

### Procedure

Three human coders jointly coded the recall data from the training data set using AUTOCODER. The human coders were careful not to examine the test data, so the dictionaries created as a result of coding the training data were likely to not contain all concepts, complex propositions, and statistics necessary to code the test data set. Text segments in the test data were then identified by the three human coders as well. AUTOCODER then assigned the "most probable" complex proposition to each text segment using the information content score described in the previous section. The three human coders then coded the test data without the use of AUTOCODER and measures of agreement between AUTOCODER's performance and the human coder performance on the test data set were recorded.

### Results and Discussion

In order to compare performance of AUTOCODER and the human coder on the test data set, three different measures of agreement were used. All measures were computed individually for each text across all relevant subject data. It is important to emphasize that AUTOCODER always codes the same set of protocol data in exactly the same manner with 100% reliability. Thus, the agreement measures actually are measures of the validity as opposed to the reliability of AUTOCODER's coding performance.

### Agreement Measures

The first measure was *percent agreement* which is defined as the percentage of times the two coders agree that a proposition was mentioned in the recall protocol plus the percentage of times the two coders agree that a proposition was not mentioned. One difficulty with the percent agreement measure is that percent agreement can be artificially increased by simply increasing the number of complex

propositions in the proposition dictionary! Accordingly, other agreement measures were considered.

The second measure of agreement was Cohen's Kappa score (Cohen, 1960) which essentially corrects for agreement by chance. The formula for Cohen's Kappa is given by:  $\kappa = (p - p_c) / (1 - p_c)$  where  $p$  is the *percent agreement* described in the previous paragraph and  $p_c$  is the expected agreement between the two coders if the coding strategy of one coder provided no information (i.e., was statistically independent of the coding strategy of the other coder). The performance of the model for the percent agreement and kappa agreement measures on the training data set is provided in Table 1. The quantity  $N$  denotes the number of opportunities for agreement. Typically, in the text comprehension literature, Percent agreement scores for coding data which are above 90% and kappa scores which are above 70% are deemed acceptable for publication. The data was also analyzed using a third more stringent agreement measure we call *sequential agreement*. Sequential agreement is typically not computed. But since the same coder has identified the text segments in both the training and test data, the percentage of times both the human coder and AUTOCODER agreed upon the coding of a particular text segment across recall protocols could be computed. This coding criterion thus takes into account the sequential structure of the recall data unlike the previously described agreement measures which are typically reported in the literature.

### Analysis of Training Data

Table 1 shows the performance of AUTOCODER on the training data set using standard agreement measures, while Table 2 shows the performance of AUTOCODER using the sequential agreement measure. As can be seen from Tables 1 and 2, AUTOCODER's performance clearly demonstrates that it is picking up on a sufficient number of statistical regularities from the skilled human coder's data to almost completely reconstruct the skilled human coder's decisions.

Table 1: Performance of Autocoder on Training Data (Standard Agreement Measures)

Text	N	Percent Agreement	Cohen Kappa
"Miser"	192	95%	91%
"Cuckoo"	336	93%	84%
"Doctor"	228	99%	97%
"Eagle"	384	97%	93%

Table 2: Performance of Autocoder on Training Data (Sequential Agreement Measures)

Text	N	Percent Agreement
"Miser"	111	90%
"Cuckoo"	111	86%
"Doctor"	105	98%
"Eagle"	150	92%

### Analysis of Test Data

Tables 3 and 4 show the performance of AUTOCODER on the test data set using the standard agreement measures and the sequential agreement measure. As can be seen from Tables 3 and 4, AUTOCODER's performance is almost comparable to experienced human coders keeping in mind the limitation that the test data set was parsed into text segments corresponding to complex propositions by a human coder. On the other hand, the AUTOCODER methodology has the important advantage that it is entirely well-documented and can be reliably implemented by computer software (unlike coding schemes implemented by human coders).

Table 3: Performance of Autocoder on Test Data (Standard Agreement Measures)

Text	N	Percent Agreement	Cohen Kappa
"Miser"	192	83%	65%
"Cuckoo"	336	88%	71%
"Doctor"	228	88%	75%
"Eagle"	384	84%	66%

Table 4: Performance of Autocoder on Test Data (Sequential Agreement Measures)

Text	N	Percent Agreement
"Miser"	111	69%
"Cuckoo"	111	67%
"Doctor"	105	76%
"Eagle"	150	68%

To provide a qualitative feeling regarding AUTOCODER's performance, Table 5 shows AUTOCODER's "coding" of the protocol data of Subject 12 who was assigned to the test data set.

It is extremely encouraging (despite the simple texts considered in this initial study) that the performance of the AUTOCODER algorithm was so effective on the test data. In almost all cases, AUTOCODER automatically and reliably coded the data at an almost publishable agreement level using completely documented and accessible algorithms. We are excited and pleased with these preliminary results even though the text segments in the test data had to be pre-

parsed by a human coder. Future work in this area is currently being pursued.

Table 5: AUTOCODER's "coding" of novel recall data

Human Recall Data	AUTOCODER Interpretation

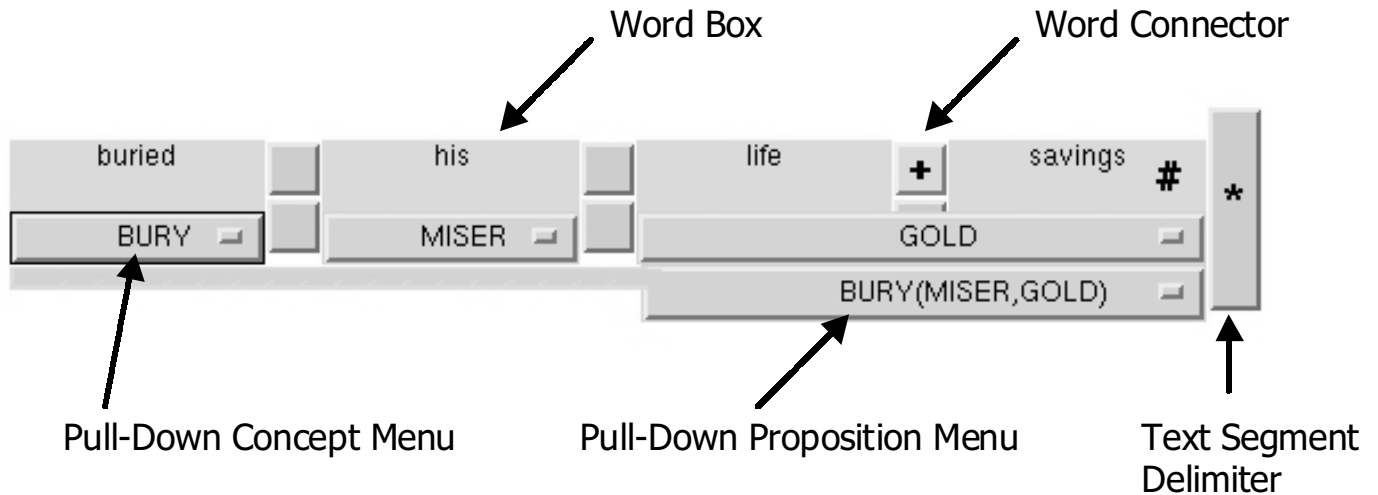

Figure 1. A portion of the AUTOCODER user-interface associated with the coding of the phrase "buried his life savings". Each word in the text appears in a particular window called the *word box*. Word boxes can be connected to form word phrases using the *connector button*. Beneath each word phrase is a pull-down *concept menu*. Another pull-down *proposition menu* which lists the set of available complex propositions which can be assigned to the phrase is also displayed to the user. Both concept and proposition menus provide facilities for the addition of new concepts and propositions by the skilled human coder. Menu choices are made by a skilled human coder for the purposes of providing training data for the Hidden Markov Models (HMMs). The HMMs are then used to automatically make "most probable" menu selections without the aid of a skilled human coder through the use of the Viterbi algorithm for HMMs as described in the text.

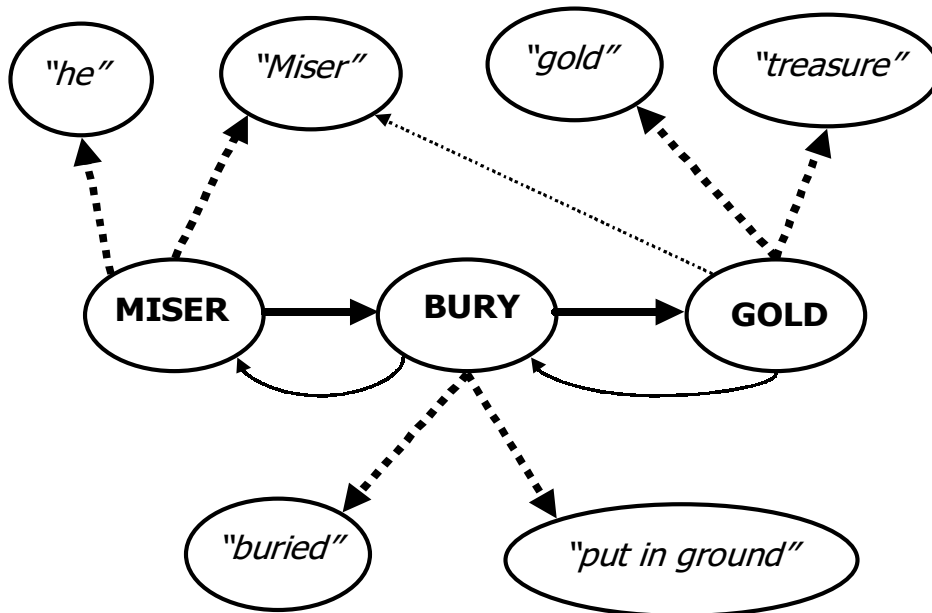

Figure 2. Each complex proposition is represented by its own HMM (Hidden Markov Model). In this figure, the HMM for the proposition **BURY(MISER, GOLD)** is graphically displayed. Transition probabilities are represented by solid arrows while emission probabilities are represented by dashed arrows. Line thickness indicates the relative magnitude of the corresponding transition or emission probability. Thus, the line thicknesses for the emission probability  $P(\text{Word} = \text{"gold"} \mid \text{Concept} = \text{GOLD})$  and transition probability  $P(\text{Concept} = \text{GOLD} \mid \text{Concept} = \text{BURY}, \text{Proposition} = \text{BURY(MISER, GOLD)})$  are both much thicker than the line thicknesses for the emission probability  $P(\text{Word} = \text{"Miser"} \mid \text{Concept} = \text{GOLD})$  and transition probability  $P(\text{Concept} = \text{BURY} \mid \text{Concept} = \text{GOLD}, \text{Proposition} = \text{BURY(MISER, GOLD)})$ .

# A Rarity Heuristic for Hypothesis Testing

## Abstract

This paper presents the results of two experiments designed to investigate the processes underlying the effects of beliefs about probabilities on an hypothesis testing task. Both experiments demonstrate that although such effects exist, they are inflexible in the face of explicit statistical and implicit contextual manipulations of the likely information to be gained from selecting evidence concerning rare features. It is argued that these results suggest the operation of a rarity heuristic in hypothesis testing whilst possible adaptive functions for such a heuristic are discussed.

## Probabilities and Hypothesis Testing

Over the last ten or more years, human hypothesis testing, which previously had been viewed as being prone to bias (Wason, 1960; Doherty et al, 1979), has been rehabilitated. One of the central claims to be made during this process of rehabilitation is that human hypothesis testing is in some way adapted to the probabilistic structure of our environment. For example, Klayman and Ha (1987) have argued that confirmation, verification and matching biases, amongst others, may be viewed as the result of a generalised positive test strategy in hypothesis testing. Klayman and Ha demonstrated how such a strategy could be a good heuristic in environments with a realistic probabilistic structure. Their claim is that hypothesis testing tasks such as Wason's 2 4 6 task lead to non-normative behaviour because they encourage participants to adopt a generally sensible strategy in an experimental situation whose probabilistic structure does not match the strategy.

More recently, Oaksford and Chater (1994), in the spirit of Anderson's (1990) more general 'rational analysis' of cognition, have proposed a decision-theoretic account of Wason's selection task (Wason, 1966). This account is based on both the probabilistic structure of the task itself and assumptions about people's understanding of abstract conditional hypotheses. Our aim in this paper is to extend the study of probabilistic effects to another hypothesis testing task and to gain some insight into the mechanisms underlying such effects.

## Probabilities and Pseudodiagnosticity

Feeney, Evans and Clibbens (1997) have considered the role of background probabilities in determining performance on the pseudodiagnosticity (PD) task. Pseudodiagnosticity (Doherty et al, 1979) is the tendency to select information relevant to just one of a pair of hypotheses when trying to decide between them. An example of the standard paradigm used to investigate pseudodiagnosticity is taken from Mynatt, Doherty and Dragan (1995):

Your sister has a car she bought a couple of years ago. It's either a car X or a car Y but you can't remember which. You do remember that her car does over 25 miles per gallon and has not had any major mechanical problems in the two years she's owned it.

You have the following information:

A. 65% of car X's do over 25 miles per gallon.

Three additional pieces of information are also available:

B. The percentage of car Y's that do over 25 miles per gallon.

C. The percentage of car X's that have had no major mechanical problems for the first two years of ownership.

D. The percentage of car Y's that have had no major mechanical problems for the first two years of ownership.

Assuming you could find out only one of these three pieces of information (B, C or D) which would you want in order to help you to decide which car your sister owns? Please circle your answer.

In the standard PD task, as above, an anchor is provided (item A) which provides some potentially supportive evidence for one of the two hypotheses presented in the scenario. This we term the *focal* hypothesis. According to Doherty and his colleagues, the normatively correct answer to this problem is to choose item B which provides - in Bayesian terms - a completed likelihood ratio and allows the diagnosticity of the evidence to be assessed. For example,

we might discover that only 25% of Y's do over 25 mpg, favouring X or that 90% of Y's do over 25 mpg, favouring the Y hypothesis. However, the more common response is for people to choose item C, thus learning more about X. In the study quoted, 28% of participants chose B (deemed correct), 59% chose C and 13% chose D. In the absence of information about Y, however, items A and C provide only pseudodiagnostic evidence for X.

The original interpretation of this apparent error by Doherty et al (1979) - with general support in the later literature - was that it constituted a form of confirmation bias similar to that observed on other tasks such as the Wason 2 4 6 problem (see Evans, 1989, Klayman, 1995 for extended discussion of confirmation bias effects). It is supposed that people think only about the focal hypothesis, fail to consider alternatives and try to find evidence to confirm their favored hypothesis.

However, the analysis of the task becomes more complex if one takes into account background beliefs that the participant may bring to the experiment. Suppose, for example, that you were told that your sister's car had a radio and a top speed of over 165 miles per hour. If the information provided was then that most X's have a radio, according to the standard normative analysis people ought to choose to discover whether most Y's also have a radio. However, since they know a priori that most cars have radios, the participants could reason that this will be true of most Y's as well and that nothing will be learned by choosing this option. On the other hand discovering whether X does over 165 miles an hour (a rare feature among cars) would provide good evidence relative to background beliefs about the likelihood of this feature. Given these beliefs, such evidence could be regarded as being implicitly diagnostic rather than as being pseudodiagnostic. In this case, one can actually argue that the PD choice is correct, because its expected information gain (Oaksford, Chater & Larkin, 1999) or epistemic utility (Evans & Over, 1996) is higher, relative to background beliefs.

Feeney, Evans and Clibbens (1997) have shown that when the initial piece of evidence concerns a rare feature and the second piece concerns a common feature, then people will seek to discover a second piece of evidence about the rare feature, leading to a large drop in the usual PD choice rate. This tendency, to make diagnostic selections when evidence concerning a rare feature is available has been replicated on three different variants of the task (Feeney, Evans and Venn, 2000). In a separate version of the paradigm in which participants rate their degree of belief in the focal hypothesis after one or two pieces of 'pseudodiagnostic' information, we also found (Feeney, Evans and Clibbens, in press) that people are significantly more confident in a hypothesis supported by rare rather than common evidence. These findings support the view that rare information is taken to be implicitly diagnostic.

Whilst the experiments described above have established a robust influence of feature Rarity, it is not clear whether this is due to tacit influence of background beliefs or

whether people are consciously reasoning about the expected epistemic utility of the evidence. This ambiguity is indicative of a more general confusion (Oaksford Chater & Larkin, 1999; Klayman and Ha, 1987) in the literature on hypothesis testing where it is unknown whether people's apparent sensitivity to the probabilistic structure of their environment is the result of hard-wired heuristics, or is due to extensive on-line processing of environmental probabilities. We will now describe two experiments designed to resolve this ambiguity.

## Experiment 1

In this experiment, we used problems which were structurally identical to those used by Mynatt et al (see above). In Mynatt et al's experiment participants received a scenario containing a target object, said to possess two features, and two hypothesised categories. Next participants received a piece of evidence concerning the rate at which one of the hypothesised categories possessed one of the features. Finally, participants were asked to select one of the remaining three pieces of information to help them make a judgement about category membership.

In Experiment 1 we manipulated the relationship between the rarity of the evidential features and the explicit information presented about the rate at which features were present under either hypothesis. In the belief-compatible conditions, participants were told that a rare feature was present in only 10% of cases for the initial hypothesis (e.g. 10% of car X's do over 165 mph) or that a common feature was present in 80% of cases (e.g. 80% of car X's have radios). In the belief-incompatible conditions, participants were told that the rare feature was present in 80% of X's or that the common feature was present in 10% of X's. If a simple rarity heuristic is operating then we would expect participants still to favour rare features regardless of the explicit information given. However, if they are reasoning on-line about the probability of the evidential features then the percentage data should interact with the Rarity manipulation. Specifically, when told that the common feature is present in only 10% of X's (common feature, belief-incompatible), we might now expect diagnostic choices to go up (and focal choices to be suppressed) even though these involve the common feature. This is because people could reason that most Y's will probably have the feature and hence the choice will be diagnostic. When told that 10% of X's contain the rare feature (belief-compatible) we might also expect a drop in the usual diagnostic choice rates for rare evidence since they will expect Y to have a similar rate. Hence, the on-line processing hypothesis predicts a cross-over interaction between the two variables.

## Method

One hundred and eighty seven students from the University of Plymouth took part in this experiment which had a 2x2 between participants design. Each participant received a booklet comprising of an instructions page and four

problems. The basic structure of the problems used was identical to that used by Mynatt et al. The factors manipulated were Rarity and the strength of the initial statistic presented (we will refer to this variable as the Percentage variable). The Rarity manipulation in this experiment was between participants and was achieved by manipulating the first feature about which participants were given some evidence. These features were chosen on the basis of a pre-test and are shown in Table 1.

Table 1: Results of pre-test on materials used in Experiments 1 and 2.

Content	2 <sup>nd</sup> Feature	1 <sup>st</sup> Feature - Common	1 <sup>st</sup> Feature - Rare
House	Garage	Garden	Swimming pool
Engineer	Company car	Earns £14,000 pa	Earns £60,000 pa
Car	Has a radio	Top speed 90 mph +	Top speed 165 mph +
Holiday Villa	Built last 20 years	£150 per week	£1000 per week

The Percentage manipulation was achieved by manipulating, between participant, the strength of the initial piece of evidence. Half of the participants were told that 10% of instances of the focal category shared a feature with the target whilst the other half were told that this figure was 80%. The problem contents employed in this experiment concerned a house, an engineer, a car and a holiday villa. The order of the evidential options was counterbalanced whilst the order of the problems was randomised.

## Results and Discussion

Evidence selection patterns, when collapsed across experimental condition, are very similar for all problem contents. On the Engineer problem 41% of selections were of B (diagnostic selections), 50% were of C (further information about the focal hypothesis) and 9% were of D (information for the non-focal hypothesis concerning the second feature). The equivalent statistics for the Spanish Villa problem are 37%, 50% and 13%, 42%, 44% and 14% for the Car problem and 41%, 50% and 9% for the House

Table 2: Item choices as a percentage of total choices in each condition for Experiment 1.

	Rare		Common	
	10	80	10	80
Item B	47%	43%	41%	28%
Item C	42%	44%	46%	63%
Item D	11%	13%	13%	9%

problem. Selection frequencies for the entire experiment broken down by experimental condition are presented in Table 2. The mean number of pseudodiagnostic, or item C, choices was calculated for each participant across the four

problem contents. The mean number of item C choices, broken down by Rarity and Percentage Type, is presented in Figure 1. A 2x2 between-participants Anova was carried out on the mean number of item C choices. A significant main effect was found for Rarity ( $F(1, 183) = 4.53$ ,  $MSE = 2.40$ ,  $p < .04$ ). The mean number of item C choices made by participants in the Rare and Common conditions was 1.70 ( $S.D. = 1.57$ ) and 2.18 ( $S.D. = 1.54$ ) respectively. Neither

Figure 1: Mean Number of Focal Selections by Condition in Experiment 1.

the main effect of Percentage ( $F(1, 183) = 2.98$ ,  $MSE = 2.40$ ,  $p > .08$ ) nor the interaction between Rarity and Percentage ( $F(1,183) = 1.19$ ,  $MSE = 2.40$ ,  $p > .25$ ) were found to be statistically significant.

These results suggest the operation of a rarity heuristic in hypothesis testing. Our results contained a significant main effect of Rarity, although the apparent interaction fell short of significance. Whilst it is clear from Table 2 and Figure 1 that the percentage information has no effect on choice rates for rare information, Figure 1 does reveal a marginally significant trend ( $p < .06$ ) for common choices to be debiased in the belief-incompatible condition.

The trend for focal selections to increase when the initial evidence is that less than 50% of focal instances possess a common feature was found previously by Mynatt et al (1993) and interpreted by them as due to the initial evidence disconfirming hypothesis X and switching focus to Y. Although this trend is also consistent with an on-line processing hypothesis, that hypothesis also predicts a corresponding increase in focal choices when rare information was present at 80%. The latter trend was clearly absent. However, the trend which is to be seen in our data is consistent with the claim, made by Mynatt et al, that people select evidence relevant to the hypothesis they believe to be true.

## Experiment 2

In our previous experiment we demonstrated that people are relatively insensitive to explicit changes in the initial piece of information that they receive and that the rarity effect is

robust in the presence of such changes. In Experiment 2 we aimed to test whether people are sensitive to contextual changes which should also affect the epistemic utility of their choices.

In this experiment we attempted to reduce the implicit diagnosticity of the rare features by presenting them in a context where they would not be rare. For example, in the Car scenario both types of car were said to be sports cars and hence much more likely to have a high top speed. As all participants in the experiment were told that 80% of Xs possessed either the common or rare features used in previous experiments, the implicit change to the scenarios was the only difference between the two conditions run in this experiment and the 80% conditions of the previous experiment. Combining both sets of conditions gives us a 2x2 design with rarity of initial feature and relationship between alternatives the between subject variables.

### Method

One hundred and four new participants from the University of Plymouth were recruited for this experiment each of whom received a booklet comprising of a set of instructions and four problems. The instructions for this experiment were identical to those used in Experiment 1 whilst the problem contents used were almost identical to those used in the previous experiments. The rarity manipulation in this experiment was achieved with the same features as used in previous experiments and all participants were told that 80% of instances of the focal category shared a feature with the target object.

The difference between the new conditions in this experiment and the 80% conditions of the previous experiment is the implicit diagnosticity of the rare feature. Thus, we will refer to the second between participants factor in this experiment as Implicit Diagnosticity.

### Results and Discussion

Once again, selection patterns, when collapsed across our new experimental conditions, are very similar for all four problem contents. On the Engineer problem 37% of

Table 3: Item choices as a percentage of total choices in each condition for Experiment 2.

	Low Implicit Diagnosticity (Exp. 2)		High Implicit Diagnosticity (Exp. 1)	
	Rare	Com	Rare	Com
Item B	42%	34%	43%	28%
Item C	47%	54%	44%	63%
Item D	11%	12%	13%	9%

selections were of B, 50% were of C and 13%% were of D. The equivalent statistics for the Villa problem are 35.5%, 52% and 12.5%, 38%, 51% and 11% for the Car problem

and 40%, 49% and 11% for the House problem. Selection frequencies for the entire experiment broken down by experimental condition are presented in Table 3.

The mean number of item C choices was calculated for each participant across the four problem contents. The mean number of C choices, broken down by Rarity and Implicit Diagnosticity, are presented in Figure 2. In order to examine the effect of our Implicit Diagnosticity manipulation a 2x2 between participants Anova (with Rarity as the second factor) was carried out on the mean number of item C choices made by participants in this experiment and participants in the 80% conditions of Experiment 1. Once again, a significant main effect was found for Rarity ( $F(1, 199) = 5.745$ ,  $MSE = 2.365$ ,  $p < .02$ ). The mean number of item C choices made by participants in the Rare and Common conditions was 1.81 (S.D. = 1.57 and 2.33 (S.D. = 1.55) respectively. Neither the main effect of Implicit Diagnosticity ( $F(1, 199) = 0.235$ ,  $MSE = 2.365$ ,  $p > .6$ ) nor the interaction between Rarity and Implicit Diagnosticity ( $F(1,199) = 0.95$ ,  $MSE = 2.248$ ,  $p > .33$ ) were found to be statistically significant.

Figure 2. Mean number of focal selections in Experiment 2 as a function of condition.

These results demonstrate the persistence of people's tendency to make fewer focal choices when the initial piece of information concerns a rare feature, even when the implicit diagnosticity of that rare feature has been contextually reduced. This provides further evidence of a robust rarity heuristic that is relatively insensitive to contextual variations.

### General Discussion

The first conclusion to be drawn from the results of the experiments described in this paper is that they support the findings of Feeney, Evans and Clibbens (1997; in press). People are sensitive to the probabilities of the evidential items about which they reason on the PD task. More important is our failure to moderate the effects of feature rarity using either an explicit statistical manipulation or an

implicit contextual manipulation. The failures of these manipulations suggest that the effect of feature rarity is mediated via a hard-wired heuristic rather than any sophisticated on-line processing of probabilities. Whilst this heuristic is sensitive to rare features of objects, it is insensitive to changes in explicit statistical and implicit contextual information which affect the diagnosticity of those features. Accordingly, although we agree with Oaksford, Chater, and Larkin (1999) who argue that the very existence of probabilistic effects in hypothesis testing tasks indicates that people perform some on-line processing of probabilities, we feel that our results strongly suggest that the extent of such processing is severely limited. The effects of feature rarity on the PD task seem instead to be due to the operation of a relatively inflexible rarity heuristic.

### Functional and Dysfunctional Aspects of a Rarity Heuristic

As with any heuristic in judgement or hypothesis testing, a rarity heuristic conveys both advantages and disadvantages. Most obviously, given the results of our experiments, an inflexible rarity heuristic renders the information processor insufficiently sensitive to changes in the diagnosticity of rare experimental features. However, as we have claimed elsewhere (Feeney et al, in press), sensitivity to feature rarity allows us to use our background beliefs about the probability of the evidence to evaluate hypotheses even in the light of normatively incomplete evidence. For example, imagine you have been asked to decide whether your sister's car, which possessed a top speed of over 165 mph and a radio, is a model X or a model Y. Given your background knowledge about the features, you can be more confident that the car is an X when told that 95% of Xs have a top speed of over 165 mph than when told that 95% of Xs have a radio. Thus information about feature rarity may be used to make a decision even when normatively complete evidence is missing.

As well as supporting inference with incomplete information, we believe that another candidate function for a rarity heuristic in hypothesis testing might be checking the limitations of hypotheses. Defining the scope of hypotheses in this way has recently become a topic of interest for cognitive psychologists. For example, Lopez (1995) has found that the majority of participants presented with a premise such as:

Dogs have a merocrine gland 1

and asked if they would prefer to find out whether wolves or bulls had a merocrine gland in order to check the more general premise that

All mammals have a merocrine gland 2

preferred to check bulls rather than wolves. This preference is viewed as being normatively correct as it obeys the notion that the more diverse is the evidence in favour of a hypothesis the stronger the support for that hypothesis is (see Carnap, 1951; Popper, 1959). Osherson, Smith, Wilkie,

Lopez and Shafir (1990) have proposed a model of category based induction which captures the diversity principle. This model accounts for people's preference for diverse premises by supposing that the strength of a categorical argument depends on the degree to which the premise categories are similar to both the conclusion category and instances of the lowest level category which includes both premise and conclusion categories.

There are situations in which it may be impossible to make the similarity calculations upon which Osherson et al's model relies. For example, it is common in the literature on category-based induction to use premises with blank predicates i.e. premises about which the participant is unlikely to have any a priori beliefs. This is done to minimize the effects of the predicate on participants' judgements. It is also possible to use blank premise categories in these experiments where the participant had no knowledge about the premise and conclusion categories except their size. In this case although the information required for a similarity calculation is unavailable one can check whether a general hypothesis also applies to a rare or unusual event. Thus we can greatly increase our confidence in the hypothesis (when it can account for the rare event) or limit the hypothesis (when it cannot).

The importance of such a limiting function may be seen when one considers that several lines of theoretical and experimental work suggest that it is the interaction between a heuristic or strategy and the environment in which it is used which determines the success or failure of that heuristic (e.g. Evans, Handley, Harper and Johnson-Laird, 1999; Gigerenzer et al, 1999). This argument was most explicitly made by Klayman and Ha (1987) who defined the probabilistic structure of environments where their positive test strategy would not be successful. The consequences of a mismatch between the environment and the positive test strategy is most dramatically illustrated by the failure of participants on Wason's 2 4 6 task to limit their initial rule thereby leading to a failure to discover the experimenter's more general rule.

The experiments described in this paper demonstrate the use of a heuristic which counteracts the effects of a positive test strategy. The standardly obtained finding on the pseudodiagnosticity task is that subjects tend to search for more information about the hypothesis supported by the existing evidence. In most cases this leads to pseudodiagnostic responding. In our experiments we have demonstrated that the tendency to select information about rare features produces diagnostic responding. In a similar fashion, one can imagine a scientist who is committed to a hypothesis that is too narrow but, because of the use of a positive test heuristic, is unable to find disconfirmation. The attempt to apply this hypothesis to a rare event or phenomena may provide the evidence required for the scientist to broaden the hypothesis.

Whilst we see the diversity principle (Osherson et al, 1990; Lopez, 1995; Spellman, Lopez and Smith, 1999) and a rarity heuristic as being complementary, there is an

important distinction to be drawn between them. Lopez (1995) has argued that the diversity principle does not breach the positive test heuristic. One of the adaptive functions of the rarity heuristic, on the other hand, is that - as in the experiments reported in this paper - it does violate a strategy based on positive testing. Its existence and use in everyday hypothesis testing is likely to be one reason why we are not surrounded by the calamitous results of a reliance on positive testing.

## Conclusion

In conclusion, we have demonstrated that the effects of rarity on hypothesis testing, although present, are insensitive to statistical and contextual manipulation. We have argued that these results support the existence of a Rarity heuristic in hypothesis testing. Finally, we claim that if such a heuristic does exist, it is likely, in many cases, to complement the operation of other heuristics known to operate when people select information to help them find out about the world.

# Modeling Orientation Effects in Symmetry Detection: The Role of Visual Structure

Ronald W. Ferguson (r-ferguson@northwestern.edu)

Department of Computer Science, Northwestern University  
1890 Maple Avenue; Evanston, IL 60201, USA

## Abstract

Symmetry detection is a key part of human perception. One incompletely understood aspect of symmetry detection concerns *orientation effects*. The best-known orientation effect is the *preference for vertical symmetry*, where symmetry around a vertical axis is detected more quickly and accurately than symmetry at other orientations. Current symmetry detection models have difficulty explaining this effect. Using MAGI (Ferguson, 1994), we show how orientation effects may be caused by interactions between the perceived visual relations and the current reference frame. As evidence for this explanation, we simulate several orientation characteristics, including the preference for vertical symmetry and Wiser's (1981) theory of "intrinsic axes". Finally, we successfully simulate the results of a classic study by Palmer and Hemenway (1978) which explores the relationship between the preference for vertical symmetry, multiple symmetries, and inexact symmetry. Collectively, these results show that orientation effects may be due to characteristics of detected visual relations rather than either exact point-to-point equivalencies or the bilateral symmetry of the visual system.

## Introduction

Symmetry detection is a core mechanism in perception, shape recognition, and perceptual organization. Yet the processes underlying symmetry detection are only partially understood. Studies of symmetry detection have revealed psychological characteristics more complex than previously assumed even a few decades ago.

One such set of characteristics are *orientation effects*: interactions between symmetry detection and the visual reference frame. Orientation effects are interesting because they separate human performance in judging symmetry from symmetry's geometric definition. In geometric terms, symmetry is orientation-invariant, yet human symmetry detection depends critically on a figure's orientation. In addition, under certain circumstances symmetric figures also

influence the visual reference frame.

Orientation effects can be placed into three broad categories: the preference for vertical symmetry, the preference for multiple symmetries, and the effect of symmetry on a figure's object-centered reference frame.

**Preference for vertical symmetry.** Bilateral symmetry is more quickly and accurately detected when the symmetry axis is vertical (Attneave & Olson, 1967; Bornstein & Krinsky, 1985; Chipman & Mendelsohn, 1979; Corballis & Roldan, 1975; Goldmeier, 1936/1972; Julesz, 1971; Mach, 1893/1986; Palmer & Hemenway, 1978). In most cases, vertical symmetry is easier than horizontal symmetry, which in turn is easier than diagonal symmetry.

A longstanding explanation for the preference for vertical symmetry is that it depends on the human visual system's own vertically bilateral structure. In this framework, originally suggested by Mach (1893/1986), human vision provides better and faster results for symmetries aligned with its own symmetric structure. Several visual subsystems have been proposed as this effect's locus, from eye placement (Mach, 1893/1986) to the corpus collosum (Braitenberg, 1984; Herbert & Humphrey, 1996). However, most of these explanations focus on the retina and structures just beyond it (Corballis & Roldan, 1975; Jenkins, 1982; Julesz, 1971). Thus, these explanations are known as *retinocentric models*.

Retinocentric models, while theoretically elegant, fail to explain a key result: vertical symmetry is still preferred when the retina is *misaligned* with the symmetry axis. Rock and Leaman (1963) showed that the preference for vertical symmetry is still present when a figure is vertical with respect to the gravitational reference frame, but the subject's head is tilted 45° away from vertical.

**Symmetry in figures with intrinsic axes.** The preference for vertical symmetry disappears or is greatly attenuated for

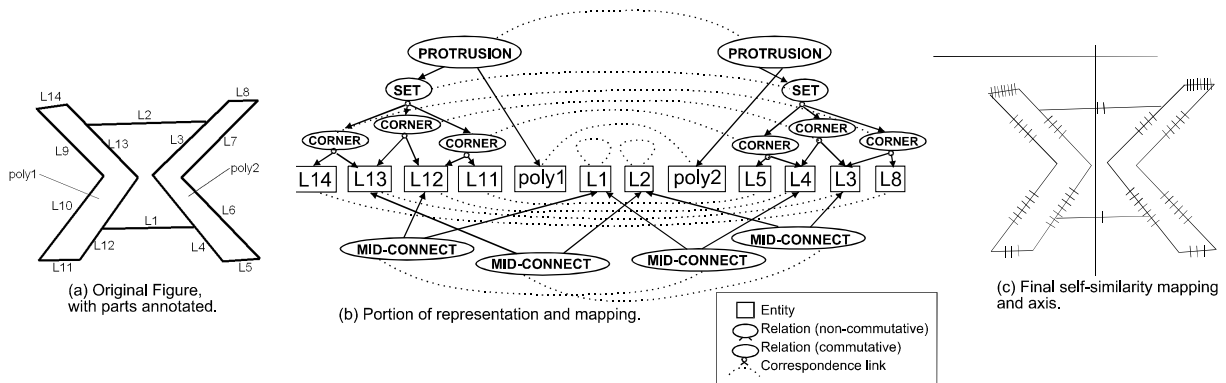

Figure 1: MAGI detects symmetry by aligning visual relations. Figure (a) shows a line drawing given to MAGI as a vector graphics file, with its vector elements labeled. Figure (b) shows a subset of the figure's visual relations (12 of 18 entities, 14 of 118 spatial relations) generated for those visual elements. Dotted lines indicate mapping links produced by MAGI. Note that two line segments, L1 and L2, map to themselves. Figure (c) indicates the full set of entity correspondences (using hash marks) and the axis produced by MAGI.

some kinds of figures. Figures with a good "intrinsic axis" (Palmer, 1983; Wiser, 1981) apparently impose their own reference frame, allowing recognition at any orientation.

**Preference for multiple symmetries.** Symmetry is also judged more quickly and accurately when a figure contains multiple symmetries (Royer, 1981; Wagemans, Van Gool, & d'Ydewalle, 1991). The preference for multiple symmetries is separate from the preference for vertical symmetry, and can produce additive results (Humphrey & Humphrey, 1989; Palmer & Hemenway, 1978).

Orientation effects pose significant challenges for cognitive models of symmetry detection, which have difficulty modeling interactions between symmetry detection and the visual reference frame. Some symmetry detection models, such as the so-called "brushfire" models (Blum & Nagel, 1978; Brady, 1983), do not use the reference frame at all. Other models use the reference frame in a limited sense – for example, utilizing it to find horizontally-aligned dots to link in symmetric dot patterns (Jenkins, 1983; Wagemans et al., 1991). These latter models can partially explain the preference for vertical symmetry by positing that some fixed set of orientations are tried until symmetry detection succeeds. At the same time, these models apply only to dot patterns, and cannot easily be extended to orientation effects found in more complex stimuli, such as polygons. More problematic, however, is that these models cannot explain how figures with good intrinsic axes eliminate the preference for vertical symmetry, nor why the order of preferences is first vertical, then horizontal, then diagonal (instead, it is typically assumed that this set of orientations results from either natural selection or perceptual learning in a world rich in vertically-symmetric objects). Finally, because these models assume a fixed orientation for each symmetry-detection attempt, and require exact symmetry, they have difficulty detecting even minor deviations from the assumed set of orientations (e.g., symmetry at a 38° angle).

A clue to resolving this quandary may be found in recent evidence that perceptual relations, such as connectivity relations and boundary characteristics, play a role in symmetry detection. Baylis and Driver (1994) provide evidence that symmetry detection in polygons may depend in part on curvature minima along figure boundaries. Ferguson, Aminoff & Gentner (1996) showed that specific qualitative differences, such as concavity or number-of-vertices mismatches, contributes to the speed and accuracy of symmetry judgments. Wagemans' bootstrap model (Wagemans et al., 1991) uses sets of conjoined "virtual quadrilaterals" to add higher-order structure to symmetric dot patterns, allowing the model to detect skewed symmetry.

If perceptual relations play a role in symmetry detection, they may be linked to orientation effects. Some have suggested (Goldmeier, 1936/1972; Rock, 1983) that the preference for vertical symmetry may be rooted in the phenomenological reversibility (or commutativity) of left-right spatial relations, which is not true of above-below relations. In other words, the preference for vertical symmetry is a product of how spatial relations, rather than symmetry-detection processes, depend on visual orientation. For our purposes, we term this the *horizontal commutativity conjecture*.

In this paper, we use MAGI (Ferguson, 1994; in preparation), our model of symmetry detection, to show why and how the horizontal commutativity conjecture may be true. The resulting explanation avoids at least three problematic assumptions of previous models: 1) that the symmetry detection process must use a set of fixed orientations; 2) that symmetry must be exact; or 3) that symmetry-detection is retinocentric.

This paper is arranged as follows. First, we briefly describe the MAGI model. Then, MAGI is used to explain the preference for vertical symmetry and the effect for intrinsic axes. We then perform an in-depth simulation of a classic study of the orientation effects for multiple and near symmetries (Palmer & Hemenway, 1978). We conclude by discussing the implications of these results, the model's limitations, and possible future research.

### The MAGI model of symmetry detection

The basis of the MAGI model (Figure 1) is that *symmetry is like analogy*. Specifically, symmetry may use the same cognitive processes found within other analogical reasoning such as analogy, similarity and memory access. As a result, symmetry may share the flexibility and domain-generalizability found in these other kinds of analogical reasoning.

MAGI models symmetry detection within the framework of structure mapping. MAGI creates a within-description mapping using the constraints of Structure Mapping Theory (Gentner, 1983) to align similar sets of relational structure. In other forms of analogical reasoning, such as similarity comparison and analogy, the mapping process aligns relations in base and target descriptions. In MAGI's symmetry detection, mapping is performed over a single relational description. MAGI also uses additional mapping constraints to maximize the self-similarity of the mapped portions.

For visual figures<sup>1</sup>, MAGI works directly from a vector-based line drawing. To obtain a description of the visual relations in the drawing, MAGI uses GeoRep (Ferguson & Forbus, 2000), a spatial representation engine. GeoRep represents visual relations detected early in perception, including element connectivity (such as corners and intersections), parallel elements, horizontally- and vertically-oriented structure, and protrusions and indentations in the figure boundary. MAGI then performs a self-similarity mapping over this relational description (Figure 1 shows an example of GeoRep's representation and MAGI's mapping).

MAGI's algorithm (see Ferguson, 1994, in preparation) is very similar to the Structure Mapping Engine (SME; Falkenhainer, Forbus, & Gentner, 1989; Forbus, Ferguson & Gentner, 1994). MAGI's self-similarity mappings are created using a local-to-global mapping process that enforces a set of six mapping constraints. Four of these constraints are adopted from SME: 1) the *tiered identity* constraint, which allows only expressions with identical predicates to align; 2) the *one-to-one mapping* constraint; 3) the *parallel*

---

<sup>1</sup> MAGI can also be used on non-visual stimuli, such as story narratives (Ferguson, 1994) or diagrams containing conceptual as well as visual regularity (Ferguson & Forbus, 1998). However, here we concentrate on visual symmetry alone.

*connectivity constraint*, which mandates that any aligned expression must also align its arguments; and 4) the *systematicity constraint*, which prefers large interconnected mappings with deep relational structure to smaller or unconnected mappings.

MAGI's final two constraints are specific to symmetry detection. The *limited self-matching* constraint states that an expression or entity may map to itself (i.e., self-match) only when it is the argument of an expression that is not a self-match. In Figure 1, this allows entity L1 to map to itself, because two separate *mid-connect* expressions involving L1 are aligned. The *maximal individuation* constraint encourages mappings that maximize the interconnectivity of each of the two mapped parts, and minimize the interconnectivity of the mapped parts with one another. In Figure 1, this constraint distributes the mapped *mid-connect* expressions to provide maximum entity overlap with other mapped expressions, such as the mapped *protrusion* expressions.

These constraints, as enforced by MAGI, produce one or more symmetry mappings. Each mapping contains a set of aligned entities and expressions and a systematicity score.

In MAGI, as in SME, systematicity is measured using a "trickle-down" structural evaluation mechanism (Forbus & Gentner, 1989). This mechanism gives higher scores to deeper expression matches and to matched entities with many matched superexpressions. For MAGI, this score is an approximate measure of "how symmetric" an object seems. For example, visualize a square and the X-shaped figure from Figure 1. Both figures have perfect geometric symmetry, but to MAGI, the X-shaped figure will have higher systematicity than the square because mapped expressions in the former are deeper and more interconnected than in the latter. Similar effects could be found even if we controlled for equivalent figure size and the number of segments.

A mapping also produces candidate inferences (as in SME) by carrying over unmapped structure that intersects mapped structure. Candidate inferences often indicate qualitative differences between the sides of the figure.

Once MAGI has found a self-similarity mapping, it uses the set of aligned entities to determine the axis. Using a Hough transform voting algorithm (Duda & Hart, 1987), MAGI produces either an axis or an object-centered reference frame for the mapping.

The nature of analogical mapping provides MAGI with a number of useful characteristics not found in other symmetry models. MAGI's symmetry detection is extremely

robust in the face of minor asymmetries and distracters. Symmetry mappings can also indicate qualitative differences between otherwise symmetric figures by producing candidate inferences. Finally, MAGI can link perceptual and conceptual symmetries in diagrams (Ferguson & Forbus, 1998), showing how self-similarity is utilized in perceptual reasoning tasks.

## Modeling the preference for vertical symmetry and intrinsic axes

Using the MAGI model, it is possible to test the horizontal commutativity conjecture. We begin by assuming that some visual relations are *orientation-dependent* (such as the *above* relations highlighted in Figure 2-A). Along with having orientation-dependent relations, we also can assume that vertically-oriented visual relations are directed, while horizontally-oriented relations are commutative. There is substantial evidence of just this dichotomy in human visual processing (Rock 1983). Humans often confuse left and right, but seldom confuse up and down.

Now we can see how mapping relational structure affects the produced mapping. Given (A), MAGI produces a vertical symmetry mapping. The vertical mapping is due to the alignment of many orientation-dependent visual relations, including the *above* relations. When the figure is rotated 45° (B) and then remapped, the set of orientation-dependent relations changes with it, and this affects the elements that MAGI aligns. Even though all the visual elements have moved relative to (A), MAGI's mapping of (B) is also vertical due to this new set of orientation-dependent relations. In other words, MAGI exhibits a preference for vertical symmetry.

Note that orientation-dependent visual relations do not dictate the mapping MAGI produces. Orientation-dependent relations are only part of the set of visual relations for any given figure, and for that reason, figures with sufficient visual structure can be mapped at many different orientations.

This explains why some figures may have good intrinsic axes that eliminate the preference for vertical symmetry. Figure 2-C shows MAGI's mapping of one of Wiser's (1981) example figures. Because the visual structure of this figure is distinctive enough to produce a symmetry mapping without orientation-dependent relations, this figure produces an axis at almost any orientation.

## How symmetry can adjust the frame of reference

This demonstration, however, only partially answers questions about the nature of orientation effects. If this model is correct, then how does the visual system detect symmetry in figures that neither have a good intrinsic axis nor are oriented vertically? Does the system have to try many different orientations, either serially or in parallel?

No, it doesn't. Instead, MAGI can use the initial partial mapping of a figure to find a potential new reference frame, and then shift the frame of reference to obtain a new representation of the figure. With this new representation, it can then reconstruct the symmetry of the figure as if it was presented in a vertical orientation.

Figure 2: How orientation-dependent relations affect MAGI's symmetry mapping. Vertically-oriented relations in A and B enforce different mappings, even though the figures are identical. The preference for vertical symmetry can be overcome if there is sufficient structure when orientation-dependent relations are absent, as in (C), redrawn from Wiser (1981).

Figure 3: How a partially-correct mapping may guide reference frame re-orientation. The mapping for A, produced with a gravitational reference frame, is partially correct but contains errors (dotted lines) and has low systematicity. Still, it suggests a new reference frame at  $-45^\circ$  degrees. When that new reference frame is adopted, the richer relational description produces the correct correspondences and has much greater systematicity.

Figure 3 shows how this may occur. In the original figure (A), the mapping created by MAGI is only partial, and the resulting mapping has low systematicity and some incorrect correspondences. This is because the figure has insufficient visual structure to produce the correct mapping at this orientation (i.e., it does not have a good intrinsic axis). However, this partial mapping is sufficient to produce a potential new orientation for the figure, based on the parts of the mapping that do correspond. When the reference frame for the figure is set at this new orientation (B), the figure can be mapped as if it were at the vertical orientation, producing a richer set of orientation-dependent relations, and an axis is produced. In other words, the partial symmetry mapping tells the system to "tilt its head," and when it does so, it is rewarded by a set of visual relations that lead to a much richer symmetry mapping.

Although we do not yet have a theory of what mapping characteristics lead the viewer to re-orient the visual reference frame given a partial mapping (it may depend on several factors, including the task demands), clearly it is possible for the viewer to shift the reference frame using these clues. As a result, it is possible to see symmetry at an angle without presuming that the symmetry detection process must choose a set of orientations beforehand. One possible characteristic allowing a reference frame shift might be the systematicity of the initial mapping, a factor we return to in the next section.

### A Simulation in Depth

We now show the results of a simulation of an experiment (Palmer and Hemenway, 1978) testing both the preference for vertical symmetry and the effect of multiple symmetries.

Palmer and Hemenway's study used a set of 30 stimuli (Figure 4). The figures are 16-gons, containing five different symmetry types: single, double, and quadruple symmetry, rotational symmetry, and near symmetry. These figures were displayed at four different orientations: tilted left ( $-45^\circ$ ), vertical ( $0^\circ$ ), tilted right ( $+45^\circ$ ), and horizontal ( $+90^\circ$ ). In the first experiment, subjects had to judge whether the stimulus was mirror symmetric (requiring negative responses for rotational and near symmetry). Response latency and accuracy were measured.

F					

Figure 4: The stimuli used in Simulation 1 (redrawn from Palmer and Hemenway, 1978) arranged by symmetry type.

Figure 5: Palmer & Hemenway Experiment 1 results. Graph shows response time latency at four symmetry orientations. Redrawn from Palmer & Hemenway.

Figure 6: Results of simulating Experiment 1 using MAGI. Graph shows average systematicity score of each figure's best mapping (the Y-axis is inverted for easier comparison to Figure 5). Aside from the rotational symmetry results, MAGI duplicates the experimental results, with consistently higher systematicity scores for figures more quickly detected by human subjects.

Palmer and Hemenway's results (Figure 5) show a clear preference for vertical symmetry, with vertical better than horizontal, and horizontal better than diagonal (Figure 5 shows response latencies – accuracy results were similar). An effect was also found for multiple symmetries, with quadruple better than double, and double better than single symmetry.

For our simulation, the study's 30 stimulus figures were given to MAGI as line drawings. Each figure was presented at up to four orientations, as in the original study. We then used the systematicity score of MAGI's top mapping as a measure of the strength of the relational symmetry.

The results from MAGI are shown in Figure 6. With the exception of rotational symmetry, the results closely mirror those of Palmer and Hemenway, with vertical symmetry having the highest systematicity score, followed by horizontal symmetry and diagonal symmetry. Notably, these effects are reproduced separately for double, single, and near symmetries, as in the original study. MAGI's results also reproduce the effect for multiple symmetries, with quadruple symmetry producing the highest systematicity scores, followed by double symmetry, and then single and near symmetries. These latter two symmetry types produce roughly equal results, as in the original experiment.

The one difference between the two graphs are the results for rotational symmetry. For both MAGI and humans, rotational symmetry results varied only slightly with respect to orientation. However, while rotational figures showed the worst latencies for humans, the systematicity scores MAGI produced are average relative to the other symmetry types. One explanation for this difference, as noted in Palmer and Hemenway's analysis, is that in the original experiments subjects were to accept only mirror-symmetric figures, and thus had to reject rotationally symmetric figures. This means that the high latencies in the original experiment may not be due to a low sense of the figures' symmetry, but because subjects' needed to avoid that sense to produce a negative response. MAGI was not constrained to judge only mirror symmetry, and so frequently found rotational mappings.

We briefly note a second result. In a second experiment, Palmer and Hemenway showed subjects the same 30 figures solely in the vertical orientation, meaning that subjects no longer had to look for symmetry at multiple orientations. This had the effect of greatly decreasing the average response latencies (from a mean of 2626 ms. to 1111 ms.). While accuracy and response time results for quadruple, double, and single symmetry maintained their previous ordering, the error rate for near symmetry shot up from 1.4% to 16.7% from the first to the second experiment, an error rate more than twice the rate for any other symmetry type, while the error rate for rotational symmetry decreased.

The MAGI model suggests a possible explanation. Because the experiment's demand characteristics reduced response time, and because only vertical symmetry was used, it would no longer be necessary to consider partial mappings as indicators of alternative symmetry orientations. Simpler factors, such as the lack of candidate inferences (indicating qualitative asymmetry) might suffice. This strategy is not problematic for quadruple, double, or single symmetries, since exact symmetries do not produce

candidate inferences. Nor is it a problem for rotational symmetries, which always produce candidate inferences. However, near-symmetric figures produce few or no candidate inferences in MAGI. When MAGI was run on the near-symmetric figures, each figure only produced a few candidate inferences and one (in Figure 4's row E) produced none. The relative scarcity of candidates inferences may have made asymmetry detection difficult for near-symmetric figures and lead to subjects' high error rate.

## Conclusion

These results demonstrate that a structure-mapping model of symmetry detection can concisely explain orientation effects using a few simple assumptions: 1) that visual structure is at least partially orientation-dependent; 2) symmetry detection is performed by mapping visual structure; and 3) partial mappings are used to find potential mappings and suggest alternate frames of reference. Using this simple model, we simulated the preference for vertical symmetry, showing that the preference for vertical over horizontal symmetry, and for both over diagonal symmetry, was not the result of a pre-established list of potential orientations, but the natural result of a visual system where vertically-oriented relations are phenomenological different than horizontally-oriented relations (the horizontal commutativity conjecture). Similarly, we showed that the preference for multiple symmetries could be modeled with the same assumptions. We showed the correctness of this model by running it on the stimuli of Palmer & Hemenway (1978), which tested both of these effects, and MAGI reproduced the same general pattern of results. Finally, we showed why some figures with good "intrinsic axes" (Palmer, 1983; Wisner, 1981) do not show the same preference for vertical symmetry (an explanation currently beyond the capabilities of other models of symmetry detection). This defined conditions when the sense of symmetry is strong enough to overcome effects of orientation. These collective results suggest that a structure-mapping model of symmetry detection, such as MAGI, could provide a better analysis of a wide variety of symmetry-related phenomena.

There are several limitations with the current model, however. Because the relational mapping depends on the visual relations found in the figure, representation assumptions can drastically change MAGI's results. In the current study, we have attempted to minimize this effect by using GeoRep's default representation engine, which builds a set of relations based on the visual relations assumed to be built by Ullman's universal visual routines (Ullman, 1984). However, further research is needed to test the reliability of these assumptions. MAGI's dependence on spatial relations leaves open the question of exactly when quantitative differences (such as small differences in the angles of corresponding corners) are detected. When such differences exist, but these differences are not qualitative, MAGI does not detect them. Other limitations of GeoRep and MAGI precluded other possible simulations. Because GeoRep does not have a model of grouping, it was not possible to model orientation effects based on grouped items (Palmer, 1983).

This research also creates interesting new questions. The effect for multiple symmetries bears closer analysis. Initial results suggest that the effect is a result of the greater number of visual relations found in figures with multiple symmetries, as well as the greater systematicity of systems with many similar subparts. However, this result should be tested in another domain.

### Acknowledgments

This research was supported by the Cognitive Science and Computer Science programs of the Office of Naval Research, by DARPA's High-Performance Knowledge Bases initiative, and by the National Science Foundation under the Learning and Intelligent Systems program. ### Abstract

Our goal was to examine the plasticity of the human visual system at mid to high levels of visual processing. It is well understood that early stages of visual processing contain cells tuned for spatial frequency and orientation. However images of real-world objects contain a wide range of spatial frequencies and orientations. We were interested in how different spatial frequencies and orientations are combined. We used a pattern discrimination task - observers were asked to discriminate small changes in a “wicker-like” stimulus consisting of six superimposed sinusoidal gratings. Observers were asked to discriminate a 15% spatial frequency shift in two of these sinusoidal components, which were masked by four noise components. We found large amounts of perceptual learning for this task – over eight sessions of training observers’ average percent correct increased by 31%, corresponding to their thresholds dropping to a third of their initial values. Further experiments suggest that learning was based on changes within a mid level stage of processing intermediate between low-level analyzers tuned for orientation and spatial frequency and high-level pattern matching or object tuned cells. This mid level stage seems to be “very roughly Fourier” and combines information from individual gratings using probability summation. This stage of processing is also remarkably plastic compared to earlier stages of processing.

### Introduction

A great deal is known about low level visual pattern analyzers and their role in visual perception. At early stages of processing retinal input is represented by low level analyzers tuned for spatial frequency and orientation with receptive fields of limited spatial extent - properties very similar to simple cells in V1 (see Graham, 1989 for a review). However images of real-world objects contain a wide range of Fourier components, and therefore the combination of information across these low level analyzers is necessary to reliably recognize objects. Evidence suggests that there may be mid level mechanisms selectively pooling information across low level analyzers tuned for a wide range of spatial frequencies or orientations (e.g. Georgeson, 1992; Derrington & Henning, 1989; Burr & Morrone, 1994; Graham & Sutter, 1998; Olzak & Thomas, 1999).

It has been argued that relatively early stages of the visual system (V1) change with training (e.g. Ball & Sekuler, 1987; Fahle & Edelman, 1992; Sagi & Tanne,

1994; Ahissar & Hochstein, 1995,1996; Saarinen & Levi, 1995; Fahle & Morgan, 1996; Schoups & Orban, 1995). In addition, some learning effects have been noted (Olzak, personal communication, 1995; Fiorentini & Berardi, 1981) for tasks involving compound grating discriminations thought to involve mid level mechanisms.

The following experiments provide support for the existence of mid-level mechanisms pooling over analyzers tuned for spatial frequency and orientation. These mid level mechanisms are shown to be far more adaptable as a function of experience than low level analyzers.

### Experiment 1

The purpose of Experiment 1 was to measure learning for a complex “wicker” stimulus that required observers to combine information over a wide range of spatial frequencies and orientations.

### Methods

Figure 1: Diagram of the task used in the experiment.

Five observers were asked to perform a four alternative forced choice discrimination task (Figure 1). Four stimuli were presented sequentially in time. A two-dimensional white noise pattern was presented after each stimulus to reduce afterimage interference. Observers were asked to

indicate which of the four stimuli was different from the others using a key press. There are two important advantages of this four alternative forced choice procedure. First, the chance success rate was 25%, thereby providing more information per trial than a two alternative forced choice task. Second, such a task allows a same-different judgment without potential criterion effects (observers showing a bias towards responding same or different). The task was carried out using free-fixation. Observers were given auditory feedback and were self paced. Observers completed eight sessions, and completed 250 trials per session. Observers never carried out more than a single session in a day, and carried out three to five sessions a week.

Figure 2: Panel A. Illustration of a typical stimulus. Panel B. Fourier representation of stimuli. The radius represents spatial frequency and the angle represents orientation. One signal component had a spatial frequency of 2.55 or 3.45 cycles/degree, an orientation of  $-45^\circ$  and contrasts varying between 1.6-12.8%. The other signal component had a spatial frequency of 7.65 or 10.35 cycles/degree, an orientation of  $45^\circ$  and contrasts varying between 5.5-44%. There were four sinusoidal noise components, represented by empty circles: 1) spatial frequency of 9 cycles/degree,  $-45^\circ$  orientation, 11% contrast 2) spatial frequency of 3 cycles/degree,  $45^\circ$  orientation, 3.2% contrast 3) spatial frequency of 4.3 cycles/degree,  $0^\circ$  orientation, 7.1% contrast 4) spatial frequency of 6.2 cycles/degree,  $0^\circ$  orientation, 7.1% contrast.

Figure 2 Panel A shows what a typical stimulus looked like. Each stimulus contained two signal compo-

nents and four sinusoidal noise components. Figure 2, Panel B represents the stimuli in Fourier space using polar coordinates. The radius represents spatial frequency and the angle represents orientation. The black filled circles represent the two possible signal components. These signal components were widely separated in orientation (at least  $90^\circ$  to each other) and widely separated in spatial frequency (approximately two octaves apart). One signal component was centered on 3 cycles/degree and had an orientation of  $-45^\circ$  and the other signal component was centered on 9 cycles/degree and had an orientation of  $45^\circ$ . Observers were asked to detect a 15% shift in the spatial frequency of the signal components, represented by the black arrows. The contrasts of the signal components were manipulated (based on pilot data) so each observer was presented with a range of difficulty levels. The empty circles in Figure 2 represent the four sinusoidal noise components that were added to the stimulus.

Stimuli were modulated spatially by a two dimensional Gaussian envelope with a sigma of 0.5693 degrees and temporally by a Gaussian envelope of sigma 0.237 seconds centered within a 0.67 second temporal window. The phases of the sinusoidal noise components were varied randomly across each interval of each trial. The phases of the signal components were varied randomly between each trial, and remained constant across the four intervals within each trial. Stimuli were presented using the VideoToolbox and Psychophysics Toolbox extensions (Brainard, 1997; Pelli, 1997).

Observers were undergraduate or graduate students from the University of Rochester, varying in age between 19-28 years of age. Observers had normal or corrected to normal vision. Further details of this experimental procedure are described in Fine & Jacobs (2000).

## Results and Conclusions

The black squares in Figure 3 show the percent correct as a function of session averaged across observers in Experiment 1 (black squares). All five observers showed a significant improvement in their performance over eight sessions. Observers' average percent correct increased by 31%, corresponding to a two-third decrease in their thresholds.

Most perceptual learning studies have been carried out using simple stimuli (grating discrimination or Vernier tasks). Learning effects for these low level tasks tend to be small or non-existent in the fovea (e.g. Fiorentini and Berardy, 1981, Beard, Levi and Reich, 1995). In contrast, we found large learning effects in the fovea, suggesting strongly that our task is mediated by a higher stage of processing than more simple tasks, and that this stage of processing is far more plastic than earlier stages.

These improvements in performance with practice were relatively long lasting, none of the observers showed any

decline in performance when retested more than a month after training.

It is worth noting that observers showed faster improvement for easier stimuli than for more difficult stimuli, suggesting possible bootstrapping from easy to difficult stimuli (Ahissar & Hochstein, 1997).

Figure 3: Percent correct as a function of session averaged across observers with the sinusoidal noise components (Experiment 1 - black squares) and without the noise components (Experiment 2 - empty circles). The x-axis shows the session and the y-axis shows the percent correct. Standard error bars are shown.

## Experiment 2

The extent of learning found in Experiment 1 suggests that performance in our task might be mediated by a mid level stage of processing rather than earlier stages. Experiment 2 was designed to exclude the possibilities that the learning found in Experiment 1 was due either to learning in low level mechanisms, or to improved non-visual cognitive strategies (such as learning the key press procedure, learning to fixate, learning the temporal structure of the task, etc.).

If the learning demonstrated in Experiment 1 was due to tuning changes within low level analyzers tuned for both spatial frequency and orientation then removing the sinusoidal noise components would not affect the amount of learning shown. The sinusoidal noise components in Experiment 1 were positioned so as to be invisible to

analyzers tuned for the spatial frequency and orientation of the signal components (see Figure 2, Panel B) - every noise component differed from the signal components by at least 45 degrees of orientation or almost two octaves of spatial frequency. Estimates of the tuning of low level analyzers by other authors predict little low level masking between sinusoidal components separated by either two octaves of spatial frequency or 45 degrees orientation (Graham, 1989).

If the learning in Experiment 1 was due to non-visual cognitive strategies then we would expect an equal amount of learning in Experiments 1 and 2 - the only difference between the two experiments was in the visual stimulus.

## Methods

Display and task were identical to those used in Experiment 1. Only the stimulus differed in Experiment 2, in that the sinusoidal noise components (the empty circles of Figure 2) were no longer present - i.e. observers were asked to discriminate changes in spatial frequency within a simple plaid pattern.

Without the noise components the task would be trivially easy for the contrast levels and spatial frequency shifts used in Experiment 1. The difficulty of the task was adjusted by reducing the spatial frequency shift to between  $\pm 2.5\%$  and  $\pm 12.5\%$  (as opposed to 15% in Experiment 1) to avoid ceiling effects.

Three observers were given six sessions of training on the task.

## Results and Conclusions

As shown by the empty circles in Figure 3, observers showed much less learning without the sinusoidal noise components. Observers showed some learning between sessions 1 and 2, but little learning after the second day. There was no significant drop in threshold across the three observers.

Differences in the amount of learning between Experiment 1 and 2 cannot be explained by ceiling effects. Initial performance was closely matched for the majority of subjects. In Experiment 1 three of the five observers in performed between 50-60% correct in the first session. In Experiment 2 two of the three observers performed between 50-60% correct in the first session. In addition, none of the observers' performance reached 90% correct by the end of training in either experiment.

There was some learning ( $\sim 7\%$ ) between the first and second day in both Experiment 1 and Experiment 2. Given that we used naïve observers we think it likely that these learning effects are mainly due to non-visual factors - learning the key press procedure etc. However an alternative possibility is that this learning between the first and second day was due to learning in low level analyzers.

In any case, most of the learning shown in Experiment 1 was *after* the second session and cannot be due either to learning in low level analyzers or to learning better non-visual cognitive strategies.

### Experiment 3

We were interested in how observers might be combining information from the two signal components. We have found that observers' performance in Experiment 1 can be well described using an independent probability summation model where observers correctly discriminate the "odd man out" if they detect a shift in either component (Fine & Jacobs, 2000). Experiment 3 was designed to further test whether observers' ability to combine information could be reasonably approximated using an independent probability summation model.

Other possible combination models include non-independent combination of information from the two signal components (as suggested by Olzak and Thomas, 1999) or some type of "pattern" or "template" matching.

The task carried out in Experiment 1 can be subdivided into two tasks, as shown in Figure 4. In the *same sign* task the "odd man out" was distinguished from the distracting stimuli by both signal components being shifted in the same direction in Fourier space. In half the trials both signal components were shifted higher in spatial frequency, as shown in Figure 4 Panel A. In the other half of the trials both signal components were shifted lower in spatial frequency.

In the *opposite sign* task the "odd man out" was distinguished from the distracting stimuli by both signal components being shifted in opposite directions in Fourier space. In half the trials the high spatial frequency component was shifted higher in spatial frequency, and the low spatial frequency component was shifted lower. In the other half of the trials, as shown in Figure 4 Panel B, the high spatial frequency component was shifted lower in spatial frequency, and the low spatial frequency component was shifted higher.

Independent probability summation implies that detecting a shift in the low spatial frequency signal component is unaffected by the direction of the shift in the high spatial frequency signal component, and vice versa. Any relationship between the directions of the spatial frequency shifts within the two signal components would be invisible to such a mechanism. Consequently, according to an independent probability summation model we would expect perfect transfer of learning from same sign to opposite sign tasks.

According to most non-independent models, including pattern matching, one would expect incomplete transfer between the two stimuli.

### Methods

Display and task were identical to those used in Experiment 1, however observers were either exclusively trained with same sign stimuli, then tested with opposite sign stimuli, or were trained with opposite sign stimuli, then tested with same sign stimuli. Four observers were tested in all, two were trained with same sign stimuli and two were trained with opposite sign stimuli. Observers were given six sessions of training before being tested with the novel stimuli.

Figure 4: Polar plot of the stimuli used for the transfer of task experiment. Panel A shows the same sign shift stimulus and Panel B shows the opposite sign shift stimulus.

### Results and Conclusions

None of the four observers showed any drop in performance when tested with the novel stimulus. Interestingly only one of the four observers even noticed that the stimulus had changed. This perfect transfer of learning between same and opposite sign tasks is consistent with observers combining information independently, and is incompatible with most non-independent models (Olzak & Thomas, 1999), including pattern matching.

Interestingly, the shift in the signal components in the same sign task is compatible with a change of scale (as if both signal components moved closer or further away from the observer), while the shift in the signal components in the opposite sign task is compatible with a change in shape. The total transfer of learning between the two tasks suggests that "scale-invariance" may not yet be differentially encoded at this stage of processing.

### General Conclusions

Our data support the existence of a mid level stage of processing intermediate between low and high levels of visual processing. This level of processing seems to be

“very roughly Fourier” in that it still represents stimuli in terms of their spatial frequency and orientation. Information from low level analyzers tuned for spatial frequency and orientation seems to be combined using probability summation. This stage may be responsible for beginning to selectively process information, extracting the combinations of spatial frequency and orientation that define meaningful objects. As our knowledge of the mechanisms underlying mid level visual tasks increases it should be possible to ask increasingly refined questions about the role of these mid level mechanisms, and in particular, the role adaptability plays in allowing such mechanisms to represent an unpredictable world. Interestingly, our studies show that this mid level stage of processing seems to be far more plastic than earlier stages.

As cells become more specific in what they represent, an increasing number of cells become necessary if all possible stimuli are to be represented. This is the paradox of the “grandmother cell” – not every possible object can have its own feature detectors in the brain without a prohibitive number of cells. Despite this apparent paradox, cells in the brain have been shown to be remarkably specific (e.g. Desimone, Albright, Gross, & Bruce, 1984; Logothetis, Pauls, Poggio, 1995). Neural plasticity may be a way of alleviating the trade-off between cell specificity and limited cell numbers. By dynamically changing neural representations as a function of experience cells can be preferentially allocated to represent behaviorally important stimuli. If this is the case, then we should find an intimate relationship between plasticity and specificity - as representations become more selective, they should also become more plastic.

### Acknowledgments

This work was supported by NIH grants R29-MH54770, P30-EY01319 and EY 01711. We would like to thank R. Aslin, G. Boynton, K. Dobkins, N. Graham, D. MacLeod, W. Makous, L. Olzak and two anonymous reviewers for their advice and comments, and E. Bero, L. O’Brian, A. Pauls and M. Saran for help conducting the experiments.

# Decoding Syntactic Parameters: The Superparser as Oracle

**Janet Dean Fodor (jfodor@gc.cuny.edu)**

## Abstract

Syntactic parameter setting has proven extremely difficult to model. The original 'switch-setting' metaphor failed because parametrically relevant properties of a natural language sentence cannot be recognized without considerable structural analysis. The result has been a move to trial-and-error learners which attempt to guess a grammar that can analyze (parse) the current input sentence. But standard variants of grammar guessing are wasteful of the parametric information in input sentences because they use it only as feedback after a candidate grammar has been chosen. We show here that performance is significantly improved by a 'superparsing' routine which constructs a candidate grammar on-line in response to the properties of the input sentence. No sentences then need to be discarded for lack of a grammar to parse them. The gain in learning speed can be quantified in terms of the average number of sentences required for convergence. Superparsing can be achieved by the normal sentence parsing routines, applying a grammar that incorporates all possible parameter values. The superparsing learner is robust and imposes no special demands on the input.

## Natural Language Acquisition

Children exposed to a sample of sentences from a natural language acquire its grammar in a few years. There is as yet no computational model of the acquisition process that is both effective and psychologically realistic. The conception of the learner's task was greatly simplified with the advent of parameter theory (Chomsky, 1981, 1995) under which a natural language grammar consists of an innate component (Universal Grammar, UG) and a selection from among a finite set of properties by which languages can differ (the parameters). Depending on the particular linguistic theory assumed, a parameter might be a choice between grammar rules, or between the presence or absence of a rule in the grammar. But as developed in the Chomskyan framework a parameter specifies a more abstract property of grammatical derivations, such as the direction of case assignment by a verb, or the derivational level at which a universal constraint applies, or, in more recent versions, the 'strength' of a syntactic feature on a tree node. The learner's task is to select the correct setting for each relevant parameter, i.e., each parameter whose value contributes to the derivation of at least one sentence of the target language. Though the concept is simple, the task is more challenging than was originally appreciated.

The earliest idea was that some property of an input sentence would trigger the correct setting of each parametric switch. But the needed property detectors could not be devised, because the characteristic properties of sentences derived by means of some parameter value  $v$  (inter alia) are

not sufficiently uniform and superficially identifiable (Clark, 1994; Gibson & Wexler, 1994). To find the abstract properties that identify  $v$ , the derivation of the sentence must be computed, i.e., the sentence must be parsed. But parsing is work, and the computational workload of a learner must be kept within psychologically plausible limits. The problem is that when the parser lacks the correct grammar, as it does by definition in a learning event, it must apparently try out multiple grammars until it finds a successful one. Even though the number of parameters is limited, there are too many possible grammars for it to be feasible for a learner to try them all on a single sentence, either serially or in parallel.

This is where current learning models diverge. Some test one grammar per sentence (e.g. Gibson & Wexler, 1994, henceforth GW94) and are very slow to converge on the correct grammar. Others test batches of grammars at a time (e.g. Clark, 1992; Nyberg, 1992) and thereby go beyond what it is plausible to suppose a child is capable of. In this paper we discuss a novel way to use the parser to decode the parameter values that license an input sentence, without undue use of resources (Fodor, 1998a). We provide here a quantitative assessment of the substantial increase in learning speed that this model permits compared with traditional grammar guessing models.

## A Simple Model of Grammar Selection

A learning event begins with the learner receiving a novel input sentence  $s$ , a sentence of the target language not licensed by the learner's current grammar  $G_c$ .  $G_c$  may have some parameters set to correct values, but it also has one or more set to incorrect values or not set at all. The learner first attempts to parse  $s$  with  $G_c$ . If the parse were successful, no change would be made to  $G_c$ ; this is error-driven learning (Gold, 1967). Since by hypothesis  $G_c$  does not license  $s$ , this parse attempt fails, and the learning device seeks an alternative grammar. To preserve psychological plausibility we will make the strong assumption here that only one more parsing attempt may be made on this same input. Hence, the task of finding a new grammar that does license  $s$  must be achieved by means of just one parse. If it is not,  $s$  must be discarded and learning must await further input. Each such discard increases the total number of inputs needed before the target grammar is attained, and hence decreases the speed of learning and increases the effort expended. It is important, therefore, for the learner to make good use of the one parse test of a new grammar that it is able to conduct.

However, standard grammar guessing procedures extract only minimal information from their interrogation of the input. Because of the single-parse restriction, just one

grammar must be selected to undergo the parse test, and this selection must of necessity be made *prior* to parsing. The success or failure of this parse attempt with the hypothesized grammar,  $G_h$ , provides feedback on the basis of which the learner decides whether or not to adopt  $G_h$ .<sup>1</sup> If the parse is successful the learner will adopt  $G_h$ ; if the parse fails the learner is assumed to retain  $G_c$ . This policy of shifting to a new grammar only if it licenses the current input is the **Greediness** constraint of GW94 and others. If  $G_h$  happens to be the target grammar, it will be retained permanently and learning is complete. A grammar is correct for the target language if it has the target value for each parameter relevant to the language. If some parameters are irrelevant to the target language there will be an equivalence class of correct parameters. For convenience in what follows we will refer to these grammars collectively as 'the target grammar',  $G_t$ .

### Assessing Grammar Selection Efficiency

A simple random choice learning model such as this will demonstrably converge on the target grammar (Berwick & Niyogi, 1996). However, learning is slow largely because the learning component bases its actions on the mere fact that some randomly chosen  $G_h$  does, or does not, license  $s$ . We will show that learning could be substantially faster if instead the parser could reliably identify for the learner a grammar that licenses  $s$ . For the present let us suppose that this information is provided to the learner by an oracle. Later we will show how this oracle can be implemented.

Given  $G_c \neq G_t$ , what is the probability that the learner will shift to  $G_t$  as a result of an encounter with an arbitrary input sentence  $s$ ? At the point where  $G_c$  is rejected, the random choice learner (without oracle) picks an alternative from among the set of all possible grammars, of which there are  $2^n$  for  $n$  binary parameters. (For simplicity we treat  $G_c$  as a candidate grammar even though it has just failed.) Of these,  $2^i$  are correct (are in the equivalence class  $G_i$ ) where  $i$  = the number of parameters irrelevant to the target language  $e$ . Thus the probability that the learner's selected  $G_h$  is  $G_t = 2^i/2^n$ . Observe that this is not sensitive if  $s$  uniquely determines every parameter value in the target grammar, the learner has no more chance of guessing correctly than if  $s$  is fully ambiguous. This is because, as noted, this learner must make its selection *before* testing out the selected grammar on  $s$ , and so it cannot restrict its guesses to grammars which license  $s$ .

Imagine now that this learning device is equipped with an oracle which offers the learner a grammar that licenses  $s$  (any one of the grammars in the domain that do so). Then the learner could take this grammar to be  $G_h$ , and avoid wasting attention on any grammar that does not license  $s$ . Let us say that a learning device which considers only grammars that

license the current input meets the **Licensing** condition.<sup>2</sup> For a learner that satisfies Licensing, the chance of hypothesizing  $G_t$  would be  $1/A$ , where  $A$  is the degree of ambiguity of  $s$ , measured as the number of grammars in the domain that license  $s$  divided by  $2^i$  (the irrelevance factor). Clearly this is responsive to how informative the language sample is. For extremely ambiguous input ( $A$  approaching  $2^{n-i}$ ), the success rate is hardly better than without the oracle. But if  $s$  is unambiguous with respect to even one relevant parameter, the probability of a successful guess is increased.

This shows up in the speed of learning, estimated in terms of the number of inputs required, on average, to arrive at  $G_t$ . This is the reciprocal of the probability of a successful guess.<sup>3</sup> For the oracle learner this is  $A$ ; for the random guess learner, it is  $2^{n-i}$ . Table 1 shows the differences in average number of inputs consumed for various values of  $A$  and numbers of relevant parameters ( $= 2^{n-i}-A$ ). On average, performance is improved by a factor of  $(2^{n-i}-A)/2^{n-i}$ . The oracle learner, unlike the random choice learner, benefits to the extent that the input constrains the set of candidate grammars.

Table 1  
Reduction due to oracle in average inputs to convergence

Avg. A	Number of parameters relevant to $G_t$ ( $=n-i$ )				
	10	15	20	25	30
1	1023	32,767	1,048,575	33,554,431	1,073,741,823
10	1014	32,758	1,048,566	33,554,332	1,073,741,822
100	924	32,668	1,048,476	33,554,422	1,073,741,724
1000	24	31,768	1,047,576	33,553,432	1,073,740,824
1 million	-	-	48,576	32,554,432	1,072,741,824
1 billion	-	-	-	-	73,741,824

The values of  $A$  range from 1 to  $2^a$ , where  $a$  is the number of parameters relevant to  $G_t$  whose values  $s$  does not determine. For a simple example: Assume that 30 parameters are relevant to  $G_t$  and  $a = 25$ . Such a sentence might be licensed by exactly 2 grammars, with opposite values for each of those 25 parameters. Or it might be licensed by grammars with all possible combinations of values for those parameters, of which there are  $2^{25} = 33,554,432$ . The former situation we will term **sparse ambiguity**, and the latter **dense ambiguity**; clearly, all situations in between are possible also.

It seems likely that the parametric ambiguity of natural

<sup>1</sup>Licensing is related to Greediness but the difference between them is important. Licensing applies in the selection of  $G_h$ , while Greediness governs only the grammar adoption stage at the end of each learning event. A learner that respects Licensing can also respect Greediness. The simple learning model discussed above shows that it is possible to obey Greediness but not Licensing.

<sup>2</sup>Licensing is related to Greediness but the difference between them is important. Licensing applies in the selection of  $G_h$ , while Greediness governs only the grammar adoption stage at the end of each learning event. A learner that respects Licensing can also respect Greediness. The simple learning model discussed above shows that it is possible to obey Greediness but not Licensing.

<sup>3</sup>Homogeneity is assumed in these calculations; no grammar is antecedently more likely than any other to license  $s$  or to be  $G_t$ .

languages is quite sparse ( $A$  much less than  $2^3$ ). In the miniature natural language domain defined by 3 parameters presented in GW94, ambiguity is less than fully dense in every one of the 11 sentence types in which two or more parameters are ambiguously expressed. It remains to be seen how this scales up in a domain of more realistic size. But the principle is clear. With maximally sparse ambiguity, a sentence could be ambiguous with respect to every parameter and nevertheless offer the oracle learner a 50% chance of guessing the target grammar. In general, for a constant degree of parametric ambiguity in terms of  $a$ , sparse ambiguity is more informative for a learning system capable of making use of it, i.e., a learning system that has knowledge of which grammars do and do not license the current input.

In a simple random choice system this information is unobtainable. It could be established only by testing every possible grammar on  $s$ , which clearly violates the limit of one parse per sentence (plus the original parse with  $G_c$ ). Of course, this one-parse limit is just one instantiation of a practical ban on excessive processing, and the limit might be raised to two or three parses per sentence. But this will make little difference. In order to significantly reduce the amount of input needed for convergence, it would be necessary to permit testing of each sentence with as many grammars as required to find one that licenses it.<sup>4</sup>

However, there are other ways of improving the quality of grammar selection which do not presuppose an ability to sort grammars into those that do and do not license  $s$ . We review these in the next section. Their effects are less easy to quantify, but it is highly doubtful that either singly or jointly they could substitute for the usefulness of a Licensing oracle.

### Criteria for Grammar Selection

Given a particular input sentence  $s$  from the target language, which grammar in the domain is it optimal for a learner to hypothesize? The grounds for selecting a grammar may be of several kinds, differing with respect to how much information they draw from the current learning situation. The preference for one grammar over another may be (a) independent of the current situation, or it may (b) reference the current grammar, and/or it may (c) reference properties of the current input. Some criteria of this latter kind may (d) require parsing of  $s$  with more than one new grammar, and thus exceed the limit on feasible processing for a learner without an oracle, which must select candidate grammars before knowing how they relate to the input.

#### (a) Orderings on the Class of Grammars

Grammar orderings may be imposed by linguistic principles of markedness. One value of a parameter may be less marked (more favored) than its other value; e.g., local binding of anaphors may be less marked than long-distance anaphors (Manzini & Wexler, 1987). Or parameters may be ordered with respect to each other: the marked value of one parameter may be less marked than the marked value of another

<sup>4</sup>Parse-testing two grammars on  $s$  would double the chance of guessing  $G_c$ . This would be helpful as if  $s$  were unambiguous with respect to one parameter. However, testing  $m$  grammars on each sentence would increase the chance of success only linearly in  $m$ , not exponentially.

parameter (Clark, 1989). Linguists have mostly been cautious about embracing markedness theory, but many markedness-type rankings are nevertheless implicitly assumed in linguistic descriptions (Wacholder, 1995). Also under type (a): grammars could be prioritized by linguistic maturation if, as has been proposed, some aspects of UG develop later than others (Wexler, 1999).

Criteria of type (a) may be helpful in resolving parametric ambiguities. To the extent that linguistic markedness has an impact on the frequency of grammar adoption by language communities (though this is a fraught topic), type (a) criteria can reflect the antecedent likelihood that any given grammar is the target. They may also reduce effort by holding learners to simpler or linguistically more natural grammars as long as the evidence permits.

#### (b) Rankings Relating to $G_c$

One  $G_c$ -related criterion is the Single Value Constraint (SVC) of GW94, which requires the learner to select grammars that differ from  $G_c$  in the value of just one parameter. Another is the assumption of 'indelible' or 'deterministic' learning, which requires that  $G_h$  include  $G_c$ . For parameter theory this is taken to mean that once a parameter has been set, it may never be switched to its other value (Clahsen, 1990/91).

Type (b) criteria reflect what has already been gained by experience of the target language, insofar as this is compressed into the grammar  $G_c$  that the learner has been led to so far. (A learner is standardly assumed to have no memory of past inputs or past grammar hypotheses, other than their legacy in determining the current grammar.) Because of Greediness, a grammar that has been adopted by the learner may be assumed to be more likely to have some parameters correctly set than an arbitrary grammar in the domain; and a grammar similar to such a grammar may be presumed to share its virtues. The worth of these considerations has been disputed, but we need not enter the debate here; see Berwick & Niyogi (1996) and Sakas & Fodor (in press) for discussion. Clearly it is desirable for a learning device to have some way to hold onto past gains. To adopt a completely fresh hypothesis at each step, as permitted in an unconstrained guessing model, does nothing to improve the probability of success as learning proceeds.

#### (c) Rankings Based on Properties of $s$ Identifiable by Parsing $s$ with at Most One New Grammar

Type (c) criteria are sensitive to the current input but compatible with the ban on excessive processing even for a learner that first selects a grammar and then tests it. Input-sensitive criteria can deliver hard information. They constitute the learner's contact with the facts of the language and so should be a particularly helpful guide to the correct grammar.

Greediness and error-driven learning fall under type (c) as well as (b), since they refer to  $s$  as well as  $G_c$ . Greediness ranks all grammars that do not license  $s$  lower than  $G_c$ . The requirement of error-driven learning ranks  $G_c$  above all other grammars if  $G_c$  licenses  $s$ . These two input-sensitive criteria can be incorporated into a simple grammar guessing procedure without a Licensing oracle, because each can be checked with limited resources: a parsing attempt with  $G_c$

for error-driven learning, and then with one new grammar for Greediness.

By contrast, some input-sensitive selection criteria do not qualify as type (c) conditions because they require (or may do so) the checking of two or more new candidate grammars. This threatens to violate the ban on excessive processing for a learner without oracle. Licensing (as opposed to Greediness) is one casualty already noted: it imposes the tough requirement that a grammar must be known to be capable of parsing  $s$  in order to be selected for parsing  $s$ . Also not possible under type (c) is comparison of the derivations assigned to  $s$  by different candidate grammars, as would be necessary for application of a structural simplicity metric.

Even the grammar-similarity constraints of type (b) are affected by the limitation on processing. The SVC has been demonstrated by GW94 to be too stringent in that, in conjunction with Greediness, it can trap the learner at a local maximum where there is no grammar that both licenses an input sentence and differs from  $G_c$  in only one parameter value. If a range of alternative grammars could be evaluated, a more general **Closeness** criterion could be applied instead. The learner would adopt the grammar most similar to  $G_c$  among those that license  $s$  (with dead heats resolved by random choice or other criteria). The adopted grammar would differ from  $G_c$  by only one parameter value in many cases, but could differ by two or more if necessary. This would maintain the fruits of past learning while eliminating all local maxima. (Note that Closeness can be seen as a generalization of error-driven learning:  $G_c$  is to be changed only to the extent that is necessary in order to license the input.) But for this we must move up to type (d) criteria, which are not feasible for a standard grammar guessing learner.

#### **(d) Rankings Based on Properties of $s$ Identifiable Only by Evaluation of Multiple New Grammars**

Closeness is an ideal similarity metric but (unlike the less flexible SVC) it is a comparative criterion which demands knowledge of all the grammars that license  $s$ , so that the one most similar to  $G_c$  can be selected. This puts it beyond the scope of any resource-limited pre-parse grammar selection process. Also falling under type (d) would be a simplicity measure which favors grammars that assign the smallest syntactic tree, or the shortest transformational derivation, compatible with the word string. This selection criterion seems very plausible both linguistically and psychologically, but is not easy to impose. How could a resource-limited learner set about discovering which of a million or a billion grammars assigns the simplest structure to  $s$ ?

In general: Adding suitable grammar selection principles to a random choice learner can improve performance, compensating in part for inefficiency due to inability to discriminate between grammars that do and do not license  $s$  before committing resources to those that do not. However, the present analysis of grammar selection strategies makes clear that the most potent selection principles are also beyond the reach of such a system, and for much the same reason. We next show that both weaknesses can be remedied by the same means. With one change in how the parse test is conducted, the guessing learner can gain both a Licensing oracle which eliminates useless grammar guesses, and also the powerful type

(d) criteria which improve the quality of guesses in case more than one grammar meets the Licensing condition, i.e., in case of parametric ambiguity.

### **Superparsing: A Constructive Process of $G_h$ Selection**

Inefficiency results from formulating a grammar hypothesis in advance of parsing the input string. This was assumed to be unavoidable, given the patent unfeasibility of first analyzing the string with all grammars as a basis for selecting one from among them. But if an optimal grammar choice cannot be made *before* parsing  $s$ , or *after* parsing  $s$ , perhaps it can be made *in the course* of parsing  $s$ . The solution we will outline is to let the ongoing parse shape the formulation of  $G_h$ . Total parametric decoding cannot be achieved by this means, for reasons we will explain, but most of the desirable learning characteristics we have been seeking do follow. By the end of the parse, the learner will know of one grammar that licenses  $s$ . Hence there will be no wastage of input due to lack of a grammar to parse it. The grammar the parser finds will always be drawn from among the  $A$  grammars that license  $s$ , rather than from the total set of  $2^n$  grammars (or  $2^{n-i}$  relevant grammars), so the learner will be taking full advantage of parametric disambiguation provided by the input. Where disambiguation is not total, Closeness and a structural simplicity metric can be applied to choose a good candidate, as indicated below.

Selecting a grammar that licenses  $s$ , during the course of parsing  $s$ , is feasible. Fodor (1998a) suggested the following procedure. The parsing routines set about parsing  $s$  with the current grammar  $G_c$ . If  $s$  is not licensed by  $G_c$  this parse attempt will break down at some place in the sentence. When it does, the parser should not stop and merely report back its failure, as we assumed earlier. Instead, it should supplement  $G_c$  with all possible parameter values and continue processing  $s$  with this 'supergrammar'  $SG$ .  $SG$  must afford at least one parse for  $s$  (as long as the sentence contains no unknown lexical items, and does not cause a severe 'garden path' beyond the capacity of the parser to recover from; see Fodor, 1998b). Where there is a choice of analysis for  $s$ , priority is given to the parameter values in  $G_c$ ; this incorporates the error-driven learning condition. But new parameter values can be made use of as needed. Any new parameter value that is found to be necessary for parsing  $s$  is adopted by the learner. Thus, the superparser shuttles through the sentence flipping parameter settings as it goes, in response to the demands of the input sentence. Its output consists of (i) a complete parse tree, and (ii) a grammar that satisfies Licensing.

If  $s$  is fully unambiguous with respect to all the parameter values it expresses, the superparser has no choices to make (above the usual within-grammar ambiguity resolution choices of normal sentence processing). If  $s$  is ambiguous with respect to  $a$  parameters,  $SG$  assigns it up to  $2^a$  distinct parse trees. In principle the parser might identify them all. In practice it could not, since this would require massive parallel parsing which would violate the general ban against excessive processing (even though it doesn't strictly violate the one-parse-per-sentence constraint imposed above). More reasonable is to suppose that the parser employed by the

learner for superparsing is the same parser that will be used throughout life for sentence comprehension. A standard assumption is that this is a serial device which, when it hits a point of ambiguity, selects one structural analysis to pursue for the sentence.<sup>55</sup> (Parallel parsing models have been proposed, but to conserve resources their parallelism is strictly limited, and their consequences for superparsing do not differ significantly from those of serial parsing.) Thus the superparser may be faced with choices to make between alternative ways of resetting parameters to assign an analysis to *s*. It can output only one of the *A* grammars that would satisfy Licensing. The choice between them might be random, or other selection criteria must be invoked.

Markedness and conservatism criteria (types (a) and (b)) could be employed, as well as input-sensitive type (c) criteria. The more powerful type (d) criteria such as Closeness and a minimal structure constraint are also available in this system. In fact, both of the latter are more or less automatic consequences of superparsing given that the human parser is a least-effort device (Inoue & Fodor, 1995). For instance, the Minimal Attachment parsing strategy entails that superparsing will prefer simple, compact trees over more complex ones; the learning device inherits this and so favors grammars that assign simpler structures. A conservative policy of staying close to the previous grammar will result if, as is natural, the parser makes the effort of changing parameter settings in  $G_c$  only when it is forced to do so to avoid parse failure. Again, parser preference translates into learner preference. In much the same way, frequency sensitivity in parsing could lead to frequency-sensitive learning (e.g. Charniak, 1993).

The exact mix of these various criteria remains to be established (e.g., Minimal Attachment versus minimal resetting of parameters). The supergrammar model allows various policies for resolving conflicts; which of these is adopted by human learners is an empirical question. To the extent that these criteria help the learner select an optimal grammar from among those that license *s*, the fact that they can be applied by a superparsing learner means that its efficiency gain compared with pre-parse selection criteria is even greater than was calculated above (Table 1). However, exact benefits are not easily quantified. The effects of Closeness and other such rankings are complex, and are best assessed by simulation studies. This awaits future research.

### Limitations of Superparsing

Does superparsing as a means of parameter setting carry significant costs to offset these advantages, so that no net gain in efficiency results? This appears not to be so.

As noted, the parsing routines need not be unusually powerful. The mechanism can be the normal human sentence parsing device, which clearly must be present in children for comprehension of sentences already licensed by the current grammar. Thus, all that is special about the superparser is that

it applies the supergrammar, augmented with all possible parameter values. This could exact a heavy cost in on-line processing due to the massive ambiguity of sentences in relation to the supergrammar, far greater in many cases than ambiguity levels relative to a settled adult grammar. However, the added cost of ambiguity is negligible as long as no attempt is made to compute all analyses of a sentence. For a serial parser, alternative parses are evaluated only momentarily as each new word is encountered and attached into the parse tree. They are not pursued through the sentence, and are not multiplicative. As soon as one of the alternatives has been chosen, the others can be forgotten. And arguably, even the selection process is cost-free in a least-effort system, since it consists of adopting the first (simplest) attachment option that is computed (Frazier & Fodor, 1978; Lewis, 1999). The only difficult analyses will be (i) those the human sentence parser has trouble with even when the grammar is settled, e.g., center-embedded constructions; and (ii) analyses which are not complex in themselves but are systematically masked by more attractive analyses allowed by the supergrammar. Grammar guessing models without superparsing would suffer from (i), but not from (ii). The incidence of such cases is not known. They could lead to false negative reports from the parser to the learner, indicating wrongly that *s* is not licensed by the grammar being tested. For examples and discussion see Fodor (1998b).

A requirement for smooth functioning of the superparsing routine is that the parameter values defined by UG are such that they can be added into a natural language grammar without altering its basic character. The competing values of one parameter must be able to co-exist in the same grammar without internal contradiction. And the parameter values temporarily added into  $G_c$  to create the supergrammar should be no harder to access and use on-line than other elements of natural language grammars. This may preclude any kind of precompiling process by which the combination of  $G_c$  and the added parameter values is reformulated for convenience in parsing, since the computational costs of repeated compiling would be added into the workload of the superparser. For some kinds of parameters (e.g., Subjacency applies at Surface Structure or at Logical Form; Huang, 1981/82) these conditions are hard to meet. But a variety of current linguistic theories conceive of parameter values as fragments of tree structure (see Fodor, 1998c), and these 'treelets' do meet the needs of superparsing. They can be directly added into a normal grammar to create another perfectly normal grammar, only slightly more complex than the original, and yet incorporating all the structural options that UG permits.

The one limitation of superparsing that is unavoidable is that it delivers only one structural analysis for each sentence. Because of the ban on excessive processing, it is impossible for the parser to present the learning component with all analyses for *s*, to compare and evaluate in order to make the best possible guess. The process of selecting one of the licensing grammars is piecemeal and order-dependent as each ambiguity must be resolved as it arises on-line. Interestingly, this appears to do relatively little damage, because there seems to be an excellent fit between the choices made on-line by the human parser and the choices that a well-designed learning device would be expected to favor: the minimization of derivational complexity, and the minimization of grammar

---

<sup>55</sup>In a serial parse, the selected resolution of an ambiguity may prove to be incorrect, by failing on subsequent words of the sentence. In a garden path situation such as this the superparser would engage in reanalysis procedures just as the human parser normally does in the case of a garden path.

revision. Whether this is merely a coincidence is not clear, but at any rate it is fortunate for superparsing as a method for parametric decoding.

## Summary and Conclusions

A start has been made here on quantifying the efficiency advantage of a learning device which has the ability to read off a set of parameter values for licensing a sentence, in the course of parsing that sentence in the normal way for comprehension. The superparsing approach was developed originally for a different purpose. It was designed to provide a feasible ambiguity detection system, so that all parametrically ambiguous input could be discarded. This permitted development of a non-guessing learning routine, capable of error-free parameter setting based exclusively on unambiguous items in the input sample (Fodor, 1998a). Whether this is the best research goal, either for modelling human learning or for engineering applications, remains to be seen. The error-free learner has the advantage that it never has to re-set a parameter. Also, once it has set a parameter it can ignore the alternative value of that parameter thereafter, so the size of the domain to be searched for  $G_i$  shrinks as learning proceeds. It is an empirical issue whether these benefits balance the need to discard all ambiguous sentences in the input sample. It is therefore of interest, as we have shown here, that superparsing can also make a useful contribution to a grammar guessing routine.

To the extent that the input sample does carry parametric information, superparsing allows the learner to exploit it. Despite its modest consumption of resources, and despite its practical inability to list all parametric analyses of a sentence, the superparser nevertheless extracts from a sentence *all* the definitive parametric information it contains. If a sentence is compatible with only one grammar in the whole domain, the superparser will identify that grammar and the learning component will adopt it. If a sentence is less informative, e.g., is compatible with a thousand grammars, the superparser will identify one of the thousand. (Which one of the thousand it identifies depends on which ambiguity resolution criteria it applies on-line.) All parameter values expressed unambiguously by a sentence will be set correctly by the time it has been parsed. The values of the other parameters can only be guessed. They will be left unchanged from previous learning where possible; otherwise they will be changed to some combination of values which licenses  $s$ .

The superparsing learner is quite undemanding about the nature of its input. For example, it does not require a language to contain unambiguous triggers for all of its parameter values. A simple random grammar guessing learner also needs no unambiguous triggers, but that is because, as noted above, it gains hardly more from unambiguous than from ambiguous input. By contrast, a non-guessing error-free learner is very choosy; it needs an unambiguous trigger for each parameter, and moreover it needs some of these to be fully unambiguous (i.e., unambiguous with respect to all parameters they express). The superparsing learner has the dual virtues that it can use the information in fully unambiguous triggers when they are present, but it can also make progress when input sentences are ambiguous with respect to many (or even all) of the parameters they express. Thus it is robust as well as efficient.

## Abstract

A connectionist architecture comprised of cell assemblies was developed and applied to the problem of speech perception at the phonemic and lexical levels. The problem addressed involved a disagreement amongst theorists over the possible sources of lexical priming effects. Speech was encoded in the model as the temporal activity of phoneme units that are connected to higher-level word assemblies. The lexical layer was topographically organized based upon similarity of phonemic structure. Lateral inhibition at the lexical level was shown to be both necessary and sufficient to support results from phonological priming experiments involving human participants.

## Introduction

Speech processing represents a rich source of constraints for the development of neural models of cognition. These constraints are particularly challenging since they often arise out of the temporal nature of the task, a weakness of most connectionist models. This paper presents a connectionist model that addresses a long-standing matter of controversy in the psycholinguist literature involving a task that is highly temporal in nature.

The model task involves lexical contact, which is defined as the phase of speech processing whereby the representations activated by the speech input make initial contact with the lexicon. The data comes from a series of studies to test a variety of priming conditions (Hamburger & Slowiaczek, 1996; Slowiaczek & Hamburger, 1992). The basic design of these studies involved prime words that are related to target words by sharing initial phonemes (i.e. "black" and "bleed" share two initial phonemes). Primes are presented 500 ms. before the targets and the subject's only task, called shadowing, is to repeat the target word aloud as quickly and accurately as possible. The major result is that when three initial phonemes are shared, response time actually slows by about 40 ms. whereas there is very little effect when one or two phonemes are shared (Hamburger & Slowiaczek, 1996).

The model for these data is based upon a variant of Hebb's cell assembly called TRACE (Kaplan, Sonntag, & Chown, 1991). The cell assembly is particularly suited for this type of modeling since it is well grounded biologically and was originally proposed to address issues of temporal processing in a neural framework. TRACE modeled a single cell assembly and has since been extended to model

multiple cell assemblies in a more general system called multiTRACE (Chown, 1994; Sonntag, 1991).

## Lexical and phonological priming

The data from Slowiaczek and Hamburger suggest that phonologically similar words compete at the lexical level of speech recognition (1996). Specifically, this competition was observed in a priming paradigm whereby the primes were phonologically related to target words by the number of initial phonemes. The critical number of overlapping initial phonemes was three, for primes that were presented 500 ms before the targets. Additionally, this data also elucidated the cause of a facilitatory effect (a decrease in RT) in the low-similarity case (1- to 2- phoneme overlap) that was presenting some difficulty in interpretation.

It was suggested from other studies that low-similarity facilitation only occurs if the phonological relatedness proportion (PRP) is high (50 %) (Goldinger, Luce, Pisoni, & Marcario, 1992). That is, the number of trials containing phonological overlap was manipulated across subject groups, and it was only in groups containing a majority of trials with phonological overlapping (high PRP) that displayed facilitation effects (Hamburger & Slowiaczek, 1996). Goldinger et al. explained this prelexical facilitation effect by suggesting that subjects were strategically assuming that the initial phoneme of the target would be the same as that of the prime, because the majority of previous trials had been this way (1992). When the experiment was controlled for subject expectancy, however, this facilitatory effect was virtually eliminated and only the 3-phoneme overlap interference was observed (Hamburger & Slowiaczek, 1996). Nevertheless, there remains a debate in the literature over whether either effect truly comes from competition among lexical candidates or whether it is simply an artifact of the experimental design.

A different kind of priming has been studied with a smaller interstimulus interval (the time between the end of the prime word and the beginning of the target) of 50 ms. Goldinger et al. found that for uncommon targets (low-frequency words) preceded by phonologically related primes, response time was increased (1992). This phonological inhibition result is included to provide a bigger picture of the priming literature, but was not a focus of this work.

## The multiTRACE model

Hebb developed the cell assembly construct to address questions concerning the temporal nature of neural processing. Essentially a cell assembly is a large collection of neurons which act in concert and which have temporal extent due to their recurrent connections and their corresponding ability to “reverberate.” Hebb’s theory lost favor initially in part because he omitted inhibition, a construct for which there was no evidence at the time. More recently, however, cell assemblies have undergone something of a revival as advances in neuroscience have been incorporated in the theory (Kaplan, et al., 1991) and experimental evidence for their existence has been found (Amit, 1995).

In the Kaplan model of cell assemblies, called TRACE (Tracing Recurrent Activity in Cognitive Elements), the emphasis was on simulating the internal dynamics of a population of neurons that would comprise a cell assembly. In the TRACE model various neural control mechanisms were postulated to play different functional roles in the cognitive system. For example, inhibition is useful as a selection mechanism when multiple cell assemblies are competing to become active. A major addition to cell assembly theory by the Kaplan group was to add fatigue to counterbalance the reverberation inherent in a highly recurrent system.

TRACE, which serves as the basis for multiTRACE, uses a set of difference equations that are updated at each time step to model the collective behavior of a large group of neurons. The equations model various biological functions such as activity, neural fatigue, short-term connection strength, long-term connection strength, sensitivity to firing, and network or external input (Table 1).

Kaplan et al. argued that units built with these basic properties have a number of advantages over the simple units used in many traditional connectionist models (1991). Different levels of activity in a cell assembly, for example, can serve different cognitive purposes, such as coding for conscious versus unconscious processing. The major questions left open by the original work on TRACE was how the notion of a single cell assembly could be extended to the cognitive system as a whole.

Table 1: The basic multiTRACE equations

Update Equations	Delta Equations
$A(t+1) = A(t) + \Delta A$	$\Delta A = (A + \bar{A}I)\bar{A}V - A^{\theta_L} + A\bar{A}^{\theta_C}\bar{V}$
$F(t+1) = F(t) + \Delta F$	$\Delta F = \phi_g A\bar{F} - \phi_d F$
$S(t+1) = S(t) + \Delta S$	$\Delta S = \sigma_g AS - \sigma_d S$
$L(t+1) = L(t) + \Delta L$	$\Delta L = 0.0$
	$V = \frac{1}{v}(S + L)F$
	$I = I^{exc} - I^{inh}$ (expanded in text)

$\theta_l$  : unit loss  
 $\theta_c$  : inh. competition  
 $v$  : normal factor  
 $\phi_g$  : fatigue growth  
 $\phi_d$  : fatigue decline  
 $\sigma_g$  : STCS growth  
 $\sigma_d$  : STCS decline

A: activity  
F: neural fatigue  
S: short-term connection strength  
L: long-term connection strength  
I: network input

\*  $\bar{X}$  denotes quantity  $(1 - X)$

The multiTRACE model extends the cell assembly idea by building models with collections of cell assemblies. Sonntag originally created multiTRACE to study sequence learning in the context of cell assemblies (1992). Chown later extended the model to deal with other forms of learning, for example modeling the effects of the arousal system on learning (1994). The development of multiTRACE has been increasingly less abstract, starting from the very general problem of modeling sequences, to the current work which addresses a very specific body of data.

### Applicability to lexical priming

The multiTRACE framework provides a natural way to model the lexical priming data presented in the previous section. Each phoneme and lexical unit is represented by a cell assembly as part of a hierarchical structure (Fig. 1). Phonemes which are part of a word are strongly linked to the lexical units at the higher level (e.g. the phoneme “b” will be strongly linked to the cell assembly representing “black” but not the one representing “flack”). The activation of the lexical units at the higher level corresponds to perception and therefore the ability of the subject to repeat the word. The theory is that competition between these units accounts for the differences in timing.

This sort of perceptual competition forms the basis of a number of connectionist models and stems from evidence that similar concepts tend to interfere with each other more than dissimilar ones as part of what Kinsbourne called “the functional cerebral distance principle” (Kinsbourne, 1982). This interference comes in the form of lateral inhibition between cells near each other in the cortex. The idea is simple; words that are similar (e.g. “black” and “blast”) will be stored in nearby locations in cortex, meaning that they will greatly inhibit each other. As one becomes highly active during perception it will naturally inhibit the other, making perception a kind of winner-take-all proposition. In terms of the brain, the cell assemblies underlying these representations will be close to each other. A given cell assembly will have a kind of inhibitory surround which will typically prevent its close neighbors from being simultaneously active (Fig. 1).

In the context of a cell assembly model the interference seen when the target word shares three phonemes with the prime must come from competition, and the competition must come from the prime word itself. Since the prime word and the target word share three initial phonemes in common they will be represented very near each other in the brain, and therefore they will have a great deal of lateral

Figure 1: The two-tiered connectionist architecture. (Inhibitory output shown only for BLAST unit)

inhibitory connections. These data are very useful for extending cell assembly theory because they provide a number of useful constraints on the temporal dynamics of cell assembly activation, as well as information on the general layout of cell assemblies in the cortex.

### The implementation

In the original implementations of multiTRACE it was not necessary to explicitly model lateral inhibition as the model was not applied to highly similar concepts as is the case here. In updating the model we devised a scheme, based upon Kinsbourne’s functional distance principle, whereby the lateral inhibitory connections between cell assemblies was determined by the shared number of phonemes. This rule also reflects the spatial layout of inhibitory processes in association cortex, as well as areas like the early visual system, where lateral inhibition is widely known to exist and has important functional implications, such as enhancing contrast sensitivity.

The competition generated by lateral inhibition results from an active cell assembly. Since the priming effects vary according to the test conditions it is important to understand the factors that affect the time course of activity in a cell assembly. In Hebb’s original formulation the only was a cell assembly’s capacity for reverberation (in the multiTRACE model this comes in the form of internal long term connection strength or LTCS). Later through simulation it was determined that inhibition was necessary as a control mechanism (Rochester, et al., 1956). More recently, Kaplan et al. (1991) did a series of simulations showing that with the addition of two more biologically and theoretically motivated mechanisms – fatigue and short term connection strength (STCS) – that it was possible to model different time courses of activity corresponding to different parts of the cognitive hierarchy. For example, cell assemblies near

the perceptual interface would be expected to have a high refresh rate in order to be ready for the next input. On the other hand cell assemblies that participate in long term planning would be expected to stay active for longer periods of time. In our model we conceptually represent these differences as different hierarchical layers.

Although it is possible that hierarchy can emerge naturally in a flat network structure, we felt that such a network design would quickly become confusing and therefore limiting. Additionally, our network structure reflects the layered organization of human cerebral cortex. Groups of multiTRACE units were combined into layers in the current system, and static properties of individual units were inherited from their “parent” layers. It is our conjecture that nearby layers will have similar parametric properties (e.g. in the perceptual layer cell assemblies will all tend to have high refresh rates). The lexical priming data provides an excellent test of such conditions and the potential usefulness of the cell assembly construct, since it can be applied to model widely different types of cognitive functioning.

The basic structure of the simulation was based upon a two-tiered network with each tier representing a different level of the cognitive hierarchy. In this case, because each layer is part of the perceptual interface, they have virtually identical parameter settings (Table 2). The primary layer contained units responsive to phonological stimuli theoretically produced by the primary and secondary auditory cortices. The secondary layer comprised of lexical units that respond to the phonological structure of a spoken word, not its meaning. For example, a lexical unit for “blast” received equal vertical connections from the phonemic /b/, /l/, /a/, /s/, and /t/ units. Because the data from Hamburger and Slowiaczek was not concerned with the typicality effect, we built in the assumption that all of the cell assemblies had the same internal connection strength (1996). Differences in typicality could easily be modeled by introducing variability in connection strength within cell assembly units.

Table 2: Layer parameters and timings

Parameter	Phonemic layer	Lexical layer
Fatigue growth	0.15	0.15
Fatigue decline	0.04	0.04
STCS growth	1.0	1.0
STCS decline	0.2	0.2
Activity duration	300 ms	700 ms
Fatigue recovery	500 ms	950 ms

\* STCS: Short-term connection strength

Despite both layers of units being similar in their static properties, their differentiation in cognitive speed emerged as a function of the hierarchical structure. The units in the word layer received input from several phonemic units over the course of time, depending on the length of the spoken word. Since the mapping between layers was not one-to-one, average unit durations were 300 ms and 700 ms for the phonological and lexical layers, respectively (Table 2). Fatigue recovery times, being dependent on activity, were similarly proportioned.

The topological organization of the lexical layer was also an important component of the current model. Interference, as suggested by the Hamburger and Slowiaczek data (1996), results from competition at the lexical level and is a function of word-form similarity. Therefore, the lexical map was built using the amount of initial phoneme overlap between lexical units as a distance approximation in cognitive space. The amount of inhibition imposed on some target unit  $k$  is a function of the distance to a neighboring unit  $j$ , as well as this neighbor’s activity and fatigue level:

$$I_{jk}^{inh} = \frac{A_j(1 - F_j)}{D_{jk}} \quad (1)$$

j: source unit  
k: target unit  
D: distance  
t: Time

The net inhibitory input for a lexical unit then becomes the combination of local inhibition and regional inhibition imposed on the layer. This regional inhibition is a positive feedback mechanism that controls the spread of activity in a given region, in this case a layer, and is based upon the total activity in that layer:

$$I_k^{inh} = \frac{1}{L} \left( \sum_{j=1}^n I_{jk}^{inh} \right) + G \left( \sum_{i=1}^n A_i \right) \quad (2)$$

n: number of units in a layer  
G: global inhibition factor (0.5)  
L: lateral inhibition factor (2.0)

The excitatory input to a cell assembly in multiTRACE is computed in a conventional connectionist manner. However, the sum of a unit’s long-term connection strength and short-term connection strength to another unit serves as the weight value ( $w_{ij}$ ) typically seen in most connectionist models:

$$I_{jk}^{exc} = (LTCS_{jk} + STCS_{jk}) A_j \quad (3)$$

$$I_k^{exc} = \sum_{i=1}^n I_{jk}^{exc} \quad (4)$$

j: source unit  
k: target unit  
n: number of incoming connections for unit  $k$

### Simulation design and procedure

As in the original experiment, four prime conditions were created: *no relation* and three degrees of *phoneme overlap* (1-3). The representative words for each condition are presented in Table 3; the actual words were chosen arbitrarily for demonstrative purposes.

Table 3: Simulated experiment design

Condition	Prime	Target
No relation	“dream”	“black”
1-phoneme overlap	“bind”	“black”
2-phoneme overlap	“blues”	“black”
3-phoneme overlap	“blast”	“black”

In order to simulate an incoming stream of speech, the phoneme units comprising the prime and target words were activated in a serial manner, separated by an interval ranging from 20-40 ms, with a greater spacing reserved for vowel sounds. Using this approximation method, the experiment was easy to simulate. The set of phonemes corresponding to the prime word were activated first, followed by the target phoneme string 500 ms after the prime sequence had concluded.

The simulations were expected to show that there is a fundamental difference in processing between the high similarity (3-phoneme overlap) and low similarity conditions (no relation and 1-phoneme overlap). That is, the response time of the target word unit represented at the lexical level should be increased due to the earlier presentation of the prime word stimulus.

### Results

Our initial experiments show the relevant trends in the data (Table 4); interference resulting from lexical competition was observed in the high-similarity conditions (2- and 3-phoneme overlap) and not in the low-similarity conditions (0- and 1-phoneme overlap). To date we have not replicated the exact time-course for this interference that was found in the behavioral evidence, but we have found that the general trends are simple to generate in the model. Since the model presented here is considerably simpler than that of its human counterpart, and does not take into account the effects of semantic top-down influence, for example, which may also affect timing, we do not wish to spend too much of our effort trying for an exact match at this stage.

Table 4: RT differences (experimental – control) in simulated and actual experiment

Condition	Simulation (ms)	Actual (ms)
No relation	-	-
1-phoneme overlap	0	-4
2-phoneme overlap	40	-8
3-phoneme overlap	190	36

In the 3-phoneme overlap condition, the competition between “black” and “blast” is striking (Fig. 2). The time course of the prime word’s activity is sufficiently slowed in this condition as well as in that of the target’s. That is, be

Figure 2: Competition between the “black” and “blast” lexical units

cause “blast” and “black” share three initial phonemes, each unit receives considerable input from the incoming speech stream. However, when the fourth segment of the speech stream (/s/) is presented to the phoneme layer, the net input for the “blast” unit begins to dominate over that of the “black” unit (Fig. 3). This initial competitive advantage is then reinforced by the increasing lateral inhibition “blast” is imposing on “black,” effectively increasing the competitive gap. However, the presentation of the target word 500 ms later in addition to the fatigue of the “blast” unit will allow “black” to win the second competition, albeit more slowly than in the control condition.

Figure 3: Net input for “blast” and “black” units

## Conclusion

This work serves two purposes. First, we have presented a biologically grounded model that addresses a key controversy in the psycholinguistics literature. Our results support Hamburger and Slowiaczek’s theory that the lexical priming results can be explained in terms of competition between phonologically similar words. Second, their data provides crucial constraints in exploring the temporal dynamics of neural processing in cognition.

For better or worse the dominant connectionist modeling paradigm has long been back-propagation. In recent years, however, interest has grown in recurrent models such as the one presented in this paper. The development of such models will be predicated upon their ability to account for psychological data with a temporal component. This work represents an important step in that direction. The data being modeled required incremental changes in an existing model. As the goal of our continuing research is not to alter previous work in order to support future data, this current work was successful in that components were identified—lateral inhibition and layering—that when inserted into the existing model were able to support the new data. Also, while these additions extend the modeling capabilities of current cell assembly implementations, they do not accomplish this at the cost of simplicity. That is, lateral inhibition and hierarchy fit very naturally into the multiTRACE model and are well supported theoretically.

With regards to the specific modeling task discussed here, future work will involve observing the competition dynamics as the scale of the system is increased. The high-similarity interference phenomenon was observed in a system constructed from roughly ten words, but now that the architecture is in place it will be possible to see how robust the effect will be as the number of words is increased. Another goal of this continued effort will be to reduce the amount of manual network design, because that has resulted in a more discrete representation of the lexical space under study than may be desired to obtain truly generalized conclusions. At the time of publication, however, a sampling of systems of roughly 160 to 200 words generated from a normal distribution have produced statistically significant effects similar to those discussed here (including low-similarity facilitation), and it has been shown that the amount of inhibition at the lexical level is crucial to mimicking the behavioral evidence.

In addition to the artificial nature of the network construction, this discreteness in representation is also a by-product of the necessary simplicity of the current multiTRACE model, in that individual network units represent populations of neurons, thereby limiting our knowledge of how the simulated assemblies can relate to one another in a neurobiological sense. For example, it is not clear to what degree cortical representations for words are distinct or if they overlap. However, this simplicity in the model does not damage its biological credibility. That is, because the internal representations of these simulated cell assemblies remains unspecified, theoretically this allows neurons to be redundantly represented across several units in the model.

## Acknowledgments

The authors would like to thank Louisa Slowiaczek for her invaluable assistance in this project. The first author was partially funded by a Hughes grant during the summer.

# The Resemblance of One-year-old Infants to Their Fathers: Refuting Christenfeld & Hill (1995)

Robert M. French, Serge Brédart, Johanne Huart, Christophe Labiouse  
Department of Psychology  
University of Liège, 4000 Liège, Belgium  
(rfrench; Serge.Bredart; jhuart; clabiouse @ulg.ac.be)

## Abstract

In 1995 Christenfeld and Hill published a paper that purported to show at one year of age, infants resemble their fathers more than their mothers. Evolution, they argued, would have produced this result since it would ensure male parental resources, since the paternity of the infant would no longer be in doubt. We believe this result is false. We present the results of two experiments (and mention a third) which are very far from replicating Christenfeld and Hill's data. In addition, we provide an evolutionary explanation as to why evolution would *not* have favored the result reported by Christenfeld and Hill.

## Introduction

Science overwhelmingly favors positive results. To appreciate this, one need look no further than the almost exclusive emphasis on Type I error detection in the social sciences and the quasi-religious status of the inequality " $p < 0.05$ ." Since everyone knows that the null hypothesis cannot be proved, only rejected, it follows that the only results worth pursuing are those that involve the rejection of a null hypothesis. This is why it is so much harder to establish (and publish) negative results. But sometimes null hypotheses are rejected incorrectly and subsequently setting the record straight proves to be very difficult indeed. For every published rejection of a null hypothesis, a far greater number of failures-to-replicate are usually necessary to convincingly establish that the published result was most probably in error.

Although examples of this problem abound, it is instructive to briefly recall the well-known experiments on the chemical transfer of memory done by McConnell (1962) and others. Planarian worms were trained to respond in a certain "correct" way to a light source. These worms were then killed and their RNA fed to a new set of worms, who, by dint of having ingested the previous worms' RNA, would supposedly respond correctly to the light source more often than worms in a control group. Once this result, buttressed by theoretical arguments about the role of RNA in memory, was published it became very hard to unseat it, in spite of numerous failures-to-replicate (e.g., Bennett & Calvin, 1964; Byrne et al., 1966). Thus, even though numerous failure-to-replicate papers had begun to appear as early as 1964, many courses on memory into the 1970's still included McConnell's results on the chemical transfer of memory (see, for

example, Munn, Fernald, & Fernald, 1969; Hilgard, Atkinson, & Atkinson, 1971).

In this paper we will present two negative results that we hope will help serve to establish the falsehood of a published result — namely, the claim of greater resemblance between one-year-old infants and their fathers than their mothers (Christenfeld and Hill, 1995). This result received very wide international attention when it was published in 1995. The result is now cited often but we believe, both for theoretical and empirical reasons, that it is wrong. In the present paper, we will present our own failures-to-replicate the original results and will give a theoretical justification for our results. We hope that this will lead other researchers to also critically examine the originally published results of Christenfeld and Hill before they become firmly, and in our opinion wrongly, entrenched as fact.

The remainder of this paper is organized as follows. We begin by briefly presenting the claim of Christenfeld and Hill (1995). This will be followed by the results of two independent experiments (i.e., different subjects, different sets of stimuli, etc.) that fail to replicate their results. We will then give a theoretical justification for why evolution would most likely have produced our results and not those of Christenfeld and Hill.

## Christenfeld & Hill (1995): One-year old Infants Resemble Their Fathers

Christenfeld and Hill (1995) reported a result in 1995 that appeared in *Nature* and received considerable attention throughout the world, both in the scientific and the popular press. They claimed to have found greater facial resemblance between one-year-old children and their fathers than between one-year-old children and their mothers. Their result had wide appeal, in particular, because it seemed to agree with a prediction of evolutionary psychology (Gaulin and Schegel, 1980) — namely, that "It could then be to a baby's advantage to look like the father, to encourage paternal investment [on the part of the male parent]" (Christenfeld & Hill, 1995) since a mother can be quite sure that the baby is hers but the father cannot.

According to Christenfeld and Hill, greater father-child resemblance would be to the baby's advantage because it would encourage the father's investment in its survival, since he would be able to clearly identify

the child as his own. This would tend to produce a differential survival rate among children who, at age one (when they were most in need of resources from the father for their survival), looked like their fathers and those who did not.

### Overview of the Two Experiments

In an initial experiment (not reported here) involving 200 subjects done soon after Christenfeld and Hill's paper first appeared, we were unable to reproduce their results. We thought that perhaps there might be some problem with the photographic stimuli we were using. (Christenfeld and Hill declined our request to make their original stimuli available.) We therefore created a second set of stimuli, careful to make sure that there the photos displayed no beards, glasses, hats, or other features that might distract from the identification task. However, once again, we failed to replicate Christenfeld and Hill's results. These results are reported in Experiment 1 (see Brédart & French, 1999).

We then created another, entirely new set of stimuli and designed the experiment to record participants' reaction times during identification. As before, we found virtually no difference in the level of correct identification of children and their real mother compared to children and their real father. Further, in addition to repeating the results of the first experiment, there was no significant difference between correct child-mother and child-father identification times.

We have now attempted to reproduce Christenfeld and Hill's result with three different sets of stimuli with three different groups of participants using two different measures (% of correct identification and reaction time). In no case did we find any significant differences in father-infant and mother-infant identification. In other words, we have what we believe to be good empirical evidence that belies the originally reported findings of Christenfeld and Hill.

### Experiment 1<sup>1</sup>

#### *Subjects*

One hundred and eighty undergraduate students at the University of Liège participated in the experiment. Thirty subjects (15 female and 15 male) were randomly assigned to each condition. Their ages ranged from 18 to 30 years (mean age = 21.84).

#### *Stimuli and materials*

Twenty-eight Caucasian families provided five photographs: three photographs of the same child at one year, three years, and five years, as well as one photograph of the mother and one photograph of the father taken when the child was approximately one year old. For fourteen families, the child was a girl, for the

other fourteen families the child was a boy. The stimuli presented to subjects were scanned versions of these photographs (size = 5x4 cm) of faces. None of the faces had glasses, beards or moustaches.

#### *Procedure*

On each trial, participants were presented with the face of a child and, according to the condition, the faces of three women or three men. Their task was to identify the child's parent among the three presented adult faces. There were 28 trials (14 different girls and 14 different boys). The photographs were displayed in the same way as in the Christenfeld and Hill study: the child's face was presented in an upper position and the three adults' faces were placed beneath the child's face. The presentation positions of the adult photos were appropriately randomized. Participants were tested individually. Each were each presented with the 28 sets including one child and three possible parents in a different random order.

#### *Results*

The design of the experiment was as follows. The age of the child (one-year-old, three-year-old and five-year-old) and the sex of the parent were between-subjects factors while the sex of the child was a within-subjects factor. A 3 (age of the child) X 2 (sex of the parent) X 2 (sex of the child) ANOVA with repeated measures on the last factor revealed a significant main effect of the age of the child ( $F(2,174) = 6.614, p < .01$ ), no main effect of the sex of the parent ( $F(1,174) < 1$ ) and no main effect of the sex of the child ( $F(1,174) < 1$ ). The analysis revealed no significant interaction between the first two factors ( $F(2, 174) < 1$ ), no significant interaction between the second and the third factor ( $F(1,174) < 1$ ) and no three-way interaction ( $F(2,174) < 1$ ). The main effect of the age of the child was qualified by a significant interaction between this factor and the sex of the child ( $F(2,174) = 5.988, p < .01$ ), but the magnitude of this interaction effect is low ( $\eta^2 = 0.06$ ). This interaction was analyzed using Tukey HSD post-hoc tests. These tests showed that, while the level of parent identification from pictures of girls did not change across the three ages, it did for pictures of boys. Parent identification was better for five-year-old boys than from one-year-old boys ( $p < .0001$ ) and than for three-year-old boys ( $p < .01$ ). No significant difference appeared between one-year-old and three-year-old boys ( $p = 0.56$ ). Post-hoc tests indicated no significant effect of the sex of the child on parent identification at age one, three or five (all  $p$ 's  $> .10$ ).

A control analysis taking the items as the random factor was also carried out. This analysis did not reveal any significant main effect of the sex of the child ( $F(1,26) < 1$ ), of the sex of the parent ( $F(1, 26) < 1$ ) and of the age of the child ( $F(2, 52) = 1.982, p = 0.15$ ). Nor did it reveal any interaction effect (all  $p$ 's  $> .20$ ). The results of this control analysis confirmed that the

---

<sup>1</sup> Originally appeared in *Evolution and Human Behavior*. Reprinted with permission.

significant interaction effect obtained in the preceding analysis was not a strong effect.

Figure 1. Mean number of correct identifications (out of 30) of parents of children at various ages (one-SD error bars). There is no significant difference in the level of correct identification of mothers versus fathers based on children's faces.

To reiterate, our analyses showed *no significant difference between the level of correct identification of mothers and the level of correct identification of fathers from children's faces* (Figure 1 and Table 1). Christenfeld and Hill (1995) did not perform a direct comparison between levels of identification of mothers and fathers. They simply compared the level of identification of mothers and fathers to the chance level of 33.3 percent by means of student t-tests, the items being the random factor. We also carried out this analysis for our data by comparing the mean number of identifications to chance ( $1/3 \times 30$  subjects = 10). At all ages tested, our results indicate that, while correct identification of mothers and fathers was significantly, although not overwhelmingly, higher than chance, there is no significant difference between the degree of father-identification and mother-identification.

It is particularly important to note that while the degree of correct association of parents with children is anywhere between 7 and 14% higher than chance, it remains surprisingly poor. In all cases, *non-identification exceeds 50%*.

## Discussion

Present results do not replicate those of Christenfeld & Hill's (1995) study. Young children aged 1, 3 and 5 do not appear to resemble their fathers significantly more than they resemble their mothers.

It could be objected that the sample of faces used in this experiment is not a representative one. In fact, there is no clear reason why our sample of items would not be representative of the larger Caucasian population in general, and, crucially would be less representative than Christenfeld and Hill's original sample. Indeed, we used photographs from 28 families, whereas Christenfeld and Hill's stimuli were drawn from 24 families. Our stimuli were collected in the same way as those in the Christenfeld and Hill study, i.e. by asking

friends, colleagues and acquaintances for photographs. We do not see any a priori reason why such a procedure would lead to the construction of an unrepresentative set of faces.

Age	Parent	Mean no. of identifications (SD in parentheses)	Student <i>t</i>	<i>p</i>
1	Father	12.893 (5.363)	2.854	<.01
	Mother	11.929 (5.937)	1.719	<.05
3	Father	13.178 (6.464)	2.602	<.01
	Mother	13.321 (5.644)	3.114	<.01
5	Father	14.143 (4.859)	4.512	<.001
	Mother	14.143 (6.996)	3.134	<.01

Table 1. Mean number of correct identifications (out of 30) as a function of the children's age and the parent's sex. Standard deviations are in parentheses. Note the absence of any significant difference in levels of correct identification of fathers and mothers based on a child's facial appearance.

Is our failure to replicate Christenfeld & Hill possibly attributable to an inappropriate sample of pictures that allowed *no* null hypothesis to be rejected? This would be very unlikely, because in *all six cases* of mothers and fathers for 1, 3, and 5 year old children, we found that the resemblance of parent to child is, as one would expect, significantly better than chance. In short, our sample *did* demonstrate a significant resemblance between parents and children, but *not that there was a significantly greater* resemblance between fathers and their children compared to mothers and their children. This means that our failure to find a significant difference in the resemblance of fathers-to-children versus mothers-to-children was not simply due to an insufficient amount of detail to be able to make resemblance assessments of any kind.

## Experiment 2

### Subjects

Forty-four undergraduate volunteers (22 females, 22 males) participated in the experiment.

### Stimuli and materials

Thirty-two Caucasian families provided three photographs: one photograph of a child at one year, one photograph of the mother and one photograph of the father taken when the child was approximately one year old. For sixteen families, the child was a girl, for the other sixteen families the child was a boy. The stimuli presented to subjects were scanned versions of these photographs (size = 5.5 x 4.5 cm) of faces. None of the faces had glasses, beards or moustaches. Stimuli were presented using E-prime® on a PC.

### Procedure

On each trial, participants were presented with the face of a child and, according to the condition, the faces of three women or three men. All photographs were displayed on the computer screen. Their task was to identify as quickly and as accurately as possible the child's parent among the three presented adult faces. Participants responded by pressing a key on the numeric keypad of the computer keyboard (1 = left photo choice, 2 = middle photo choice and 3 = right photo choice). There were 32 trials (16 different girls and 16 different boys). The position of the real parent among the three adult photos was appropriately randomized. Each participant was presented with the 32 sets consisting one child and three possible parents in a different random order. The experiment was preceded by a short practice session using four trials that were not employed later in the experiment.

### Results

The experiment had a repeated measures design with two factors : the gender of the parent and the gender of the child. One item was removed because the proportion of correct mother-infant identification was below the 2SD cutoff.

The first dependent measure was the proportion of correct identification of the parent. A 2 (gender of the parent) X 2 (gender of the child) ANOVA with repeated measures on both factors revealed no main effect of the gender of the parent ( $F(1,43) < 1$ ), no main effect of the gender of the child ( $F(1,43) < 1$ ), and no interaction effect ( $F(1,43) < 1$ ). See Table 2.

Parent	Infant gender	
	Girl	Boy
Mother	0.41 (0.16) 2.72 secs (0.85)	0.39 (0.16) 2.72 secs (0.88)
Father	0.38 (0.19) 2.82 secs (1.0)	0.38 (0.19) 2.73 secs (1.2)

Table 2. Mean proportions of correct identifications of parents, and mean correct RTs (in seconds) as a function of the gender of the child and the parent. Standard deviations are given in parentheses.

A control analysis taking the items as the random factor was also carried out and revealed the same pattern of results: none of the main and interaction effects were significant (all  $F_s < 1$ ).

The level of identification of mothers and fathers was also compared to the chance level of 33.3 percent by means of student t-tests, the subjects being the random factor. The overall mean level of correct identification of both mothers ( $m = 0.397$ ;  $t(43) = 3.696$ ;  $p < .001$ ) and fathers ( $m = 0.381$ ;  $t(43) = 2.436$ ;  $p < .05$ ) was significantly higher than chance.

The second dependent measure was the response latency (RTs). Mean correct recognition RTs to the

mother and the father were computed for each subjects and submitted to a 2 (gender of the parent) X 2 (gender of the child) ANOVA. Five subjects were excluded from this analysis: two subjects whose RTs were particularly slow (RTs > 2 SD from the sample average) and three subjects who did not provide any correct recognition in one subcategory of items. This analysis revealed no main effect of the gender of the parent ( $F(1,38) < 1$ ,  $p = 0.49$ ), no main effect of the gender of the child ( $F(1,38) < 1$ ;  $p = 0.53$ ), and no interaction effect ( $F(1,38) < 1$ ;  $p = 0.71$ ). See Table 2.

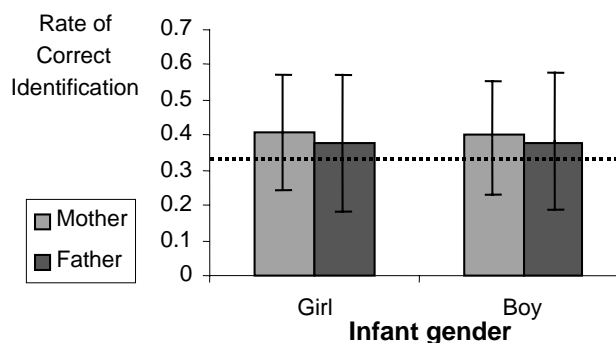

Figure 2. As in the first experiment, Exp. 2 shows no significant difference between child-father and child-mother rates of correct identification (1 SD error bars). The dotted line indicates chance level of identification.

Figure 3. There is no significant difference between child-father and child-mother reaction times for correction identifications (1 SD error bars).

A control analysis taking the items as the random factor was also carried out and revealed the same pattern of results: none of the main and interaction effects were significant (all  $F_s < 1$ ).

### Discussion

This second experiment was, above all, designed to repeat and refine the results obtained in Experiment 1. Entirely new stimuli (i.e., black-and-white photographs of adults and infants) were used. And, unlike the first experiment in which children of ages 1, 3 and 5 were used, here we focused exclusively on one-year old infants. (This was because the claim of Christenfeld and Hill bears specifically on one-year old infants: it is at that age that infants supposedly resemble their fathers

more closely than their mothers.) The stimuli in this experiment were presented on a computer monitor instead of using the actual photographs, as in the first experiment. And, of course, all of the participants were different from the first experiment.

All of the results of the first experiment were reproduced in this second experiment. As in the first experiment, we found that the level of correct identification of infant-father pairs was not significantly higher than that of infant-mother pairs. We also found that, as in the first experiment, that both the levels of infant-father and infant-mother identification are significantly above chance, as one might expect. Finally, we found no significant difference in the reaction times for correct responses for both infant-father and infant-mother pairs. In other words, there is no significant difference in the speed with which people can correctly identify an infant's mother or its father.

As in Experiment 1, these results are in clear contradiction with Christenfeld & Hill (1995).

## General Discussion

The evolutionary analysis of Christenfeld and Hill is based on the supposed advantage to one-year old babies of looking more like their father than their mother in order to encourage greater resource investment on the part of the father, thereby improving their chances of survival. This theory is certainly appealing, but we believe it is undermined by a number of considerations that we will review below.

We must begin by returning to the fundamental postulate of Darwinian evolution, namely that the ultimate winners in the game of evolutionary competition are those individuals who succeed in passing on the greatest amount of their genetic material to subsequent generations. Now, there would be little obvious evolutionary pressure for a child to resemble its mother, since the maternity of a child is never in doubt. This allows us to take the degree to which a child resembles its mother as a baseline of parent-child resemblance.

The essence of the argument against greater resemblance between fathers and their infants as opposed to infants and their mothers is based on the following simple observation: If father-child resemblance was strong enough to enable a father to be certain when a child was his, it would presumably also permit a father to identify that a child *was not his* (Brédart & French, 1999). Now, in the event that a child was not his, the chances of his withholding resources from the child (or very possibly killing the child outright) would be high. Even today, step-children are far more likely to be killed by step-parents than by natural parents. In the U.S. in 1976, for example, Daly and Wilson (1988) reported that children living with one or more substitute parents were *sixty-five times* as likely to be fatally abused as children living with their

biological parents. Other studies report similar patterns of child mistreatment (for a recent short review see Daly and Wilson, 1996). Animal research has also shown the prevalence of infanticide by male rodents, carnivores and, in particular, primates (Hdry, 1979).

For much of the two-million year pre-agricultural course of human existence, three important conditions prevailed: male parental investment (Trivers, 1972) was necessary to ensure the survival of offspring, males were unable to completely control all possible sexual contact of their mates, and, finally, few individual males were able to provide resources for many females (Symons, 1987). Under these conditions, if babies had unambiguously resembled their fathers, a highly monogamous society would likely have emerged because few females would have risked the possibility of fathering another male's child, given that the bastard child would have been recognized as not belonging to her "official" (investing) mate (see also comments by R. Dawkins and other discussants following a paper by Wilson and Daly, 1997) and would thus have risked maltreatment and, quite possibly, death. In short, few females would have engaged in extra-pair copulation (EPC). However, in reality, this is contradicted by the fact that occasional EPCs by both sexes seems to be a universal feature of monogamous species (Mock and Fujioka, 1990), including humans. For example, rates of human misassigned paternity (based on blood typing tests) of 6-30% have been reported in studies done in southern England (Edwards, 1957; Philipp, 1973), 9% among the Venezuelan Yanomanö (Neel and Weiss, 1975; Smith, 1984), and 10% in rural Michigan, (Smith, 1984). Baker and Bellis (1995) have estimated a cross-cultural median EPC figure of 9%, with a range from 1.4-30%. Further, in a survey of 2078 English women, Bellis and Baker (1990) found that extra-pair copulations are significantly more likely to be timed just before ovulation than in-pair copulations. From his model of parent-infant resemblance, Pagel (1997) recently concluded that "even small amounts of paternity uncertainty are sufficient to select against parent-infant resemblance" (p.973).

Moreover, if relatively high father-child resemblance were the norm, evolution would tend to produce progressively greater degrees of father-child resemblance because any degree of resemblance significantly below that norm would engender suspicions on the part of the resource-providing male concerning the child's paternity. This would likely lead to a higher degree of resource-withholding than if the child had unambiguously resembled the father, which would ultimately translate into a lower rate of survival among those children who did not closely resemble their fathers. In other words, once evolution had established a trend of father-child resemblance in excess of baseline resemblance, there would be evolutionary pressure towards ever greater resemblance. One would therefore expect, after three

million years of selection, that there would now be a very *strong* tendency of father-child resemblance with respect to mother-child resemblance. However, our results — as well as those by Christenfeld and Hill — demonstrate that this is not the case. Indeed, in Christenfeld and Hill's data correct identification of fathers from infant faces occurred only in 49.2 percent of cases. In the two experiments reported in the present paper, the mean rate of correct identification for the father's of one-year-old children was only 10% higher than chance in the first experiment and 5% higher than chance in the second.

For these reasons, we believe that the original results reported by Christenfeld and Hill (1995) of greater father-child than mother-child resemblance in young children are most likely incorrect.

### Conclusion

We believe that the experimental results presented by Christenfeld & Hill (1995) are most likely in error. We have attempted on three separate occasions to reproduce their results, each time with new photographic stimuli and new participants. We have used two separate measures (percentage of correct identifications and reaction times for correct identifications). In all cases, we have seen no evidence whatsoever of the results reported in their paper. In this paper we report two of our experiments. In addition, we provide a theoretical justification of the outcome of our experiments. We believe that the evidence presented in this paper casts serious doubt on the originally published study by Christenfeld and Hill.

# Memory versus Perceptual-Motor Tradeoffs in a Blocks World Task

## Abstract

Using information *in-the-world* as *external memory* may be a low-cost alternative to internal memory: storage is free, and retrieval is often quick (involving a saccade) and reliable. However, when the cost of accessing external information increases, *in-the-head* storage and retrieval may become the least-cost solution. We employ the rational analysis framework (Anderson, 1990) to study the effect of varying the cost of information access on interactive behavior. Increasing the cost of information access induced a switch from information in-the-world (the perceptual-motor strategy) to information in-the-head (the memory strategy). Given the effort and unreliability of internal storage, the threshold for switching from an in-the-world to an in-the-head strategy is surprisingly low.

## Introduction

Information stored *in-the-world* can be considered as *external memory* (O'Regan, 1992). Information is retrieved from external memory via visual perception as rendered by the appropriate saccades and fixations. Recent research has suggested that when information in-the-world is readily accessible, internal storage is not needed (Ballard, Hayhoe, & Pelz, 1995); perceptual-motor strategies will be deployed to reacquire information as needed. However, when the cost of information access was increased from a simple saccade to a head movement, the perceptual-motor strategy was replaced with a strategy that placed task-relevant information into working memory (Ballard et. al., 1995). This suggests that the decision to store information in-the-head versus in-the-world is sensitive to least-cost considerations.

## The rational analysis framework

One explanation for this kind of trade-off was given by Anderson (1990). Anderson casts human memory as an optimization process. In his rational analysis framework, the goal of human memory is to retrieve knowledge that would allow us to perform the task we are currently facing. The optimization process maximizes the *expected utility* of the memory system by balancing the cost of memory search against an assumed constant expected gain<sup>1</sup> of retrieving a

desired memory item for the current task. A clear cost of memory search is time (and possibly a metabolic cost associated with time). Under Anderson's rational analysis framework, the human memory system would search a memory structure until the probability of getting the desired memory item (the expected gain) is lower than the cost of further search (i.e., when the expected utility becomes negative).

If information in the external environment can be considered as an external memory store, the cost in searching for the relevant information in the external environment can be taken as the "memory" search cost as in Anderson's rational analysis framework. In most tasks, the information stored in the external environment is continuously available (high expected gain and fixed expected cost).

If the only cost associated with internal memory were a search cost, then we would expect that in most situations internal search would be faster than external search. However, for internal memory a significant additional cost is internal storage (encoding). Storage costs would seem to be particularly problematic in the type of real-time, dynamic tasks studied by Ballard and associates. For example, in a task that required frequent memory updates, Altmann and Gray (2000) estimated that approximately 10 cycles of encoding with a duration of approximately 100 msec per cycle are needed to encode an item so that it can be retrieved 5,000 msec later. In contrast, the time for a saccade and dwell is typically estimated as 230 msec (Card, Moran, & Newell, 1983, pp. 25-28).

Compared to a memory strategy that includes encoding plus retrieval, a saccadic eye movement to a known location has a much lower time cost. Therefore, under many conditions, the expected utility of using the external environment as external memory is much higher than that of the internal human memory system. However, when the cost of information access from the external environment is high enough, the expected utility of external memory would be lower than that of internal memory. In this case, the rational analysis framework would predict a shift from external memory to internal memory. In other words, people would be more likely to adopt a memory strategy than a perceptual-motor strategy.

Unlike retrieving an item from a known external location with a saccade and dwell, retrieving an item from memory is

---

<sup>1</sup> The expected gain is defined as the product of P and G, where P is the estimated probability that the target memory item can be found, and G is the gain associated with retrieving the target

---

memory item. If C is the memory search cost, then expected utility  $E = PG - C$ .

subject to interference from previously encoded as well as other currently encoded items. If we make the additional assumption that the strength of an encoded trace fluctuates as a function of noise (Altmann & Gray, 1999; Anderson & Lebière, 1998), then retrieval from memory may take longer and is more error prone than the corresponding retrieval from the external environment. The rational analysis framework suggests that searching for an item should stop as soon as the expected gain from finding the item is less than the cost of searching. Therefore given an assumed constant expected gain, the higher the search cost of a memory item, the fewer items would be searched for and inspected before the memory system would stop searching. Since the more items the memory system considers, the more likely that the target item can be found (thus improving accuracy), increasing the search cost implies a decrease in accuracy; that is, an increase in errors. Therefore the rational analysis framework not only predicts that increasing the cost of information access in the external environment would induce a shift from external memory to internal memory, but also an increase in errors.

In this paper, we employ the rational analysis framework to study the effect of varying the cost of information access on interactive behavior. Specifically we test two predictions that we have derived from the rational analysis framework: that an increase in the perceptual-motor cost of information access will induce a shift from an external to an internal memory strategy, and that this switch will occur even though the internal search is difficult and error prone.

## Experiment

The blocks world task is based on the paradigm used by Ballard et al., (1995). The task is to copy a pattern of colored blocks shown in the *target* window to the *workspace* window, using the colored blocks in the *resource* window (for our version see Figure 1).

To do the task, participants have to remember three pieces of information: (a) the color of the block to be copied, (b) the position of the block to be copied, and (c) which blocks have or have not been copied. The first two pieces have to be obtained from the target window whereas the third piece has to be obtained by comparing the target window with the workspace window.

Ballard reported a point-of-gaze (POG) sequence of target window, resource window, target window, workspace window (TRTW). The implication of this sequence is that during the first POG to the target window (T) subjects encoded the color of the block and then picked up a block from the resource window (R). On the next POG to the target window (T) subjects encoded the block's location in the pattern. They then moved to the workspace window (W) and placed the block in the appropriate location.

As the effort needed to acquire information from a window increased from a POG to a head movement the sequence tended to change to TRW. In this case, the implication is that subjects encode both the color and the position during the first (and only) POG to the target window (T). The encoded trace persists as the subject acquires the block from the resource window (R) and places it in the workspace window (W).

Unlike Ballard et al., in our Block World task all three windows were covered by gray boxes. Throughout the task only one of the windows could be uncovered at a time. The resource and workspace windows were uncovered by moving the mouse cursor into the window. They were covered again when the mouse cursor left the window. The effort required to uncover the target window varied between each of our three conditions.

To access the information in the target window participants could adopt either a predominately perceptual-motor or a predominately memory strategy. As per Ballard et al.'s TRTW strategy, the predominately perceptual-motor strategy would entail one uncovering at the target window to obtain color information and another to obtain position information. In contrast, a predominately memory strategy (TRW) would entail one uncovering at the target window to obtain both color and position. Deciding which blocks remained to be copied would entail a second set of strategies. On these strategies Ballard is silent. However, a predominately perceptual-motor strategy might entail multiple quick uncoverings between the target and workspace window. A predominately memory strategy might entail encoding the color and position of multiple blocks at one glance.

Figure 1. The blocks world task. In the actual task all windows are covered by gray boxes and at any time only one window can be uncovered. The window at the top left is the target window, at the bottom the resource window, and at the top right the workspace window.

## Method

### Participants

Forty-eight George Mason University undergraduates participated in the study for course credit and were randomly assigned to one of the three experimental conditions.

### Equipment and software

The experiment was written in Macintosh Common Lisp and was conducted with a Macintosh PowerPC connected to

an extended keyboard, a mouse, and a 17-inch monitor. All mouse movements and keypresses were recorded and saved to a log file with 16.67 msec accuracy.

The blocks (48 x 48 pixels) that constitute each pattern were randomly chosen with the constraint that no color was used in one pattern more than twice. The blocks were placed at random in the target window's 4 x 4 grid. The workspace window was the same size as the target window and contained the same, non-visible, 4 x 4 grid.

### Design and Procedure

The three conditions were designed to vary the cost of uncovering the target window. In the *low-cost* condition, participants had to press and hold down a function key. (Participants were asked to use different hands for the keyboard and the mouse.) The target window remained uncovered until they released the key, or until the mouse cursor entered either the workspace or resource window. Once the target window was covered, to uncover it again participants had to release the key and press it again (this is to avoid the strategy of holding the key down throughout the task). In the *control* condition, the conditions for uncovering the target window were the same as for the workspace and resource windows. The target window was uncovered when the mouse cursor entered the window. The *high-cost* condition was similar to the control condition, except that participants had to move the mouse cursor inside the target window and endure a one second lockout before the target window was uncovered.

To select a block, participants moved the mouse cursor to the resource window and mouse clicked on the desired colored block. The mouse cursor then changed to a small version (16 x 16 pixels) of the selected block (eliminating the need to remember its color). To place a block in the workspace window, the cursor was moved to that window (which was then uncovered), moved to the desired position, and then clicked. When the participants believed that the pattern had been copied to the workspace window, they press the "Stop-Trial" button. A feedback window indicated whether the copied pattern matched the target pattern. If the pattern was different, participants were required to go back to finish the task before they could move on to the next pattern.

At the beginning of the experiment, instructions were given and participants were led through one demonstration trial by the experimenter. Participants then completed 40 trials. The whole experiment lasted about 45 minutes.

## Results

### Trial Time

The first ten trials of the experiment were considered practice and were excluded from further analyses. Analysis of variance (ANOVA) of time for condition by trial showed significant main effects of condition ( $F(2, 45) = 9.11, p = 0.0005, MSE = 726$ ), and of trial ( $F(29, 1305) = 131.6, p < .0001, MSE = 53.2$ ). There was no interaction between trial and condition. To determine whether the main effect of conditions was solely due to the one second delay in the

high-cost condition, the per trial time in this condition was adjusted by subtracting the amount of delay for each time the target window was uncovered. After the adjustment, the main effect of condition was not significant ( $F(2, 45) = .969, p = .39, MSE = 564$ ). However, the main effect of trial remained significant ( $F(29, 1305) = 120.1, p < .001, MSE = 46.0$ ). Orthogonal linear contrasts showed a significant linear downward trend of time across trials for the low-cost condition ( $p = .0001$ ), control condition ( $p = .0001$ ), and high-cost condition ( $p = .0001$ ), suggesting speed-up across trials. No other higher order trends were significant. The interaction between trials and conditions was not significant.

### Use of the Target Window

The trial time results seem to suggest no difference between conditions. However, detailed analyses revealed the effects of the cost of information access. An ANOVA on the number of times the target was uncovered showed a significant main effect of condition ( $F(2, 45) = 10.17, p = .0002, MSE = 159$ ). Planned comparisons revealed a significant difference between the high-cost and control ( $p = .0045$ ), as well as high-cost and low-cost conditions ( $p < .0001$ ) (See Figure 2). Subjects in the high-cost condition uncovered the target window significantly fewer times than the other two conditions. However, there was no significant difference between the low-cost and control condition.

Figure 2. Mean number of times per trial that subjects uncovered the target window.

ANOVA on the time subjects spent looking at the model showed that there were significant main effects of conditions ( $F(2, 45) = 20.6, p < .0001, MSE = 300$ ), with the high-cost condition significantly spending more time than the low-cost condition ( $p < .0001$ ), or the control condition ( $p < .0001$ ). The difference between the low-cost and control condition was not significant. Overall, there was a significant downward linear trend of time spent on the target window across trials ( $p = .0002$ ). However, orthogonal linear contrasts showed that the downward linear trends for the high-cost ( $p = .02$ ) and control condition ( $p = .001$ ) were significant, but that the trend for low-cost condition ( $p = .10$ ) was not (see Figure 3).

Figure 3. Time spent on looking at the target window.

For each trial, we looked at how many colored blocks the subjects copied following each of their first four accesses of the target window. We conducted a 3 x (4 x 30) ANOVA on conditions, the nth (1 to 4) uncovering of the target window, and trial (11-40). There were significant main effects of conditions ( $F(2, 45) = 19.5, p < .0001, MSE = 7.75$ ), and the nth uncovering of the window ( $F(3, 135) = 39.5, p < .0001, MSE = 13.3$ ). The interaction between conditions and the nth window uncovering was significant ( $F(6, 135) = 7.8, p < .0001, MSE = 13.2$ ) (see Figure 4). The main effect of trials was not significant. No other interactions were significant.

Figure 4. The number of colored blocks copied after each uncovering of the target window.

**Summary.** The analysis of how the target window was used suggest that although there was no significant difference in trial times between conditions, the strategies used by the subjects in the high-cost condition were very different from the other two conditions. Subjects in the high-cost condition uncovered the target window a fewer number of times and copied more colored blocks after each uncovering at the target window. Figure 4 illustrates the interaction between

condition and the number of blocks copied in the first four uncoverings of the target window. Clearly, the significant decrease in the number of blocks copied within a trial is at least partially due to the decreasing number that remained to be copied. However, this potential artifact does not explain the significant interaction. Subjects in the high-cost condition tended to copy more blocks in the first few accesses at the target window. In contrast, in the low-cost condition, subjects tended to copy the same number of blocks after each access. This suggests that subjects in the high-cost condition tended to adopt a memory strategy - memorizing the information of the colored blocks to reduce their reliance on the external display. On the other hand, as the cost of information access was low subjects in the low-cost condition relied more on a perceptual-motor strategy - getting the information from the display when needed.

With practice, subjects in the high-cost condition spent less time looking at the target window, but copied more colored blocks after each uncovering. This increase in efficiency (measured in terms of the time required to memorize the information of a fixed number of colored blocks) partly explains the speed-up across trials in the high-cost condition. However, the same trend was not observed in the low-cost condition. It seems that practice had no significant effect on the use of the target window in the low-cost condition (in terms of number of times they uncovered at the target window, number of colored blocks copied after each uncovering, and time spent on the target window per uncovering).

### Strategies

A finer-grained analysis is needed to understand the actual differences in strategies used. For each copied block, we extracted the sequence in which subjects uncovered windows. In the notation below, these sequences are abbreviated using the first initial of the window name. Wb indicates that they uncovered the workspace window and placed a block, Wu indicates that they uncovered the workspace window but did not place a block. For example, TRWb refers to a target-source-workspace windows sequence that ends with the placement of a block.

Table 1. Strategies used by subjects. T = uncover target window, R = uncover and pick a colored block from resource window, Wb = put selected colored block to workspace window, Wu = uncover workspace window. For example, TWuRWb represents the strategy in which the subject uncovered the target window, uncovered the workspace window, went to the resource window, picked up a colored block, and put the colored block in the workspace window.

	Low-cost	Control	High-cost
Strategy	Strategy	Strategy	Strategy
TRWb	53%	TRWb 49%	TRWb 38%
RWb	33%	RWb 38%	RWb 58%
TRTWb	5%	TRTWb 7%	TWuRWb 1%
Total	5537	5496	5752

Table 1 shows the three most common sequences used by the subjects in the three conditions (as well as the percentage of the total that these sequences represent). We

can see that the top 2 sequences (TRWb and RWb) constituted almost 90% of all the sequences used<sup>2</sup>.

Although the two dominant strategies were the same, the effect of information access cost on strategy used was clearly seen. With increasing cost, the use of the TRWb strategy decreased, while the use of RWb increased. This change of strategy nicely indicates the shift of reliance from external to internal memory. This is consistent with the results on the use of target window described above. With increasing cost of information access, subjects tended to uncover the target window less, spent more time per uncovering (time that we presume was spent encoding more information into internal memory), and used the pure memory strategy (RWb) more.

Figure 5. Number of use of strategies per trial. T = uncovering the target window, R = uncovering the resource window and picked a colored block, Wb = putting the colored block in the workspace window.

To further understand the strategy change across trials, we looked at three combinations of the two dominant strategies. We extracted the number of times subjects used either the TRWb, TRWbRWb, or TRWbRWbRWb strategy<sup>3</sup> in each of the trials. This analysis is similar to that shown in Figure 4. It captures how often subjects placed 1, 2, or 3 blocks following a single glance at the target window. A 3 x (3 x 30) ANOVA on conditions, strategies, and trials found no significant main effect of condition ( $F(2, 45) = 1.92, p = .16, MSE = 16.0$ ), nor trials ( $F(29, 1305) = .835, p < .72, MSE = 24.2$ ). However, the main effect of sequence was significant ( $F(2, 90) = 14.6, p < .0001, MSE = 19.8$ ), as was the interaction between sequence and condition ( $F(4, 90) =$

<sup>2</sup> Interestingly, TRTW, the dominant strategy described in Ballard et al (1995), was not one of the dominant strategy in this task. The difference might be that all windows in this task were covered by gray boxes, and the lower-cost saccadic strategy described in Ballard et al (1995) was not supported.

<sup>3</sup> In our categorization, these categories were mutually exclusive. Therefore, the run TRWRWRW was categorized as an instance of the TRWRWRW strategy, but was not included in the count for TRWRW or TRW.

10.9,  $p < .0001$ ) (see Figure 5). No other interactions were significant. Planned comparisons showed that all differences between the three sequences were significant ( $p < .05$ ).

The analysis further confirms the shift from the use of external to internal memory with increasing information access cost. The TRWb strategy, in contrast to the TRWbRWb and TRWbRWbRWb strategies, allowed subjects to acquire only the information necessary to copy the next colored block from the target window (external memory). Figure 5 shows that in the high-cost condition, subjects used the TRWbRWbRWb significantly more than the TRWb strategy. It suggests that subjects tended to transfer more information from the target window (external memory) to internal memory, and performed the task based on the information retained in internal memory.

### Errors and Comparisons

To test the predictions of errors from our rational analysis, we looked at the way in which different strategies affected the patterns of errors made by subjects. An error could involve placing a block with the wrong color, placing a block in the wrong position, or both. Only errors made before the subjects clicked on the "Stop-Trial" button were counted. A 3 x 30 ANOVA of the number of errors made per trial on conditions and trials was conducted. There was a significant main effect for conditions ( $F(2, 45) = 11.6, p < .0001, MSE = 1.39$ ), but not for trials ( $F(29, 1305) = 1.1, p = .33, MSE = .75$ ). The interaction between conditions and trials was not significant ( $F(58, 1305) = 1.2, p = .10$ ). The row labeled "Errors" in Table 2 shows the mean number of errors made by the subjects. The low error rates were not surprising given the simplicity of the task. However, there were significant differences between conditions. Planned comparisons showed that subjects in the high-cost condition made significantly more errors than the other two conditions ( $p < .001$  for low versus high,  $p < .0001$  for control versus high). This result supports our second prediction: that increase in information access cost increases errors.

Table 2. Mean number of errors, errors uncorrected, and comparison episodes per trial before the subjects thought they were done (when they pressed the "Stop-Trial" button.)

Dependent Variable	Conditions (cell means)		
	Low-cost	Control	High-cost
Errors	.41	.33	.68
Uncorrected	.10	.08	.14
Comparisons	.57	.31	.17

To find out whether there were differences in the subjects' ability to detect errors, we conducted a 3 x 30 ANOVA on the number of uncorrected errors after the subjects clicked on the "Stop-Trial" button by condition and trial. As suggested by the middle row of Table 2, there was no significant main effect on conditions ( $F(2, 45) = 1.26, p = .29, MSE = .365$ ). However, there was a significant main effects of trial ( $F(29, 1305) = 1.54, p = .03, MSE = .173$ ). There was a significant downward linear trend on the number of uncorrected errors across trials ( $p = .006$ ).

The decrease of the number of uncorrected errors (without any significant increase in the number of errors made) suggested that with practice, subjects in the high-cost condition became better at detecting and correcting their errors. We therefore turned our focus on how often the subjects compared the pattern in the workspace with that in the target window. The comparisons between the two windows not only served the function of error detection, but could also let the subjects keep track of what blocks had or had not been copied. As described before, this information was another critical piece of information that had to be remembered to do the task.

The number of comparison episodes was extracted. A comparison episode started when the participant went from the workspace to the target window (or vice versa) without having a block selected. Any consecutive uncoverings of the workspace and target window were counted as part of the same comparison episode. An ANOVA of the number of comparison episodes showed a significant main effect on conditions ( $F(2, 45) = 6.3, p = .004, MSE = 3.17$ ), with the low-cost condition having significantly more comparison episodes than the other two conditions (see the bottom row of Table 2). The result again confirmed our prediction: when the cost of information access is low, people prefer to adopt a perceptual-motor strategy to memory strategy.

To summarize, the memory strategy adopted by subjects in the high-cost condition seemed to be more error-prone than the perceptual strategy in the low-cost condition. However, in all conditions most errors were detected and corrected. There was therefore no significant difference in the number of uncorrected errors between conditions. The differences in number of comparison episodes revealed another aspect of the strategy difference. In the low-cost condition, subjects made many more comparisons of the workspace and the target window, further supporting the hypothesis that they did not keep track of which blocks had been copied. In contrast, the number of comparison episodes in the high-cost condition was much lower, suggesting that subjects stored the information in working memory, reducing the reliance on the external environment. A second function served by these comparisons might have been to detect and correct errors. By relying on the external display, errors could be corrected without much memorization. In contrast, subjects in the high-cost condition relied more on their memory to keep track of their task as well as to detect and correct errors. It was also shown that over practice, subjects in the high-cost condition did manage to reduce the number of uncorrected errors.

## Conclusions and Discussions

The results support two predictions derived from Anderson's (1990) rational analysis framework. Given an assumed constant expected gain, when the cost of accessing information in-the-world increased, the cost of a perceptual-motor strategy becomes greater than the cost of a memory strategy. Under such conditions, the *optimal* strategy is to

encode task-relevant information from the external environment into working memory, thereby reducing reliance on the external environment. The results indicate that when the cost of accessing external information is high, people invest more time storing information in their internal environment and rely less on the external environment to do the task. In contrast, when the cost of accessing external information is low, people spent less time encoding and rely more heavily on the external environment.

Our second prediction was upheld as well. In the high-cost condition this switch to the memory strategy was made despite its higher error rate. Indeed, the decrease in the number of uncorrected errors indicates that with practice our subjects became better at detecting and correcting errors. This finding suggests subjects were *optimizing* the strategy to reduce the overall effort required to do the task.

Under the rational analysis framework, cognition tends to optimize performance by balancing costs and benefits in a given information processing task. Our results show that the cost of information access could induce a switch from reliance on information in-the-world (perceptual-motor strategy) to in-the-head (the memory strategy). We found that although memory is a limited resource, there are conditions under which people can use it to *optimize* performance.

## Abstract

Recent studies have shown that infants have access to highly useful language acquisition skills. On the one hand, they can segment a stream of unmarked syllables into words, based only on the statistical regularities present in it. On the other, they can abstract beyond these input-specific regularities and generalize to rules. It has been argued that these are two separate learning mechanisms, that the former is simply associationist whereas the latter requires variables. In this paper we present a correlational approach to the learning of sequential regularities, and its implementation in a connectionist model, which accommodates both types of learning. We show that when a network is made out of the right stuff, specifically, when it has the ability to represent sameness and the ability to represent relations, a simple correlational learning mechanism suffices to perform both of these tasks. Crucially the model makes different predictions than the variable-based account.

## Background

Two recent papers in *Science* have demonstrated the remarkable language learning abilities that are possessed by infants. In both cases the infants were presented with sequences of syllables embodying some sort of regularity and later tested with sequences that agreed or disagreed in certain ways with the training set. In the experiments of Saffran, Aslin, and Newport (1996), eight-month-olds heard strings of syllables consisting of randomly concatenated three-syllable “words,” sequences which never varied internally. Thus the transition probabilities within words were higher than between words. Later the infants were able to differentiate between these words and non-word three-syllable sequences which they had either heard with less frequency than the words or not heard at all. This is taken as evidence that they had picked up the statistics in the training set. Marcus, Vijayan, Bandi Rao, and Vishton (1999) presented seven-month-olds with series of three-syllable sequences separated by gaps. Each sequence consisted of two different syllables arranged in a fixed pattern, AAB, ABB, or ABA. For example, in the ABB condition, the presented patterns included sequences such as *le di di* and *ji je je*. Later the infants responded differently to novel sequences of three syllables which matched the pattern they had been trained on than to novel sequences which did not. This is taken as evidence that they had in some sense picked up the rule implicit in the training patterns.

Marcus et al. (1999) and Pinker (1999) argue that the two studies, taken together, point to at least two distinct learning mechanisms which are behind language learning. One of these, revealed in the experiments of Saffran et al. (1996),

can learn relationships such as the tendency for *ti* to immediately follow *ga*. It is sensitive to the content of the items, not caring about the similarity among different items. For Pinker (1999), this is just the *associationism* proposed in the eighteenth century by Hume and still proposed as the fundamental mechanism of the mind by modern connectionists and others. The other mechanism, revealed in the experiments of Marcus et al. (1999), can learn relationships such as the fact that the first syllable in a sequence is the same as the second but different from the third. This mechanism ignores specific content, caring only about sameness or difference. In this sense the second mechanism seems to require *variables*, placeholders which are ignorant of their specific content. For Pinker (1999), this mechanism is an instantiation of what was proposed by the early rationalists and what we think of today as “symbolic.” Thus Marcus et al. (1999) and Pinker (1999) now believe that the mind, specifically the portion of it used in language learning, is both associationist and symbolic.

The question, as Marcus et al. (1999) make clear, is not whether connectionist networks can learn to solve both kinds of tasks, but what sorts of mechanisms are required and whether these differ for the two tasks. In this paper, we present a model of the learning of regularities in patterns which accommodates both kinds of patterns in terms of **correlations**. We argue that a correlational account, to deal with the tasks in Marcus et al.’s experiment, needs two mechanisms in addition to those usually found in such accounts, neither of which amounts to explicit variables. We show how a connectionist network implementing this theory (the PLAYPEN architecture) can learn aspects of the Saffran et al. task, as well as the Marcus et al. task. What is crucial about this account is not that it handles variable-like behavior within a correlational framework but that it makes predictions that differ from the variable-based account.

## Pattern Regularity Learning

Saffran et al.’s and Marcus et al.’s experiments are not directly comparable. In Saffran et al.’s experiments, the boundaries between the patterns must be extracted, while these are provided in Marcus et al.’s task. However, both are learning tasks in which the learner is presented repeatedly with patterns consisting of sequences of syllables and extracts some sort of regularity from the sequences.

We agree with Marcus et al. and Pinker that there are other differences in what is going on in these two tasks, but we believe that both are fundamentally statistical, based on the extraction of **correlations** from input patterns. The main dif-

ference, we argue, lies in what sort of correlations: whether they are content-specific, as in Saffran et al.'s experiments, or relational and based on similarity among the elements within the sequences, as in Marcus et al.'s experiments.

We will consider tasks that are more general than those in the two original sets of infant experiments, what will refer to as **pattern regularity learning**. A learning trial for such a task consists of a pattern (not necessarily auditory) composed of elements arranged in a particular way (either sequentially or spatially), and the regularity consists of tendencies for patterns to resemble each other in particular ways. Resemblances between patterns make reference to the **position** of elements within their patterns, where position may be defined spatially or temporally. Regularity could be concerned only with a single pattern position and not with intra-pattern relationships; for example, *all patterns begin with ba*. But we will only be concerned with regularities that make reference to intra-pattern relationships, as was the case in both sets of infant experiments.

### Content-Specific Regularities

In Saffran et al.'s experiments, the resemblances between patterns concern the **specific content** of the patterns. That is, it is particular syllables which are involved in the regularities; certain combinations of syllables tend to recur. The simplest content-specific regularities (other than those that make reference to only a single pattern element) are those involving **pairwise** co-occurrences of specific elements or element features. Examples of such regularities are the following: *ba tends to be followed by gu*; *syllables beginning with b tend to be followed by syllables beginning with g*.

But the regularities in Saffran et al.'s experiments are more complex than these. Rather than simple pairwise regularities, the regularities concern co-occurrences of pairwise co-occurrences. Examples of such **higher-order** regularities are: *when gu is preceded by ba, it tends to be followed by li*; *when a syllable beginning with g is preceded by a syllable beginning with b, it tends to be followed by a syllable beginning with l*.

Not surprisingly, these statistical, content-specific regularities can be handled in a straightforward fashion in connectionist networks. Weights in most connectionist networks represent **correlations** between elements, and the regularities we have been describing are just that. However, correlations between correlations, as in the higher-order regularities, require "handle" units responsible for pairs of particular elements. These handle units can then be joined by connections whose weights encode the higher-order correlations. Figure 1 shows a network of this type. The network is of the attractor (generalized Hopfield) type, and weights are adjusted using the Contrastive Hebbian Learning algorithm (Hopfield, 1984; Movellan, 1990). For simplicity's sake, we assume separate units for the different pattern positions, ignoring the (non-trivial) problem of how element representations are shared across different positions, and we consider only the case of patterns consisting of three elements. Pairwise regularities are represented by strong weights joining pairs of PATTERN units to single CORRELATION units. Higher-order regularities are represented by strong weights on connections joining CORRELATION units. Note that this approach assumes

that higher-order regularities presuppose the pairwise regularities which they are built on. Note also that when there are multiple higher-order regularities, as in Saffran et al.'s experiments, for example, the CORRELATION layer permits these different regularities to be kept separate: one set of units and connections might represent the *ba gu mi* pattern, another the *vi ja lo* pattern.

Figure 1: Network for learning content-specific regularities. Only some units and connections are shown.

Just what gets learned by such a network and how it generalizes depend on how the pattern elements are represented. We assume multiple levels of representations differing in coarseness. That is, at the least coarse level, the elements are represented in terms of the largest number of classes; at the most coarse level, they are grouped in terms of a small number of classes. Representations in connectionist networks also differ in the extent to which they are distributed vs. local. Assuming local representations for the sake of simplicity, syllables might be represented at multiple levels of coarseness as shown in Figure 2. Thus the syllable *bis* turns on a unit specific to that syllable, a unit responding to all syllables beginning with *b* and a unit responding to all consonant-vowel-consonant syllables.

Figure 2: Representation of syllables at multiple levels of coarseness. Only a few units are shown. Arrows represent excitatory connections joining units at different levels of coarseness. Not shown are inhibitory connections forcing winner-take-all at a given level.

## Relational Regularities

Alternately, regularity within a set of patterns may be in terms of the similarity of elements within patterns; that is, the regularity may be **relational** rather than content-specific. Again the regularities may be pairwise or higher-order. Examples of pairwise relational regularities are the following: *the first element is the same as the second element; the first element tends to begin with the same consonant as the second element; the first element is different from the second.* Examples of higher-order relational regularities are the following: *the first element tends to be the same as the second element and different from the third; when the first element begins with the same consonant as the second element, the second element has the same vowel as the third.*

In these terms, then, Marcus et al.'s experiments involved both pairwise and higher-order relational regularities, as well as pairwise and higher-order content-specific regularities, though only the relational regularities are reflected in the test items.

In what follows, we discuss how relational regularities, as well as content-specific regularities, are handled within the PLAYPEN architecture.

## Accommodating Relational Regularities in a Connectionist Network

Our claim is that relational regularities, like content-specific regularities, are correlations, that is, that they involve statistical patterns of co-occurrence. Further we show how relational correlations can be learned in a connectionist network that differs from more conventional networks in that it has an explicit means of representing and learning about similarity/difference. This requires two augmentations to conventional networks: (1) a second dimension (the "binding" dimension), in addition to activation, along which units vary, and (2) "handle" units which respond to either sameness or difference on the binding dimension.

We view the task presented to the learner in Marcus et al.'s experiments as one of **grouping**, a fundamental aspect of all perceptual processing, both by humans and machines. Presented with a visual or auditory scene, people attempt both to segment it into distinct regions and to group regions together. They segment and group by making use of featural similarity, proximity, and common fate, as well as top-down knowledge of the domain. For segmentation, proximity obviously plays a large role, but for grouping, featural similarity may override proximity. Thus in rhythm perception, where grouping has been studied extensively (Handel, 1989), two elements that are separated by another may be grouped together because of their similarity to each other on some dimension. While segmentation and grouping are in some sense opposing processes, both amount to the **binding** together of regions that would otherwise not be associated with one another.

Thus any cognitive architecture that handles segmentation or grouping must offer a solution to the "binding problem," the problem of how to represent the short-term situation in which distinct cognitive units are treated as part of the "same thing." This problem has been discussed extensively in recent connectionist literature, and a family of related connectionist solutions has been proposed (Shastri & Ajjanagadde, 1993). All of these involve the augmentation of conventional archi-

tectures and algorithms with a further dimension in addition to activation along which processing units can vary. We will refer to this as the "binding dimension." Binding two units then corresponds to coincidence of those two unit's values on the binding dimension. Most often the binding dimension involves the firing of units, and binding itself is synchronization of firing (Hummel & Biederman, 1992; Mozer, Zemel, Behrmann, & Williams, 1992; Shastri & Ajjanagadde, 1993; Sporns, Gally, Reeke, & Edelman, 1989). In PLAYPEN we make use of a simpler approach: alongside its activation, each unit is characterized by an **angle**, ranging from 0 to  $2\pi$  radians. The particular value taken by a unit's angle is not what is relevant; it is its value relative to that of other units in the network. Units with similar angles are temporarily "bound" together, treated as "the same thing"; units with very different angles (differences close to  $\pi$  radians) are treated as "different things."

To permit the representation and learning of relational correlations, we need one further augmentation. Rather than taking the form of simple connections between units, relational correlations are implemented via "handle" units called **relation units**. These are of two types, **sameness units**, which tend to be activated if their input units are activated and have similar angles, and **difference units**, which tend to be activated if their input units are activated and have different angles. Each of these units represents a pairwise relational correlation of one type or the other, and the connections joining these units represent higher-order relational correlations. Thus the architecture we proposed for learning content-specific correlations (Figure 1) becomes that shown in Figure 3 for relational regularities. Again the network is of the attractor type. We have modified the standard input and activation functions and the Contrastive Hebbian Learning algorithm (Movellan, 1990) to accommodate angles and relation units. For details, see Gasser and Colunga (1998).

Figure 3: PLAYPEN network for learning relational regularities. Only a few units are shown. Difference relation units appear as diamonds, sameness relation units as ovals. Unit angles are indicated by arrows. A single unit within each pattern position has been activated, leading to the activation of some relation units.

Note that each unit in this network (as in the network in Figure 1) has specific content, but in addition, at any point in time, through its angle, each unit also represents a hypothesis about how the elements in the pattern are to be grouped.

### Simulation of Marcus et al.'s Experiment

Now consider again the task of Marcus et al.'s experiment. First, we agree with Seidenberg and Elman (1999) that knowledge about syllable similarity would have been learned prior to the experiment so should already be in place in the architecture. For the PLAYPEN model, this knowledge takes the form of connections (via sameness and difference units) representing the similarity or difference between syllables or syllable features. When the units representing pairs of syllables are clamped in the PATTERN layer, that is, when their activations are fixed at some positive value but their angles are still allowed to vary, these connections cause similar syllables to have the same angle and different syllables to have different angles.

We again assume a range of degrees of coarseness in syllable encodings and, for simplicity, local encodings. The presentation of a pattern, say, *le le di*, takes the form of the clamping of PATTERN units corresponding to these syllables in the relevant sequential positions. Syllable units at greater degrees of coarseness are activated (inhibitory connections between incompatible syllable units prevent all syllable units from being activated as a result of feedback from the coarse units). Further because of the built-in (or previously learned) relational connections implementing similarity, the angles of the syllables take on a pattern representing the *grouping* of the pattern elements: the first two elements make up one group, the third element another. The activated PATTERN units cause particular CORRELATION units to be activated. For example, the difference unit representing *le* in second position and *di* in third position and the difference unit representing some CV syllable in second position and some CV syllable in third position are both activated. Contrastive Hebbian Learning results in the strengthening of connections both into and between the activated CORRELATION units, as well as possibly the weakening of other connections that are not joined by activated units. Figure 4 shows some of the units and connections that are involved.

We simulated Marcus et al.'s task by training networks of this type on one of the three grammatical rules: AAB, ABA, or ABB. In each case, the set of training patterns consisted of four different syllable sequences, each formed by randomly combining syllables following the appropriate grammatical rule. Each network was trained on 50 repetitions of the training set.

The networks were then tested on 12 sequences, four each of the three kinds of grammatical rules, by clamping the units corresponding to each sequence. Each of the test sequences was novel; that is, it was formed by combinations of syllables that had never been seen before.

Since training the network leads to the strengthening and weakening of connections into and within the CORRELATIONS layer, test patterns should result in more activation on the CORRELATIONS layer if they are consistent with the training set. Thus familiarity with a test pattern was measured in the network as activation of the CORRELATIONS

Figure 4: PLAYPEN Network implementing Marcus et al. Only a few units are shown. Connections implementing similarity between PATTERN element units and inhibitory connections between incompatible element units are not shown. The activated (black) units in the PATTERN layer are those that would be active following the presentation of the pattern *le le di*. Four of the relation units that would be activated as a result of this are shown, and ten connections that would be strengthened during the resulting learning. Two of these connections, those joining the units in the CORRELATIONS layer, represent higher-order relational correlations.

units. Because the PATTERN units include very general ones (for example, one that is activated for any CV syllable in second position), the CORRELATIONS layer should be activated relatively highly even by specific syllable sequences it has not been trained on, as long as they are consistent with the training rule.

The average results from 10 networks trained on each grammatical pattern are shown in Figure 5. The total activation of the CORRELATIONS layer was averaged over four trials of each of the test words. The expected interaction between training rule and testing rule is highly significant ( $p < .001$ ). As shown in Figure 5, the CORRELATIONS layer is more activated for novel sequences that follow the grammatical rule the network was trained on than for novel sequences that follow either of the other two rules.

There are several points to note about the way the network learns the tasks.

1. Each unit in the network encodes content information as well as relational information. Thus an activated CORRELATION unit represents at the same time the co-occurrence of particular syllables (or syllable types if it is connected to relatively coarse PATTERN units) and the co-occurrence of syllables bearing a particular similarity relation to one another.
2. Though it cannot perform the segmentation that is a part of Saffran et al.'s task, this network can learn the content-specific correlations in the three-syllable patterns in the task. Since each of the patterns consists of three different syllables, the PATTERN units would take on three differ-

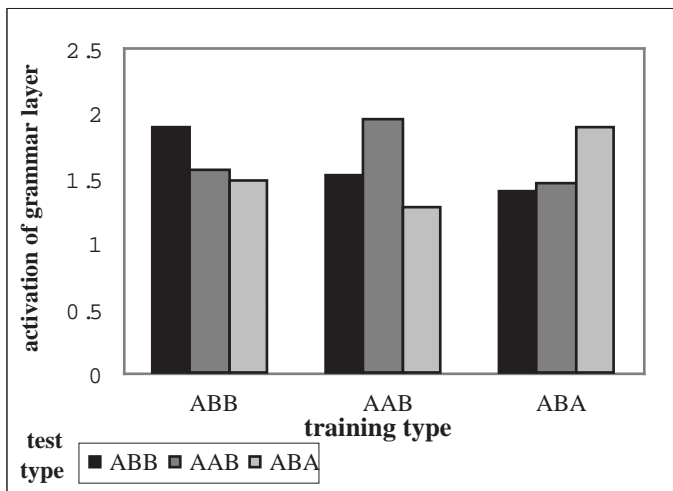

Figure 5: Networks that have been trained on sequences following a certain grammatical pattern respond with more activation to *novel* sequences obeying that same pattern than to novel sequences obeying other patterns.

ent angles for each pattern, activating difference units in the CORRELATIONS layer and resulting in learning on the connections between these units (representing higher-order content-specific regularities).

- While this was not true of Marcus et al.’s task, a set of patterns may embody more than one higher-order relational regularity. For example, in a set of four-element patterns, some patterns might be consistent with the rule AABB and others consistent with the rule ABBA. While we are unaware of experiments testing the ability of subjects to extract such rules, we assume that the ability to learn multiple rules is necessary for language acquisition. A network like that in Figure 4 (but with four positions) could learn both regularities, each as patterns of connections between the six pairwise relational regularities.

## Contrasting Two Accounts of Relational Pattern Learning

### A Rule-Based Account

A number of models have been proposed to handle the results of Marcus et al.’s experiments (Christiansen & Curtin, 1999; Seidenberg & Elman, 1999). Here we contrast only ours and the rule-based account proposed by Marcus (forthcoming). Marcus argues that tasks such as this one, in fact higher cognition and language generally, rely on the learning and manipulation of **explicit rules** containing **abstract variables**, placeholders that apply to any member of a given class.

Having been trained on a pattern learning task of the type in Marcus et al.’s experiments, the learner extracts an explicit rule of the form AAB, where A and B are now abstract variables in Marcus’s sense, and the variables are all associated with some class, say the class of CV syllables (the experiments demonstrate only that infants generalize to other members of this class).

Now consider what patterns will be recognized as familiar after training. Obviously patterns that are identical to those

appearing during training are familiar; if the learner heard the sequence *le le di* during training, that sequence will be recognized later on because it matches the AAB rule. Likewise any pattern consisting of three members of the relevant class for the variables in which the first two elements are identical also matches. So if the relevant class is CV syllables, even if the syllables *ko* and *bi* did not appear during training, the pattern *ko ko bi* will be treated as familiar, apparently just as familiar as *le le di* since all members of the class match the variables equally well. Furthermore, the sequences *le le le* and *ko ko ko* are also familiar since, assuming these variables behave like those in first-order predicate calculus, the rule does not force the third element to be different from the first and second.<sup>1</sup>

Now consider what patterns would fail to be treated as familiar. Since identity is all-or-none, patterns in which the first two elements are only similar, such as *le le di* (where  $\varepsilon$  is the vowel in *bed*) would be treated as unfamiliar. Likewise patterns in which the elements are outside the class over which the variables are defined would not be recognized. Thus, again assuming that CV syllables are the relevant class, *les les dis* would not be seen as familiar.

### The Relational Correlation Account

The relational correlation account that we have presented in this paper differs from the rule-based account in that content still matters. This is because, even when what is learned are relational, rather than content-specific, correlations, the correlations apply only to a certain range of elements. The extent of this range depends on the encoding coarseness of the PATTERN units in question, but given a range of degrees of coarseness, we can expect some relatively content-specific relational correlations to be learned, along with some more general relational correlations.

The implication is that the network’s response will depend on the degree of similarity between the training and test patterns, as well as on whether the training rule is followed. Patterns that are identical to the training patterns should result in the greatest familiarity. Those that are similar should be treated as less familiar. Those that are quite different, as in Marcus et al.’s experiments, should be still more surprising (though still less so than novel patterns that do not follow the rule).

For the network, the notion of the class over which a variable is defined does not exist. Because CVC syllables share some features with CV syllables, we can expect some generalization to CVC patterns that follow the rule, especially if they share segments with the training syllables.

Further, sameness and difference have equal status in the network, so trained on AAB patterns, the network cannot help but learn that the third element is different from the first and second, as it learns that first and the second are the same. This contrasts with the rule-based approach which requires the learning of an extra predicate to encode the distinctness of the third element.

Finally, difficulty of pattern learning should depend on the number of distinct syllables in the word. When a pattern has

<sup>1</sup>Of course, the learner could also extract in addition the explicit constraint that the third element differs from the first and second, but this would seem to be learning “more” than just the rule, so harder or less likely.

three distinct elements, the built-in connections implementing inter-element similarity and difference cause the activated PATTERN units to repel each other's angles, resulting in three different angles. However, depending on the magnitude of the weights connecting the units, there is also an attractor in the network at which there are only two different phase angles. At the same time, relation units can represent only binary relations, and strong associations between relation units can only develop for different relational regularities involving the same two objects (as in Marcus et al.'s experiments). Thus PLAYPEN has a strong preference for *two*, and in a four-syllable version of Marcus et al.'s experiment, we would expect that sequences such as ABCC would be confused with AABB and ABBB. In symbolic models, on the other hand, there is no built-in preference for a particular number of variables.

### Conclusions and Future Work

In this paper we have shown how a connectionist network with a mechanism for grouping together activated units (angles) and a mechanism for representing primitive relational knowledge explicitly (relation units) can learn the task of Marcus et al.'s experiments. While a PLAYPEN network is perhaps not a conventional neural network, we do not believe it has variables hidden in it. But whether it does or not, the key issue should be whether this model makes different predictions from alternate models, specifically from rule-based models. We have argued in the last section that this is the case. Most of these predictions are testable, and we are currently performing an experiment using visual patterns and adult subjects to test the role of similarity to training patterns in the learning of relational regularities. Preliminary results indicate that subjects are more accurate and faster at judging the familiarity of patterns following the training rule when their content is similar to that in the training patterns, as predicted by our model.

Another potential contribution of our model is the placing of "rule" learning in the context of segmentation and grouping. If we are right, then for auditory patterns such as those in the two sets of infant experiments discussed here, the considerable research on rhythm processing (Handel, 1989) is relevant and should lead to a range of predictions. For example, we might expect the relative timing or loudness of the syllables in patterns to play a role in what is learned.

Relations obviously play a fundamental role in human cognition, and we have argued elsewhere that the relational correlation framework embodied in PLAYPEN accommodates relations without sacrificing the distributed representations and simple Hebbian learning that characterize connectionist networks. Indeed the original motivation for PLAYPEN was the learning of spatial relation terms in language rather than the learning of sequences of syllables. We believe the importance of Marcus et al.'s experiments is not to demonstrate that infants can make use of variables but to show that they are good learners of relational correlations, a capacity that will be crucial as they are exposed to language in all its complexity.

## Abstract

Most tasks can be pursued by using different strategies (Logan, 1985; Reder & Schunn, 1998). In this paper we focus on strategies of learning from worked-out examples. Within a resource-oriented framework these different strategies can be classified according to their costs and benefits. These features may determine which strategy will be selected for accomplishing a task in situations with certain resource limitations. We investigate specific hypotheses about strategic adaptations to resource limitations (e.g., time pressure or lack of prior knowledge) within a hypertext-based learning environment. A comparison of the strategy selection of good and poor learners is used to assess the degree of subjects' resource adaptivity. Ideas for modeling resource-adaptive selection of strategies within the ACT-R architecture are discussed.

## Resource-Adaptive Selection of Strategies

According to Reder and Schunn (1998) individual performance differences in learning and problem-solving tasks may not only depend on the *variability of cognitive parameters* (e.g. speed of processing, working-memory capacity) or on interindividual differences in the *availability of strategies* for solving the same task. Instead subjects may differ with regard to their *ability of shifting strategies* as a consequence of changes in task demands or other situational parameters. Therefore, the *adaptive selection of strategies* should be of major importance for success in learning and problem solving. Theoretically, *associative approaches* explain strategy selection as a reaction to cues related to certain strategies (cf. Reder & Schunn, 1998). On the contrary, *rational approaches* assume that subjects choose strategies according to their costs and benefits in terms of resource demands and expected utility (cf. Payne, Bettman & Johnson, 1993; Logan, 1985). In our paper we prefer a rational approach which is based on a wide conception of resources comprising all internal and external means that are useful or necessary for solving a specific task. We focus on internal resources like prior knowledge and external resources like learning time and external information. The *costs* of adopting a specific strategy increase with its resource demands. Besides differences in costs, strategies may additionally differ with respect to their *benefits* (e.g., effectiveness in solving the task at hand, success in solving subsequent tasks, acquisition of different kinds of knowledge).

To describe processes of strategy selection within a resource-based framework *two different types of resource adaptivity* have to be distinguished: (a) On the one hand evolution may have forced cognitive systems to generally employ *resource-adapted strategies*, i.e. strategies that do not lead to optimal task performance but that are compatible with the usual limitations of processing resources. According to this assumption resource-adapted behavior will be even displayed in situations with relatively high resource availability. A well known theoretical approach to resource-

adapted behavior that may be applied to strategy selection is the concept of *satisficing* (Simon, 1990). According to this concept bounded rational agents do not select the most effective strategy for solving a task but rather set a specific aspiration level (probably associated with the value of the respective goal) and select a strategy that exceeds it. (b) On the other hand cognitive systems may be *resource-adapting* in that the strategies employed to pursue a certain task are additionally constrained by the configuration of resources currently available for the agent. If resources like knowledge, time or external information are restricted, strategies should be adopted that are less demanding with respect to these resources. These strategic shifts may compensate for performance impairments expectable without such adaptations. Severe limitations of specific resources or certain combinations of resource limitations may prove impossible to compensate. Taken together it can be postulated that subjects generally choose satisficing strategies even when no strong resource limitations are present. Additionally they should adapt to specific limitations by choosing strategies that are more frugal with respect to these limited resources. Therefore, our main aim is to determine whether subjects working under certain resource limitations employ the same strategies as subjects without such limitations or whether they adapt to these limitations in a useful way.

## Learning from Worked-Out Examples

In our empirical work we are specifically interested in strategies of learning from worked-out examples from the domain of probability word problems. Worked-out examples are instances of a certain problem type together with a detailed solution. They facilitate the learning of abstract procedures for later problem solving (Cummins, 1992; Catrambone, 1998) and the solving of novel problems by analogy (Gick & Holyoak, 1983; Reed, 1999). Prerequisites for the use of examples for knowledge acquisition and application are the generation of suitable example representations and the initiation of appropriate cognitive processes working on these representations. For our purposes strategies of learning from worked-out examples can be described on two dimensions: *rare versus frequent use* of examples and *brief versus extensive use* of examples. Van Lehn and Jones (1993) found that better learners preferred a rare use of examples and tried to solve training problems on their own. While good learners only inspected examples for getting specific information, poor learners referred back to examples as often as possible.

Beyond differences in the frequency of example use learners can use examples more or less extensively depending on the degree of example elaboration during learning. These elaborations may comprise the abstract deep structure of an example problem, the subgoal structure of its solution (Ca-

trambone, 1998), or the similarities and differences of the example compared to other examples from the same problem type (Cummins, 1992). Chi, Bassok, Lewis, Reimann & Glaser (1989) found that learners who elaborated examples during study substantially differed in their performance from learners that didn't elaborate on example problems. According to Chandler and Sweller (1991, p. 294) these results "indicate the importance to learning of an ability to properly process worked examples". Therefore, strategy selection in learning from worked-out examples may have a major influence on the quality of knowledge acquired.

## Hypotheses

Based on the underlying theoretical framework we derived five experimental hypotheses about resource-limitations in learning from worked-out examples and about adaptive strategy selection: (a) Learning may be impaired if relevant resources like learning time, prior knowledge or external information are severely limited. (b) Different resource limitations may not act additively but interact with each other if more than one resource is limited. Therefore, different combinations of resource-limitations may result in different patterns of performance impairments. (c) Strategy shifts may help compensate for performance impairments associated with certain resource configurations, though some combinations of resource limitations may prove impossible to compensate by strategic choices. Hence, good and poor learners may differ in strategic variables under some but not under all resource configurations. (d) It can be expected that subjects select faster but less accurate processing strategies if learning time is limited. In the case of limited prior knowledge or external information, subjects may select less information-demanding strategies even if these strategies involve time-consuming inferences. (e) The dimensions rare - frequent use of examples and brief - extensive use of examples should be useful to characterize strategies for learning from worked-out examples and to describe relevant strategy shifts.

To investigate these hypotheses we conducted a series of three experiments in which subjects' had to work on a learning and problem-solving task from the domain of probability word problems. We developed a hypertext system to serve as experimental environment that allowed us to log subjects' strategic decisions in great detail. With regard to our hypotheses a question of central importance is whether possible strategic differences between experimental conditions can be interpreted as adaptive. To answer this question we employed the method of contrasting *strategic differences between experimental conditions* with *strategic differences between good and poor learners* within experimental conditions. This approach allows us to decide whether subjects who learn under a specific configuration of resource limitations change their behavior in a direction that can be identified as useful given this configuration of resources.

## Experiment 1

### Method

**Participants** The subjects were 46 students of the University of the Saarland (UdS), Germany who either participated for course credit or payment. Average age was 24.5 years.

**Materials and procedure** In the hypertext environment a short introduction to the domain of combinatorics was presented and subjects were instructed to solve a number of *probability word problems* following a *self-paced learning phase*. In the learning phase of the experiment subjects could retrieve *abstract explanations* of six solution principles from the domain of combinatorics (with their associated formula) by clicking on the respective links in the navigation bar. In the *test phase* the instructional information of the learning phase was no longer available. Three test problems were presented on the screen and one of the test problems had to be selected to begin with. In this experiment *no worked-out examples* were included because in the first step we wanted to study performance and strategy selection in learning with purely abstract information.

**Design and dependent measures** As independent variables time pressure and prior knowledge were manipulated by implementing three different learning conditions. In the *baseline condition with high resource availability* subjects possessed relatively high domain-specific prior knowledge and were instructed to take as much time as needed to understand the solution principles and then to begin with the test phase by clicking on the respective link. In the *condition with low prior knowledge* learning time was likewise unlimited, but subjects were rather unfamiliar with the domain of combinatorics. In the *condition with low learning time* we restricted the learning time of subjects with high prior knowledge to seven minutes (i.e., about two thirds of the mean learning duration in the condition without limitations). To induce time pressure subjects were informed that they would only be granted two thirds of the time usually needed for the learning phase. When the learning time (visible for the subjects on a digital clock) expired, the first page of the problem solving phase was automatically presented on the screen and subjects were instructed to begin working on the test problems. During problem solving there were no time limits. In the test phase the subjects had to mark the appropriate solution principle and the values of two variables for each of the three test problems in a multiple-choice form available in the hypertext environment. No calculations had to be made. One error was assigned for each wrong answer. Problem-solving time as well as total learning time, mean reading time per abstract page presented and frequency of retrieving abstract information pages were recorded by using logfiles. Following the test phase subjects had to pass a knowledge test with ten multiple-choice questions related to abstract concepts from the domain of combinatorics. One error was assigned for each wrong answer. Similar conceptual questions were posed as a pretest at the beginning of the experiment to control for domain-specific prior knowledge. Additionally, we registered subjects' last math grade as a general measure of mathematical ability which ranged from grade one (best) to grade six (worst).

## Results and Discussion

First we investigated whether the three learning conditions differ with regard to performance and strategy measures. For this reason, we used the *baseline condition with high resource availability* as a point of reference and contrasted its data with the two other conditions (see table 1).

Table 1: Means and significance of differences

Learning without worked-out examples	A: Low prior knowledge	B: Base-line	C: Low learn. time	Significance of Difference
Problem-solving errors	52.3 %	32.5 %	42.1 %	A >> B << C
Knowledge-test errors	35.4 %	8.9 %	17.1 %	A >> B = C
Math grade	2.2	2.1	1.7	A = B = C
Pretest errors	65.8 %	32.2 %	30.2 %	A >> B = C
Frequency / abst. info.	22	24	15	A = B > C
Mean time / abst. info.	84 sec.	69 sec.	31 sec.	A = B >> C
Total learning time	823 sec.	722 sec.	397 sec.	A = B >> C
Problem solving time	782 sec.	726 sec.	759 sec.	A = B = C

Note: >>:  $p \leq .05$ ; >:  $p \leq .10$ ; =:  $p > .10$  (p-values result from one-tailed t-tests)

A comparison with the *low-prior-knowledge condition* (A versus B) reveals strong differences in problem-solving errors and knowledge-test errors while there are no differences with regard to strategic measures. This may imply that subjects with low prior knowledge don't try to compensate for their performance impairments by increasing problem-solving time or learning time if only abstract information about the solution principles is available in the learning environment. Comparing the baseline condition with the *low-learning-time condition* (B versus C) yields similar differences in problem-solving errors while there are no differences with regard to knowledge-test errors. In addition, both conditions differ with respect to strategic measures. Compared to subjects in the baseline condition subjects under time pressure retrieve abstract information pages less frequently and spend less time on each abstract information page. This change in strategic behavior is not obligatory as subjects could as well have reacted to time pressure by only reducing the mean time reading abstract information but not the retrieval frequency (as they do in experiment 2).

In a second step we evaluated the adaptivity of strategy shifts in experiment 1 by comparing good and poor learners within the experimental conditions with regard to the strategy measures listed in table 1 (post-hoc median splits according to problem-solving performance). To rule out the hypothesis that differences between good and poor learners are caused by differences in prior knowledge or math grade we inserted these variables as covariates in the statistical comparison of good and poor learners. The respective analyses of covariance reveal that there are no differences with regard to strategy measures distinguishing between good and poor learners. This implies that subjects' strategic options (modifying the frequency or intensity of processing abstract information) are unsuitable for improving problem-solving in the conditions with purely abstract information. Accordingly, efficiency impairments caused by restrictions in either prior knowledge or learning time cannot be easily compensated by strategic shifts in this experiment. Therefore, no resource-adaptive processes of strategy selection could be evidenced here. We conducted experiment 2 to investigate whether strategies of information processing are of greater importance in example-based learning.

## Experiment 2

### Method

**Participants and materials** The subjects were 46 students of the UdS who either participated for course credit or pay-

ment. Average age was 24.5 years. In experiment 2 the hypertext environment was supplemented by a single worked-out example per solution principle.

**Design and dependent measures** The same three learning conditions as in experiment 1 were implemented. Time pressure was induced analogously to experiment 1 by restricting learning time to nine minutes. The learning environment was augmented by a single worked-out example for each solution principle. These examples as well as the abstract information of the learning phase were no longer available in the test phase. Dependent measures were problem-solving errors, knowledge-test errors, domain-specific prior knowledge, last math grade, mean reading time per example provided, frequency of example retrieval (number of clicks), mean reading time per abstract information page, frequency of abstract information retrieval (number of clicks), total learning time, and problem-solving time.

### Results and Discussion

Compared to the baseline condition with high resource availability subjects in the *low-prior-knowledge condition* show substantial performance impairments in problem solving and in the knowledge test (see A versus B in table 2). Furthermore, there are significant differences with regard to strategic measures between the two experimental groups. Subjects with low prior knowledge spend more time on learning and especially show an increased frequency of retrieving abstract information as well as an increased mean time reading these pages. There are, however, no differences concerning the use of examples between the two groups. Comparing the baseline condition with the *low-learning-time condition* (B versus C) yields similar differences in problem-solving errors and knowledge-test errors. With respect to strategic measures, subjects in the low-learning-time condition retrieve examples less frequently and spend less time reading examples and abstract information. Interestingly, subjects under time pressure retrieve abstract information more often than baseline subjects.

Table 2: Means and significance of differences

Learning with one worked-out example	A: Low prior knowledge	B: Base-line	C: Low learn. time	Significance of Difference
Problem-solving errors	55.4 %	32.0 %	54.5 %	A >> B << C
Knowledge-test errors	36.8 %	13.1 %	20.9 %	A >> B < C
Math grade	2.6	1.9	2.0	A > B = C
Pretest errors	66.1 %	33.3 %	32.3 %	A >> B = C
Frequency / example	8	7	3	A = B >> C
Mean time / example	56 sec.	44 sec.	14 sec.	A = B >> C
Frequency / abst. info.	22	13	16	A >> B < C
Mean time / abst. info.	62 sec.	45 sec.	37 sec.	A >> B > C
Total learning time	1047 sec.	809 sec.	516 sec.	A > B >> C
Problem solving time	600 sec.	606 sec.	571 sec.	A = B = C

Note: >>:  $p \leq .05$ ; >:  $p \leq .10$ ; =:  $p > .10$  (p-values result from one-tailed t-tests)

A comparison of good and poor learners within the experimental conditions reveals the following strategic differences: In the *baseline condition* good learners spend more time reading examples than poor learners. In the *low-prior-knowledge condition* there are no strategic differences between good and poor learners. This implies that the performance in this condition may not easily be improved by

strategic shifts. Nevertheless, subjects with low prior knowledge try to improve their performance by learning longer (increased frequency and time reading abstract information). This shift, however, only increases costs in terms of time investment but doesn't yield any benefits in terms of performance. Therefore, subjects in this condition don't behave resource-adaptive.

In the *low-learning-time condition* good learners invest more time reading examples than do poor learners. In the light of this finding, it can be recommended that subjects under time pressure should save time by reducing time for abstract information processing without simultaneously confining the processing of examples. As the data in table 2 reveal, subjects under time pressure do not follow this recommendation towards resource-adaptive behavior. They only show a slight reduction in the mean reading time per abstract information page while there is a substantial decrease in the mean time reading examples. The respective interaction is significant and indicates that no resource-adaptive strategy shift took place. To conclude, performance impairments due to lacking prior knowledge cannot be compensated by selecting different strategies. Therefore, subjects' attempts to improve performance are in vain. On the other hand, performance impairments due to time pressure may be compensated by focussing on example information. Unfortunately, subjects do not shift their strategies in this direction. Therefore, no resource-adaptive strategy selection could be found in experiment 2.

We finally compared all six conditions from experiment 1 and 2. Contrasting the two conditions with low prior knowledge doesn't reveal any decrease in problem-solving errors due to the provision of examples. However, subjects in the one-example condition need less time for problem solving which indicates a slight increase in overall efficiency. A similar pattern of results can be found for the two baseline conditions. Unexpectedly, subjects in the low-learning-time condition deteriorate significantly with regard to problem-solving errors when provided with one example. Their problem-solving time is decreased analogously to the two other resource conditions. The respective interaction between time pressure (with/ without) and example availability (with/ without) with regard to problem-solving errors is significant.

To sum up, in our experimental setting learning with examples doesn't seem to be more effective than learning with only abstract information. At least the mere provision of instructional examples is obviously not sufficient to improve learning. Rather, the availability of examples must be accompanied by an extensive example-processing. As the differences between good and poor learners in the baseline condition and in the low-learning-time condition reveal this is crucial to performance. Furthermore, we found first support for the assumption that different kinds of resources may interact with regard to their effects on learning and problem solving. The augmentation of abstract information with one worked-out example slightly improves problem solving (i.e., reduces problem-solving time) if prior knowledge is restricted while it can have detrimental effects on problem-solving errors in the case of time limitation. In order to test whether these effects can also be observed when providing more than one example we conducted a third experiment.

## Experiment 3

### Method

**Participants and materials** The subjects were 43 students of the UdS who either participated for course credit or payment. Average age was 24.7 years. In experiment 3 the hypertext environment was supplemented by three worked-out examples of varying complexity to illustrate the application of each solution principle to different problem situations.

**Design and dependent measures** The same three conditions as in experiment 1 and 2 were used in this experiment. Time pressure was induced by allowing 13 minutes for learning in the time-limited condition. Dependent measures were the same as in experiment 2.

### Results and Discussion

Compared to the baseline condition with high resource availability subjects in the *low-prior-knowledge condition* again show an increase in both types of error rates (see table 3, A versus B). With regard to strategic measures, subjects with low prior knowledge spend less time reading examples but simultaneously show an increase in time reading abstract information. Their time for problem solving is slightly decreased. Surprisingly, the comparison between the baseline condition and the *low-learning-time condition* (B versus C) shows that time pressure does not lead to impairments in problem solving like it did in experiment 1 and 2. There are, however, differences in knowledge-test errors as expected. Concerning strategic measures, subjects under time pressure spend less mean time reading examples and retrieve examples less frequently.

Table 3: Means and significance of differences

Learning with three worked-out examples	A: Low prior knowledge	B: Baseline	C: Low learn. time	Significance of Difference
Problem-solving errors	50.3 %	32.5 %	28.9 %	A >> B = C
Knowledge-test errors	33.7 %	13.6 %	22.0 %	A >> B < C
Math grade	2.8	2.0	2.5	A >> B = C
Pretest errors	59.6 %	29.4 %	35.6 %	A >> B = C
Frequency / example	13	17	7	A = B >> C
Mean time / example	25 sec.	32 sec.	9 sec.	A < B >> C
Frequency / abst. info.	28	23	21	A = B = C
Mean time / abst. info.	71 sec.	49 sec.	54 sec.	A > B = C
Total learning time	1179 sec.	1153 sec.	751 sec.	A = B >> C
Problem solving time	522 sec.	640 sec.	753 sec.	A < B = C

Note: >>:  $p \leq .05$ ; >:  $p \leq .10$ ; =:  $p > .10$  (p-values result from one-tailed t-tests)

Comparing good and poor learners within the *baseline condition* shows that good learners spend more time on learning (especially on abstract information pages) and more time on problem solving. In the *low-prior-knowledge condition* good learners' frequency of retrieving examples and of retrieving abstract information is increased as well as their mean time reading example pages. Hence, it would be resource-adaptive in this condition to study abstract information and example information more intensively and in a well-balanced way. However, subjects with low prior knowledge even show a reduced mean time reading examples compared to subjects in the baseline condition. Furthermore, there is a significant cross-interaction between prior-knowledge (with/ without) and retrieval frequency of

different instructional material (examples/ abstract information). This interaction shows that low-prior-knowledge subjects focus on the retrieval of abstract information instead of handling examples and abstract information in a well-balanced way. In the *low-learning-time condition* good learners show an increased frequency of retrieving abstract information and examples. Thus a useful recommendation to subjects working under time constraint could be to retrieve example information and abstract information in a well-balanced way. A significant cross-interaction between time pressure (with/ without) and retrieval frequency of different instructional material (examples/ abstract information) reveals that subjects under time pressure focus on the retrieval of abstract information instead of handling examples and abstract information in a well-balanced way. Their behavior can thus not be classified as resource-adaptive. However, this is the only condition in which time pressure does not lead to significant performance impairments. This unexpected finding can be explained by considering that subjects more or less ignored the examples provided and therefore could spend the same amount of time in processing abstract information as subjects without time pressure and without instructional examples (i.e., baseline condition in experiment 1). Accordingly, their performance is comparable to that condition.

Contrasting the results from experiment 2 and 3 reveals that subjects with three examples learning in the baseline condition and in the low-prior-knowledge condition do not perform any better than the respective subjects in the one-example conditions. As explained before, improvements under time pressure are presumably not attributable to the provision of three examples but rather to the fact that subjects ignore the examples to save time for processing abstract information. The augmentation of instructional resources to three examples therefore does not prove as beneficial as could be expected when considering theories of learning by analogy (Gick & Holyoak, 1983) or theories of learning from worked-out examples (Cummins, 1992; Quilici & Mayer, 1996). At least the *mere provision* of three examples is obviously not sufficient to improve learning. Rather, the provision of multiple examples must be accompanied by a balanced processing of example information and of abstract information in order to acquire the relevant knowledge for problem solving. As the differences between good and poor learners in each of the three-example conditions reveal this is crucial to performance. Contrary to subjects learning with one example who profit most from studying the example intensively subjects learning with three examples should equally focus on abstract information. This finding fits theoretical assumptions about schema abstraction and the acquisition of transferable knowledge according to which it is necessary to compare different examples with respect to relevant abstract properties to induce theoretical concepts that may be applicable to analogous problems (Cummins, 1992).

## General Discussion

Contrary to our *first hypothesis (a)* we found that limitations of relevant resources are not always associated with performance impairments and accordingly that the provision of

relevant resources is not always associated with performance improvements. E.g., the provision of additional instructional information doesn't always improve problem-solving. It can even lead to impairments if subjects are overwhelmed by information selection and integration. This interpretation is in line with the fact that subjects with low learning time suffer from the provision of one example and that they resign from the processing of examples when provided with three examples. Furthermore, as postulated in our *second hypothesis (b)* effects of resource limitations are not always additive, but may even be cross-interacting. For example, the augmentation of instructional resources by worked-out examples is slightly beneficial for subjects with low prior knowledge (decreased problem-solving time), while it can even have harmful effects for subjects with low learning time (increased problem-solving errors). Contrary to our *third hypothesis (c)* no cases of resource-adaptive strategy shifts could be identified. There are no patterns of differences between experimental conditions that can be classified as adaptive with respect to differences between good and poor learners within these experimental conditions. Our *fourth hypothesis (d)* stating that subjects with limited learning time should select faster but less accurate example processing strategies was confirmed in experiment 2 and 3. Contrary to our expectations, subjects with low prior knowledge do not adopt more time-consuming strategies of example processing. Finally, as predicted in the *fifth hypothesis (e)*, the dimensions brief versus extensive use (time per example provided) and rare versus frequent use (frequency of example retrieval) are important dimensions for describing strategies of learning from worked-out examples. This can be inferred from the differences between good and poor learners and between experimental conditions with respect to these variables.

In conclusion, our experiments show that strategic options to improve one's learning performance become the more numerous the more instructional material is provided. At the same time it could be demonstrated that one has to make use of these strategic options, i.e., adopt adequate strategies in order to benefit from this additional information.

## Cognitive Modeling Approach

In the next step we intend to develop a more detailed model of resource limitations and their influences on processes of strategy selection. Within a cognitive science framework high-level processes of executive control like strategy selection in learning and problem-solving may be best modeled by means of cognitive architectures that are designed as comprehensive theories of human cognitive abilities. As a theoretical basis for the cognitive modeling of strategy selection in learning from worked-out examples we will refer to the ACT-R architecture (Anderson & Lebiere, 1998) that is based on a rational analysis approach compatible with our framework of resource-adaptive strategy selection. If one defines strategies for performing tasks as sets of procedures or operations that may be adopted in order to implement a certain goal, strategies can be easily represented in ACT-R by sets of productions that are sufficient to solve a task successfully. Based on this representation, two mechanisms of

action control can be distinguished in ACT-R that are useful in modeling strategy selection.

On the one hand, processing in ACT-R is controlled by the *currently active goal*. Productions referring to other than the current goal cannot be selected for execution. Strategy selection by setting strategy-specific subgoals can be interpreted as a choice process that is based on discrete symbolic knowledge and may be useful to model more deliberate aspects of strategy selection. Accordingly, goal setting implies that the accomplishment of the current task is interrupted for a period of meta-level decision making.

On the other hand, control in ACT-R is determined by the *mechanism of conflict resolution* that selects one of the conflicting productions that are compatible with the current goal for the next processing step. Strategy selection based on conflict resolution may be described as a subsymbolic process embedded within the fundamental mechanisms of the architecture. Conflict resolution is assumed to be an automatic process that is not consciously accessible and accordingly is initiated without changes in the current goal of information processing. ACT-R's mechanism for conflict resolution is based on an estimation of the expected gain  $E$  of the conflicting productions. For every feasible production  $i$  the value of  $E$  is determined by the formula  $E = P G - C$  with  $P$  being the expected probability of goal achievement when using  $i$ ,  $G$  being the goal value, and  $C$  being the expected costs of goal achievement when using  $i$ . Within this framework the resource limitations studied in our experiments can be modeled as follows.

**Time pressure** In ACT-R the goal value  $G$  is operationalized by the maximum amount of time that may be invested for goal achievement. Costs of goal achievement  $C$  are likewise measured by the time needed for goal accomplishment. Based on these conventions the mechanism of conflict resolution inherently produces a speed-accuracy trade-off depending on the available time. Time pressure will result in a decrease of  $G$ , leading to a lower weight of success probability and a higher weight of processing costs in production selection. As a result, less effective but at the same time less costly strategies will be selected for task accomplishment. Thus ACT-R enables the modeling of subjects' adaptation to limitations in time resources by automatic strategy shifts.

**Lack of prior knowledge** Limitations in domain-specific knowledge can be represented as gaps in declarative knowledge, i.e., the appropriate conceptual apparatus to encode the instructional material. In ACT-R these limitations can be best represented by missing chunk-types (representing concepts). Thus gaps in prior knowledge cannot be compensated automatically. Rather a deliberative setting of a specific learning goal may be necessary to first initiate activities to acquire the required conceptual knowledge.

**Limited external information** If external information necessary for the execution of the production with the highest expected gain in the conflict set is lacking this production is automatically abandoned in ACT-R and a production with less expected gain is selected that matches the currently available information. Thus a task can be handled successfully as long as there are productions available whose information demands are satisfied by the current external in-

formation. Augmenting external information beyond these minimal requirements will improve performance if this information can be encoded correctly and if there are productions available that properly use this information within the time available. To model the interaction between time limitations and example availability with regard to problem-solving errors we assume that subjects under time pressure may lack the necessary time to process example information properly. This may explain why the provision of one worked-out example is harmful for low-learning-time subjects while subjects with sufficient learning time don't show any efficiency impairments.

# A Neural Network Model of Concept-influenced Segmentation

Robert L. Goldstone (rgoldsto@indiana.edu)  
Department of Psychology, Indiana University  
Bloomington, IN 47405 USA

## Abstract

Several models of categorization assume that fixed perceptual representations are combined together to determine categorizations. This research explores the possibility that categorization experience alters, rather than simply uses, descriptions of objects. Based on results from human experiments, a model is presented in which a competitive learning network is first given categorization training, and then is given a subsequent segmentation task, using the same network weights. Category learning establishes detectors for stimulus parts that are diagnostic, and these detectors, once established, bias the interpretation of subsequent objects to be segmented.

## Concept Learning and Perception

The current research explores the influence that learning a new concept has on the segmentation of objects into component parts. Recently a number of researchers have argued that in many situations, concept learning influences the featural descriptions used to describe a set of objects. Rather than viewing perceptual descriptions as fixed by low-level sensory processes, this view maintains that perceptual descriptions are dependent on the higher-level processes that use the descriptions (Goldstone, Steyvers, Spencer-Smith, & Kersten, 2000; Schyns, Goldstone, & Thibaut, 1998). Evidence for this view comes from the study of expert/novice differences (Lesgold et al., 1988), influences of acquired concepts on the interpretation of stimuli (Wisniewski & Medin, 1994), and influences of category learning on psychophysical measurements of perceptual sensitivity (Goldstone, 1994).

## Experiential Influences on Object Segmentation

One type of influence of concept learning on perceptual learning may be to alter how objects are segmented into parts. Objects often have more than one possible segmentation. The letter "X" can be viewed as comprised of two crossing diagonal lines, or as a "V" and an upside-down "V" that barely touch at their vertices. The segmentation of scenes into parts depends upon experience. Behrmann, Zemel, and Mozer (1998) found that judgments about whether two parts had the same number of humps were faster when the two parts belonged to the same object rather than different objects. Further work has found an influence of experience on subsequent part comparisons. Two stimulus components are interpreted as belonging to the same object if they have co-occurred many times (Zemel, Behrmann, Mozer, & Bavelier, 1999). Thus,

experience with particular feature combinations determines whether or not features will be integrated into a single object.

Pevtzow and Goldstone (1994; reported in Goldstone et al., 2000) explored the influence of category learning on segmentation with the materials shown in Figure 1. We pursued the idea that how psychologically natural a part is might depend on whether it has been useful for previous categorizations. Naturalness was measured by how quickly subjects could confirm that the part was contained within a whole object (Palmer, 1978). To test this conjecture, we gave participants a categorization task, followed by part/whole judgments. During categorization, participants were shown distortions of the objects A, B, C, and D shown in Figure 1. The objects were distorted by adding a random line segment that connected to the five segments already present. Subjects were given extended training with either a vertical or horizontal categorization rule. For participants who learned that A and C were in one category, and B and D were in another (a vertical categorization rule) the two component parts at the bottom of Figure 1 were diagnostic. For participants who learned that A and B belonged in one category, and C and D belonged to the other category (a horizontal rule), the components on the right were diagnostic.

Figure 1: Pevtzow and Goldstone (1994) stimuli

During part/whole judgments, participants were shown a whole, and then a part, and were asked whether the part was contained in the whole. Participants were given both present and absent judgments, and examples of these judgments are shown in Figure 2. Note that the two parts shown in Figure 2 were both potentially diagnostic during

the earlier categorization training. Whether or not a part was diagnostic was independent of the appearance of the part itself, depending only on how the four objects of Figure 1 were grouped into categories.

Figure 2: Part/whole present and absent judgments

The major result was that subjects were faster to correctly respond "present" when the part was diagnostic than when it was non-diagnostic. To the extent that one can find response time analogs of signal detection theory sensitivity and bias, this effect seems to be a sensitivity difference rather than a bias difference, because absent judgments also tended to be faster for diagnostic than nondiagnostic parts. Given that a category part that was diagnostic for the horizontal categorization group was nondiagnostic for the vertical group, these results indicate that it is not simply the physical stimulus properties that determine how readily a person can segment an object into a particular set of components; segmentation is also influenced by the learned categorical diagnosticity of the components

### Modeling Interactions Between Concept Learning and Segmentation

We model the result from these experiment using a modified competitive learning network (Rumelhart & Zipser, 1985). As with the experiment, the network is first given categorization training, and then is given a subsequent segmentation task, using the same network weights. The goal of the modeling is to show how categorization training can prime the segmentation network such that objects will tend to be segmented into parts that were previously diagnostic for categorization.

#### The Categorization Network

The categorization network has three layers of units: one representing the input patterns, one representing a bank of learned detectors, and one reflecting the category assignments of the inputs. Both the weights from the input patterns to the detectors and the weights from the detectors to categories are learned. The categorization task uses a modified unsupervised competitive learning algorithm (Rumelhart & Zipser, 1985), but includes a top-down influence of category labels that incorporates supervised learning. The network begins with random weights from a two-dimensional input array to a set of detector units, and from the detectors to the category units. When an input pattern is presented, the unit with the weight vector that is closest to the input pattern is the "winner," and will selectively adjust its weights to become even more specialized toward the input. By this mechanism, the originally homogenous detectors will become differentiated

over time, splitting the input patterns into categories represented by the detectors. The competitive learning algorithm automatically learns to group input patterns into the clusters that the patterns naturally form. However, given that we want the detectors to reflect the experiment-supplied categories, we need to modify the standard unsupervised algorithm. This is done by including a mechanism such that detectors that are useful for categorizing an input pattern become more likely to win the competition to learn the pattern. The usefulness of a detector is assumed to be directly proportional to the weight from the detector to the presented category which is provided as a label associated with an input pattern. The input-to-detector weights do not have to be set before the weights from detectors to categories are learned.

In addition to modifying the unsupervised development of hidden-layer detectors by considering their usefulness for categorization, a second modification of the standard competitive learning algorithm is required to fix one of its general problems in optimally making use of all detectors to cover a set of input patterns. This problem is that if multiple input patterns are presented that are fairly similar to each other, there will be a tendency for one detector to be the winner for all of the patterns. As a result, the winning detector's weight vector will eventually become similar to the average of the input patterns' activations, while the rest of the detectors do not learn at all. This situation is suboptimal because the input patterns are not covered as well as they would be if the unchanging detectors learned something. The standard solution to this problem is called "leaky learning" and involves adjusting both winning and losing detectors, but adjusting losing detectors at a slower rate (Rumelhart & Zipser, 1985). To understand the more subtle problem with this solution, imagine, for example, that four input patterns naturally fall into two groups based on their similarities, and the network is given four detectors. Ideally, each of the detectors would become specialized for one of the input patterns. However, under leaky learning, one detector will tend to become specialized for one cluster, a second will become specialized for the other cluster, and the remaining two detectors will be pulled equally by both clusters, becoming specialized for neither. Note that it does not help to supplement leaky learning by the rule that the closer a detector is to an input pattern, the higher its learning rate should be. There is no guarantee that the two "losing" units will evenly split such that each is closer to a different cluster.

Other researchers have noted related but not identical problems with competitive learning and have suggested solutions (Grossberg, 1987). Our current solution is to conceptualize competitive learning as not simply a competition among detectors to accommodate a presented input pattern, but also as a competition among input patterns to be accommodated by a given detector. Input patterns are presented sequentially to the network, and as they are presented, the closest input pattern to each detector is determined. The learning rate for a detector is set to a higher value for its closest input pattern than for other

inputs. In this manner, detectors that are not the winning detector for a pattern can still become specialized by becoming unequally influenced by different patterns. In addition, the learning rate for a detector when presented with an input pattern will depend upon how well the input is currently covered by existing detectors. This dependency is required to allocate detectors to input regions where they are required. Putting these considerations together, the activation of detector  $i$  when presented with pattern  $p$ , is

$$A_{i,p} = \sum_{h=1}^n I_{h,p} W_{i,h} + \sum_{j=1}^c STW_{j,i}$$

where  $I_{h,p}$  is the activation of input unit  $h$  for pattern  $p$ ,  $W_{i,h}$  is the weight from input  $h$  to detector  $i$ ,  $S$  is the strength of the top-down pressure on detector development,  $T$  is the teacher signal (if Pattern  $p$  belongs to Category  $j$  then  $T=1$ , otherwise  $T=-1$ ), and  $W_{j,i}$  is the weight from Detector  $i$  to Category Unit  $j$ . The second term increases the activation of a detector to the extent that it is useful for predicting the input pattern's categorization. The detector activation will determine which detector is the "winner" for an input pattern. As such, detectors that are useful for categorization will tend to become winners, thus increasing their learning rate.

Input-to-detector weights are learned via top-down biased competitive learning using the following equation for changing weights from input pattern  $h$  to Detector  $i$ :

$$\Delta W_{i,h} = \begin{cases} M(I_{h,p} - W_{i,h}) & \text{if } \forall x(A_{i,p} \geq A_{x,p}) \\ N(I_{h,p} - W_{i,h})K_p & \text{if } \forall y(A_{i,p} \geq A_{i,y}) \\ O(I_{h,p} - W_{i,h})K_p & \text{otherwise} \end{cases} \text{otherwise}$$

where  $M$ ,  $N$ , and  $O$  are learning rates ( $M > N > O$ ), and  $K_p$  is the distance between pattern  $p$  and its closest detector. This distance is inversely related to the cosine of the angle between the vector associated with the closest detector and  $p$ . This set of learning rules may appear non-local in that all detectors are influenced by the closest detector to a pattern, and depend on previous presented inputs. However, the rules can be interpreted as local if the pattern itself transmits a signal to detectors revealing how well covered it is, and if detectors have memories for previously attained matches to patterns. When an input pattern is presented, it will first activate the hidden layer of detectors, and then these detectors will cause the category units to become activated. The activation of the category unit  $A_j$  will be

$$A_j = \sum_{i=1}^d A_i W_{j,i}$$

where  $d$  is the number of detectors. Detector-to-category weights are learned via the delta rule  $\Delta W_{j,i} = L(T - A_j)A_i$  where  $L$  is a learning rate and  $T$  is the teacher signal described above.

We formed a network with 2 detectors units and 2 category units, and presented it with four input patterns. We gave the network four patterns that were used in experiments with human subjects. These patterns are not identical to the patterns shown in Figure 1, but are of the

same abstract construction. When the patterns were categorized as shown in Figure 3A, such that the first two patterns belonged to Category 1, and the second two patterns belonged to Category 2, then on virtually every run, the detectors that emerged were those reflecting the diagnostic segments -- those segments that were reliably present on Category 1 or Category 2 trials. The picture within a detector unit in Figure 3 reflects the entire weight vector from the 15 X 15 input array to the detector. When the same patterns are presented, but are categorized in the orthogonal manner shown in Figure 3B, then different detectors emerge that again reflect the category-diagnostic segments. In both cases, each detector will have a strong association to one and only one of the category units. This is expected given that one of the factors influencing the development of detectors was their categorical diagnosticity. For the results shown here, and the later simulations to be reported, the following parameter values were chosen:  $M=0.1$ ,  $N=0.05$ ,  $O=0.02$ , and  $S=0.1$ . Activation values were between  $-1$  and  $+1$ . One hundred passes through the input materials were presented to the network. In the example shown in Figure 3, only 30 passes with each of the

Figure 3: Categorization-dependent detectors are acquired

4 patterns was required for the complete specialization of detectors to input patterns.

### The Segmentation Network

The basic insight connecting categorization and segmentation tasks is that segmentation can also be modeled using competitive learning, and thus the two tasks can share the same network weights and consequently influence on each other. Competitive learning for categorization sorts complete, whole input patterns into separate groups. Competitive learning for segmentation takes a single input pattern, and sorts the pieces of the pattern into separate groups. For segmentation, instead of providing a whole pattern at once, we feed in the pattern one pixel at a time, so instead of grouping patterns, the network groups pixels together. Thus, each detector will compete to cover individual pixels of an input pattern such that the detector with the pixel-to-detector weight that is closest to the pixel's

actual value will adapt its weight toward the pixel's value, and inhibit other detectors from so adapting. With this technique, if the pattern in Figure 4 is presented to the network, the network might segment it in the fashion shown in Panel A. Panels A-D show the weights from the 15 X 15 input array to each of two detectors, and reflect the specializations of the detectors. The two segments are complements of each other — if one detector becomes specialized for a pixel, the other detector does not.

Unfortunately, this segmentation is psychologically implausible. No person would decompose the original figure into these parts. To create psychologically plausible segmentations, we modify the determination of winners. Topological constraints on detector creation are incorporated by two mechanisms: A) input-to-detector weights "leak" to their neighbors in an amount proportional to their proximity in the 15 X 15 array, and B) input-to-detector weights also spread to each other as a function of their orientation similarity, defined by the inner-product of four orientation filters. The first mechanism produces detectors that tend to respond to cohesive, contiguous regions of an input. The second mechanism produces detectors that follow the principle of good continuation, dividing the figure "X" into two crossing lines rather than two kissing sideways "V"s, because the two halves of a diagonal line will be linked by their common orientation. Thus, if a detector wins for pixel X (meaning that the detector receives the more activation when Pixel X is on than any other detector), then the detector will also tend to handle pixels that are close to, and have similar orientations to, Pixel X. The segmentation network, augmented by spreading weights according to spatial and orientational similarity, produces segmentations such as the one shown in Panel B of Figure 4.

Although the segmentation in Panel B is clearly superior to Panel A's segmentation, it is still problematic. The pixels are now coherently organized in line segments, but the line segments are not coherently organized into connected parts. Spreading weights according to spatial similarity should ideally create segmentations with connected lines, but such segmentations are often not found because of local minima in the harmony function (the value N defined on the next page). Local minima occur when a detector develops specializations for distantly related pixels, and these specializations develop into local regions of mutually supporting pixels. Adjacent regions will frequently be controlled by different detectors. Each of the detectors may have sufficiently strong specializations for local regions that they will not be likely to lose their specialization, due to the local relations of mutual support.

Our solution to local minima is to incorporate simulated annealing, by which randomness is injected into the system, and the amount of randomness decreases as a function of time. Unlike standard annealing techniques, we reduce the amount of randomness in the system over time, but do so by basing the amount of randomness on the current structural goodness of a solution (Hofstadter & Mitchell, 1994).

The segmentation network works by fully connecting a 15 X 15 input array of pixel values to a set of N detectors. Although ideally the value of N would be dynamically determined by the input pattern itself, in the current modeling, we assume that each object is to be segmented into two parts (as did Palmer, 1978). When an input pattern is presented, the pixels within it are presented in a random sequence to the detectors, and the activation of Detector i which results from presenting Pixel p is

$$A_{i,p} = \sum_{h=1}^n I_h W_{i,h} S_{h,p}$$

where  $I_h$  is the activation of Pixel h,  $W_{i,h}$  is the weight from Pixel h to Detector i, and S is the similarity between pixels h and p. As such, detectors are not only activated directly by presented pixels, but are also activated indirectly by pixels that are similar to the presented pixels. Thus, a detector will be likely to be strongly activated by a certain pixel if it is already activated by other pixels similar to this pixel.

The similarity between two pixels h and p is determined by

$$S_{h,p} = T \frac{\sum_{i=1}^n G_{ih} G_{ip} L_{i,h,p}}{n} + U e^{-D_{h,p} C}$$

Where T and U are weighting factors,  $G_{ih}$  is the response of orientation filter i to Pixel h,  $L_{i,h,p}$  is the degree to which Pixels h and p fall on a single line with an orientation specified by filter i,  $D_{h,p}$  is the Euclidean distance between Pixels h and p, and C is a constant that determines the steepness of the distance function. Four orientation filters were applied, at 0, 45, 90, and 135 degrees. The response of each filter was

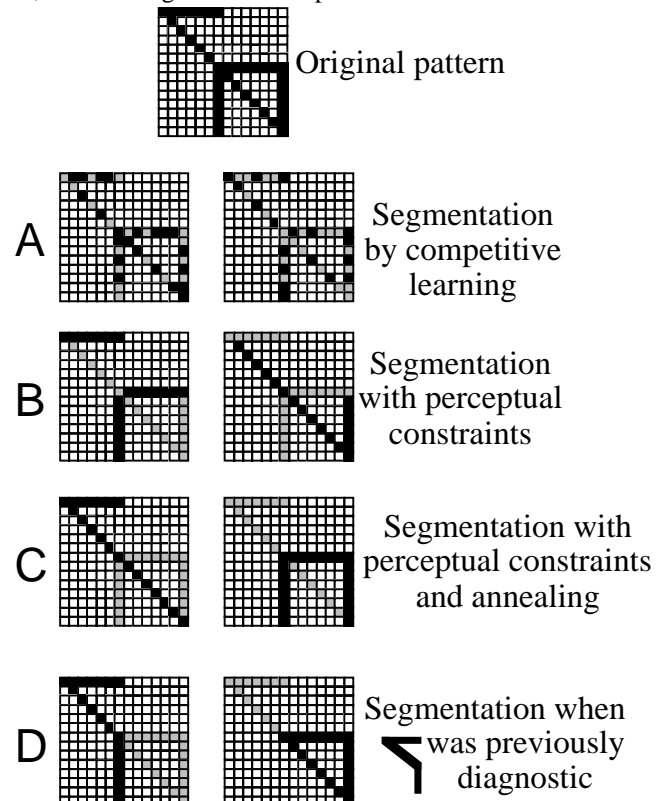

Figure 4. Segmentations of the original figure with incremental improvements from A-D.

found by finding the inner product of the image centered around a pixel and a 5 X 5 window with the image of one of the four lines. Thus, the greater the overlap between the line and the image, the greater will be the output of the filter for the line. The alignment of two pixels along a certain direction was found by measuring the displacement, in pixels, between the infinite length lines established by the two pixel/orientation pairs.

Pixel-to-Detector weights are learned via competitive learning:

$$\Delta W_{i,p} = \begin{cases} M(I_p - W_{i,p}) + \text{Random}(-N,+N) & \text{if } \forall x(A_{i,p} \geq A_{x,p}) \\ \text{Random}(-N,+N) & \text{otherwise} \end{cases}$$

Where M is a learning rate, and Random(-N,+N) generates Gaussian random noise between + and - N. The amount of noise, N, in adjusting weights is a function of the harmony across all detectors relative to R, the maximal harmony in the system:

$$N = R - \sum_{i=1}^n \sum_{p=1}^m \sum_{h=1}^m I_h I_p W_{i,h} W_{i,p} S_{h,p}$$

As such, if similar pixels in similar states have similar weights to detectors, then the harmony in the system will be high, and the amount of noise will be low. Thus, the amount of randomness in the weight learning process will be inversely proportional to the coherency of the current segmentation. These learning equations allow the network to regularly create the segmentation shown in Panel C of Figure 4.

In the simulations of the segmentation network to be reported, no attempt was made to find optimally fitting values of the constants. T and U were set at 0.5, M was set at 0.1, and C was set to 1.

### Combining the Networks

Considered separately, the categorization and segmentation networks each can be considered to be models of their respective tasks. However, they were also designed to interact, with the aim of accounting for the results from Pevtzow and Goldstone's (1994) experiments with human subjects. The segmentation network, because it shares the same input-to-detector weights that were used for the categorization network, can be influenced by previous category learning. Detectors that were diagnostic for categorization will be more likely used to segment a pattern because they have already been primed. Thus, if a particular shape is diagnostic and reasonably natural, the network will segment the whole into this shape most of the time, as shown in Panel D Figure 4. In short, category learning can alter the perceived organization of an object. By establishing multi-segment features along a bank of detectors, the segmentation network is biased to parse objects in terms of these features. Thus, two separate cognitive tasks can be viewed as mutually constraining self-organization processes. Categorization can be understood in terms of the specialization of perceptual detectors for particular input patterns, where the specialization is influenced by the diagnosticity of a segment for

categorization. Object segmentation can be viewed as the specialization of detectors for particular parts within a single input pattern. Object segmentation can isolate single parts of an input pattern that are potentially useful for categorization, and categorization can suggest possible ways of parsing an object that would not otherwise have been considered.

In order to model the results from the earlier human experiments, the network was first trained on distortions of the patterns A, B, C, and D shown in Figure 1, with either a horizontal or vertical categorization rule. As with the human experiment, the distortions were obtained by adding one random line segment to each pattern in a manner that resulted in a fully contiguous form. Following 30 randomly ordered presentations of distortions of the four patterns, the segmentation network was then presented with the original object shown in Figure 5. Segmentations were determined by examining the stable input-to-detector weight matrix for each of the two detector units.

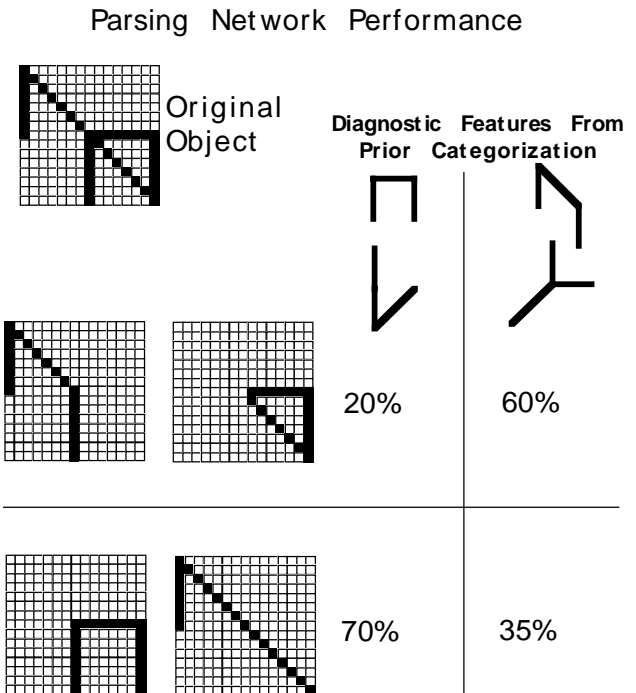

Figure 5. The segmentation of an ambiguous object is influenced by prior category learning.

One hundred subjects were simulated in each of the two pre-segmentation categorization conditions. As the results from Figure 5 indicate, the segmentation of the ambiguous original object is influenced by category learning. In particular, the original object tends to be segmented into parts that were previously relevant during category learning (column percentages do not add up to 100% because of rarely occurring alternative segmentations). As such, the results from Pevtzow and Goldstone (1994) are predicted under the additional assumption that response times in a

part/whole task are related to the likelihood of generating a segmentation that includes the probed part.

In a subsequent test of the networks, the actual wholes used by Pevtzow and Goldstone (1994) in their part/whole task were presented to the segmentation network. Each whole was presented 200 times, 100 times preceded by each of the two possible categorization rules. Out of the 24 whole objects tested, segmentations involving categorization-relevant parts were produced more often than segmentations involving irrelevant parts for 19 of the objects. This comparison controls for any intrinsic differences in naturalness between segmentations of a whole object because the parts that are categorization-relevant for half of the simulated subjects are irrelevant for the other half. As such, the results from Figure 5 generalize to the actual materials used in the experiment. Human subjects and the simulation were exposed to same image-based materials, rather than presenting a digested and abstracted stimulus representation to the simulation.

## Conclusions

A pair of neural networks were presented that learned to group multiple objects into categories, and learned to group parts from a single object into segments. More importantly, the computational modeling provides a mechanism by which one type of grouping influences the other. Category learning causes detectors to develop, and once these detectors have developed, there is a tendency to use the detectors when segmenting an object into parts.

Future work will be necessary compare the model to other existing models that allow for experience-dependent visual object segmentation (e.g. Behrmann et al., 1998; Mozer, Zemel, Behrmann, & Williams, 1992). Two extensions of the model would clearly be desirable: 1) allowing the model to determine for itself how many segments a pattern should be decomposed into, and 2) allowing the computed segmentation of a single pattern to influence its categorization. The latter extension is required to fit human experimental evidence suggesting that not only does category learning influence segmentation, but the perceived segmentation of an object influences its categorization (Schyns et al, 1998; Wisniewski & Medin, 1994).

The computational model, and associated experimental results, support theories that propose that categorization does not simply employ fixed descriptions such as geons, textons, holons, oriented lines segments, or spatial filters, but also creates new object descriptions. The primary advantage of such a state of affairs is that the perceptual system can become tuned and specialized to environmental demands. Cognitive science researchers who have proposed particular fixed sets of primitives have been clever, and have designed primitives that are useful for representing words, objects, and events. However, everyday people may be almost as clever as these researchers have been, and may be able to come up with their own sets of elements tailored to important categorizations (Schyns et al, 1998). Once created, these elements are then used for interpreting

subsequently encountered objects. To the person who has a hammer, the world looks like a nail, and to the person who has learned that a particular configuration is relevant for categorization, the world looks like it is composed out of that configuration.

## Abstract

SLIP (*Strategy Length & Internal Practicability*) is a new model of basic-level performance that postulates two computational constraints on the basic-levelness of a category: the number of feature tests required to place the input in a category (*Strategy Length*) and the ease with which these tests are performed (*Internal Practicability*). This article reports three experiments that examined the validity of SLIP in two-level taxonomies of computer-synthesized artificial objects. Experiment 1 isolated *strategy length*, Experiment 2, *practicability*, and Experiment 3 explored the interactions of these factors. Whereas SLIP predicted the RT of these experiments, two established basic-level models of basic-level performance, Jones's (1983) *category feature-possession* and Corter and Gluck's (1991) *category utility*, did not.

What distinguishes your cellular phone, your fountain pen, your computer, your house, and other everyday objects of yours from those of your neighbors is often a combination of features. For example, to identify your pink Porsche 911 in a parking lot also comprising a pink Toyota Tercel and a lime Porsche 911, you must examine both the *color* and the *shape* of the cars. This is so because real-world things share many features. The hierarchical organization of categories is a direct consequence of this sharing of features.

In a seminal article, Rosch, Mervis, Gray, Johnson & Boyes-Braem (1976) distinguished between three natural levels of categorization hierarchy (or taxonomy), the subordinate (e.g., "Porsche 911"), basic (e.g., "car") and superordinate (e.g., "vehicule"), from the most specific to the most general. Of all these levels, they showed that the basic was the best in many respects. People tend to: designate things by their basic-level names; list many more features at the basic level than at any other level; decide more rapidly that things are members of their basic categories than of any others; and so on.

SLIP (*Strategy Length & Internal Practicability*) is designed to model one of the most important index of basic-level performance: categorization speed. It postulates an ideal categorizer that performs the fewest possible number of features tests to classify things. Its name is derived from the fact that its attention slips off its ideal track once in a while.

Going back to the parking lot example, you had to check both the *color* and the *shape* of cars to find your pink Porsche 911. Fewer tests would have not lead to a definitive decision (because there were also a lime Porsche 911 and a pink Toyota Tercel). We call this optimal series of tests a *strategy*. Two aspects of strategies fully determine the response time of SLIP: their *length* and their *internal practicability*. Strategy length is simply the minimal number of tests required to complete a

strategy. In the parking lot example, strategy length is equal to 2 (one test on *shape*; one test on *color*). The longer a strategy associated with a category, the more time it will take to categorize an object in this category. The second factor of SLIP—*internal practicability* (or *practicability*, for short)—is simply the ease with which a particular test in a strategy can be executed (e.g., the number of features that uniquely define this category). The greater the practicability of a category, the less time it will take to verify that an object belongs to this category. SLIP integrates strategy length and internal practicability to predict categorization time (see the Appendix for formal details).

In Gosselin and Schyns (1997, 1999) we demonstrated that the principles of SLIP better predict the results of 22 classic basic-level experiments (from Rosch et al., 1976; Murphy and Smith, 1982; Mervis & Crisafi, 1982; Hoffmann & Ziessler, 1983; Murphy, 1991; Lassaline, 1990; Tanaka & Taylor, 1991; Johnson & Mervis, 1997; and Gosselin & Schyns, 1998) than the leading models (e.g., Jones's, 1983, *category feature-possession* and Corter & Gluck's, 1991, *category utility*).

No matter how successful, these simulations are *a posteriori* accounts of data. The validity of SLIP would be better tested with a direct examination of strategy length and internal practicability<sup>1</sup>. In three experiments, we isolated the possible role of these factors on basic-levelness. Specifically, Experiment 1 isolated the effect of strategy length, Experiment 2, the effect of internal practicability, and Experiment 3 the interactions of the two factors.

## Experiment 1

Experiment 1 examines the effect of *strategy length* on basic-levelness. Strategy length is the minimum number of required feature tests to perform a given categorization.

Experiment 1 is set up as a category verification task of two two-level taxonomies of artificial objects (see Figure 2). The taxonomies are designed to induce orthogonal patterns of categorization speed across conditions. In the HIGH\_FAST taxonomy, overlap of geons between categories defines a shorter strategy at the higher than at the lower level. In the LOW\_FAST taxonomy, different geon arrangements yield the reverse situation—i.e. longer strategies at the top than at the bottom level. SLIP predicts that shorter strategies are completed faster than longer strategies, irrespective of categorization levels.

<sup>1</sup> Furthermore, it must be noted that our data set of 22 published experiments is itself biased to mid-then-high-then-low level. Any model that predicts this RT sequence will be 58% right, irrespective of the actual hierarchy.

Hence, on the basis of only strategy length, SLIP predicts orthogonal categorization performance across taxonomies.

## Method

### Participants

Twenty University of Glasgow students with normal or corrected vision were paid to participate in the experiment.

### Stimuli

Stimuli were computer-synthesized chains of four geons (see Figure 1) similar to those used in Tarr, Bülthoff, Zabinski and Blaz (1997) in the context of object recognition. We designed stimuli with a three-dimensional modeling software on a Macintosh computer.

Figure 1. A four-geon chain used in Experiment 1.

Five geons defined the categories of the HIGH\_FAST taxonomy. One different geon defined each one of three high-level categories. Each one of six possible low-level categories was further specified by one of the two remaining geons. Figure 2 illustrates this taxonomy.

Figure 2. The HIGH\_FAST taxonomy of Experiment 1. The geons specify the defining information of each category. The bottom geon chains are the two PIM exemplars (they are also LAR exemplars) used in the experiment.

In Figure 2, strategy length equals 1 for the higher-level categories. A length 1 strategy means that only one feature needs to be tested (the feature defining each high-level category) to determine the membership of the objects at this level. Strategy length equals 2 at the lower-levels, because these categorizations require two feature tests. The longer strategies arise from the overlap of features across lower-level categories. Shortly put, in the taxonomy of Figure 2, lower-level categorizations require conjunctions of features to be tested. This difference between strategy lengths across the levels of a taxonomy is the backbone of Experiment 1. To create the actual

experimental stimuli, we further added two geons that served as *fillers* to obtain six four-geon objects. Fillers were identical across objects and so could not be used to categorize them. We created two exemplars per low-level category by changing the location of the diagnostic geons in the chain (see Figure 2, the bottom geon chains).

Nine geons defined the LOW\_FAST taxonomy. A unique combination of two geons (sampled from a set of three) defined each one of three top-level categories (see Figure 3). High-level strategies had length 2 because a two-geon conjunction had to be tested. A unique diagnostic geon further specified the bottom-level categories. Bottom-level categories had length 1 strategies because a single feature test determined membership. Figure 3 shows the LOW\_FAST taxonomy. We added one filler to generate six four-geon chains. From these, we created two exemplars per category (see Figure 3).

Figure 3. The LOW\_FAST taxonomy of Experiment 1. The geons specify the defining information of each category. The bottom geon chains the two PIM exemplars (they are also LAR exemplars) used in the experiment.

### Procedure

The procedure followed closely that of Murphy (1991). In a learning phase, participants were evenly split between the learning of the HIGH\_FAST and LOW\_FAST taxonomies. We instructed participants to learn the names and the defining geon(s) of nine categories. Participants saw their taxonomy on a sheet of paper (see Figures 2 and 3); this learning phase was not constrained in time.

We tested participants' knowledge of the taxonomy by asking them to list the features associated with each category name. Learning criterion was to list twice in a row, without any mistake, the defining features of each category. Corrective feedback was provided.

When subjects knew the taxonomy, a category verification task measured categorization time at each level. Each trial began with the presentation of a category name. Subjects could then press the "continue" computer keyboard button to see the list of all learned definitions on the screen (each definition corresponded to a set of geons per category). Participants had to identify the list associated with the previously shown category name. This insured that subjects accessed the representation of this category. After a 200 ms delay, an object appeared on the screen. Subjects had to decide—as fast as they possibly could—whether or not the named category and the object matched by pressing the "yes" or "no" computer keyboard key. We recorded response latencies. Note that low-level categories are more numerous than high-level categories. We normalized the number of positive and negative trials

with the constraint of equating the number of trials per level.

### Results and discussion

We performed the analysis of RTs on the correct positive trials that were within two standard deviations from the means. Table 1 reports the mean RTs at the low- and high-levels for the two taxonomies tested (see Observations in Table 1).

Table 1. Mean RTs for the Positive Trials of All Experiments As Well As Predictions of SLIP, Category Feature-Possession, and Category Utility (Erroneous Predictions Are Shaded).

	Model	Level	
		Low	High
Exp. 1, HIGH_FAST	Observation	1,256	896
	Possession	2	3
	Utility	.195	.222
	SLIP	6.4	3.2
Exp. 1, LOW_FAST	Observation	948	1,240
	Possession	1	3
	Utility	.25	.333
	SLIP	3.2	6.4
Exp. 2, HIGH_FAST	Observation	788	660
	Possession	1	3
	Utility	.375	.500
	SLIP	3.2	2.286
Exp. 2, LOW_FAST	Observation	740	774
	Possession	3	1
	Utility	.624	.500
	SLIP	2.286	3.2
Exp. 3, EQUAL	Observation	672	680
	Possession	1	5
	Utility	.176	.260
	SLIP	1.714	1.714
Exp. 3, SL_DOWN	Observation	920	1,058
	Possession	1	5
	Utility	.250	.333
	SLIP	1.714	3.429
Exp. 3, IP_UP	Observation	928	775
	Possession	1	5
	Utility	.250	.333
	SLIP	6.857	3.429

A two-way (GROUP x STRATEGY LENGTH) ANOVA of the RTs with repeated measures on one factor (STRATEGY LENGTH) revealed a main effect of STRATEGY LENGTH,  $F(1, 18) = 77.08, p < .0001$ , (mean length 1 strategies = 922 ms verification time; mean length 2 strategies = 1248 ms verification time), meaning that participants systematically verified length 1 strategies faster than length 2 strategies, irrespective of the considered level (low vs. high). Neither the interaction between GROUP and STRATEGY LENGTH,  $F(1, 18) = .84, ns$ , nor the main GROUP effect,  $F(1, 18) = .02, ns$ , were significant. The error rate was low overall and was not correlated with RT ( $r = -.17, ns$ ), ruling out a speed-accuracy trade-off.

Remember that SLIP predicts that length 1 strategies should be completed faster than length 2 strategies, irrespective of categorization level (see SLIP in Table 1 for numerical predictions with  $S = .25$ ). The data reported here confirms that strategy length, rather than categorization level, determines participants RTs.

## Experiment 2

Practicability refers to the ease with which the features identify a category at any level of a taxonomy. A category has high practicability if many of its defining features are uniquely diagnostic of this category (or if the features occupy few positions across exemplars). It will have low practicability if only one feature defines the category (or if the features can occupy many positions across exemplars). Practicability has so far been the only factor under study in basic-level experiments (see Gosselin & Schyns, 1997). Never has it been shown, however, that practicability could affect the basic-levelness of all categorization levels.

Experiment 2 isolates practicability in a two-level taxonomy using objects similar to those of Experiment 1. All strategies had length 1 but the high and low levels differed in practicability. In the HIGH\_FAST condition, high-level strategies had greater practicability than low-level strategies. The opposite applied to the LOW\_FAST condition, with low-level strategies having higher practicability. SLIP predicts that categories with higher practicability will be verified faster, irrespective of their level in the taxonomy.

### Method

#### Participants

Twenty students from University of Glasgow with normal or corrected vision were paid to participate in the experiment.

#### Stimuli

Stimuli were similar to those of Experiment 1: four-geon chains synthesized with a three-dimensional modeling software on a Macintosh computer.

The HIGH\_FAST condition used 10 diagnostic geons. Three different geons defined each one of two high-level categories; one different geon further defined each low-level category (see Figure 4). We generated two exemplars per category by changing the location (either rightmost or leftmost of the chain) of the three geons

defining the high-level categories (see Figure 4).

Figure 4. The HIGH\_FAST taxonomy of Experiment 2. The geons specify the defining information of each category. The bottom geon chains are the two NOP exemplars (they are also LAR exemplars) used in the experiment.

The LOW\_FAST condition involved fourteen diagnostic geons. A single diagnostic geon defined each one of two high-level categories, and three different geons further defined each one of four low-level categories (see Figure 5). As before, we created two category exemplars by changing the location (either far right or far left of the object) of the triplets defining the low-level categories (see Figure 5).

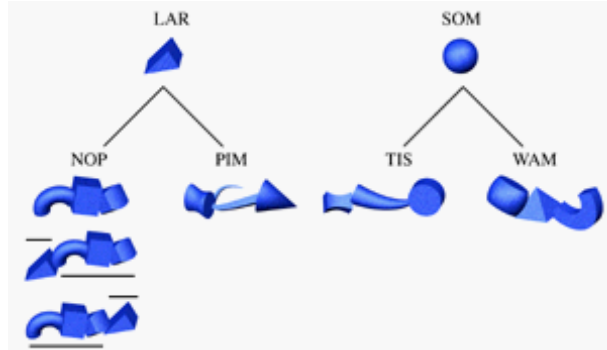

Figure 5. The LOW\_FAST taxonomy of Experiment 2. The geons specify the defining information of each category. The bottom geon chains are the two NOP exemplars (they are also LAR exemplars) used in the experiment.

Practicability is greater for high-level categories in the HIGH\_FAST condition and for the low-level categories in the LOW\_FAST condition because more unique features are associated with the top- and bottom-level categories, respectively. SLIP predicts a faster verification performance for categories with higher practicability (high in HIGH\_FAST and low in LOW\_FAST) irrespective of the level of the taxonomy considered.

#### Procedure

The procedure followed in all respects that of Experiment 1: Participants were randomly assigned to the HIGH\_FAST and LOW\_FAST conditions. They were taught their respective taxonomy before being measured on the categorization speeds of its levels. Each one of 280 trials consisted in the initial presentation of a category name followed by an object. Participants had to decide as fast as they possibly could whether the two matched and we recorded response latencies.

#### Results and discussion

We analyzed only the correct positive trials RTs within two standard deviations from the means. Table 1 shows the mean RTs at the low and high-levels for the HIGH\_FAST and for the LOW\_FAST taxonomies.

A two-way (GROUP x PRACTICABILITY) ANOVA on the RTs with repeated measures on one factor (PRACTICABILITY) revealed a main effect of practicability,  $F(1, 18) = 16.83$ ,  $p = .001$  (mean verification time = 700 ms for high practicability strategies; 781 ms for low practicability strategies). Out of 20 participants, only three did not respond faster to the greater practicability categories. Neither the GROUP x PRACTICABILITY interaction,  $F(1, 18) = 5.53$ , ns, nor

the main GROUP effect,  $F(1, 18) = .06$ , ns, were significant. The error rate was low overall and was not correlated with RT ( $r = .05$ , ns), ruling out a speed-accuracy trade-off.

In sum, SLIP predicted that greater practicability strategies should yield faster categorization decisions (see SLIP in Table 1 for numerical predictions with  $S = .25$ ). The results of Experiment 2 reveal that this factor determined RTs at different categorization levels.

### Experiment 3

Experiments 1 and 2 respectively revealed that strategy length and internal practicability—the two computational determinants of SLIP—can contribute independently to faster categorizations at any level of a taxonomy. Experiment 3 further explores how these two factors interact to determine performance.

There are many possible interactions to investigate and we will not investigate them all. Instead, we have selected to examine three scenarios that selectively change the fastest categorization level by selectively modifying either strategy length or internal practicability.

In the EQUAL scenario, strategies at the high and low-levels have an equal length of 1 and a constant practicability. SLIP predicts that in these circumstances, categorization speeds should be equal across levels. EQUAL is our baseline condition. In the SL\_DOWN scenario, practicability is constant across levels, but whereas low-level strategies have length 1, high-level strategies have length 2. SLIP predicts faster categorizations at the lower level. The IP\_UP scenario preserves the difference in strategy lengths, but it changes the fastest categorizations to the higher level by decreasing the practicability of the low level.

Together, EQUAL, SL\_DOWN and IP\_UP illustrate how the faster categorization level can go up and down a taxonomy by changing strategy length or the internal practicability, the two factors of SLIP.

#### Method

##### Participants

Thirty students from University of Glasgow with normal or corrected vision were paid to participate in the experiment.

##### Stimuli

Stimuli were similar to those of Experiments 1 and 2: geon chains designed with a 3D-object modeling software.

Nine diagnostic geons entered the composition of categories in the EQUAL, SL\_DOWN and IP\_UP conditions. In EQUAL, one geon defined each one of the nine categories of the taxonomy (see Figure 6). We added four fillers to each defining geon to form a total of six six-geon chains. We placed the geons defining the high-level categories at the far left of the chains, and those defining the low-level categories at the far right (see Figure 6).

Figure 6. This illustrates the EQUAL taxonomy of Experiment 3. The geons specify the defining information of each category. The bottom geon chain is the PIM exemplar (it is also a LAR exemplar) used in the experiment.

In SL\_DOWN, a unique combination of two of the nine geons defined each top-level category. The addition of one different geon further defined each lower-level category. (SL\_DOWN employed the Experiment 1, LOW\_FAST taxonomy but with a different set of geons). We produced six six-geon chains by adding three fillers. We placed the geon pairs defining the high-level categories at the far left of the chains, and those defining the low-level categories at the far right.

These chains also served to construct the exemplars of condition IP\_UP. Here, we generated four exemplars per category by changing only the location in the chain of the single geon defining the low-level categories (one of the four rightmost positions in the six-geon chains).

#### Procedure

The procedure was almost identical to that of experiments 1 and 2. Participants were randomly assigned to one of three conditions (EQUAL, SL\_DOWN, and IP\_UP). Following a learning of their taxonomy, they did 240 verification trials. Each trial consisted in the presentation of a category name followed by an object. Participants had to decide whether these matched and we measured response latencies.

#### Results and discussion

We performed the analysis of RTs on the positive, correct trials that were within two standard deviations from the means. Table 1 shows the mean RTs.

A two-way (GROUP x LEVEL) ANOVA with repeated measures on LEVEL revealed a significant interaction between GROUP and LEVEL,  $F(2, 27) = 11.85, p < .001$ , simple main effects of GROUP(SL\_DOWN) by LEVEL,  $F(1, 27) = 10.58, p = .003$ , GROUP(IP\_UP) by LEVEL,  $F(1, 27) = 13.09, p = .001$ , and GROUP(EQUAL) by LEVEL,  $F(1, 27) = .04, ns$ . The error rate was low overall and was positively correlated with RT ( $r = .31, p < .05$ ), ruling out a speed-accuracy trade-off.

SLIP predicted all the results observed in Experiment 3 (see SLIP in Table 1 for numerical predictions with  $S = .25$ ). Participants categorized equally fast at both levels in EQUAL. Increasing the strategy length of the higher level in SL\_DOWN induced faster categorizations of the lower level. Diminishing practicability at the lower level then made the high level faster. Thus, the two computational factors of SLIP predicted speed of categorization in taxonomies.

#### General Discussion

SLIP (Strategy Length & Internal Practicability) is a new model of basic-level performance. Three verification experiments tested the two computational determinants of the model: strategy length and internal practicability. In Experiment 1, strategy length was shown to decide basic-levelness. In Experiment 2, practicability was shown to be a second determinant of basic-level performance. In Experiment 3, interactions between strategy length and internal practicability in SLIP predicted the observed RTs.

SLIP performance can be compared to that of two well-established measures of basic-levelness, *category feature-possession* (Jones, 1983) and *category utility* (Corter & Gluck, 1990). The predictions of the models are given in Table 1. The scores of both category utility and category feature-possession should be inversely proportional to RTs; SLIP's scores should be directly proportional to RTs. The best predictor is SLIP with seven correct RT patterns out of seven, followed by category feature-possession with a hit rate of 5/7 (the mistakes have been shaded in Table 1), and trailed by category utility with a 4/7 hit rate.

It is instructive to decompose these scores into strategy length and internal practicability scores. For the conditions testing only practicability (Experiment 2, HIGH\_FAST and LOW\_FAST, and Experiment 3, EQUAL and IP\_UP), category feature-possession and category utility both predict 3/4 of all RT patterns. We have demonstrated elsewhere (Gosselin & Schyns, 1999) that these models are biased to faster responses at higher levels.

Interestingly, for the conditions testing only strategy length (Experiment 1, HIGH\_FAST and LOW\_FAST, and Experiment 3, EQUAL and SL\_DOWN) category feature-possession and category utility only predict 4/8 and 2/8 of the RTs, respectively. (Note that Experiment 3, EQUAL, is included in the break-down into strategy length and internal practicability; it is an extreme case of both.) This confirms the argument that category feature-possession and category utility neglect strategy length as a specific factor of basic level performance (Gosselin & Schyns, 1997). This is a serious problem because attributes do overlap between categories in the real-world, and so strategy length is an important factor of categorization performance outside the laboratory.

To the extent that any model of categorization implements computational constraints (even if these are not well specified), the conclusion is that those of SLIP are closest to those underlying the speed of access to the categories of a taxonomy.

## Appendix

A category is defined by a list of features. Typically, some of these features are unique to this category and some overlap with the defining features of other categories. An optimal strategy is the shortest series of tests on the features defining the category. We posit that SLIP categorizers always use optimal strategies. We call redundant features, or set of redundant features, the collection of features which, individually, provide exactly the same information as to the category membership of objects. In other words, testing one, two, or more redundant features does not provide more information.

Formally, we will say that a strategy is a series of sets of redundant features. It has succeeded whenever all sets of redundant features have been completed in a specific order. And a set of redundant features is completed as soon as a test on the presence of one of its redundant features has been performed.

This usually happens after a succession of misses. The probability of having  $t-1$  successive misses is given by  $(1 - \Psi_j)^{t-1}$  where  $\Psi_j$  – when redundancy of sets of features and the number of possible configurations that these can take in objects are taken into account – is equal to  $C_j(I-S) + C_jSR$ ; that is, the practicability of set of redundant features  $j$  or the probability that it will be completed after a single attempt.  $S$  is the probability of a random slip (it was arbitrarily set to .5 throughout the simulations), and  $C_j$  is the probability that the target features will be in the expected configuration (1 / number of configurations). Thus the first term of  $\Psi_j$  is the probability that the SLIP categorizer will guess the feature configuration correctly and that it

will not slip.  $R_j$  is the probability that a random slip will result in a diagnostic test ([cardinality of  $j$ ] / [number of features in objects]). The second term of  $\Psi_j$  is the probability that the categorizer will slip, but that it will guess the correct configuration and will perform a diagnostic feature test.

The probability of a hit is simply 1 minus the probability of a miss. Thus, the probability that the set of redundant features  $j$  will be completed after  $t$  trials is

$$(1 - \Psi_j)^{t-1} \Psi_j,$$

and the probability that a strategy of length  $n$  will have succeeded after  $t$  trials in a certain configuration of hits and misses is

$$\prod_{j=1}^n (1 - \Psi_j)^\Phi \Psi_j,$$

where  $\Phi$  is a function of  $j$  (it will remain unspecified) which gives the number of misses for the  $j$ th set of redundant features for that particular configuration. Usually, more than one such configuration exist. In fact, the number of possible configurations is easy to compute. The last hit necessarily happens at the  $t$ th trial; the  $n-1$  other hits, however, can happen anywhere in the  $t-1$  trials left, in order. Therefore, the number of possible configurations is the number of combinations of  $t-1$  items taken  $n-1$  by  $n-1$  that is,

$$\lambda = \binom{t-1}{n-1} = \frac{(t-1)!}{(t-n)!(n-1)!}.$$

We can now give the global shape of the probability that a strategy of lengths  $n$  will succeed after  $t$  trials:

$$\sum_{i=1}^{\lambda} \prod_{j=1}^n (1 - \Psi_j)^\omega \Psi_j,$$

where  $\omega$  is a function of  $i$  and  $j$  that specify the number of misses for the  $j$ th set of redundant features for the  $i$ th configuration of hits and misses. We call this the Response Time Function (RTF). We still have to specify  $\omega$ . We will establish a connection between this function and multinomial expansions. The multinome  $(a_1 + a_2 + \dots + a_n)^{t-n}$

expands into  $\lambda$  different terms, and the sum of the  $n$  exponents of each term is equal to  $t-n$ . It follows that  $\omega$  gives the  $j$ th exponent of the  $i$ th term in this multinomial expansion.

As a global measure of basic-levelness, we use  $t\_mean$ , the mean number of tests required to complete a strategy. When internal practicability is constant within a strategy (this is true for all experiments reported in this article), the RTF is a Pascal density function and, thus,

$$t\_mean \text{ is equal to } \frac{n}{\Psi}.$$

# Latent Semantic Analysis Captures Causal, Goal-oriented, and Taxonomic Structures

## Abstract

Latent Semantic Analysis (LSA) has been used to represent the domain of computer literacy in AutoTutor, a fully automated computer tutor. The analyses in the present study support the claim that the 200-dimensional LSA space captures aspects of the structured mental models that underlie computer literacy. Knowledge structures were constructed that contained causal networks, goal/plan/action hierarchies, and taxonomic hierarchies. The proximity of a pair of nodes (i.e., concept, state, event, action, goal) in these structures predicted the cosine similarity scores that are routinely computed in LSA analyses.

## Representing World Knowledge with Conceptual Graph Structures

World knowledge has traditionally been captured by knowledge structures throughout the history of cognitive science, artificial intelligence, and discourse processes. The knowledge structure structures include semantic networks, taxonomies, causal networks, planning networks, ontological trees, spatial region hierarchies, and various other classes of conceptual graph structures (Golden, 1997; Graesser & Clark, 1985; Kiel, 1979; Lehmann, 1992; Lenat, 1995; Norman & Rumelhart, 1975; Schank & Abelson, 1977; Trabasso, van den Broek, & Suh, 1989; Sowa, 1983). A knowledge structure contains a set of categorized nodes that refer to concepts, events, processes, states, actions, goals, and other ontological classes. The nodes are connected by

relational arcs that also are assigned to various categories, e.g., is-a, has-as-parts, cause, reason, enables, contains, etc. A particular package of knowledge may incorporate spatial composition, causal networks, goal hierarchies, taxonomic hierarchies and other viewpoints. All of these viewpoints allegedly can be represented as a set of categorized nodes that are integrated by a set of directed, relational arcs.

It is a time consuming, methodical task to map out knowledge structures for a domain of knowledge. Developers of expert systems and other knowledge based systems would require a decade to perform the knowledge engineering that is needed for a system of reasonable scope with widespread practical applications (Lenat, 1995). There are authoring tools that guide either experts or novices in the building of the knowledge structures (Williams, Hultman, & Graesser, 1998). The structures are built in a principled fashion that caters to the constraints of the composition rules, so guidance is needed to prevent illegal compositional structures. All of this takes training and experience that can be measured in months or years. However, conceptual graph structures are powerful theoretical entities because they support the intelligent procedures and processes that operate on the representations, as in the case of retrieval, classification, summarization, problem solving, question asking, question answering, and so forth.

The distance between two nodes in a conceptual graph structure is frequently regarded as a metric of conceptual relatedness. That is, the conceptual relatedness between

nodes A and B decreases as a function of the number of arcs that exist on a legal path between A and B. For example, if 1 arc separates A and B on a causal chain, then A and B are strongly related, compared to the case where 4 arcs separate two nodes on a causal chain. The structural proximity between any two nodes that are connected by a legal path of arcs is designated as its structural-proximity (A, B).

### Representing World Knowledge with Latent Semantic Analysis

Researchers have more recently turned to Latent Semantic Analysis (LSA) because it provides an approximation of the representation of world knowledge, but in a very short period of time -- measured in weeks, days or even hours. LSA is a statistical representation of a body of world knowledge that is reflected in a large corpus of textual documents (Landauer & Dumais, 1997; Landauer, Foltz, & Latham, 1998). LSA capitalizes on the fact that particular words appear in particular texts (called "documents"); the cooccurrence of words in documents reflects the constraints that exist in world knowledge. The input to LSA is a cooccurrence matrix that specifies the number of times that word  $W_i$  occurs in document  $D_j$ . These frequencies are adjusted with a logarithm transformation that also corrects for the base rates of words appearing across documents. A word is a distinctive index for a document to the extent that its occurrence in the document is above the base rate for that word across documents. A standard statistical method, called singular value decomposition, reduces the large  $W \times D$  cooccurrence matrix to  $K$  dimensions (typically, 100 to 500 dimensions). Each word, sentence, or text ends up being represented as a weighted vector on the  $K$  dimensions.

The similarity or conceptual relatedness between two bags of words (A and B) is computed as a geometric cosine (or dot product) between the two vectors. The values normally range from 0 to 1. This LSA match between two language strings is designated as its LSA-match (A, B). The LSA match can be high even though there are few, if any words in common between the two strings. LSA allegedly goes well beyond simple string matches because the meaning of a language string is partly determined by the company (other words) that each word keeps (Landauer & Dumais, 1997).

The empirical success of LSA has been promising and sometimes remarkable. Landauer and Dumais (1997) created an LSA representation with 300 dimensions from 4.6 million words that appeared in 30,473 articles in Grolier's Academic American Encyclopedia. They submitted to the LSA representation the synonym portion of the TOEFL test, a test developed by the Educational Testing Service to assess how well non-native English speakers have mastered the words in the English language. The test has a four-alternative, forced choice format, so there is a 25% chance of answering the questions correctly. The LSA model selected the alternative that had the highest match with a

comparison word. The LSA model answered 64.4% of the questions correctly, which is essentially equivalent to the 64.5% performance for college students from non-English speaking countries. LSA has had remarkable success in capturing the world knowledge that is needed to grade essays of students (Foltz, 1996), to assign texts to students of varying abilities to optimize learning (Wolfe, Schreiner, Rehder, Laham, Foltz, Kintsch, & Landauer, 1998), and to provide effective feedback in the training of summarization skills (E. Kintsch, W. Kintsch, Laham, Landauer, DePaula, Schreiner, Stahl, & Steinhart, 2000). There are now LSA-based graders of essays that assign grades to essays with the validity and reliability of human experts in composition (Foltz, 1996). In our research on computer literacy, LSA has been quite successful in evaluating the quality of college students' answers to deep reasoning questions and to the contributions of learners during the tutorial interactions with AutoTutor (Graesser, Wiemer-Hastings, Wiemer-Hastings, Harter, Person, & the TRG, 2000; Wiemer-Hastings, Wiemer-Hastings, Graesser, and the TRG, 1999).

The success of LSA is quite remarkable given that it was never designed to capture many of the traditional problems in language understanding systems, such as word order, syntax, quantification, and negation. There are other corpus-based probabilistic models that capture word order and syntax (Burgess, Livesay, & Lund, 1998; Charniak, 1993) but the present study focuses on the capabilities of LSA.

At this point, there is a great deal of uncertainty about what is being represented in the  $K$ -dimensional spaces of LSA. One optimistic possibility is that the  $K$  dimensions reflect ontological categories, semantic features, and structural compositions of mental models that would be directly adopted in structural theories of world knowledge representation. For example, a simple and straightforward assumption would be that particular banks of the  $K$  dimensions of LSA would have a one-to-one or many-to-one mapping onto ontological categories (Chi, Slotta, & de Leeuw, 1994; Keil, 1979), to conceptual primitives (Miller & Johnson-Laird, 1976; Norman & Rumelhart, 1975; Schank & Abelson, 1977), or to the domain-specific features that are associated with a particular topic. Very few researchers would go out on the limb and propose an elegant mapping between the  $K$  dimensions of LSA and sophisticated theories of world knowledge. However, most researchers would seriously entertain the possibility of weaker correspondences. At the other end of the continuum, there are researchers who believe that the  $K$  dimensions have nearly an arbitrary mapping to the attributes of mature theories of world knowledge (Landauer & Dumais, 1997).

A somewhat different question addresses whether the LSA space is capable of recovering aspects of the deeper mental models that underlie text (Forbus, Gentner, & Law, 1995), or what is sometimes called situation models (Kintsch, 1998). Foltz, Britt, and Perfetti (1996) reported evidence

that suggested that LSA does capture mental model representations to some extent, whereas Perfetti (1998) has expressed doubts that LSA captures the representations and processes of psychological models. LSA may capture shallow knowledge rather than deep knowledge. That is, LSA may capture the sort of word associations that are reflected in the archives of dictionaries and encyclopedias, but may not penetrate the deeper mental models. On the other hand, LSA may be successful in capturing aspects of the deeper situation model. An accomplished expert on some topic certainly does know how to use the right bags of words at the right time; the systematic use of words in particular documents may be recovered in the LSA solution spaces. At this point in the science, however, there is not enough empirical evidence to support one position or another.

The present study hopes to shed additional light on what is captured by the LSA representations. An LSA space has been developed in the domain of computer literacy. This LSA representation has been used in a fully automated computer tutor, called AutoTutor (Graesser, Franklin, Wiemer-Hastings, & the TRG, 1998; Graesser et al., in press; Graesser et al., 2000; Wiemer-Hastings, Graesser, Harter, & the TRG, 1998). In addition to the LSA space, AutoTutor has dozens of conceptual graph structures that capture knowledge in a more structured form. The present study examines whether the structural composition of the conceptual graph structures can predict the LSA match scores. That is, is there a significant correlation between structural proximity and LSA match scores when we examine taxonomic hierarchies, causal networks, and goal structures? A positive correlation would support the claim that LSA spaces to some extent recover aspects of the mental models. A zero correlation supports the claim that the K dimensional LSA spaces have an unsystematic mapping onto structural theories of knowledge representation.

### **Corpus of Texts and LSA Space on Computer Literacy**

A 200-dimensional LSA space was developed for the domain of computer literacy during the development of AutoTutor. The corpus of included (a) two books on computer literacy, (b) 30 articles that focus on hardware, operating systems, and the internet, and (c) AutoTutor's curriculum script of lessons, example problems + solutions, and questions + answers. An LSA analysis requires the preparation of a document by word (D x W) co-occurrence matrix. Each cell in the matrix specifies the number of occurrences of word  $W_i$  in Document  $D_j$ . In order to prepare the DxW matrix, the researcher needs to define what constitutes a document unit. A single document was defined as (a) a paragraph in the case of the textbooks and 30 articles and (b) a sentence that conveys a lesson, a good

answer, or piece of a solution in the case of the curriculum script. An LSA analysis was performed on the 2.3 MB corpus of documents, yielding a solution with 200 dimensions.

The 200-dimensional LSA was validated in our assessments of AutoTutor (Graesser et al., 2000; Wiemer-Hastings et al., 1999). For example, Wiemer-Hastings et al. (1999) analyzed how well the LSA space on computer literacy could accurately evaluate a sample of 192 answers to the questions in the curriculum script. College students enrolled in the computer literacy course answered the questions in the curriculum script by typing in their answers into a web cite facility. The data were collected after the college students had read the relevant chapters in the book and had received a lecture on each macrotopic (i.e., hardware, operating system, Internet). Trained experts (such as graduate research assistants) also rated the 192 answers to the questions. The results of correlational analyses revealed that the LSA did an excellent job evaluating the quality of student answers. The correlation between LSA's answer quality scores and the mean quality scores of the experts was .49. This correlation is indistinguishable from the .51 correlation between the ratings of the two intermediate experts (i.e., the individuals who normally grade exams in a college computer literacy course). Graesser et al. (2000) reported that AutoTutor's LSA component did an excellent job discriminating the ability of learners who interact with AutoTutor in a multi-turn tutorial dialog. LSA was capable of discriminating different classes of student ability (good, vague, erroneous, versus mute students) and in tracking the quality of contributions in tutorial dialog.

The LSA space in AutoTutor was adopted in the present study. We computed the LSA-match scores between pairs of nodes in the conceptual graph structures that had been prepared for topics on hardware, operating systems, and the internet.

### **Conceptual Graph Structures on Topics in Computer Literacy**

AutoTutor's architecture includes a set of conceptual graph structures on the various topics in the curriculum script. A typical structure contains approximately 10 to 30 nodes. We randomly selected 12 conceptual graph structures in the present analysis, including 4 structures for hardware, 4 for operating systems, and 4 for the internet.

The 12 knowledge structures were composed by applying the conceptual graph structure (CGS) representations developed by Graesser (Graesser & Clark, 1985; Graesser et al., 1992; Graesser, Wiemer-Hastings, & Wiemer-Hastings, in press; Williams, Hultman, & Graesser, 1998). The CGS's have 5 node categories: concepts, states, events, goals, and style specifications. There are 22 basic arc categories. The composition of these conceptual graph structures is not arbitrary, but is based on formal and conceptual constraints

that have been studied for several decades in artificial intelligence (Lehmann, 1992). The categories of nodes and arcs are sufficient for implementing computational models of question answering which have been validated in experiments on adults (Baggett & Graesser, 1995; Graesser & Hemphill, 1991; Graesser, Lang, & Roberts, 1991).

Three types of knowledge structures were directly analyzed in the present study: taxonomic hierarchies, causal networks, and goal hierarchies. A node was included in the present analysis if and only if it was part of any of these three types of structures. The composition of these three types of structures is specified below.

### Taxonomic Hierarchies

Concept nodes are connected by *is-a* arcs. For example, the concepts Norton Antivirus, utility program, and tool would be connected by two *is-a* arcs:

(concept-1: Norton Antivirus) –*is-a*→  
 (concept-2: utility program) –*is-a*→  
 (concept-3: tool)

The structure distance is 1 between concepts 1 and 2 and between concepts 2 and 3; the structural distance is 2 between concepts 1 and 3.

### Causal Networks

State and event nodes are connected by arcs that signify Cause, Enables, Subprocess, and Implies (see Graesser & Clark, 1985 and Graesser, Wiemer-Hastings, & Wiemer-Hastings, in press for more complete definitions of arcs). Some of these categories of nodes and arcs are illustrated in the following chain.

(state-1: the operating system is stored on the hard disk) – Enable→  
 (event-2: the operating system is loaded onto the computer) –Subprocess→  
 (event-3: the operating system gets into RAM) –Cause→  
 (event-4: the CPU executes instructions)

The structural distance is 1 between nodes 1&2, 2&3, and 3&4, is 2 between nodes 1&3 and 2&4, and is 3 between nodes 1&4.

### Goal-structures

Goal nodes are connected to other nodes by virtue of arcs that signify Reason, Manner, Initiate, and Outcome. For example, the following three goal nodes form a goal hierarchy via a Reason arc.

(goal-1: user types in command) –Reason→  
 (goal-2: user starts word processing software) –Reason→  
 (goal-3: user writes article)

The goals are triggered by various events and states in the world by virtue of Initiate arcs, whereas Outcome arcs specify whether or not the goals are achieved.

### Scaling of Pairs of Nodes on Structural Proximity

Pairs of nodes in the 12 conceptual graph structures were scaled on structural proximity with respect to taxonomic hierarchies, causal networks, and goal structures. A node in a structure was included in the analysis if and only if it was part of one or more of these three types of structures. When considering all 12 conceptual graph structures, there were 536 pairs of nodes in the analysis. A pair of nodes (A and B) was scaled on causal proximity by computing the reciprocal of the structural distance on a legal causal path between A and B (i.e., 1/distance). Thus, if two nodes have a structural distance of 1, 2, 3, versus 4 arcs on a legal path, then the causal proximity scores would be 1.00, .50, .33, and .25, respectively. If there is no legal causal path that connects A and B, the causal proximity score is 0. Goal proximity and taxonomic proximity were computed in a similar fashion for all 536 nodes. The mean proximity scores were .07, .31, and .40 for the taxonomic, causal, and goal proximity scores, respectively; the corresponding standard deviations were .26, .40, and .45.

### Relationship Between LSA Match Scores and Structural Proximity Scores

The analyses uncovered a robust relationship between the LSA match scores and the structural proximity scores. Consider first the causal proximity scores. The mean LSA match scores were .47, .35, and .24 when the causal proximity scores were 1.00, .50, and .33 or lower (but not 0), respectively. When analyzing the goal proximity scores, the LSA match scores were .53 and .42 for goal proximity scores of 1.00 and .50 or lower (but not 0), respectively. The taxonomic proximity scores rarely went lower than 1.00 when considering nonzero values, so we could not isolate a sensitive gradient for this proximity score. The overall mean LSA match score was .44 (SD = .30).

A multiple regression was conducted to assess the extent to which the LSA match scores could be predicted by the taxonomic, causal, and goal proximity scores. The three predictor variables together explained a significant 9% of variance in the LSA match scores,  $F(3, 532) = 16.46, p < .05, R^2 = .09$ . All three predictors had a significant unique impact on the LSA scores, with beta weights of .14, .31, and .47 for taxonomic, causal, and goal proximity, respectively.

We performed some follow-up multiple regression analyses that statistically controlled for some potential extraneous variables. One extraneous variable was the length of the node descriptions, as defined by the number of words in the pair of nodes. Those who have conducted research on LSA have reported that lengthier descriptions have a slight tendency to produce higher LSA matches when

two bags of words are compared (Rheder, Schreiner, Wolfe, Laham, Landauer, & Kintsch, 1998; Wiemer-Hastings et al., 1999). The mean length of the node descriptions in our sample was 10.62 words in the node pair ( $SD = 4.03$ ), or 5.31 words per node. A second extraneous variable was the number of nouns that overlap between the pair of nodes. Overlapping nouns are analogous to argument overlap in propositional theories of text processing (Graesser, Millis, & Zwaan, 1997; Kintsch, 1998); the fact that constituents refer to the same entity is one important foundation for coherence in discourse processing. However, from the standpoint of the present analyses, we would not be particularly surprised if the LSA match scores could be explained by mere noun overlap because it is analogous to a keyword overlap. The mean number of overlapping nouns in a node pair was .71 ( $DS = .67$ ).

Table 1 presents the results of the multiple regression analysis that predicted LSA match scores as a function of the three structural proximity scores, length, and noun overlap. The five predictor variables accounted for a significant 55% of the variance in LSA match scores,  $F(5, 530) = 128.05$ ,  $p < .05$ ,  $R^2 = .55$ . When considering the two extraneous variables, noun overlap had a robust impact on the LSA match scores whereas length had no significant effect. Although noun overlap was robust, the three structural proximity variables still had a significant unique impact on the LSA match scores in the multiple regression analyses. Interestingly, we did not find the noun overlap scores to be correlated very highly with the taxonomic, causal, and goal proximity scores,  $r = -.18$ ,  $.25$ , and  $-.02$ , respectively. Overlap in predicates was also analyzed but the correlations were also modest or nonsignificant. These results support the claim that the structural proximity scores have an impact on LSA match scores over and above keyword matches.

Table 1: Multiple regression analyses that predict LSA match scores

Predictor Variable	beta-weight	t-score
Taxonomic proximity	.14	4.08 *
Causal proximity	.11	2.17 *
Goal proximity	.15	2.94 *
Length (number of words)	-.02	.75
Noun overlap	.72	23.20 *

\* significant at  $p < .05$ .

## Conclusions

The results of this study support the claim that LSA captures aspects of the mental models that underlie computer literacy. The content of the mental models includes taxonomic structures, causal networks, and goal/plan/action hierarchies. The LSA match scores between pairs of nodes in the conceptual graph structures can be predicted by taxonomic, causal, and goal structural proximity. The structural proximity scores predict LSA match scores over and above noun overlap, keyword overlap, and the number of words in the node descriptions.

Aside from demonstrating that LSA captures aspects of mental models, we have demonstrated that LSA can be useful for performing semantic and conceptual analyses on relatively short verbal descriptions. Researchers have sometimes claimed that LSA is only useful when analyzing lengthier verbal descriptions on the order of a paragraph. The present study supports the claim that LSA can be useful for compositional analyses on individual words and short sentences of 5-6 words. Additional research is needed to identify the limits of LSA in recovering different aspects of semantics and world knowledge.

## Abstract

Are human contingency judgments based on associationistic principles such as cue competition or on normative principles as specified by rational-cognitive models? In this study, participants learned to predict an outcome from several simultaneously presented cues. They were asked to judge the cues in regard to causal power or statistical concepts such as probability or relative frequency. Uniform application of associationistic principles implies cue-interaction effects of blocking (Experiment 1) and conditioned inhibition (Experiment 2) for all judgments. A rational-cognitive framework predicts cue-interaction effects for causality judgments, but not for probability and relative frequency judgments. The results support the rational-cognitive framework on all accounts.

## Introduction

The ability to detect causal relations in the environment is of utter importance to all organisms. Fortunately, at first glance, at least, we seem to adjust well to such demands. We readily formulate hypotheses about plausible causal relationships and contingencies. Research deriving from the associationist tradition, however, suggests that this optimistic view is unwarranted. It is proposed that, because of cue-interaction effects, our representations are distorted. This study pits a more optimistic view of human contingency judgment based on the metaphor of the mind as an “intuitive scientist” against this associationist view. It does so by comparing causality judgments with probability and relative frequency judgments in an inductive contingency judgment task.

Imagine that you suffer from an allergic reaction, which you believe originates from eating shellfish. It seems reasonable to assume that this hypothesis of causality originates in your recollection of similar events, in this case your memory of eating shellfish and suffering from allergic reactions. Of course, most meals that you have eaten contained neither shellfish nor resulted in allergic reactions. Still your memory tells you that the allergic reaction on numerous occasions co-occurred with dishes that included shellfish. You also recall dinners which included shellfish but which did not lead to allergic reaction, and times when the allergy sprung up in the absence of shellfish. One popular notion is that memories of previous events are categorized in what resembles a 2×2 matrix. In this *contingency matrix* the presence and absence

of a predictor event and an outcome event constitute the two axes.

Table 1: A contingency matrix.

	Outcome	No outcome
Predictor present	A	B
Predictor absent	C	D

According to a normative model, judgments of covariation are based on conditional contingency: that is, on the probability of the outcome (e.g., allergy) in the presence and absence of the predictor (e.g., shellfish). Formally, this can be expressed by the  $\Delta p$  algorithm:

$$\Delta p = \left(\frac{a}{a+b}\right) - \left(\frac{c}{c+d}\right), \quad (1)$$

where  $a$ ,  $b$ ,  $c$ , and  $d$  are the number of times that events A, B, C, and D in the contingency matrix have occurred. A positive contingency is perceived if Cell A and D contain more occurrences than Cell B and C ( $\Delta p > 0$ ). Similarly, a negative contingency is indicated by a negative  $\Delta p$  and a zero  $\Delta p$  indicates no contingency. Perceptions of causal relations are thought to be based on observed covariation registered in a form equivalent to the contingency matrix, and computed by the  $\Delta p$  algorithm. Chapman and Robbins (1990) examined two effects that in a conspicuous way violate the normative  $\Delta p$  model: the cue interaction effects referred to as *blocking* and *conditioned inhibition*.

## Cue Interaction Effects

The allergic reaction used in the example exemplifies a simple causal relation where one potential cause is evaluated with respect to its assumed effect ( $C \rightarrow E$ ). However, such occurrences of unambiguous sole cues seldom arise beyond the realms of clinical test scenarios. Instead, we often evaluate complex situations where multiple potential causes may produce an effect ( $C_1, C_2 \dots C_n \rightarrow E$ ). In Experiment 1 of Chapman and Robbins (1990) participants examined the relationship between the change in prize of four individual stocks (predictors) and the stock market as a whole (outcome). In the first phase, either stock A increased in value, followed by an increase in the value of the market, or stock C increased without a market increase. In the second phase, either of pairs of stocks AB or

$CD$  increased, in both cases followed by a market increase. On one third of the trials in Phases 1 and 2 no stocks increased and the market remained unchanged. After each phase, participants rated the extent to which an increase in each stock predicts a market increase on a scale from -100 to 100. (See Table 2.)

Table 2: The design in Chapman and Robbins (1990).

Phase 1	Phase 2	Test 2
$A+, C-, \emptyset-$	$AB+, CD+, \emptyset-$	$B < D$

Note. (+) = outcome, (-) = no outcome,  $\emptyset$  = predictor absent.

If the normative  $\Delta p$  model is correct the frequency of occurrences between each predictor and the outcome is mapped within separate contingency matrices. This means that each predictor is evaluated in isolation with contingency judgments based on the recollection of frequencies. Because the Stocks  $B$  and  $D$  appear an identical number of times, always in the presence of the outcome, these two stocks should receive identical ratings of predictability in Test 2.

As it turns out, the ratings for individual predictors *interact*. In this case the interaction is *blocking*: of two cues with identical contingencies with the outcome, systematically lower ratings are given to the cue presented with a previously established predictor than to the cue presented with a non-predictor. In a second experiment, Chapman and Robbins examined *conditioned inhibition*. In this design, a predictive cue is followed by the outcome, except when it occurs with a second cue. The second cue, referred to as the inhibitor, is rated lower in predictability than a control cue that has the same objective contingency with the outcome. Cue-interaction such as blocking and conditioned inhibition casts doubt on the  $\Delta p$  model as a descriptive model of human judgment of causation and covariation. The question is whether these results are best explained by an *associationist* or, what we refer to as, a *rational-cognitive* framework.

### Associationist Framework

Cue-interaction is routinely observed in studies of animal learning. This has been taken to indicate that human behavior in contingency judgment tasks is best described by a “grand theory” of learning based on the principles that apply to animal conditioning. Associationistic models therefore adhere to a strong analogy between conditioned ( $CS$ ) and unconditioned ( $UCS$ ) stimuli in classical conditioning and predictors and outcomes in human contingency judgments. Contingency judgments are seen as being based on the associative strength of the relationship between conditioned stimuli (predictors) and the unconditioned stimuli (outcomes). In a multiple-cue task, each  $CS$ - $UCS$  association is based on the informative strength of  $CS_x$  with respect to the  $US$ , in competition with all the  $CS$ s present.

The model most often called upon to explain cue interaction effects is the *Rescorla-Wagner model* (Rescorla & Wagner, 1972), hereafter referred to as the R-W model.

Formally, the model states that:

$$\Delta V_x^{n+1} = \alpha_x \beta_1 (\lambda_1 - V_{total}^n), \quad (2)$$

where  $\Delta V_x^{n+1}$  is the change in associative strength ( $V$ ) of  $CS_x$  as the result of pairing it with  $UCS_I$  on trial  $n+1$ ,  $\alpha_x$  is a learning rate parameter representing the associability of  $CS_I$ , and  $\beta_1$  is the corresponding parameter for  $UCS_I$ ,  $\lambda_1$  is the maximum associative strength that the  $UCS$  can support, called the asymptote ( $\lambda_1 = 1$  in the presence of the  $UCS_I$ , 0 in its absence), and  $V_{total}^n$  is the total associative strength of all  $CS$ s on trial  $n+1$ .

Equation 2 describes the change in associative strength of a  $CS$  as a function of the current associability of the  $UCS$  and  $CS$ , in relation to the remaining associability of the  $UCS$  ( $\lambda_1 - V_{total}^n$ ). A consequence of Equation 2 is that learning will occur only when an outcome is unexpected or surprising in the light of one’s expectations.

According to the R-W model, the blocking described by Chapman and Robbins (1990) is due to cue competition. Once a  $CS_I$ - $US$  association is established, any new  $CS_2$  that is presented with the previous association ( $CS_I, CS_2 \rightarrow US$ ) will not become associated with the outcome. Equation 2 states that the change in associative strength on trial  $n+1$  is defined by the difference between the asymptote ( $\lambda$ ) and the total associative strength ( $V_{total}^n$ ) on trial  $n$ . Since  $CS_I$  already predicts the outcome there is no room for  $CS_2$  to become associated with the  $US$ . In comparing  $CS_2$  with another stimulus  $CS_3$  that has an identical outcome contingency the R-W model thus predicts that  $CS_2$  will be valued as less associative than  $CS_3$ .

Conditioned inhibition is seen as the opposite of excitation. According to the R-W model this phenomenon is expressed by ( $\lambda_1 - V_{total}^n < 0$ ). Since the asymptote itself can never be negative, the expression will only be true when  $V_{total}^n$  is larger than zero, that is, when some excitation already has occurred. Say that stimulus  $CS_I$  leads to an outcome  $E$ , while stimulus compound  $CS_p, CS_2$  leads to absence of the outcome. If later tested individually,  $CS_I$  receives an excitatory value, while  $CS_2$  receives an equally strong inhibitory (negative) value, making the total associative value equal to zero. A number of alternative models have surfaced within the associationistic tradition (e.g., Gluck & Bower, 1988; Pearce, 1994; Van Hamme & Wassermann, 1994). Siegel and Allan (1996) singled out the R-W model as the most successful model and, for the purpose of this paper, the R-W model will represent the associationist framework.

### Rational-Cognitive Framework

A number of theoreticians (Waldmann & Holyoak, 1992; Cheng, 1997) propose that the observation of cue interaction effects does not pose a threat to models based on the  $\Delta p$  algorithm. These results merely indicate the inapplicability of the contingency matrix model to situations involving multiple causes. Imagine that someone claims that alcohol consumption causes lung cancer. In support for this claim it is noted that consumers of alcohol more often suffer from lung cancer than others. With the knowledge that alcohol consumption often is accompanied by smoking this line of reasoning may strike you as odd. Instead it

seems reasonable to assume that smoking is the real cause for the increased risk of cancer.

The difference is that your antagonist is considering a simple causal relationship (unconditional contingency) while you apply a more complex analysis of causal relationships, taking into account the *conditional contingency*. This means that the causal relationship is viewed in the context of the presence and absence of alternative causes. In the smoking example, it is nearly impossible to incorporate all of the potential alternative causes. However, the idea is that, like “intuitive scientists” (Kelley, 1967), we have the capacity to control, at least, for “likely” alternative causes (see also Spellman, 1996).

According to a cognitive-rational approach people store information about events in frequency format. This information is available for different forms of analyses by application of cognitive algorithms. Complex causal relationships require a more sophisticated algorithm than the simple  $\Delta p$  rule (Cheng & Novick, 1990; Cheng, 1997). In *Power PC theory* (Cheng, 1997), for example, the strength of a causal factor is estimated by the conditional contingency: that is, the contingency when other potential causes are controlled for<sup>1</sup>. According to this view, cue interaction is viewed as a consequence of the *participants’ attempts to control for alternative causes*. In Chapman and Robbins (1990), Experiment 1, for example, the participants may have arrived at the conclusion that the causal relationship between Stock *B* and the outcome event (*E*) is uncertain, since its effect is nullified once control for Stock *A* is performed by a conditional contrast; ( $p(E|AB) - p(E|A) = 0$ ). Applying the same algorithm to Stock *D* indicates that *D* is a strong causal factor ( $p(E|CD) - p(E|C) = 1$ ). The controlling for alternative causes would thus lead to results that coincide with the blocking effect predicted by the R-W model.

The same line of reasoning is applicable to conditioned inhibition. Participants conclude that a stimulus has negative causal power (i. e. power to prevent an effect) due to its conditional contingency with respect to other causes (for a discussion, see Cheng, 1997). Because people are assumed to act like scientists in applying rational arguments and interpreting patterns of covariation in terms of unobservable causes, we refer to this as the rational-cognitive framework.

### The Effect of Judgment Type

If the assumption of veridical representation of frequencies in models like power PC-theory is correct, we should not expect interaction effects for judgments of probability or relative frequency (at least, to the extent that that probability ratings are based on representations of relative frequencies). This is a crucial difference between the R-W model and power-PC theory. An orthodox interpretation of the R-W model, which presupposes that the same processes underlie judgments of causality and covariation, predicts that there

should be no difference between conceptually distinct ways of probing for the relationship between cue and outcome. The judgments are mapped from associative strengths and we expect interaction effects for judgments of causality, probability, and frequency alike. In contrast, the rational-cognitive framework presupposes correct representations of environmental frequencies, which deviate from causality ratings in predictable ways. In short: With power PC-theory there is a distinction between judgments of causality and covariation, with the R-W model there is not.

Cue interaction has occasionally been reported also with judgments of probability or frequency (Chapman, 1991, Price & Yates, 1995). Nevertheless, the main body of empirical findings on blocking and conditioned inhibition rests on assessments of often vaguely defined judgment scales (e.g., predictability). We know of no study of conditioned inhibition with relative frequency or probability judgments. In this study, we thus compared judgments of a) the *causal power* of the predictor on the outcome, b) the *probability* of the outcome given the event, and c) the *relative frequency* of the outcome given that the predictor was present on the trial, in a between-subjects design. The associationist account suggests cue-interaction effects with all three judgments. The rational-cognitive approach implies cue interaction effects for causality judgments, but an absence of this effect with the other two judgments.

### Experiment 1: The Blocking Effect

Experiment 1 of Chapman and Robbins (1990) examined the blocking effect in a multiple cue task involving stock market predictions (Table 2). Participants were asked to rate the “predictability” of each stock on a scale from -100 to 100. The present experiment applies the design from Chapman and Robbins’ Experiment 1, with the addition of three new groups. In addition to predictability (to replicate their results), the participants judged either explicit causality, explicit probability, or relative frequency.

### Method

**Participants.** Participants were 64 undergraduate students from Uppsala University. They received either course credit or a movie ticket in exchange for their participation.

**Materials and procedure** The experiment was divided in two learning-phases ( $L_1, L_2$ ) and two test-phases ( $T_1, T_2$ )<sup>2</sup>, appearing in the order  $L_1, T_1, L_2, T_2$ . In each learning-phase participants were to assess whether the stock market as a whole would change in value based on the individual movement of four fictional stocks (see Table 2).  $L_1$  contained 36 trials ( $12 \times A+$ ,  $12 \times C-$ , and  $12 \times \emptyset-$ ).  $L_2$  contained 76 trials ( $24 \times AB+$ ,  $24 \times CD+$ ,  $24 \times \emptyset-$ ). In each test phase, participants assessed the relationship between the increase of each separate stock and an increased stock market. One group rated the stocks according to their *predictability* on

<sup>1</sup> It is important to note, however, that covariation is merely one component of the process of causal induction in power PC theory. Another important component is an a priori framework for interpreting input in terms of causal mechanisms (Cheng, 1997).

<sup>2</sup> Only the most central results, that is, those of the second test phase are included in the present paper.

a scale from -100 to 100, in accordance with Chapman and Robbins (1990). The other three groups rated either relative frequency (*In what percentage of the occasions on which the stock X increased, did the outcome occur?*), probability (*Given that stock X increases, what is the probability of the outcome?*), or causality (*To what degree does stock X cause the outcome?*) with respect to an increased market on a scale from 0 to 100 (a bi-directional scale does not apply to frequency and probability). The judgments were varied between groups.

## Results

The results from Experiment 1 are presented in Table 3. A blocking index was calculated by subtracting ratings to predictor *B* from ratings given to predictor *D*, where a positive score indicates a blocking effect. As illustrated in Figure 1A, both the mean predictability blocking index 27.2 and the mean causality blocking index 24.3 show significant blocking. In contrast, the mean probability blocking index 5.7 and the mean frequency blocking index -15.2 show no sign of the blocking effect (the latter is even negative).

Table 3: The average rating of stimuli *A* through *D* during test Phase II. 95% confidence intervals within parentheses.

	Predictor			
	<i>A</i>	<i>B</i>	<i>C</i>	<i>D</i>
Predictability	53.1 (21.4-84.8)	35.9 (10.2-61.7)	-10.6 (-35.3-14.0)	63.1 (35.9-90.2)
Causality	89.3 (78.133-100.4)	49.3 (34.7-63.8)	27.1 (10.1-44.1)	73.6 (55.4-91.8)
Probability	69.7 (55.1-84.2)	52.3 (43.4-61.3)	36.7 (19.5-53.8)	58.0 (43.2-72.8)
Frequency	87.5 (70.8-104.2)	98.4 (95.4-101.5)	71.6 (52.0-91.1)	83.2 (67.0-99.5)

We replicate the findings by Chapman and Robbins (1990) with blocking effects for predictability judgments, and the effect is even more consistent with the causality scale. These results support the idea that the judgment labeled predictability is interpreted as a mix of causality and covariation. Within the same settings we fail to observe cue interaction effects for probability and relative frequency judgments. This predicted pattern is significant as concluded from a planned comparison of means analysis,  $F(1, 57) = 9.8, p < .01^3$ .

The results thus support theories such as power PC theory with respect to its analysis of causal reasoning, as well as the more general notion in rational-cognitive models that (roughly) veridical representations of event frequencies are preserved. At the same time the results are in opposition to the R-W model. To extend and validate the result from the

<sup>3</sup> Because the predictability group used a bi-directional scale whereas the other groups used unidirectional scales, the scores for all groups were standardized within each condition before they were entered into the planned comparison.

first experiment, a second experiment was conducted in order to examine conditioned inhibition.

Figure 1: Panel A: Blocking effect in Experiment 1 as a function of judgment. Panel B: Conditioned inhibition in Experiment 2 as a function of judgment.

## Study 2: Conditioned Inhibition

Experiment 2 of Chapman and Robbins (1990) was the first study to examine the conditioned inhibition effect in humans. The results showed clear signs of conditioned inhibition. Williams, Sagness, and McPhee (1994) report several failures to replicate Chapman and Robbins' (1990) cue interaction effects. They reasoned that these failures might be due to the way participants approach the task. People can either interpret a stimulus compound (*A, B*) as one distinct stimulus (*AB*) or as the combination of the two stimuli (*A and B*). The former is termed a *configural encoding* while the latter is referred to as an *elemental encoding*. In a multiple cue task conditioned inhibition can not be obtained with configural encoding: the effect demands that the participants view each stimuli in isolation. Williams et al. therefore tried to experimentally encourage participants to engage in elemental encoding.

After a couple of fruitless attempts to replicate the effect we therefore abandoned the design of Chapman and Robbins (1990). Inspired by Williams et al.'s (1994) Experiment 2, we attempted to promote elemental strategies in favor of configural strategies. In order to take every measure to obtain an effect we made some additional changes. In the original task the outcome always occurs with the positive predictor alone, but never with this predictor in conjunction with the inhibitor. The deterministic design may promote the learning of explicit rules, which

might diminish a true effect. Furthermore, floor effects might mask a real effect since both the inhibitor and the control cue can be expected to be rated at the lower end of the scale.

We therefore made the task probabilistic. The outcome occurred with a probability of .95 in the presence of the positive predictors alone, and with a probability of .3 in the presence of the positive predictor in conjunction with the inhibitor. This modification deals with both of the unfortunate characteristics of the Chapman and Robbins (1990) design. In addition, separate single presentations of the negative cue which have been found to increase an effect (Williams, 1995) were added. Finally, the content of the task was changed. In the original task, the content consists of stocks that change. It could be argued that this content does not encourage inhibition since it may be hard to create a mental model of a causal mechanism of how a particular stock hinders the outcome to occur. We used a task of evaluating experimental fertilizers (cf. Spellman, 1994) where it is easier to form a model of how a particular substance may hinder growth<sup>4</sup>. To summarize: Study 2 was designed to investigate whether conditioned inhibition effects will occur also for probability and relative frequency judgments or if a dissociation will be observed between these and judgments of causality.

## Method

**Participants** Seventy-five undergraduates from Uppsala University took part in the study. They received a movie ticket or course credit in exchange for their participation

**Materials and procedure** The experiment was divided in two tasks. The first (pretraining) involved one learning phase and one test phase, the second (main experiment) was divided in two learning-phases ( $L_1$ ,  $L_2$ ) and two test-phases ( $T_1$ ,  $T_2$ ), appearing in the order  $L_1$ ,  $T_1$ ,  $L_2$ ,  $T_2$ . Both the pretest and the experiment involved the prediction of whether a plant would produce flowers or not after an observation of which fertilizers that had been added to an irrigation fluid. The learning phase of the pretraining was identical to the *Explicit Condition* of Williams et al. (1994). It consisted of  $12 \times X+$ ,  $12 \times XY+$ ,  $12 \times Y-$  and  $12 \times Z-$  trials. When finished, participants were asked to rate each fertilizer with respect to the outcome according to either causality, probability, or relative frequency<sup>5</sup> on a scale from 0-100. The purpose of the pretreatment was to encourage an elemental encoding and results of this phase were not investigated further. In Phase  $L_1$  of the main experiment either of fertilizers  $A$  through  $E$  were added to the liquid 20 times each. In the case of fertilizers  $A$  and  $B$  the plant produced flowers in 19/20 (95%) of the occasions.

<sup>4</sup> A change of content should not affect the result according to associative models, which imply independence of content. In cognitive-rational models on the other hand content may play an important role since prior causal models potentially can affect interpretation according to these.

<sup>5</sup> Due to the similar results for predictability and causality ratings in Study 1 and the deviating scale for the predictability ratings, the latter were dropped in Study 2.

Fertilizers  $C$ ,  $D$ , and  $E$  were coupled with the outcome on 6/20 (30%) occurrences. In  $L_2$  three constellations of fertilizers were followed by the outcome with a base rate of 19/20. These were  $A$ ,  $B$ , and  $AB$ <sup>6</sup>. Fertilizer  $E$ , as well as fertilizer combinations  $AC$  and  $DE$  was coupled to the outcome with a base rate of 6/20. Thus, in this design, predictor  $C$  is the inhibitor and predictor  $D$  is the control, with exactly the same contingency with the outcome and number of occurrences. Table 4 describes the conditioned inhibition design in the experiment. After the learning phases, participants rated the relationship between each fertilizer and the outcome based on causality, probability, or frequency with the same scale as described in Study 1. Throughout Study 2, each participant only made judgments for one of the three scales.

Table 4: Conditioned inhibition design in Experiment 2.

Phase 1	Phase 2	Test 2
A+ B+ C- D- E-	A+ B+ E- AB+	C<D?
	AC- DE-	

Note. (+) indicates a probability of outcome of .95, (-) indicates a probability of outcome of .3.

## Results

Table 5 presents the results of Experiment 2. To repeat, conditioned inhibition is observed if stimulus  $C$  is rated lower than stimulus  $D$ . A significant conditioned inhibition effect was found in the causality group (average difference between  $D$  and  $C = 12.4$ : See Figure 1B). In neither of the other groups is there conditioned inhibition. Both groups have higher ratings for the  $C$  than the  $D$  predictor (difference between  $D$  and  $C = -9.5$  in the frequency group and  $-7.2$  in the probability group.). In fact, this reversed difference is significant in the frequency group. A planned comparison shows that the predicted difference between the causality group and the probability and frequency groups is significant ( $F(1, 72) = 13.7, p < .001$ ). The reason for the significant difference in the opposite direction in the frequency group is unclear, but interestingly the trend was the same in Experiment 1. An explanation, (undeniably speculative) could be that higher level deductive reasoning influence frequency ratings; Maybe participants reason that since predictor  $A$  occurred often together with the outcome and predictor  $C$  often occurred in conjunction with predictor  $A$ , then predictor  $C$  probably occurred quite often together with the outcome. Note, however, that the observed significance in no way indicates that the frequency ratings are severely distorted. A comparison between true frequencies vs. rated probabilities and frequencies show that these agree approximately (although the ratings are moderately regressive). In neither case are the true frequencies excluded by the confidence intervals for the ratings, making it impossible to

<sup>6</sup> The conjunction of the positive predictors  $AB$  was included in order to eliminate the possibility that participants learned a rule implying that a conjunction of any two predictors was followed by a decreased probability of the outcome.

reject the hypothesis that these are made on basis of undistorted representations of the true frequencies. These results are in line with predictions of a rational-cognitive model, with conditioned inhibition effects only for judgments of causality.

Table 5: The average rating of stimuli A through E during test Phase II (95% confidence intervals within parentheses).

	Predictor				
	A	B	C	D	E
Causality	83.9 (78.1-89.7)	88.2 (82.0-94.5)	23.80 (16.3-31.3)	36.2 (28.8-43.5)	36.0 (27.8-44.2)
Probability	82.0 (73.9-90.1)	90.1 (85.0-95.1)	32.8 (24.3-41.2)	25.6 (17.9-33.2)	33.3 (23.8-42.8)
Frequency	79.8 (71.8-87.7)	87.4 (81.6-93.2)	33.2 (24.9-41.5)	23.7 (16.3-31.2)	29.9 (21.4-38.4)

## Discussion

In this paper, we have contrasted two different frameworks for the processes that underlie human contingency judgment. An associationist account which stresses the similarity to the processes derived from learning in animals, as epitomized in the R-W model, and one rational-cognitive account that relies on the metaphor of the mind as an intuitive scientist.

The rational-cognitive account implies that the participants can appreciate a distinction between judgments that concern the causal power of a factor, and judgments that pertain to covariation, such as probability and relative frequency. On this view, blocking and conditioned inhibition arise from appropriate considerations of the confounding between multiple potential causes. This reasoning is compatible with—and indeed presupposes—availability of accurate information about frequencies. An orthodox interpretation of the R-W model, presuming the same process behind judgments of causality and covariation, suggests no effect of the judgment type manipulation. On any account, the model does not provide an explanation for the observed effect. The results from two separate experiments, with fairly disparate designs covering the two most well known cue interaction effects clearly favor the rational-cognitive account. The participants seem to appreciate the distinction between a judgment of causality and judgments of probability and relative frequency.

These results suggest that, functionally the same behavior may be implemented by different mechanisms in different organisms. The same behavior that is computed by associationist processes in lower animals may be the results of high-level reasoning in humans. This conclusion may come as no surprise: Regardless of our ontogenetic sophistication we all share the challenge of dealing with a complex and uncertain environment, and the evolutionary and adaptive pressures we face may thus be very similar in the end.

## Abstract

This paper presents a pattern of reasoning called “function-follows-form” (FFF) uncovered through a study of scientific problem solving. In the study we modeled eleven “think-out-loud” problem-solving protocols taken by John Clement (1989). Our work involved computationally modeling the reasoning processes of eleven scientists each attempting to solve the same problem about springs. We describe experiments with two computational systems, ToRQUE and ToRQUE2, which were used to model salient reasoning found in the protocols, and we show how the use of function-follows-form reasoning patterns enables exploration and conceptual change.

## Introduction

Our research identifies and elucidates a pattern of reasoning we call function-follows-form (FFF) reasoning. We have shown that this pattern of reasoning plays an important role in exploratory problem solving, and may lead to significant change to a subject’s mental models. Here we present specification of FFF resulting from experiments with two successive computational systems called ToRQUE and ToRQUE2. The study involved modeling the problem solving of eleven scientists each attempting to solve the same problem about springs. We used “think-out-loud” protocols collected by John Clement (1989) and performed experiments testing the fidelity of our computational model with the protocols.

This research represents a melding of disciplines with the goal of understanding complex scientific problem solving. We have combined techniques from history and philosophy of science, cognitive psychology, and artificial intelligence to study the problem solving of scientists. The focus of our effort discussed here was to capture the salient aspects of problem solving for each of the scientists in the form of a general competence model, encoded in a computational system (i.e. ToRQUE2).

## Background

As a first attempt at developing an interpretation of scientific problem solving Nersessian and Greeno (1992) examined an extensive expert problem-solving protocol obtained in a “think-out-loud” interview conducted by John Clement (1989). In particular, they were interested in the second protocol (S2), because it exhibited many of the characteristics of James Clerk Maxwell’s problem-solving practices in the construction of the electromagnetic field

concept. As they interpret this protocol, the subject uses what they call “constructive modeling” to satisfy himself that his initial answer to a problem was the correct answer. They saw this process as primarily one of arriving at a model that is of the same kind with respect to the salient features of the spring problem. They argue that while this example is much more constrained than historical cases of scientific discoveries, it is still complex enough to require dealing with the many quite difficult modeling issues historical discoveries present.

Clement’s own analysis of S2’s reasoning focuses on a process he calls modeling via “bridging analogies”. He characterizes this process as one in which the subject “produces models via a successive refinement process of hypothesis generation, evaluation, and modification or rejection” (p.358, Clement 1989). It is the specific nature of the construction and “successive refinement” process that led Nersessian & Greeno to interpret S2’s reasoning as a form of constructive modeling, and subsequently led to our computational theory of generative modeling (Griffith *et al* 1996, Griffith *et al* 1997, Griffith 1999).

## The Problem

According to Clement, S2 was a computer scientist who had some training in physics. He had also passed comprehensive examinations in mathematics in the area of topology, which is highly significant to our interpretation of the protocol session.

In the protocol, S2 is asked to solve the following problem about springs:

“... a weight is hung from a spring. The original spring is replaced with a spring made of the same kind of wire; with the same number of coils; but with coils that are twice as wide in diameter. Will the spring stretch from its natural length more, less, or the same amount under the same weight? (Assume the mass of the spring is negligible compared to the mass of the weight.) Why do you think so?”

In our interpretation, S2 began the problem-solving session with an intuitive understanding that the stretch of a spring is due to its flexibility. Then he derived a new understanding that a spring maintains constant slope when stretched through torsion in the spring’s wire. So, although this is a more modest outcome of scientific reasoning than evidenced in historical cases, for S2 it was an instance of highly creative problem solving leading to conceptual change. To

find a satisfactory explanatory model for the problem solution, S2 had to generate a novel representation of how a spring works. He did so by generating a series of successive models through what we call FFF transformations.

## Methodology

This research focuses on investigating the reasoning processes found in all eleven protocols in order to place S2's creative problem-solving in a context. In so doing, we highlight the reasons that lead to his discovery of torsion as a central causal element in the function of a spring. The additional protocols show scientists attempting to solve the spring problem. All the scientists were expert problem solvers, though none were experts in the domain. The protocols were modeled in two sets. The first set of five protocols (S1-S5) was used to build and refine the ToRQUE system. The second six protocols (S6-S11) were used to evaluate the refined ToRQUE2 system. Experiments were conducted at each stage of development in order to evaluate hypotheses with respect to the methods and knowledge used by the subjects. The first set of experiments, used to refine the systems performance with respect to the first five protocols, involved the ablation and reconfiguration of tasks, methods, and knowledge in order to determine what aspects of the system enabled accurate modeling of the first five subjects. The second set of experiments were also ablation and reconfiguration experiments. For these experiments the system was left unchanged but was "reconfigured" to account for each of the remaining six subjects. This means that reasoning elements such as tasks, methods, or knowledge structures were removed or reordered but not added, and that no reimplementations were done on the ToRQUE2 system during the testing phase. Both sets of experiments looked at the choice of knowledge structures and reasoning methods used by the system, as well as the ordering and availability of knowledge and methods. The system was evaluated based on its ability to accurately model the salient reasoning of subjects.

## Ontologies for Function-Follows-Form

Function-Follows-Form transformations are based upon a series of ontological commitments with respect to the control of processing and the representation of knowledge, each of which is based upon past computational results. The language for the control of processing is called the task, method, knowledge language which is based upon a TMK architecture, while the language for representing physical systems is called the structure, behavior, function (SBF) language which was first developed as part of the theory of adaptive modeling. A reasoning packet comprises patterns from each of these languages.

*The TMK Language:* The Task, Method, Knowledge (TMK) architecture is a theory of control of processing that was first developed by Goel & Chandrasekaran (1992) in an analysis of the methods used for addressing complex tasks. This work was continued in (Goel *et al* 1994, Punch, Goel,

& Brown 1995, Goel *et al* 1996). The theory posits that high-level tasks such as conceptual design can be broken down into a hierarchy of methods and subtasks. Each task or subtask may have one or more methods that can be applied to solve the task. It also posits that each method specifies the sub-tasks that it spawns and control information for the ordering of those sub-tasks. Using multiple methods enables the architecture to account for a variety of reasoning strategies for addressing any one task, where a *strategy* is some sub-hierarchy of the task-method tree whose root is a method.

One advantage of the TMK architecture is that knowledge can have a direct effect on which method is selected to accomplish a particular task. For the purpose of modeling multiple subjects this feature is particularly important. In general each subject has different initial knowledge conditions. This means that one wants the system to be able to select different methods based on that knowledge in order to exhibit different reasoning traces. The TMK architecture allows for this kind of variation. The goal from a modeling perspective is to correctly specify the knowledge structures, reasoning strategies, and ordering of strategies, such that for any initial knowledge condition the TMK model is able to accurately account for the reasoning.

*The SBF Language:* As an initial attempt to address the issues from the Maxwell case and the Clement protocols, we attempted to model the Clement protocols using a computational theory of device design called "adaptive modeling" (Goel 1991b, 1996). This attempt led to the development of new design considerations and ultimately to a new computational theory of scientific problem solving. The theory of "adaptive modeling" takes its name from the perspective it adopts on conceptual device design. Conceptual design generally refers to the preliminary phase of the design process. The problem-solving task in this phase takes a specification of the functions of the desired device as input. It has the goal of giving a high-level specification of a structure for the device as output, where the structure can deliver the desired functions.

Kritik and IDeAL are operational knowledge systems that instantiate the theory of adaptive modeling, enable experiments with it, and provide well-defined AI languages. Built in the late eighties, Kritik integrated case-based and model-based reasoning for modeling evolutionary design of simple physical devices (Goel 1989, 1991a, 1992; Goel & Chandrasekaran 1989, 1992). The specific hypothesis in the Kritik experiments was that since the design task is a function  $\rightarrow$  structure mapping, the inverse structure  $\rightarrow$  function map of old designs may guide the adaptation of an old design to achieve a new functional specification. The structure  $\rightarrow$  function map of a device design in Kritik is specified as a Structure  $\rightarrow$  Behavior  $\rightarrow$  Function model. In an SBF model of a device the behavior mediates between function and structure: it captures teleological and compositional knowledge of a device, and provides a

functional and causal explanation of the how the structure of the device delivers its functions.

The IDeAL system builds upon the Kritik system in several significant ways. Perhaps the most significant contribution of the IDeAL system is the addition of a theory for cross-domain analogy called model-based analogy (MBA) (Bhatta 1995, Bhatta & Goel 1993, Bhatta & Goel 1997). This theory enables the system to apply abstract information that it learns in one domain such as that of electric circuits to another domain such as that of heat exchangers.

Kritik and IDeAL both focus on the task of conceptual design. In design the goal is the description of some artifact that serves a particular purpose, i.e., it has some desired function. For this reason the Kritik and IDeAL systems focus on functionally driven transformation processes. The task in scientific discovery is often one in which changes to the function are only realized after a structural change has taken place. The ToRQUE systems make use of this kind of transformation – form-based or “function-follows-form” transformations (see Griffith *et al* 1997, 1999).

In this research we have identified a series of transformational knowledge patterns that can be used to accomplish form-based transformations. We have called these patterns generic structural transformations (GSTs) because they are generic with respect to the models to which they may be applied and because they are first applied to the structure of the model and then propagated to the behavior. We have described two strategies for carrying out form-based transformations. The first is called Structure-Based Model Transformation (SBMT) and the second is called Limiting Case Analysis (LCA).

### **Function-Follows-Form Reasoning Packets**

One important task in artificial intelligence is identifying patterns of reasoning that are generic to a variety of problems. In this research we have identified several reasoning patterns using the TMK language. These reasoning patterns are packets of tasks, methods, and knowledge that frequently appear together. The most promising of these TMK reasoning packets is the FFF packet, which appears to be a general process used by expert reasoners to solve exploratory problems.

One important issue in both the historical and protocol studies is to find the function of a particular physical system given its form. For example, in the S2 case the task is to find the amount the spring will stretch given the diameter. Thus far we have developed a computational system, ToRQUE2, that models S2's discovery of torque in springs. A key computational characteristic of ToRQUE2 is its application of structural transformations to the structural and topological elements of SBF models to generate new models. To achieve FFF transformations ToRQUE2 uses the GST knowledge structures. After retrieving an initial source analog via model-based analogy, ToRQUE2 evaluates the model by attempting to reduce the differences between the

target and the analog model. This evaluation process involves retrieving generic models of physical principles (GPPs) which can explain away the differences or applying GSTs to transform the target or source models. These adaptations bring new knowledge to the task that may lead ToRQUE2 towards or away from the initial goal. ToRQUE2 discovers the GPP of torque while attempting to reduce the differences between a circular and an imaginary square coil.

*S2 protocol: line 121:* Now that's interesting...Just looking at this it occurs to me that when force is applied here [end segment], you not only get a bend on this segment, but because there's a pivot here [referring to a connection in the hexagonal coil], you get a torsion effect.. around there..[a center segment]

Through ToRQUE2 we have established that in the S2 case “function-follows-form” transformations play a significant role in the exploratory process. We hypothesize that “function-follows-form” transformations also play a significant role in Maxwell's exploration of electromagnetism.

In the following sections we present the function-follows-form reasoning packet by showing the task pattern, method pattern, and knowledge patterns that are used to carry out the reasoning, which taken together form a reasoning packet.

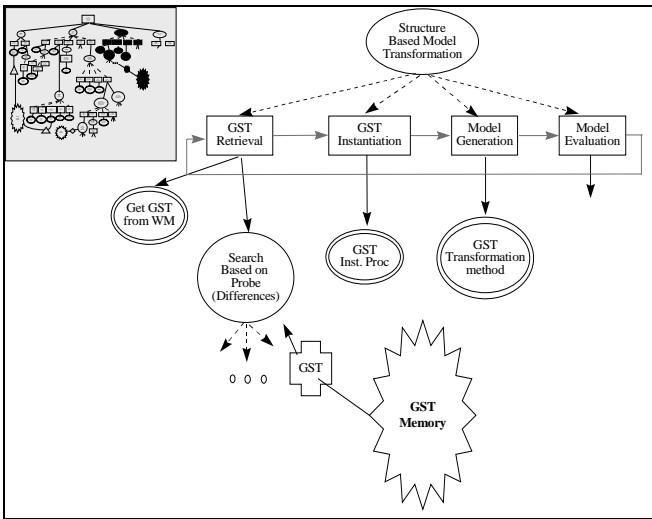

### **Function-Follows-Form Task Pattern**

In (Griffith 1999) we hypothesize that the ordering of high-level reasoning strategies proceeds from a strategy of model-based search through a process of analogy and, failing that, to processes of transformation. We are also hypothesizing that the FFF reasoning packet is used only under certain conditions. The conditions under which a method takes place is a part of its task pattern. The task pattern for FFF can be defined formally with respect to the models in memory, the target model, problem description, and the solution.

The formal task pattern for FFF is: given (1) a target model that is an element of a set of models available to the agent, (2) some problem with respect to that target model, and (3) that no solution can be generated using a search method or an analogy method, return a new model that contains a solution to the problem, such that using analogical transfer from this new model back to the target model provides a solution to the problem. The task pattern defines the problem to consist of input (the problem and the target model) and output (the solution to the problem). It also defines the situation in which the task is performed – in this case, after attempting model-based search and model-based analogy. We see this task pattern in several of the subjects including S2, S6, and S8. We also see this pattern in Maxwell's reasoning.

## Function-Follows-Form Method Pattern

The method pattern for the FFF transformation is found in the SBMT hierarchy. The method pattern in a TMK reasoning packet includes the hierarchy of subtasks that the method spawns, the ordering of these subtasks, and the knowledge that the method acquires during its processing. These aspects of the method are shown in Figure 1. The dashed lines indicate the subtasks that are spawned and the solid black lines indicate that a method or procedure is selected. The gray lines show the ordering of subtasks. The rectangles are subtasks in the method hierarchy. The single-line ellipses are methods, and the double-line ellipses are procedures. Memory is indicated by the star or seal

**Figure 1:** Function-Follows-Form Method Pattern

figure and the plus sign is a specific piece of knowledge that gets retrieved from memory.

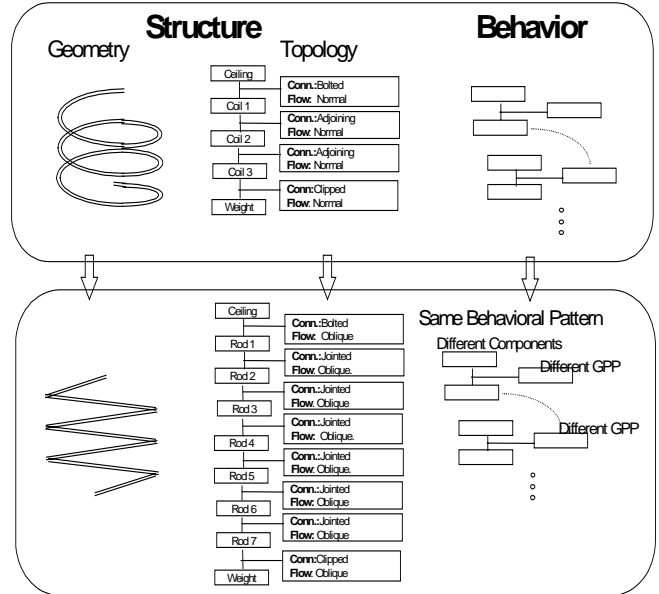

The pattern shows that SBMT is a memory-based process in which the retrieval of particular GSTs occurs when no GSTs are available in working memory. The process then instantiates the retrieved GST for the particular problem-solving situation, and attempts to generate a new model by applying the GST to the model. The process ends with an evaluation of the model that could result in the recognition of GPPs or in recursive application of the SBMT method.

## Function-Follows-Form Knowledge Patterns

The knowledge patterns for the FFF reasoning packet include SBF models as well as GSTs. GSTs are the active knowledge element in FFF. GSTs contain indexing information that allows them to be retrieved based on differences between analog models and information that indicates when they can be applied to a model. Most importantly they contain the processing information for transforming the structure (including geometry and topology) as well as the behavior of SBF models.

In Figure 2 we see one application of the function-follows-form reasoning packet. This reasoning packet

shows how the 3D-to-2D GST is applied to the spring model. First, the geometry of the spring is transformed, which results in changes to the structure. The changes lead to behavior changes in the spring. Each new component's behavior is consolidated to form a new behavioral pattern.

**Figure 2:** Function-Follows-Form in S2 Protocol

In Figure 3 we see how the function-follows-form reasoning packet is applied to our Maxwell's model construction. The top figures represent one stage in Maxwell's reasoning about the electromagnetic aether. He envisioned the aether as composed of a group of fluid vortices. The rotating circles is our representation of a cross section of a set of vortices packed together in the aether. The bottom figure shows Maxwell's representation of his model of the aether after the application of a function-follows-form transformation that changes the structure by adding "idle wheel particles" to solve the problem of friction between the vortices. The structural changes in the form of the aether result in behavioral changes. It is this model of the aether that Maxwell uses to construct the equations for electromagnetic interactions.

The significant point here is that the FFF reasoning packet was first discovered with respect to the Clement protocols, and then identified as potentially significant in interpreting Maxwell's case.

## The ToRQUE System

In this section we show how the computational model instantiated in ToRQUE2 captures the salient reasoning processes of subjects by presenting a walkthrough of the steps taken by the ToRQUE2 system when configured with our interpretation of S2's initial knowledge state.

The primary task of the ToRQUE2 system is to solve a problem. The problem in this situation can be characterized as finding a relationship between a structural concept (Cs)

(e.g. diameter) in the model and a behavioral concept (Cb) (e.g. amount of stretch).

To achieve exploration in TMK requires a working memory of target models (WMT), analogs (WMA), and

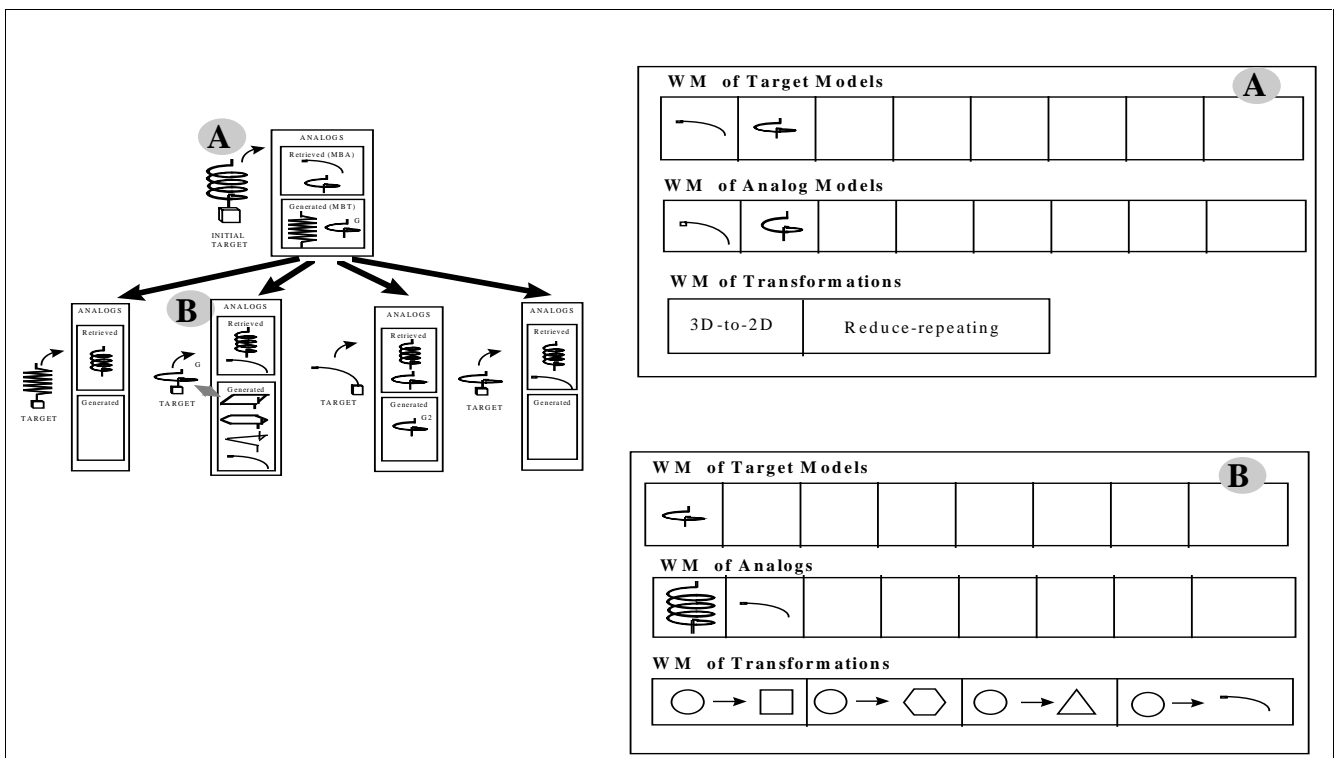

**Figure 3:** Hypothesized Function-Follows-Form in Maxwell

GSTs (WMGST). As an agent addresses its task they may come to a point where they do not know how to proceed. Past reasoning stored in working memory allows the agent to pick a GST that is related to the reasoning at hand or to reasoning that has occurred recently. This serves to

constrain the randomness of the selection of a GST. In ToRQUE2 working memory is captured in a data structure which has a last-in-first-out (LIFO) structure. Figure 4 shows two snapshots of working memory structures. The snapshot labeled (A) shows the WM during the first model-based analogy process prior to attempting any transformations. Snapshot B shows what transformations are placed on the structure when the circular coil becomes the target model. The transformation structure between A and B is the transformations performed between these snapshots. All the transformations that are retrieved are ordered and placed onto this WMGST structure. Thus one can think of this structure as using the last transformation which the agent was thinking about but did not apply. Not all transformations can be used on all models so many transformations may be rejected prior to being applied, e.g., a circle-to-square transformation is only possible if the target model is circular. Also, previously explored target models are removed from the structure such as when a coil retrieves a spring as an analog.

The exploration process proceeds through the interaction of Model-Based Analogy (MBA) and Structure-Based Model Transformation (SBMT) with the working memory structures, WMA and WMGST. MBA retrieves a set of analog models to solve the particular problem one of which is selected and the rest of which are placed in WMA. The answer that is produced from these analogs is evaluated by attempting to reduce the differences between it and the target model. One method of reducing these differences is to apply SBMT to the source or target analogs. Similarly GSTs are indexed and retrieved by these differences and one GST is applied while the remaining are placed in the

**Figure 4:** Snapshot of Working Memory Structures at Two Places in the Program State

WMGST structure. As reasoning progresses, a collection of transformations are placed into WM. In this way WM is not being used as a repository for knowledge that is currently being addressed, but as a repository for knowledge which has been retrieved but which has not been considered.

The left portion of Figure 4 depicts the models that are initially retrieved using the spring model and the models that are generated after transforming the initial target model in various ways. After the system retrieves an analog model it then evaluates that model by attempting to reduce the differences between itself and the analog model. These differences are used as indexes into a memory of generic structural transformations (GSTs). The SBMT process then applies the retrieved transformations to the target model to generate additional models. Notice that the models that are generated may be similar to retrieved analog models. These models, however, are not identical and so we have marked the generated coil model with a G. The figure shows the models that are retrieved as analogs for the spring model. These models were retrieved as functional analogs to the spring because they each supply a restorative force. Generic models such as GPPs are knowledge abstractions that can reduce the differences between two models by recognizing that the features of the analog model are also present in the target model.

One significant outcome of the ToRQUE2 experiments is that ToRQUE2 is able to model the competences exhibited by the test subjects (S6-S11) to a surprising degree of accuracy without changing anything except for the starting knowledge conditions. This means that the system could model the test subjects:

- ◆ without additional knowledge structures,
- ◆ without additional reasoning strategies,
- ◆ without altering the control architecture, and
- ◆ without altering the ordering of the strategies

Altering the starting knowledge conditions includes one or more of the following:

- ◆ removal of knowledge structure,
- ◆ removal of reasoning strategy, or
- ◆ removal of an index to a knowledge structure.

This means that the ToRQUE2 system is a representative instantiation of a general competence model for the spring problem. This means our model covers a representative subset of the possible knowledge and strategies one might use to solve the spring problem, such that it can account for both paths to the solution and paths to failure by the scientists. This lends support to our claim that “function-follows-form” transformations enable S2’s conceptual change, because it is one configuration of a representative problem-solving model.

### Acknowledgements

We would like to thank John Clement for generously supplying us with all of the “think-out-loud” protocols.

## Abstract

This paper explores how people make predictions about the future. Statistical approaches to predicting the future are discussed, focussing on the method for predicting the future suggested by J. R. Gott (1993). A generalized Bayesian form of Gott's method is presented, and a specific psychological model suggested. Three experiments show that the predictions people make about the future are consistent with a Bayesian approach.

Despite the difficulty of predicting the future, people happily do it every day. We are confident about being able to predict the durations of events, how much time we will need to get home after work, and how long it will take to finish the shopping. In many cases we have a great deal of information guiding our judgments. However, sometimes we have to make predictions based upon much less evidence. When faced with new situations our decisions about how much longer we can expect events to last are based on whatever evidence is available. When the only information we possess concerns how long a particular event has lasted until now, predicting the future becomes a task of induction.

In this paper we explore the question of how people predict the future when told only about the past. We examine a simple statistical method of predicting the future, and consider how such a method could be made sufficiently flexible to be useful in everyday situations. The resulting Bayesian model makes strong predictions about the effects of providing further information, the symmetry of this form of reasoning, and how it should be affected by prior knowledge. We test these predictions empirically.

## The Copernican Anthropic Principle

A simple solution to the problem of predicting the future was recently proposed by the cosmologist J. Richard Gott III (1993). Gott's method is founded upon what he calls the "Copernican anthropic principle", which holds that

... the location of your birth in space and time in the Universe is privileged (or special) only to the extent implied by the fact that you are an intelligent observer, that your location among intelligent observers is not special but rather picked at random (1993, p. 316)

Gott extends this principle to reasoning about our position in time – given no evidence to the contrary, we should not assume that we are in a "special" place in time. This means that the time at which an observer encounters a phenomenon should be randomly located in the total duration of that phenomenon.

Denoting the time since the start of a phenomenon  $t_{past}$ , and its total duration  $t_{total}$ , Gott forms what he terms the "delta  $t$  argument". Define the ratio

$$r = \frac{t_{past}}{t_{total}} \quad (1)$$

and assume that this is a random number between 0 and 1. It is possible to form probabilistic predictions about the value of  $r$ . For example,  $r$  will be between 0.025 and 0.975 with a probability  $P = 0.95$ , meaning that

$$\frac{1}{39}t_{past} < t_{future} < 39t_{past} \quad (2)$$

with 95% confidence, where  $t_{future} = t_{total} - t_{past}$ . Similarly,  $r$  will be less than 0.5 with probability  $P = 0.5$ , so  $t_{past} < t_{future}$  with 50% confidence.

This method of reasoning has been used to predict a wide range of phenomena. Gott (1993) tells of his visit to the Berlin Wall in 1969 ( $t_{past} = 8$  years). Assuming that his visit was randomly located in the period of the wall's existence, the 95% confidence interval for  $t_{future}$  would be 2.46 months to 312 years. The wall fell 20 years later, consistent with these predictions. Gott made similar calculations of  $t_{future}$  for Stonehenge, the journal *Nature*, the U.S.S.R., and even the human race. Subsequent targets of the principle have included Broadway musicals and the Conservative government in Britain (Landsberg, Dewynne, & Please, 1993).

## What's Bayes got to do with it?

Gott's (1993) method for predicting the future yields interesting predictions in a wide range of situations. It is simple, but could prove useful in forming effective plans and expectations about future events. On this basis, it would be plausible for people to apply similar principles when making judgments concerning time.

Despite the attractiveness of this claim, there may be good reasons why Gott's (1993) method would not belong in our cognitive armory. One reason could be the restrictive assumptions of such an inference. In many

cases in the real world where it might be desirable to predict the future, we know more than simply how long a process has been underway. In particular, our interaction with the world often gives us some prior expectations about the duration of an event. For example, meeting a 78 year-old man on the street, we are unlikely to think that there is a 50% chance that he will be alive at the age of 156.

Prior knowledge is not the only kind of information that Gott's (1993) method neglects. In some cases, our predictions are facilitated by the availability of multiple encounters with a phenomenon. For example, if we were attempting to determine the period that passes between subway trains arriving at a station, we would probably have several trips upon which to base our judgment. If on our first trip we discovered that a train had left the station 103 seconds ago, we might assume that trains run every few minutes. But, after three trips yield trains that have left 103, 34, and 72 seconds ago, this estimate might get closer to 103 seconds. And after ten trains, all leaving less than 103 seconds before we arrive, we might be inclined to accept a value very close to 103 seconds.

These limitations suggest that Gott's (1993) formalization lacks the flexibility that would be required of a method for predicting the future in real world situations. Such a method must allow for the influence of prior knowledge, and reflect the effect of multiple examples. Bayesian inference may provide a means of satisfying both of these requirements. Bayes Theorem states that

$$P(h|d) = \frac{P(d|h)P(h)}{P(d)} \quad (3)$$

where  $h$  is some hypothesis under consideration, and  $d$  is the observed data. By convention,  $P(h|d)$  is referred to as the posterior probability of the hypothesis,  $P(h)$  the prior probability, and  $P(d|h)$  the likelihood of the data given that hypothesis. In the case where the hypotheses are continuous,  $P(d)$  can be obtained by summing across  $P(d|h)P(h)$  for all hypotheses, giving

$$P(h_i|d) = \frac{P(d|h_i)P(h_i)}{\int_{h \in H} P(d|h)P(h)dh} \quad (4)$$

where  $H$  is the set of all hypotheses.

Conveniently, some work extending Gott's (1993) method into a Bayesian framework already exists. In responding to a criticism offered by Buch (1994), Gott (1994) noted that his method for predicting the future could be expressed in Bayesian terms. Using the prior  $P(t_{total}) \propto \frac{1}{t_{total}}$  and the likelihood  $P(t_{past}|t_{total}) = \frac{1}{t_{total}}$  yields the same results as his original formulation of the delta  $t$  argument.

These values are not chosen arbitrarily. The use of  $\frac{1}{t_{total}}$  for the prior is motivated by sound statistical principles (Press, 1989), and provides a scale-invariant method for distributing probability over hypotheses. In many applications it is referred to as the uninformative prior, as it is appropriate when an inference is guided by no specific prior knowledge. The use of  $\frac{1}{t_{total}}$  for the likelihood is also well motivated. The anthropic principle

essentially states that  $t_{past}$  should be viewed as having been randomly sampled from  $t_{total}$ . Assuming a uniform distribution across values of  $t_{past}$ , the probability of any particular  $t_{past}$  will be  $\frac{1}{t_{total}}$ .

Crucially, both the priors and the likelihoods of this Bayesian framework can be modified to suit the situation at hand. A simple, flexible set of priors is provided by the Erlang distribution

$$P(t_{total}) = \frac{t_{total}e^{-t_{total}/\beta}}{2\beta^2} \quad (5)$$

where  $\beta$  is a free parameter. This distribution has a broad peak at  $t_{total} = \beta$ , and decays to zero at 0 and  $\infty$ . This parameterized peaked distribution provides a simple means to summarize many of the kinds of distributions that might be encountered across temporal domains. Similarly, the effect of multiple examples of  $t_{past}$  can be introduced by modifying the likelihoods. Extending the anthropic principle, we can assume that each example is drawn independently from  $t_{total}$ . The probability of observing a set of  $n$  examples will then be  $(\frac{1}{t_{total}})^n$ .

## A Bayesian model

The specification of a Bayesian model requires identifying the distributions governing the prior probabilities and the likelihoods. For the case of predicting the future, Gott's (1993) method provides a good starting point. For each model considered in this section, we will assume that people's responses reflect the point  $t$ , such that  $P(t < t_{total}) = 0.5$ . This is essentially assuming that people adopt an unbiased criterion in making their judgments. Furthermore, we will examine the predictions of each model when provided with one, three, or ten examples of  $t_{past}$  ( $n = 1, 3, 10$  respectively).

The simplest case of Gott's (1993) method is just the delta  $t$  argument, as presented in Equation 1. The predictions of the delta  $t$  argument are shown in the leftmost panel of Figure 1(a). The predictions are unaffected by  $n$ , and are thus constant at  $t = 2t_{past}$ . This seems to defy intuition, and is the weakest of the models we will consider.

At the next level of complexity is the introduction of  $(\frac{1}{t_{total}})^n$  for the likelihood of a set of  $n$  examples and the uninformative prior  $P(t_{total}) \propto \frac{1}{t_{total}}$ , yielding the closed form prediction  $t = 2^{1/n}t_{past}$ . As shown in the second panel of Figure 1(a), the model shows an effect of the number of examples. The main problem with this model is that the prior does not make use of the flexibility provided by the inclusion of prior knowledge in inference. In particular, the uninformative prior makes scale invariant predictions about generalization, which means that  $t_{future}$  will be a constant proportion of  $t_{past}$ , whether predicting the future of the human race or a 78-year old man.

Substituting the Erlang distribution for the uninformative prior renders Equation 4 into

$$P(t_{total}|T) = \frac{(t_{total})^{1-n}e^{-t_{total}/\beta}}{\int_{t_{past}}^{\infty} (t_{total})^{1-n}e^{-t_{total}/\beta} dt_{total}} \quad (6)$$

where  $T$  is the set of  $n$  examples of  $t_{past}$ . The third panel of Figure 1(a) shows the predictions of this model for  $n = 1, 3, 10$  with  $\beta$  ranging from 0.5 to 4.5 in unit increments. The model shows reduced predictions with more examples, and increased predictions with larger values of  $\beta$ .

This third model is what will be tested against people’s predictions about the future. The use of a parameterized prior and specification of the likelihoods makes it appear somewhat more complex than Gott’s (1993) original prescription. As parsimony contributed to the psychological plausibility of the approach, this additional complexity needs to be justified. One source of justification is the success of the Bayesian framework in describing behavior in other domains. Tenenbaum (1999) discussed several examples of tasks that map naturally onto the temporal problems addressed by Gott.

The tasks considered by Tenenbaum (1999) were cases of inductive concept learning, where people learn about a concept through the provision of positive examples. An example of this kind of task would be predicting healthy levels of imaginary toxins. People would be given a number that they are told is a healthy level of a particular toxin, then asked to guess the highest level of the toxin that would be considered healthy. This situation is exactly analogous to predicting the total duration of an event from the amount of elapsed time since the start of the event. In both cases, a person is given a number that is assumed to be randomly sampled from the set of all numbers satisfying a particular criterion, and asked to judge the nature of this criterion. Since both duration and toxin levels are numbers required to be between 0 and some maximum number, this judgement requires the estimation of the maximum number ( $t_{total}$  in the case of predicting the future). Tenenbaum (1999) found that a Bayesian framework gave a good account of people’s performance on this kind of task.

## Model predictions

The Bayesian model outlined above, and depicted in the third panel of Figure 1(a), has some obvious implications. Most central is how the provision of further information should affect predictions. The tightening of the range of acceptable values of  $t_{total}$  corresponds to an important component of Tenenbaum’s (1999) account of concept learning. As people are given more examples of a concept, they become less inclined to generalize beyond the properties of those examples. In the case of predicting the future, where all hypotheses have a value of  $t_{total}$  as their sole property, this manifests as a tendency to accept the smallest possible value of  $t_{total}$  that includes all observed values of  $t_{past}$ .

The Bayesian model also clearly defines the phenomena of prediction to be symmetric. In forming a judgment about  $t_{total}$ , knowledge of  $t_{past}$  and knowledge of  $t_{future}$  are equally informative. Given one of these pieces of information, it is possible to calculate a range of acceptable values for  $t_{total}$ . If people apply similar methods in making judgments about time the effects should be maintained regardless of which of  $t_{past}$  and  $t_{future}$  are

provided. This is not an absolute symmetry, however: if scenarios in which  $t_{future}$  and  $t_{past}$  are provided differ in the distribution of prior probability, then the predicted values of  $t_{total}$  may also differ.

One further implication of the model is that manipulating the prior probability distribution across the hypothesis space will produce a general change in predictions, at least until the effect of the priors is overwhelmed by the likelihoods. In particular, inducing a prior preference for a relatively high value will bias inferences towards hypotheses around that value. If people employ approximately Bayesian methods in forming their judgments, introducing information that biases the prior probability distribution in this way should result in higher predictions, especially when those predictions are based upon few observations.

The Bayesian framework for predicting the future has three clear implications for the kind of judgments that it will produce. The effects of further information, symmetry of predictions, and effects of prior probabilities are all important properties of how these judgments are made. Experiments 1, 2, and 3 examine these predictions in turn.

## Experiment 1: New information

### Method

**Participants** Participants were 81 undergraduates from Stanford University, participating for partial course credit. The participants were randomly assigned to four groups.

**Materials** Four simple scenarios were developed for exploring the predictions of the Bayesian framework. The first scenario described a coffee shop that had recently started selling teacakes. This scenario is given below. Participants were shown  $t_{past}$ , and asked to predict  $t_{total}$ . The second scenario told participants that they were visiting a foreign country in which trains ran precisely to schedule. The schedule was set up so that exactly the same amount of time passed between successive trains. On the platform was a clock showing how long it had been since the last train arrived. Participants were told the value on the clock when they reached the station,  $t_{future}$ , and asked to predict  $t_{total}$ .

These scenarios were compared with two analogous situations that made no reference to time. One of the comparison scenarios was the healthy levels of toxin experiment described above. The second was a version of the Jeffreys (1961) tramcar problem: participants were told the serial number of a taxicab (as well as being given the information that all cabs are given a unique number between 1 and the total number of cabs in the company) and asked to guess the number of cabs in the company.

Each scenario had three sections. The first section outlined the situation and give a single number on which judgments were to be based. The second and third sections added further information, giving a total of three numbers and ten numbers respectively. The first number given was the largest, meaning that further observations would only tighten the range of generalization. The sets

of numbers given were identical for the teacake and toxin scenarios and the train and taxicab scenarios, and were approximately uniformly distributed. The largest example was 34 minutes (ng/mL) for the teacake (toxin) scenario, and 103 seconds (cabs) for the train (taxicab) scenario.

For example, the first section of the teacake scenario was

Each day, on your way to class, you walk past a coffee shop. The shop has recently started a new advertising campaign: they bake fresh teacakes regularly throughout the day, and have a clock outside that shows how long it has been since the teacakes were taken out of the oven. You are interested in buying a teacake as soon as it is removed from the oven, and wonder how often batches of teacakes are baked. Today, the clock shows that it has been 34 minutes since the last batch of teacakes was removed from the oven.

Please write down your best guess of how much time elapses between batches of teacakes, in minutes. Try to make a guess, even if you feel like you don't have enough information to make a decision - just go with your gut feeling. You may assume that the batches of teacakes are always separated by the same amount of time.

The second section gave the additional times of 21 and 8 minutes, and the third section gave further times of 18, 2, 5, 27, 22, 10 and 14 minutes.

**Procedure** The procedure used in all three experiments was identical: Each participant received a sheet providing general instructions about the task, and a questionnaire of one of four kinds.

## Results and Discussion

Plausible responses to these problems are constrained to be greater than the largest example provided. Responses were transformed such that  $t = \frac{x}{t_{past}}$ , where  $x$  is the raw score and  $t_{past}$  is the largest example, and participants who gave  $t < 1$  were excluded from the analysis, eliminating approximately 15% of the participants in each experiment. Responses more than three standard deviations from the mean were considered outliers, and were also excluded. Only one outlier was identified in the course of all three experiments.

A one-way within-subjects ANOVA showed a statistically significant effect of the number of examples for each scenario ( $F(2, 30) = 9.71$ ,  $F(2, 32) = 18.00$ ,  $F(2, 44) = 9.57$ ,  $F(2, 30) = 15.05$ , for the teacake, train, taxicab, and toxin respectively, all  $p < .001$ ). Means and standard errors are shown in Figure 1(b), which demonstrate that the two temporal tasks show a similar effect of new information to the tasks of analogous statistical structure. The Figure also shows predictions generated by the Bayesian model, using the Erlang prior with  $\beta$  set independently for each scenario. The parameterization of the distribution reflects the different priors that might exist across different scenarios, relative to the scale of the

examples selected. The values of  $\beta$  for the teacake, train, toxin and taxicab scenarios were 1.6, 5.4, 0.7 and 4.4 respectively. The peak of the Erlang prior is at  $t_{total} = \beta$ , yielding values of 54 minutes between batches of teacakes, 9 minutes 21 seconds between trains, 24 ng/mL of toxin, and 460 taxicabs, all of which seem appropriate.

## Experiment 2: Symmetry of effects

### Method

**Participants** Participants were another 77 undergraduates from Stanford University, participating for partial course credit. The participants were randomly assigned to four groups.

**Materials** Again, four scenarios were used. The teacake and train scenarios from Experiment 1 were applied to a different set of participants, and modified versions of these scenarios were generated to make it possible to test the symmetry of predictions. The new scenarios were identical to the original teacake and train scenarios, except for the provision of  $t_{future}$  instead of  $t_{past}$  - the participants were informed how long it would be before the next batch of teacakes were removed from the oven, or the next train would arrive, and were asked to predict the period that went between these events. All scenarios asked for predictions with 1, 3, and 10 examples, replicating Experiment 1.

### Results and Discussion

Responses were screened using the same procedure as in Experiment 1. Each pair of putatively symmetric scenarios was subjected to a two-way within-between ANOVA, examining the effects of number of examples and temporal direction. The train scenario showed a statistically significant effect of number of examples ( $F(2, 56) = 17.40$ ,  $p < .001$ ), and no evidence of an effect of temporal direction ( $F(1, 28) = 0.50$ ,  $p = 0.49$ ) or an interaction between the factors ( $F(2, 56) = 0.08$ ,  $p = 0.93$ ). The effect of new information reproduces that of Experiment 1, and the non-significant result for temporal direction implies that any asymmetry in prediction is too weak to be detected by the present experiment.

The teacake scenario likewise showed a statistically significant effect of number of examples ( $F(2, 60) = 22.18$ ,  $p < .001$ ). However, the results also indicated a significant effect of temporal direction ( $F(1, 30) = 4.46$ ,  $p < .05$ ) and an interaction between the two factors ( $F(2, 60) = 3.667$ ,  $p < .05$ ). This difference between the two scenarios may be a result of the way that the asymmetry introduces new information about the teacakes. Changing "the clock shows that it has been 34 minutes since the last batch of teacakes was removed from the oven" to "the clock shows that it will be 34 minutes until the next batch of teacakes is removed from the oven" provides the implication that the next batch of teacakes is currently in the oven. The time between batches of teacakes can be divided into time in the oven and time left waiting. Of these, the time the teacakes spend in the oven is less flexible. Applying the anthropic principle, the observation that the teacakes are currently in the

Figure 1: (a) Predictions of the various models, depicting point at which  $P(t < t_{total}) = 0.5$  for 1, 3 and 10 examples. On all graphs, the vertical axis shows the predicted value of  $t$  in proportion to  $t_{past}$ . (b) Results for Experiment 1. The solid line shows means (with one standard error). The dotted line shows the predictions of the Bayesian model with an Erlang prior. (c) Results for Experiment 2. (d) Results for Experiment 3.

oven suggests that the teacakes spend more time in the oven than waiting to be purchased. This correspondingly reduces the total amount of time that might be expected to pass between successive batches of teacakes.

Figure 1(c) shows the means and standard errors, which are reminiscent of those found in Experiment 1. The predictions of the model were made with  $\beta$  values of 2, 0.91, 3.75, and 2.95 for teacake-past, teacake-future, train-past, and train-future respectively. These values approximate those used in fitting the results of Experiment 1.

### Experiment 3: Manipulating priors

#### Method

**Participants** Participants were another 78 undergraduates from Stanford University, participating for partial course credit. The participants were randomly assigned to four groups.

**Materials** The teacake scenario from Experiment 1 and the train scenario from Experiment 2 were used, together with two new scenarios. The new scenarios gave participants information that was designed to alter their prior before they were given specific numbers upon which a prediction could be based. The sentence “A friend who you are walking with says that he worked in a coffee shop in the same chain last year, and that shops usually bake every two hours, although it varies from shop to shop” was added to the teacake scenario, and “In the course of your travels, you have noticed that most subway trains in this country run approximately every seven minutes, although it varies from place to place” to the train sce-

nario.

All scenarios asked for predictions with 1, 3, and 10 examples, replicating Experiment 1.

#### Results and Discussion

Responses were screened using the same procedure as in Experiment 1. The scenarios were grouped into teacakes and trains, and examined for the effect of number of examples and manipulating priors using two-way within-between ANOVAs. The teacake scenarios showed an effect of the number of examples ( $F = 25.86, p < .001$ ) and manipulating priors ( $F = 4.70, p < .05$ ), as well as an interaction between the two ( $F = 3.80, p < .05$ ). Similar results were shown for the train scenarios. There was a statistically significant effect of the number of examples ( $F = 50.31, p < .001$ ), as well as an effect of manipulating priors ( $F = 5.85, p < .05$ ). In both groups, the effect of the number of examples replicates the results of Experiment 1, and the higher means for the group given the raised prior is consistent with the predictions of the Bayesian model.

Means and standard errors are shown in Figure 1 (d), together with the model predictions. The  $\beta$  values used in fitting the data were 1.6, 3.3, 3.25, and 3.85 for the teacake, teacake-prior, train, and train-prior conditions respectively. The  $\beta$  values are greater in the conditions where the prior was raised, and give peak values of 1 hour, 52 minutes for the teacakes and 6 minutes 40 seconds for the trains. It is notable that these values are within 10% of the priors supplied in the experimental materials, supporting the efficacy of the manipulation and the appropriateness of the model.

## General Discussion

Predicting the future is a difficult task, particularly when the predictions are formed on the basis of very little information. Gott (1993) suggested a simple method for making predictions about the future. Gott's method lacks the flexibility to be useful in a wide range of real-world situations, but the same principles allow the construction of a more general Bayesian model. This model shows many similarities to Tenenbaum's (1999) Bayesian framework for inductive concept learning, which has proven successful in other domains. Experiments 1, 2, and 3 explored whether the Bayesian model provided a reasonable account of the effects of new information, the symmetry of predictions, and the effects of prior probabilities upon people's judgments about the future.

Experiment 1 showed that the effect of providing further examples conformed to the predictions of the Bayesian model: more examples promoted a reduction in the scope of generalization, with predictions becoming closer to the largest example provided. Experiment 2 showed that these predictions were symmetric in time, taking the same form regardless of whether the judgment concerned the past or the future. Experiment 3 showed that people's predictions could be affected by the manipulation of their prior expectations, and that this effect was consistent with the interaction of priors and likelihoods in Bayesian inference.

### Psychological plausibility

It seems unlikely that the participants in this experiment were consciously performing Bayesian inference. A more probable explanation is that the problem can be solved by the application of a simple heuristic, which more closely resembles the cognitive process by which answers can be reached (cf. Gigerenzer, 1999).

One simple heuristic that produces results consistent with both the data and the normative Bayesian model is the rule "The distance to extrapolate is the range of scores divided by the number of examples", which is an unbiased frequentist estimator of  $t_{total}$ . The predictions of this 'density' heuristic are shown in the fourth panel of Figure 1(a). Priors are implemented by taking the average of  $t_{past}$  and  $\beta$  before dividing by  $n$ , and the curves shown illustrate  $\beta$  ranging between 0.5 and 4.5 in unit increments. Note that the extent of generalization decreases with the number of examples, as in the present experiments.

The existence of such a heuristic does not affect the claim that people's predictions about temporal events are consistent with a Bayesian framework. The algorithmic properties of the Bayesian model and the heuristic may differ, but their computational properties are similar. In fact, producing the response  $t = t_{past} + \frac{t_{past}}{n}$ , where  $n$  is the number of examples, serves as a first order approximation of the Bayesian model with prior  $P(t_{total}) \propto \frac{1}{t_{total}}$ .

### Predicting future research

The present results provide support for the claim that a process consistent with Bayesian inference underlies peo-

ple's judgments on these tasks. However, the generality of the findings needs to be extended. In particular further scenarios need to be investigated. Demonstrating the consistency of the results across a range of contexts and set of numerical examples will increase the strength of the findings.

The model-fitting presented in the preceding experiments helps to show that the results are consistent with a Bayesian model, but one of the most important outcomes of the model-fitting is that the peak values of the prior distributions are in appropriate ranges. This provides a further avenue for future research: empirically estimating the parameters of the prior distribution, and using these results to predict the effects of providing examples. This would involve administering the scenarios without giving a time displayed on the clock, and asking people to estimate  $t_{total}$ . The resulting distribution will give a prior,  $P(t_{total})$ , that can be used to predict further responses.

Finally, it is interesting to note that the ability to predict the future may be important to domains other than conscious planning. For instance, Anderson (1990) argued that memory may display similar temporal sensitivities. The major challenge for any memory system is to index entries in a fashion whereby those that are needed will be readily available. This requires predicting the future: given an event, the expected future occurrence of the event must be inferred if it is to be indexed appropriately. Anderson (1990) suggests that these inferences occur unconsciously, and are an important part of the human memory. One attractive component of future research is thus exploring the extent to which unconscious temporal judgments reflect Bayesian principles.

# Vagueness in Context

Steven Gross (gross2@phil.upenn.edu)

Department of Philosophy; 433 Logan Hall; University of Pennsylvania  
Philadelphia, PA 19104 USA

## Abstract

This paper argues that whether an utterance of a vague term makes any contribution to propositional content is context-sensitive and that attention to this fact allows for an attractive solution to the sorites paradox.

## Introduction

A predicate is vague if it permits borderline cases such that it's neither clear that the predicate does apply nor that it doesn't.<sup>1</sup> What, for example, is the least number of hairs a man must have in order not to be bald? Vagueness is a pervasive feature of natural languages, but it has proven rather resistant to theoretical delineation. For any attempt to characterize the *semantics* of vague terms (what they *mean*) and their *logic* (what reasoning involving them is *valid*) must yield a compelling dissolution of the ancient sorites paradox, which is no easy matter. Here's a version of the paradox using the predicate 'bald':<sup>2</sup> Someone with no hairs is bald. But one hair can't make the difference between being bald and not being bald. (That is, for any number  $n$ , if someone with  $n$  hairs is bald, then someone with  $n+1$  hairs is bald.) So, someone with 1,000,000 hairs is bald. Well-nigh unobjectionable premises seem to lead by well-nigh unobjectionable reasoning to an absurd conclusion.<sup>3</sup> What has gone wrong?

The enormous literature logicians, philosophers, and semanticists have produced on vague language over the last few decades has

generated a plethora of competing possible positions, each with its own well-known problems.<sup>4</sup> These discussions have succeeded in shedding much light on the phenomenon but have not generated anything remotely approaching a consensus on the relevant issues. So, let us proceed once more into the breach.

In this paper, I defend an approach to vague language and the associated sorites paradox that emphasizes the context-sensitivity of vague terms. A term is *context-sensitive* if and only if its contribution to propositional content can vary across occasions of use without any change in the term's standing meaning in the language. (Indexical expressions, such as the pronoun 'I', provide standard examples.)<sup>5</sup> Previous approaches have adverted to context-sensitivity in attempting to defang the sorites,<sup>6</sup> but they have assumed that vague terms always make *some* contribution to propositional content, whereas I stress how considerations of conversational coherence can affect whether, in a given context, the use of a vague term succeeds in contributing to content at all.

My paper has three parts. I first put forward a necessary condition on the expression of a proposition and suggest that utterances of sentences containing vague predicates only sometimes satisfy it. Then, I argue that, in particular, the consideration of a sorites paradox can result in the violation of this condition. Finally, I briefly indicate some of the virtues embodied in this approach to vagueness.

## A Condition on the Expression of a Proposition

<sup>1</sup> This characterization is somewhat rough, but (as it's frequently noted in the literature) it's difficult to characterize vagueness in a non-theory-laden manner.

<sup>2</sup> It should be assumed throughout that the hairs on the person's head are arranged in a manner optimal for non-baldness.

<sup>3</sup> The reasoning used is simply Universal Instantiation and *Modus Ponens*. The latter alone suffices, if one replaces the universally quantified second premise with the appropriate conditionals. Note, in particular, that the principle of mathematical induction is *not* employed, though it (or some other sufficiently strong principle) would indeed be required to reach the conclusion that *no* one is bald.

<sup>4</sup> Keefe and Smith (1997) is an excellent reader, the editors' introduction providing a valuable survey of the field. Williamson (1994) is an indispensable monograph. The literature on vague *concepts* has been less well-developed and was until recently dominated by degree-theoretic approaches. But see Kamp and Partee (1995).

<sup>5</sup> This use of the term 'context sensitive'—common in semantics and pragmatics—should not be confused with its use in syntax to describe rules insensitive to surrounding syntactic context.

<sup>6</sup> See, e.g., Kamp (1981), Bosch (1983), Raffman (1994), and van Deemter (1996).

Suppose a jar contains 100 color chips, spanning red to orange in imperceptible steps, and I ask you to grab a red one for me. Surely, you can satisfy my request; and when you say “Here’s a red one,” you express a true proposition. If so, then it is *not* a necessary condition on the expression of a proposition that

- (1) the uttered predicates, as used, partition the contextually relevant domain of discourse.

For there’s no reason to think that the predicate ‘is red,’ as used on that occasion, partitions the chips in the jar.

But now suppose I ask you to sort the chips according to whether they are red or orange. You hesitate—at least, once you recognize that they form a sorites series.<sup>7</sup> I call across the room: “I’m curious—is there an even number of red ones?” You are nonplused; you’re not sure what should count here as being red or being orange. Perhaps you request some clarification. If I have none to offer (we can assume I didn’t realize that the jar contained borderline cases), you will be unable to satisfy my request. Likewise, you will be unable to judge whether the sentence ‘The number of red chips is even’ would express something true or false. *Not*, I claim, because you are ignorant of the matter, and unable to rectify your lack—but because in *this* case the lack of partition results in the failure of the predicate to express a property: an utterance of the sentence would thus fail to express a proposition (would fail, that is, to issue in something assessable for truth or falsity).<sup>8</sup> Of course, as competent speakers of English, we understand the *sentence*, we know its standing meaning in the language—so an utterance of it wouldn’t amount to gibberish; and we would know as well much else relevant to interpreting the utterance, such as which chips were in question. But here sentence-meaning and the available contextual information would not suffice to enable the expression of a proposition. Just as with reference-failure (when a putatively referring expression fails on some occasion of use to refer to anything), property-expression-failure thwarts the expression of a proposition; and the failure to partition can

induce property-expression-failure. Leaving out the connecting step, we have:

- (2) a failure of a predicate to partition the contextually relevant domain of discourse can result in the failure to express a proposition.

No doubt these glosses are prejudicially theory-laden. But I needn’t claim that mundane cases *force* us to accept (1) and (2)—only that they suggest them. It’s *prima facie* reasonable to accept (1) and (2) in light of such cases, and to that extent they are *motivated*. Let’s see where they lead: the proof of the pudding is in the eating.

If we accept (1) and (2), we will want to ask *when* the failure to partition can result in the failure to express a proposition: what distinguishes the case in which I ask you to grab a red chip, from the case in which I ask you to sort all the chips in the jar? A natural thought is that, in the first case, the lack of partition *just doesn’t matter*: we may proceed *as if* ‘red’ partitions the chips, because we may *ignore* the borderline cases as *irrelevant* to our purposes. If something along these lines is correct, then it is a condition on the expression of a proposition that

- (3) the speaker may proceed as if the uttered predicates, as used, partition the contextually relevant domain of discourse.

It is clearly a crucial question whether and to what extent this idea can be clarified. Some light is shed if we recast the condition as a constraint on *pragmatic presupposition*—that is, as a constraint on the propositions presumed mutually taken for granted in a given conversational context.<sup>9</sup> The idea is that speakers, in using predicates, act as if, or presuppose, that the predicates, as used, partition the domain. When they must also presuppose, however, that a predicate, as used, does *not* partition the domain, when the failure to partition becomes contextually salient, then the resulting set of presuppositions is obviously inconsistent and thus incoherent. The recast condition thus reads:

- (C) It is a coherent presupposition that the predicates, as used, partition the domain.

<sup>7</sup> I use the phrase ‘sorites series’ for any series from which we can construct a *prima facie* paradoxical sorites argument.

<sup>8</sup> I am thus assuming that the “epistemic” view of vagueness, according to which borderline cases reflect our often in principle ignorance, is false. Williamson (1994) defends such a position.

<sup>9</sup> For this conception of context, see Stalnaker (1974) as well as other papers now collected in Stalnaker (1999).

There is obviously much more to be said here, but again this suffices to motivate (C). What I have to say next will exhibit its attractions.

### Application to the Sorites

I have been suggesting that *whether* sentences containing vague predicates express propositions is a context-sensitive matter. Many mundane utterances of such sentences succeed in expressing propositions, but some don't—in particular, those entered in contexts in which (C) is violated. What I'll argue now is that contexts in which one considers a would-be sorites argument fall into this latter class—save when one of the argument's premises is false or its conclusion true.

So, consider a standard version of the sorites—supposing the correctness of (C). Say, for example, we have objects numbered 1, 2, 3, ..., 5,000,000 such that each is F-er than its successor, and we are presented with the following would-be argument:

F(1)  
For all x, if F(x), then F(x+1)  
 F(5,000,000),

an argument which is paradoxical if we're inclined to consider 1 clearly F, 5,000,000 clearly *not* F, and the difference among neighbors too small to make a difference.<sup>10</sup>

What can we say on my approach? If we eschew logical deviancy, to attempt to assess the crucial sorites premise is to attempt to assess as well its negation 'There exists an x such that F(x) but not F(x+1).' But, in a setting in which the objects are ordered as above, to consider *that* just is to consider what would be the assertion of a partition: one is asking whether there's a *last* x that to which 'F' applies. Whether there is in fact a partition thus matters here; the lack of one, if such there be, cannot be ignored. Considering a sorites, that is, renders it salient whether there is a partition. So, when there is *not* one, the speaker cannot simply proceed as if there were. The condition on the expression of a proposition is thus violated; attempting to use the offending predicate in this way fails to issue in an argument at all. Indeed, no use of the predicate in this context will contribute to the expression of a proposition.

That's what happens when there's *not* a partition. But what about when there *is* one? Then, of course, one of the premises will be false

or the conclusion true. If either the predicate's extension or its complement is empty, there's trivially a partition: if the former (if *no* x is F), then the first premise is false, and if the latter (if *all* x are F), the conclusion is true. If neither is empty—if it's *not* the case that, for either one side or the other, *everything* in the domain falls in it—there is then a non-trivial partition, but then the sorites premise is false: there *is* an x such that F(x), but not F(x+1).

In sum, when the sorites predicate does *not* partition the domain, sentences containing it cannot express propositions and so no argument is presented; an argument is indeed presented when the predicate *does* partition the domain, but then only one that is straightforwardly unsound. The dissolution of the sorites thus follows fairly directly from acceptance of (C).

Indeed, the dissolution is so neat that one might reasonably wonder whether I can explain the force, however illusory, the paradoxical argument seems to possess. Let me try.

So, if the sorites is correctly dissolved along these lines, why do we nonetheless feel the *force* of the argument? A first point to note is that there is a side to us (or at least to many of us) that does *not* feel the force, at least not always. We are, I suggested, nonplussed in situations where (C) is violated; we feel that something is awry. The thought that vagueness *usually* just doesn't matter—and that the puzzles to which it putatively gives rise somehow fall into the category of "don't-cares"—is quite natural: at least it's certainly one I frequently encounter. This, I think, is an important datum—and it's well-accounted for by the present approach. The view is thus consistent with—and indeed perhaps explains—an aspect of the phenomenology, if you will, of vague language use.

But yet those premises seem true and that reasoning valid. Especially those of us whom the sorites has "intermittently obsessed for years"<sup>11</sup> will want to know how a non-argument could have kept us awake so many nights. There are really two facts that need explaining: first, why the sorites seems to have force prior to exposure to my diagnosis, and, second, why this force *persists* even if one does adopt this approach.

Well, the reasoning *is* valid in the following sense: the argument has the syntactic form of a valid inference schema, one such that *if* its premises express true propositions and *if*, in the course of the reasoning, there is no equivocation-inducing context-shift, then the reasoning

<sup>10</sup> I label the second premise the 'sorites' premise and shall refer to 'F' as the 'sorites' predicate.

<sup>11</sup> I borrow this excellent description of philosophical pathology from an unpublished paper on scepticism by Rogers Albritton.

preserves truth. But what we have just seen is that there *is no one* context in which the premises express truths and the conclusion a falsehood. If it can seem otherwise, this is in part because, in our attempt charitably to interpret these sentences—to project them into an appropriate context—it is all too easy to conflate the sorites premise, in which the predicate is *used*, and the *meta-linguistic* claim that the predicate fails to partition the domain.<sup>12</sup>

Note further that this urge to construct an appropriate context is to an extent beyond our conscious control. We just can't help trying to make sense of what we perceive as linguistic tokens; we typically exercise our interpretive capacities automatically, almost as a reflex.<sup>13</sup> In particular, this is true of our ability to track contextual features relevant to the understanding of utterances of context-sensitive sentences. Indeed, this is a necessity imposed by nature's design constraints: we simply would not be able to speak, and cognize generally, with the real-time facility we do possess, if the exercise of the requisite capacities required more conscious reflection. Lacking reflective awareness of the full extent of our reliance on contextual cues, we are nonplussed when our reflexive attempts to project a sentence into an appropriate context founders.<sup>14</sup> And even if we consciously conclude that our inability to identify an appropriate context for the sorites is owing to the absence of such a context, not to our ignorance or inadequacy, this doesn't mean that the would-be argument loses all force, psychologically speaking: again, the automatic nature of our interpretive skills places them to a certain extent beyond our control. We might thus compare the *persistence* of the sorites with that of the Müller-Lyer optical illusion.<sup>15</sup>

---

<sup>12</sup>Further interference is caused by the similarity to the claim that for all  $x$ , if  $F(x)$ , then *there is prima facie reason to believe* that  $F(x+1)$ . Cf. Travis (1985).

<sup>13</sup>Cf. Fodor (1983)'s dedication.

<sup>14</sup>Note that this failure does not so readily flummox us when the dependency upon context is more obvious—as when a deranged person yells at a 'you' who clearly isn't there.

<sup>15</sup>The comparison needn't be pushed too far in order to make its point. In particular, I don't mean to imply that there exists something like linguistic experience, analogous to visual or auditory experience—though, of course, the comprehension of what is said by particular utterances requires sensory experience of some sort. Another possible point of disanalogy is that whereas the Müller-Lyer illusion arises from contingent features of our visual system, it is perhaps arguable that the kind of cognitive design constraints that power the sorites are not specific to our species, or even to

## Some Virtues of this Approach

We now have a first reason for finding our condition attractive: it yields an attractive solution to the sorites. I'll use the space remaining to indicate briefly a few further virtues of the present approach.

A. It is not uncommon for responses to paradoxes (and not just responses to the sorites) to call forth the complaint that they are unmotivated and unilluminating, mere *ad hoc* tricks tailored to finesse a local problem. The present approach, however, is not open to this charge. I have already claimed that our condition on the expression of a proposition is *motivated*. If this is right, then our response to the sorites is to that extent motivated as well. I have *also* already shown how one can locate our condition in the broader theoretical framework that identifies a context of utterance with a set of pragmatic presuppositions. This effects a unification of otherwise disparate phenomena and enables a perspicuous description of their interaction. I'll now indicate two further ways in which this approach finds place in a more general perspective and hence helps *illuminate* the phenomena in question.

First, the approach readily generalizes to various other, *prima facie* related puzzles. This is because the presence of vagueness is not the only reason why a predicate may fail to partition a domain. There are, for example, predicates whose application may depend upon a contextually varying combination of conditions (with contextually varying weights). Hard cases, in which these conditions of application seem insufficient (is coffee food?), may likewise be seen as violating our condition.<sup>16</sup> What's more, we may see such puzzles as the problem of the many and those surrounding vague identity as involving referential indeterminacy closely correlated to the failure of certain predicates to partition the domain. It seems undeniable, for instance, that a competent speaker can, on some occasion, refer to a desk; but it can seem impossible to say which of the many candidate collections of molecules is, or constitutes, the desk to which she refers. But perhaps this is a bad question: that the predicate 'is a part of the desk' fails to partition the domain, though irrelevant normally, can block the expression of a

---

those similarly constituted or organized, but rather apply to all (finite) rational agents.

<sup>16</sup> The relevant phenomenon goes by many names. I borrow the coffee example from Sorenson (1991) who labels it 'conflict' vagueness.

proposition in cases where it matters, and this is arguably correlated with, if not explanatory of, 'the desk's' contextually varying ability to refer.<sup>17</sup> Perhaps these brief remarks are insufficient to convince, but they do at least indicate how we may exploit the fact that our condition adverts to matters broader than vagueness to illuminate a variety of puzzling phenomena. The solution to the sorites would thus follow as but one consequence of a more general framework.

Second, recognizing our condition on the expression of a proposition helps illuminate what we might label the *dynamics* of vague language use. I don't have space to go much into these matters here, but the basic point is that the violation of (C) puts pressure on speakers to adjust their use of the relevant predicate so as to *restore* (C)'s satisfaction. Among the more obvious options is to *sharpen* the offending vague predicate. As your boss, for example, I might settle borderline cases by simply *stipulating* that chips shall count as red, for the purposes at hand, only if they exhibit such-and-such precisely characterized reflectance patterns. Now, the *amenability* of vague terms to such sharpening is an aspect of their standing linguistic meaning: vague terms are context-sensitive in that they may express different properties on different occasions of use, depending on the standards of precision in play. (For example, the contextually relevant standards of precision for being too young can shift, expand, and contract depending on whether we're discussing whether she may read from the Torah, drive a car, or stay up to watch the final election returns.) Sentences containing vague predicates are thus not only context-sensitive as to *whether* they express a proposition (as I urge above), they are of course also context-sensitive as to *what* proposition they express, when they express a proposition at all. And these two facets of their context-sensitivity interact, in that it is *because* of the latter that a speaker can *adjust* the context so as to avoid the failure to express a proposition allowed by the former. Adjusting a context to sharpen a predicate is clearly subject not only to semantic constraints but more generally to constraints of reasonableness. Just what these constraints are is a complex matter—but it is only the recognition of (C) as a condition on the expression of a proposition that allows us a purchase here at all.

**B.** Another common pitfall responses to the sorites must avoid is the problem of higher-order

vagueness. On my proposal, it is the salience of the failure to partition that forces us into an incoherent context: but is there, in a given sorites series, a first object the salience of which effects this context-shift? In effect, we are putting forward a meta-linguistic sorites: consider utterances of the sentences 'One grain does not constitute a heap,' 'Two grains do not constitute a heap,' 'Three grains do not constitute a heap,' . . . —which is the first utterance that fails to express a proposition?

My view, however, yields a natural answer to such questions. The predicate 'expresses a proposition' is itself vague, and so, as with all vague terms, sentences containing it will fail to express propositions when the predicate's failure to partition the domain cannot be ignored. Higher-order vagueness is thus reflected on this approach in the vagueness of the terms used to describe language use generally (and thus used to describe vagueness in particular).

Of course, it should only be expected that there be vagueness here too: why should the language used to describe language be immune to the vagueness that infects practically all empirical terms? Indeed it would be extremely surprising, if things were otherwise; the precision of this one region of language would cry out for explanation. But, in fact, as the meta-linguistic sorites itself demonstrates, there *are* borderline cases of expressing a proposition: a realistic view must therefore find proper place for them, rather than positing answers where none are to be had. Given that this region of language *does* contain vagueness, it is thus a virtue of my view that it covers these cases as part of a uniform treatment. (We also have here a further example of illumination: it is *instructive* to see how first-order vagueness among terms generally is among the sources of that vagueness to which terms used to describe language use in particular are prone.)

**C.** I have space to mention but one more virtue my approach possesses—viz., the fact that it avoids those offenses to common sense characteristic of much discussion of the sorites.

If we may measure a puzzle's difficulty by the *prima facie* absurdity of the sincerely and ably defended responses it elicits, then it is clear that the sorites ranks frustratingly high among its philosophical peers. Nihilism (the view that vague predicates are empty) provides the most extreme example, but there are also, for instance, the claims that contradictions are half-true, typically endorsed by degree-theoretic approaches; that vagueness is but an epistemic phenomenon, reflecting our (often in principle) ignorance of borderlines; and that vagueness does

---

<sup>17</sup> For the problem of the many, see Unger (1980). On vague identity, see Evans (1978).

not exist at higher-orders—there is always a sharp line between the clear and gray ranges of a predicate’s application—to which at least simpler versions of supervaluationism are committed.<sup>18</sup> Indeed, it is a common sentiment among writers on vagueness that *any* position will exact a price—so formidable is the puzzle. But the suggestion I have explored, as far as I have been able to determine, is an exception. If I am right that my view better avoids offending common sense than its competitors, it obviously possesses in that respect an enormous advantage.

I hasten to add that I do believe that my approach brings in tow some surprising *theoretical* commitments. One, which is obvious, is that one can express a proposition without the uttered predicates being associated with a determinate extension. So, propositions can’t be what many people take them to be. Another, which I did not have space to discuss here, is that, on my view, the phenomenon of vagueness imposes limits on our ability to survey our semantic competence: it restricts the propositions expressible within any given context and thus the propositions available for the construction of truth-conditions, and it likewise inhibits our ability to isolate, on the one hand, the contribution to content of linguistic meaning, from, on the other, the contribution of context. A desire to avoid these consequences would no doubt constitute a reason to resist my approach. But to question certain highly *theoretical* claims is not to maintain a *prima facie* absurd view. I would thus turn matters around: if it is only those assumptions that sustain the sorites paradox, then we have an argument for why those assumptions have to go. I won’t go so far as to claim this upshot as a further *virtue* of my view, but it certainly adds to its interest.<sup>19</sup>

## Abstract

The majority of psychological studies on causality have focused on simple cause-effect relations. Little is known about how people approach more realistic, complex causal networks. Two experiments are presented that investigate how participants integrate causal knowledge that was acquired in separate learning tasks into a coherent causal model. To accomplish this task it is necessary to bring to bear knowledge about the structural implications of causal models. For example, whereas common-cause models imply a covariation among the different effects of a common cause, no such covariation between the different causes of a joint effect is implied by a common-effect model. The experiments show that participants have virtually no explicit knowledge of these relations, and therefore tend to misrepresent the structural implications of causal models in their explicit judgments. However, an implicit task that only required predictions of singular events showed surprisingly accurate sensitivity to the structural implications of causal models. This dissociation supports the view that people's sensitivity to structural implications is mediated by running simulations on mental analogs of the causal situations.

## Introduction

In everyday life as well as in scientific research we rarely observe the behavior of complex causal networks at once. A more typical scenario is that we learn about single causal relations separately, and later try to integrate the different observed relations into a more complex interconnected causal model. For example, we might first learn that aspirin relieves headache. Later we may observe that aspirin unfortunately also creates stomach problems. Now we are in the position of putting these two pieces of knowledge together. The question is how? How are different fragments of causal knowledge integrated into coherent complex structures?

## Bayesian Causal Models

One recent approach to this problem that has become increasingly popular in the past few years postulates *Bayesian network models* for representing causal knowledge (see Pearl, 1988, 2000; Glymour & Cooper, 1999). Bayesian network models provide compact, parsimonious representations of causal relations. For example, Figure 1 displays a causal model that connects five events,  $X_1$ ,  $X_2$ ,  $X_3$ ,  $X_4$ ,  $X_5$ . One way to represent this domain is to list the

32 probabilities of the joint probability distribution,  $P(X_1, X_2, X_3, X_4, X_5)$ , by considering every combination of present and absent events. Another possible strategy is to encode the base rates and all covariations that can be computed between five events. However, even with modestly complex structures the number of covariations becomes very large, especially when more complex higher-order covariations between multiple events also are considered. Bayesian network models reduce the complexity of representing causal knowledge by distinguishing between direct causal relations (the arrows in Fig. 1), and covariations that can be derived by using information encoded in the *structure* of the causal models. The structure of causal models primarily expresses information about conditional independence between events. For example, in Figure 1 event  $X_4$  is coded as being independent of event  $X_5$  conditional upon event  $X_3$ . Conditional independence greatly simplifies computations by allowing the derivation of the indirect relations from products of the relevant components (see Pearl, 1988; Glymour & Cooper, 1999). In Figure 1 the joint probability distribution can be factorized into the product of a small number of unconditional and conditional probabilities,

$$P(X_1, X_2, X_3, X_4, X_5) = P(X_5 | X_3) \cdot P(X_4 | X_2, X_3) \cdot P(X_3 | X_1) \cdot P(X_2) \cdot P(X_1).$$

Figure 1: Example of a Bayesian Network

The distinction between direct causal relations and indirect relations can also be used for the *integration* of separate pieces of causal knowledge. Combining the information that aspirin relieves headache with the information that it additionally causes stomach problems yields a

common-cause model with aspirin playing the role of the common cause of two independent effects, relief of headache and stomach problems (see Fig. 2, left). By contrast, integrating the two causal relations “Aspirin causes stomach problems” with “Helicobacter pylorus causes stomach problems” would yield a different structure, a common-effect model, in which two independent causes converge on a joint effect (see Fig. 2, right). In both examples, two independent causal relations are being integrated. However, the outcome of the integration process is different. The two different causal models entail different implications for the indirect relations between events.

### Structural Implications of Causal Models

The basis for the possibility of integrating different causal links into coherent wholes are the structural implications of causal models. In our experiments we focused on two simple models, a common-cause and a common-effect model. Both models integrate two causal links but entail distinctly different implications for the non-causal relations.

Figure 2: Implications of Different Causal Models

Figure 2 (left) depicts a common-cause model with a common cause  $C$  producing two independent effects  $E_1$  and  $E_2$ . Common-cause models of this kind entail a (spurious) covariation among the effects. Provided the common cause independently generates the two effects, the joint probability of the effects,  $P(E_1, E_2)$ , can be calculated by taking the product of the base rate of the cause,  $P(C)$ , and the two conditional probabilities,  $P(E_1|C)$  and  $P(E_2|C)$  (see also Appendix). Thus, although the two effects may never have been observed together, the causal model still allows it to derive a prediction for the patterns that should be expected. Common-cause models clearly differ from common-effect models. Figure 2 (right) shows an example in which two causes,  $C_1$  and  $C_2$ , are linked with a joint effect  $E$ . Common-effect models do not imply covariations among the different causes of the joint effect. The causes may covary in a specific learning situation but this covariation is not implied by the model, it is something that has to be explicitly encoded. This is the reason why in the example shown in Figure 1 common effects were conditionalized on patterns of its direct causes (e.g.,  $P(X_4|X_2, X_3)$ ). However, this is only possible when all the relevant events have been observed together, and when the number of relevant patterns is small enough not to surpass information processing limitations. In more complex cases and in situations in which causal knowledge has to be generated from different learning experiences, *causal schemas* have been postulated in the literature (Pearl,

1988). For common-effect models, the *noisy-or schema* has been proposed as a plausible integration schema (see also Waldmann & Martignon, 1998). According to this schema  $P(X_4|X_2, X_3)$  can be reduced to  $[1-(1-P(X_4|X_2)) \cdot (1-P(X_4|X_3))]$ , an expression that only contains probabilities referring to direct causal relations. The noisy-or schema assumes that different causes have independent and additive influences on the common effect. Given that common-effect models do not imply covariations among the causes a further reasonable default assumption is that they occur independently. A number of psychological experiments have shown that learners indeed tend to initially assume independence (see Waldmann, Holyoak, & Fratianne, 1995).

### Sensitivity to Structural Implications: Computation vs. Causal Simulation

Previous research has demonstrated sensitivity to structural implications of causal models in causal learning (Waldmann & Holyoak, 1992; Waldmann, 2000), causal reasoning (Waldmann & Hagmayer, 1998), and categorization (Waldmann et al., 1995). The processes underlying this sensitivity are unclear, however. The standard approach within the area of Bayesian modeling is to explicitly derive the predicted event patterns or covariations and test these predictions against the data at hand. It appears unlikely that this strategy could be followed in intuitive everyday reasoning. Despite the fact that Bayesian models provide a parsimonious way of representing domain knowledge it is also clear that the explicit derivation of indirect relations is often complex and computationally demanding (Glymour & Cooper, 1999). In fact, one reason for the increasing number of automated statistical tools that are currently offered to researchers lies with the fact that the task surpasses the capacity limitations of intuitive reasoning.

However, there is an alternative, more implicit strategy. Instead of explicitly computing covariations we may form mental representations of causal structures that are analogous to the graphical structures used in Bayesian network modeling (e.g., Fig. 1). Similar to toy models, these causal models can then be used to run mental simulations (see also Barsalou, 1999). For example, instead of calculating the probability of patterns within a common-cause model with one cause and two effects we could mentally imagine the presence or absence of the cause, and then generate predictions for each individual effect based on the observed covariations between the cause and either effect. Since these predictions are triggered by a common event within a mental common-cause model the predicted patterns should show the covariations that are implied by the structure of the mental model. These covariations are not the consequence of an explicit computation, they rather are a side effect of the structure of the causal model used to simulate the causal situation in the real world. Therefore it may well be that the predicted patterns exhibit covariations of which the learners are not aware. For the learner it is only necessary to focus on the direct causal relations. All the indirect relations are taken

care of by running simulations on mental analogs of the objective causal situation.

Two experiments will be presented in which participants acquired partial knowledge about separate fragments of common-cause or common-effect models. To test whether they were sensitive to the additional covariations implied by the different causal models, two types of measures were collected. *Explicit knowledge* was assessed by means of probability estimates in which participants were requested to estimate the strength of the indirect, not directly observed relation. Based on the assumption that explicit computations of the answers to these questions are hard we expected poor performance with this task. However, the second task was designed to tap into *implicit knowledge* generated by causal simulations. In this task, participants were requested to predict the pattern of events they expected to see. For example, in a common-cause condition (see Fig. 2) the experimenter instructed participants to imagine that the cause was present and to make a prediction about the two effects. A typical finding with this type of task is that participants tend to match the probabilities they have seen in the learning situation. Since in the present task the two effects never have been seen together, direct experience with the patterns is not available. However, it is possible that participants match the probabilities for each relation independently within a mental analog of a common-cause model. The model itself generates covariations that have never been observed directly. The crucial measure in this task is the covariation between the predicted effects that can be derived from participants' responses. The causal-simulation account predicts that these patterns should display the covariations implied by the causal models even when no explicit knowledge could be detected in the explicit task.

## Experiment 1

The goal of this experiment was to investigate whether learners who have acquired partial knowledge about fragments of causal models are sensitive to the structural implications of these models. Participants were given the task to learn about the causal relations between the mutation of a gene and the prevalence of two (fictitious) substances (enzyme BST and brasus protein). We used a trial-by-trial learning procedure in which participants worked through a stack of index cards with information on the front side about whether a mutation of the gene occurred or not. By turning around the individual cards participants received information about the presence or absence of either the enzyme BST or the brasus protein. To ensure that no covariation between the enzyme and the protein could be observed the cards were divided into two different stacks, one for each substance. Participants were instructed to alternate between the stacks in the course of the learning phase. In the initial instruction the separate stacks were characterized as displaying the raw data of two different research projects located at different universities. The task and the presentation of the data were identical for all participants. They first received information about the mutation of the gene on the front side of the cards, and then were shown information about the occur-

rence of either the enzyme or the protein on the backside. The learning phase consisted of 80 cards, 40 for each substance.

Two factors, type of causal model and degree of covariation, were manipulated yielding four experimental conditions. The first factor contrasted two different causal models. One group of participants read in the initial instructions that the researchers were interested in finding out whether the mutation causally influences the two substances (common-cause model)(see Fig. 2, left). In contrast, for the second group the two substances were described as potential causes of the mutation (common-effect model)(see Fig. 2, right). The second factor manipulated the strength of the relation between mutation and the two substances. The strength was always equal for both substances and either weak or strong. Table 1 displays the absolute frequencies used in this experiment. Thus, for example, participants in the condition with strong connections saw 16 cases for each substance in which the presence of a mutation of the gene was paired with the presence of the substance.

Table 1: Frequencies in Experiment 1

	Strong Condition		Weak Condition	
	Substance	No Substance	Substance	No Substance
Mutation	16	4	10	10
No Mutation	0	20	6	14

Apart from the different initial instructions about the underlying causal model the learning phases and the test phases were identical within the conditions with strong or weak relations. Regardless of whether the mutation of the gene was introduced as a cause or as an effect, information about its presence or absence was delivered before information about the substances was given.

The learning phase was followed by a test phase in which participants' assumptions about the covariation between the two substances was assessed. This covariation had to be inferred because the two substances had never been seen together. To test whether participants were sensitive to the different implications of the two causal models we compared an implicit with an explicit measure of knowledge. In the *implicit* test procedure participants received 20 new index cards in a random order, half of them indicating that in this particular case a mutation had occurred. The rest of the index cards described cases in which no mutation had occurred. Participants' task was to predict for each case individually whether either of the two substances was present or absent. No feedback about the substances was provided during this test phase. Since patterns of substances had to be predicted it was possible to analyze the amount of covariation between the substances in the responses of the participants. We used the *phi* correlation coefficient as a measure of the degree of the implicitly predicted covariation (see Appendix). In a second task that followed the

implicit task, we investigated participants' *explicit* expectations. In this task they had to estimate the probability that the second substance is present conditional upon the first being present ( $P(\text{substance}_2|\text{substance}_1)$ ) and being absent ( $P(\text{substance}_2|\sim\text{substance}_1)$ ). As with the implicit measures the explicit estimates were transformed into *phi* correlations that allowed us to directly compare the implicit with the explicit measure.

What are the normative Bayesian predictions for the presented data? When a common-cause model is assumed it is appropriate to encode the conditional probabilities directed from the cause (i.e., mutation) to its effects (i.e., substances). In this direction, the data display a conditional probability of either substance in the presence of the mutation (i.e.,  $P(\text{substance}|\text{mutation})$ ) of .80 in the strong and .50 in the weak condition. The corresponding values in the absence of a mutation ( $P(\text{substance}|\sim\text{mutation})$ ) are 0 in the strong versus .30 in the weak condition. Taking the difference of these numbers yields the widely used *contingency* ( $\Delta P$ ) measure of statistical strength (Eells, 1991). Accordingly, the contingency is  $\Delta P = .80$  in the strong and  $\Delta P = .20$  in the weak condition.

Within the framework of a common-effect model the same data should again be analyzed from causes to effects. In this condition the substances play the role of the causes. Thus, it is appropriate to compare  $P(\text{mutation}|\text{substance})$  with  $P(\text{mutation}|\sim\text{substance})$ . The data yield a probability of the mutation in the presence of the substance of 1 in the strong and of .63 in the weak condition. The corresponding values in the absence of the substance are .17 in the strong and .42 in the weak condition. These numbers imply almost the same contingencies as in the common-cause condition of  $\Delta P = 0.83$  (strong condition) and  $\Delta P = .21$  (weak condition).

On the basis of structural information from the causal models these numbers can be used to derive the predicted covariation between the substances. While the common-effect model does not imply a covariation, the common-cause model entails that the observed joint probability should correspond to the product of the base rate of the cause and the conditional probabilities observed for each causal link. These probabilities can be transformed into a *phi* coefficient of correlation (see Appendix). The data presented imply a *phi* correlation of  $r = .67$  between the substances in the strong condition and of  $r = .042$  in the weak condition.

## Results and Discussion

The results are based on 48 students from the University of Göttingen who were randomly assigned to one of the four learning conditions. Table 2 shows the means for both the explicit and the implicit measure obtained in the four conditions.

The correlations that the participants generated in the implicit prediction task resemble very closely the ones normatively implied by the causal models. Participants in the common-cause condition generated a high mean correlation of .62 between the substances when the causal connections were strong and a mean correlation of -.004 when they were weak. In contrast, in the common-effect

condition in which they received identical learning inputs as participants in the corresponding common-cause condition the prediction responses displayed generally low correlations in both conditions. An analysis of variance revealed a significant main effect for the factor causal model,  $F(1, 44) = 7.28$ ,  $p < .05$ ,  $MSE = .14$ , and a significant main effect for the factor strength of covariation,  $F(1, 44) = 18.4$ ,  $p < 0.01$ ,  $MSE = .14$ . The interaction failed to be significant,  $F(1, 44) = 2.33$ ,  $p = .13$ ,  $MSE = .14$ .

Table 2: Means of Implicit and Explicit Measures (Experiment 1)

	Implicit Measure: Generated Correlations		Explicit Measure: Estimated Correlations	
	Common-Cause Model	Common-Effect Model	Common-Cause Model	Common-Effect Model
Strong Relations	.622	.168	.286	.161
Weak Relations	-.004	-.130	-.109	.039

The explicitly estimated correlations clearly differed from the implicitly generated ones (see Table 2). There was no significant difference of the estimated correlations in the two contrasted causal models,  $F < 1$ . Only the difference between the conditions in which strength of covariation was manipulated proved significant,  $F(1, 44) = 8.05$ ,  $p < .01$ ,  $MSE = .10$ .

These results indicate that participants showed little sensitivity to the implications of causal models when the task required explicit estimates. They seemed to be aware of the fact that the inferred covariations somewhat depend on the strength of the causal links responsible for the covariations, but they did not explicitly grasp the structural difference between common-cause and common-effect models. By contrast, the implicit measure displayed surprisingly accurate predictions. In this task, participants clearly differentiated between common-cause and common-effect models despite identical learning inputs. In our view, this finding supports the prediction that sensitivity to structural implications can be achieved by running simulations on mental analogs of causal models.

## Experiment 2

In Experiment 1 participants first were informed about whether a mutation of the gene occurred or not, and then learned for each substance separately whether it was present or absent. This procedure served the goal of presenting identical learning inputs to participants in the different conditions. It raises the question, however, whether the observed asymmetries of sensitivity to implied covariations are due to the contrasted causal models or rather to differences in the direction of required inferences during learning. In the common-cause condition learning was directed from cause to effects (predictive learning), whereas in the common-effect conditions the very same

learning items implied that learning proceeded from effect to causes (diagnostic learning). Thus, it may be speculated that differences between predictive and diagnostic learning rather than differences in the underlying causal models may be the reason for the obtained results.

The goal of Experiment 2 was to replicate the results of Experiment 1 and to control for the direction of learning. Moreover, unlike in Experiment 1 the conditional probabilities and contingencies were equalized in the contrasted conditions. Material and procedure were taken from Experiment 1. All participants had the task to learn about the causal connection between mutation and the two substances. Again, as learning input they received index cards separated into two stacks which either provided information about the relation between the mutation and the enzyme BST or between the mutation and the brusus protein. Table 3 shows the frequencies of the different patterns that were presented during the learning phase.

Table 3: Frequencies in Experiment 2

	Substance	No Substance
Mutation	25	5
No Mutation	5	25

These frequencies implied conditional probabilities between the mutation and the substances that were completely symmetric ( $P(\text{mutation}|\text{substance}) = P(\text{substance}|\text{mutation}) = .8$ , and  $P(\text{mutation}|\sim\text{substance}) = P(\text{substance}|\sim\text{mutation}) = .2$ ). Thus, the contingencies were identical in both directions ( $\Delta P = .60$ ).

Two factors were manipulated in Experiment 2. The first factor manipulated the assumed causal model by means of differential initial instructions. As in Experiment 1, the mutation of the gene was either introduced as the cause of the two substances (common-cause model) or as their effect (common-effect model). The second factor manipulated the learning direction. Learning proceeded either from causes to effects (predictive learning) or from effects to causes (diagnostic learning). Thus, half of the participants received information about the mutation first before learning about the substances whereas the other half first read information about the presence or absence of one of the substances, and then received feedback about the mutation. In fact, the same index cards were used for all participants, the only difference was which side they saw first. Information about the mutation was shown first in the predictive version of the common-cause condition and in the diagnostic version of the common-effect condition. The reversed cards showing information about the substances first were given to participants in the predictive common-effect and the diagnostic common-cause conditions. Using the procedures described in the Appendix, a  $\phi$  correlation of  $r = .37$  between the substances can be derived for the common-cause model in which they played the role of effects. This is about half the size of the implied covariation in the condition with strong relations of Experiment 1. Thus, a smaller effect

size is to be expected in the present experiment. In contrast to the common-cause model, the common-effect model does not imply any covariation between the causes. These different structural implications are, of course, independent of the direction of learning.

As in Experiment 1, sensitivity to implied covariations was assessed by means of implicit and explicit measures. Regardless of the learning direction the implicit test always presented information about the mutation of the gene as the cue for the predictions. Participants were shown 20 new cases, half of which describing mutations, and had to predict for each case individually whether either of the substances was present or not. The explicit task in which participants estimated conditional probabilities followed the implicit one (see Experiment 1).

## Results and Discussion

64 students from the University of Göttingen were randomly assigned to one of the four conditions. The means of the  $\phi$  correlations that were either generated (implicit measure) or estimated (explicit measure) in the four different conditions are shown in Table 4.

Table 4: Means of Implicit and Explicit Measures (Experiment 2)

Learning Direction	Implicit Measure: Generated Correlations		Explicit Measure: Estimated Correlations	
	Common-Cause Model	Common-Effect Model	Common-Cause Model	Common-Effect Model
Predictive	.243	.013	.258	.239
Diagnostic	.186	-.001	.129	.210

As in Experiment 1, assumptions about the underlying causal model clearly influenced the implicit measure. The main effect for the factor causal model was significant for the generated correlations,  $F = 4.97$ ,  $p < .05$ ,  $MSE = .14$ . In general, participants generated higher correlations between the substances when they were viewed as effects (common-cause model) than when they had been characterized as causes of the mutation (common-effect model). In the common-effect condition the generated covariations between the two substances (i.e., the causes) were very close to 0 which supports our prediction that independence between causes is assumed in common-effect models. Neither the factor learning direction nor the interactions with this factor proved significant ( $F < 1$ ).

In contrast to the implicit measures, no sensitivity to the structural implications of causal models could be detected with the explicit measures. In general, participants tended towards correlations that clearly differed from 0 but showed no sensitivity to the assumed causal model. None of the effects approached significance in an analysis of variance in which type of causal model and learning direction entered as factors ( $F < 1$ ).

These results clearly support the conclusions of Ex-

periment 1 by demonstrating sensitivity to structural implications with an implicit but no sensitivity with an explicit measure. Consistent with the normative analysis, the implicit measures yielded higher covariations for the common-cause than for the common-effect model. The present experiment also shows that this pattern of results is not due to differences in the learning procedure (predictive vs. diagnostic) but rather is based on differences of the assumed causal models.

## Conclusions

Research on causality belongs to the truly interdisciplinary topics of cognitive science. There are differences in the research focus between disciplines, however. Whereas the majority of studies within cognitive psychology have focused on single cause-effect relations, researchers in the areas of computer science and philosophy have become increasingly interested in complex causal structures (e.g., Glymour & Cooper, 1999; Pearl, 2000). The goal of the present research is to bridge this gap without forgetting the inherent information processing limitations of humans. It is unlikely that untutored human learners are able to store and use the complex information embodied in even fairly simple causal structures. Therefore we have focused on a more realistic task in which participants learned about different fragments of a causal model separately, and later were confronted with the task to integrate the different pieces in order to predict unobserved covariations. To solve this task correctly, knowledge about structural implications of different causal models has to be activated. Research on Bayesian networks has shown that structural information greatly simplifies causal computations but it also has demonstrated that the task still remains complex. Consistent with this analysis both experiments have demonstrated that participants showed little explicit knowledge about differences between causal models, even when the models were extremely simple. Participants' explicit judgments did not distinguish between a condition in which the target events were two effects of a common cause and a condition in which these events represented two causes of a common effect. This result raises doubts as to humans' competence to correctly learn about causal structures in the world. However, a second, more implicit measure displayed surprisingly accurate inferences. When the task required predicting individual events, participants proved sensitive to the difference between common-cause and common-effect models. This dissociation between explicit and implicit measures is consistent with the view that mental simulations of causal models support the implicit task. Generating predictions by means of a mental simulation capitalizes on causal structure without requiring explicit knowledge. As long as the mental representation mirrors the causal features of the represented domain, simulations should display the same structural constraints. Therefore causal simulations allow us to generate correct predictions without requiring complex, explicit computational inferences.

## Appendix

The following derivation shows how joint probabilities and correlations can be derived for common-cause models. In the formulas,  $s_1$ ,  $s_2$  represent the two substances and  $m$  the mutation. “~” signifies the absence of an event. The joint probability of the two substances can be computed by

$$P(s_1.s_2) = P(s_1.s_2|m) \cdot P(m) + P(s_1.s_2|\sim m) \cdot P(\sim m) \quad (1)$$

Common-cause models assume that the effects are independent conditional upon the states of the common cause, that is:

$$P(s_1.s_2|m) = P(s_1|m) \cdot P(s_2|m)$$

Thus, Equation 1 can be simplified:

$$P(s_1.s_2) = P(s_1|m) \cdot P(s_2|m) \cdot P(m) + P(s_1|\sim m) \cdot P(s_2|\sim m) \cdot P(\sim m)$$

The joint probabilities for the other patterns (e.g.,  $P(s_1.\sim s_2)$ ) can be calculated in a similar fashion. These probabilities can be used to compute *phi* correlation coefficients based on the following formula:

$$r = \frac{P(s_1.s_2) \cdot P(\sim s_1.\sim s_2) - P(s_1.\sim s_2) \cdot P(\sim s_1.s_2)}{\sqrt{(P(s_1.s_2) + P(s_1.\sim s_2)) \cdot (P(s_1.s_2) + P(\sim s_1.s_2)) \cdot (P(s_1.\sim s_2) + P(\sim s_1.\sim s_2)) \cdot (P(\sim s_1.s_2) + P(\sim s_1.\sim s_2))}}$$

This procedure of computing *phi* correlations can be applied to the patterns predicted by the participants (implicit task) as well as to the estimated conditional probabilities (explicit task).

# The Problem with Logic in the Logical Problem of Language Acquisition

Petra Hendriks (P.Hendriks@let.rug.nl)

Department of Dutch / Cognitive Science & Engineering (TCW)

University of Groningen

Grote Kruisstraat 2/1, 9712 TS Groningen

The Netherlands

## Abstract

This paper discusses the motivation behind the nativist position with respect to linguistic knowledge. In particular, the discussion focusses on the argument from the “poverty of the stimulus”, which is generally assumed to be the most important argument in favor of a nativist position. On the basis of current views on human reasoning and learning, we will argue that the logical (i.e., non-empirical) part of the poverty of the stimulus argument is invalid. This result substantially weakens the nativist position, although it does not imply that the assumption that there must exist a certain amount of innate domain-specific knowledge has to be abandoned altogether.

## 1. The Logical Problem of Language Acquisition

A fundamental assumption within modern generative syntax is the assumption that knowledge of language is for a considerable part innate. This innate knowledge takes the form of universal principles and parameters that underly all human languages (cf. Chomsky, 1986a; Chomsky, 1995). The most important argument in favor of the nativist position with respect to linguistic knowledge is the so-called poverty of the stimulus argument. The poverty of the stimulus argument yields, in Wexler’s (1991) terms, “Chomsky’s most unique argument” and “the most powerful theoretical tool that we have available to us” (see also Wexler, 1999).

This argument forms the basis of the logical problem of language acquisition, which is essentially an induction problem. A child only hears a finite number of sentences but has to generalize from this input to an infinite set of sentences that includes the input sample. This infinite set is the set of sentences generated by the language the child has to learn, which will be referred to here as the target language. What makes this induction task an extremely difficult one, however, is that an in principle infinite number of hypothetical languages is consistent with the finite input sample. The child has to single out the correct set corresponding to the target language and reject all other sets, which are incorrect hypotheses about the target language. Because every child eventually ends up speaking her mother tongue, children must be guided by constraints that allow them to reject the incorrect hypotheses. Just presenting the child with more sentences of the language she is learning (i.e., providing her with more positive evidence) does not reduce the set of hypothetical languages to the

correct one in all cases (cf. Gold, 1967). If the target language is a subset of the hypothetical language the child entertains, no amount of positive evidence will lead the child to conclude that the adopted hypothesis is incorrect. In this case, only negative evidence will suffice to reject the larger set in favor of the smaller set. However, negative evidence does not seem to occur very frequently in the language input of a child (Brown & Hanlon, 1970), and if it does occur, it usually is not very effective.

The conclusion must be that the language input of a child is insufficient (or, in other words, the “stimulus” is too “poor”) to be able to conclude to the target language. So how are children able to learn their mother tongue, if the information available to them is not sufficient to draw logically valid conclusions from it? Because this is a variant of the question Plato asked himself with respect to knowledge in general, the logical problem of language acquisition is also referred to as Plato’s problem (Chomsky, 1986b).

## 2. The Defective Nature of the Language Input

Another aspect that is sometimes mentioned in relation to the poverty of the stimulus argument is the qualitatively and quantitatively defective nature of the language input the child receives. That is, children frequently hear ungrammatical sentences from their parents and other people. Moreover, the utterances they encounter form only a small fragment of the language they are learning. These two characteristics of the language input have been argued to make language learning extremely difficult, if not impossible, without prior knowledge. The presence of many ungrammatical sentences in the language input is highly problematic because these ungrammatical sentences do not come labelled as ungrammatical. Since the set of utterances the child encounters is relatively small, relevant examples of certain grammatical constructions might not be encountered during the language-learning years. However, both the claim about the qualitatively defective nature of the language input and the claim about the quantitatively defective nature of the language input have been questioned (e.g., Pullum, 1996; Sampson, 1997).

According to Newport, Gleitman and Gleitman (1977), “the speech of mothers to children is unswervingly well formed. Only one utterance out of 1500 spoken to the children was a disfluency”. On the basis of this evidence, it

cannot be maintained that the language input to the child is qualitatively defective, or “degenerate”.

The claim about the quantitatively defective nature of the language input, that is, the non-occurrence of relevant grammatical constructions in the child’s input language, has been refuted by empirical evidence as well. The standard example Chomsky and many others use to illustrate the poverty of the stimulus argument is the formation of yes/no questions (e.g., Chomsky, 1980; Chomsky, 1988). The formation of yes/no questions is dependent on the abstract property of structure-dependency, in particular on distinguishing the main clause from embedded clauses. In order to form a correct yes/no question, the finite verb of the main clause has to be moved to the front of the sentence. To refute the simple but structure-independent and thus false hypothesis that it is the first verb in the sentence that must be moved, the child needs to encounter questions involving an embedded clause which precedes the main verb (for example, “will those who are coming raise their hands?”). Although it is claimed by Chomsky and others (without providing any empirical motivation for this claim) that these examples are very rare, Pullum (1996) found that about 12% of the yes/no questions in the corpus he searched were crucial examples which refuted the incorrect hypothesis. So, relevant sentences for the acquisition of the formation of yes/no questions are expected to occur in the input language of the child. Of course, Pullum did not show this for all other examples that have been used to illustrate the poverty of the stimulus argument, but there is no evidence that it will be different for other examples. Thus, the language input to the child seems to be neither “degenerate” nor “meager”. For this reason, I will focus on the unavailability of negative evidence as the crucial and most uncontroversial aspect of the poverty of the stimulus.

### **3. The Nativist Solution**

The solution that most generative syntacticians have adopted for the logical problem of language acquisition is to assume that the core of the grammar is already present in the child before language learning starts off. This assumption has changed the agenda of research on language learning completely. Language learning is no longer viewed as the acquisition of knowledge on the basis of information present in the input data. Rather, children are born with a “language instinct” (Pinker, 1994). Under this nativist view, language learning merely is a matter of setting the parameter values of an innate universal grammar (UG) on the basis of specific triggering experience. A nativist position is also taken in the recently developed linguistic framework of Optimality Theory (Prince & Smolensky, 1993; Prince & Smolensky, 1997), although their solution to the logical problem of language acquisition differs from the generative solution (see Tesar & Smolensky, 1998).

Although it is seldomly recognized, the logical problem of language acquisition is not an unavoidable and theory-independent problem. Even if one agrees on the mentalist claim that the human brain contains a symbolical

representation of a mental grammar (an assumption which is refuted by radical connectionists) and that this mental grammar is at least as complex as a context-free grammar, the logical problem of language acquisition only arises as a result of two additional assumptions that are generally adopted within generative syntax.

The first assumption is the assumption that syntax forms an autonomous module of language. This assumption is fundamental to generative syntax. Hence, generative syntacticians like Lightfoot (1982) and Cook and Newson (1996) illustrate the logical problem of language acquisition by putting it on a par with trying to learn chess or snooker by watching people play the game. Crucial here is the fact that chess and snooker are systems of purely formal rules that do not refer to anything outside the system. The nature of the input and output of the process of learning has implications for the type of information available to the learner. As Grimshaw (1981) puts it: because of the autonomy of syntax, “UG does not permit deduction of a syntactic analysis from an analysis of the semantics of a phrase”. In other words, because syntax is autonomous, the formal properties of the grammar must be learnt from the formal properties of the input and cannot be inferred from its meaning.

The second assumption that is crucial to the view that there exists a logical problem of language acquisition is the identification of learning a language with finding the correct hypothesis through a process of hypothesis formulation and refutation (cf. Pinker, 1989; Wexler & Culicover, 1980). Note that this view of language acquisition as hypothesis testing is not present anymore in current nativist theories of language acquisition. I will return to this point in section 5. In the next section, I will demonstrate the dependence of the logical problem of language acquisition on the assumption that language acquisition is a process of hypothesis testing and logical deduction.

### **4. Language Acquisition as Logical Deduction**

As was noted in the previous section, an assumption underlying the logical problem of language acquisition is the assumption that the child learns her mother tongue through hypothesis formulation and refutation. Now if syntax is assumed to be autonomous, this process of hypothesis testing must be a process of logical reasoning. In particular, the process of hypothesis testing must involve logical deduction. Deductive reasoning involves deriving a conclusion from given information by using a set of formal (i.e., based on the form of the input) mental operations, without adding new information. This contrasts with inductive reasoning, which involves extrapolating a rule based on limited information. If it is not assumed that children employ deductive reasoning in hypothesis testing, there would be no logical problem of language acquisition at all, since nothing prevents children from concluding to the target language in the absence of negative evidence, except for the rules of logical deduction. Of course, it then remains to be explained how children arrive at exactly the same

grammar, but note that it is an empirical issue whether children indeed do.

Very few linguists actually discuss the mechanism that is supposed to lead children to conclude to the target language in the situation sketched by the logical problem of language acquisition. Linguists who use the poverty of the stimulus argument to support their theoretical point of view but do not discuss the learning mechanism involved, sometimes have been criticized for neglecting to take into account this mechanism. A common reaction to this criticism is that the actual mechanism does not really matter because Gold's (1967) proof, that positive evidence is not sufficient to learn a context-free language, is a formal proof. Such a formal proof is argued to be independent of the learning mechanism involved. However, implicit in Gold's proof is the assumption that learning a language can be identified with logically deducing the correct hypothesis on the basis of relevant evidence. Although it has been noted that there are some problems with Gold's model of language acquisition (Elman et al., 1996; Quartz & Sejnowski, 1997), this particular aspect of Gold's model has not been mentioned before as yielding a problem.

To motivate the claim that a process of hypothesis testing forms the basis of the logical problem of language acquisition, here are a number of quotations from the literature. According to Pinker (1989), for example, "[e]xplaining successful learning basically consists of showing that the learner can entertain and stick with a correct hypothesis and can falsify any incorrect ones" (p. 6). Chomsky (1988) likens the problem of language acquisition to the endeavour of a Martian scientist trying to understand Spanish, "pursuing the methods of the sciences, the methods of rational inquiry [...] His problem is to construct a hypothesis as to what the rule is and to test it by looking at more complex examples" (pp. 41-42). Perhaps children proceed exactly as this Martian scientist did in his inquiry, Chomsky continues. But this cannot be correct, since no negative evidence is available to children. Therefore, Chomsky concludes that innate principles must guide language acquisition. The motivation for assuming that certain properties of human language must be innately determined is explained by Crain (1991) as follows: "every child comes to know facts about language for which there is no decisive evidence from the environment. In some cases, there appears to be no evidence at all; in others the evidence is compatible with a number of alternative hypotheses (including false ones)" (p. 598). Jackendoff (1994) suggests that the unconscious task of a language-learning child can be compared with the conscious task of a linguist trying to discover the basic principles of human language: "they [i.e., children] must (unconsciously) discover for themselves the patterns that permit them both to understand these sentences and to construct new sentences for other people to respond to. Whether this process of discovery goes on unconsciously in the child or consciously in the linguist, the very same problems have to be solved" (p. 27). About the only way it can be explained that children are able to learn their

language is to assume that "children have a head start on linguists: children's unconscious strategies for language learning include some substantial hints about how a mental grammar ought to be constructed".

Summarizing, the basic idea of these authors is that a strategy of hypothesis testing is not sufficient for learning a natural language in the absence of negative evidence. This rejected strategy of hypothesis testing assumes children to behave like scientists and gather evidence in order to falsify incorrect hypotheses and employ hypothetico-deductive reasoning to draw the correct conclusions. However, the strategy of hypothesis testing by hypothetico-deductive reasoning seems to be based on implausible assumptions about human reasoning, as will be argued in section 6.

## 5. Language Acquisition as Parameter Setting

Many generative syntacticians will respond to the conclusion of the previous section by claiming that this is not a correct characterization of the current view on learning within the field of language acquisition. Rather, they will argue, language acquisition is currently viewed as a (blind) process of changing parameter values on the basis of specific triggering experience (cf. Gibson & Wexler, 1994). This is indeed true for the nativist framework of Principles and Parameters Theory and the Minimalist Program. However, the notion of parameter setting was introduced (along with the concept of an innate universal grammar) as a solution to the logical problem of language acquisition. Thus, first there was the logical problem of language acquisition, which made implicit use of the assumption that children employ logical deduction. This problem was subsequently solved by assuming an innate UG, which is accompanied by its own learning mechanism: parameter setting on the basis of triggering. Parameter setting therefore is the result of an argumentation that started out with the assumption that children employ logical deduction. If it would not have been assumed that children employ logical deduction, there would be no logical problem of language acquisition to be solved, and hence there would be no motivation for innate principles and for parameters that have to be set.

Discussions about learning mechanisms should be careful to distinguish between learning mechanisms assumed prior to the acceptance of the logical problem of language acquisition, and learning mechanisms assumed as a solution to this problem. This is not a trivial warning. When Lightfoot (1998) criticizes Elman et al. (1996) for their seeming lack of interest in the linguistic motivation for the innateness claim, in particular the poverty of the stimulus argument, and contrasts this with linguists, who seem to be interested in learning issues, Lightfoot is in fact already one step too far: "[l]inguists are actively interested in questions about learning algorithms. For example, an interesting debate is emerging about a trading relation between properties of UG and learning algorithms". Since the linguists Lightfoot refers to proceed from the conclusions drawn from the poverty of the stimulus argument, their

work does not bear on the innateness debate tackled in Elman et al. Rather, these linguists have already taken sides in the innateness debate, which makes it impossible to apply their results to the same debate again.

## 6. Do People Reason Logically?

One of the central themes within cognitive science is the question pertaining to the mechanisms underlying human reasoning. To investigate the role of logic and formal rules in the process of human reasoning, Wason (1966) and Griggs and Cox (1982), among others, carried out a series of well-known selection task experiments.

In Wason's experiment (Wason, 1966; Wason, 1968; Johnson-Laird & Wason, 1977), subjects were presented with an array of cards and told that every card had a letter on one side and a number on the other side. In addition, the following rule was given: "If a card has a vowel on one side, then it has an even number on the other side". Subjects were asked to select those cards that definitely have to be turned over to find out whether or not they violate the rule. Note that this rule has the form of a logical implication: *if p then q*. In propositional logic, such a rule is false if *p* is true and at the same time *q* is false. If the subjects in Wason's experiment would reason according to the rules of deductive logic, they would choose the cards with a vowel and the cards with an odd number. All other cards are irrelevant from a logical perspective. Indeed, most subjects chose the card with the vowel. On top of that, many subjects (46%) also chose the card with the even number, although it does not matter for the validity of the rule whether the other side of this card carries a vowel or a consonant. On the other hand, a card that was overlooked by almost all subjects was the card with the odd number. If there is a vowel on the other side of this card, the rule is violated. The correct answer, namely the card with the vowel and the card with the odd number, was given by only 4% of the subjects.

Griggs and Cox (1982) presented subjects with a task that was identical in form to Wason's task, but in which the abstract problem and the abstract rule had been replaced by a concrete problem and a concrete rule: "if a person is drinking beer, then he or she must be over 19 years of age". One side of the card had information about a person's age (16 or 19 years old) and the other side had information about what this person was drinking (a beer or a coke). If human reasoning takes place purely on the basis of the form of a problem, the results of the two experiments should have been identical. However, they were not. Like in Wason's experiment, all subjects turned over the card that affirmed the antecedent of the conditional clause (i.e., the card with "drinking a beer"). In contrast with Wason's experiment, however, many subjects (74%) also turned the card with "16 years of age", whereas almost none of Wason's subjects turned the card with the odd number. So, in Griggs and Cox's experiment most subjects gave the correct answer, namely the cards with "drinking a beer" and "16 years of age".

Apparently, then, the subjects in the second experiment used semantic information to solve the problem. In the first experiment, in which only information about the form of the problem was available, only few of the subjects managed to solve the problem. This suggests that human reasoning does not rely on a kind of mental logic. Logical rules are formal rules, which only take into account the form of the basic elements, not their meanings. If only information about the form of a problem is available, as in Wason's experiment, people make mistakes. Whenever they can, they use information about the meaning of the problem and about its context. In fact, people not only make mistakes in conditional reasoning tasks like the ones discussed above, they also make mistakes in other reasoning tasks requiring logical reasoning, for example in syllogisms. Conclusions that are consistent with beliefs or desires are more likely to be accepted as valid than conclusions that are not (e.g., Janis & Frick, 1943; Mayer, 1983). In general, people are not particularly good at solving problems correctly when the problems are presented to them in an abstract form. Concrete problems are solved by using all the knowledge that is available and might bear on the problem.

## 7. What Does Reasoning Tell Us about Language Learning?

The main conclusion that can be drawn from the reasoning experiments discussed in the previous section is that adults apparently are not naturally logical reasoners. But if adults do not reason according to some kind of mental logic, and if children do not differ from adults in this respect, then one of the two assumptions underlying the logical problem of language acquisition is not valid. As was argued in section 3 and 4, the logical problem of language acquisition only exists if it is assumed that syntax is autonomous and children reason logically. If one of these assumptions does not hold, then there is no logical problem of language acquisition. This does not imply that there is no empirical problem of language acquisition, though. But it implies that it is not *in principle* impossible that children learn their mother tongue from the language input they receive. Note that we cannot conclude from this that children definitely do not possess innate knowledge of language of some kind. But since the argument based on the logical problem of language acquisition appears to be invalid, the evidence for an innate UG is substantially weakened.

One could object that there is a difference between learning and reasoning and, therefore, that it is questionable whether results from the cognitive domain of reasoning apply to the domain of learning. However, human learning often involves deductive reasoning, in which one is able to discover or generate new knowledge based on beliefs one already holds. In addition, the logical problem of language acquisition is stated in such a way that it assumes children to reason about the hypotheses that are compatible with a given set of data and draw conclusions on the basis of the sentences they encounter. As an illustration, recall from section 4 Chomsky's comparison of a child learning her

language with a Martian scientist trying to understand Spanish. So, irrespective of whether learning and reasoning must be distinguished in practice, since learning involves reasoning in the logical problem of language acquisition, the results from the selection task experiments discussed in the previous section bear on the validity of the logical problem of language acquisition.

## 8. Conclusions

The logical problem of language acquisition is taken to be one of the strongest arguments in favor of the nativist view on language, since its validity is independent of specific empirical evidence. The basic idea behind this argument is that it is impossible in principle to acquire a language solely on the basis of the language input, irrespective of the presentation of the input data and the amount of positive feedback the child gets. In this paper, it was argued that there is no logical problem of language acquisition, since the combination of assumptions on which the formulation of the problem rests cannot be maintained in the light of current views on human reasoning and learning. In particular, people do not reason logically, which was the main assumption behind the logical problem of language acquisition. This does not imply that every aspect of language must be learnt from the input and that no innate linguistic knowledge or innate linguistic mechanisms can exist. But the evidence in favor of an innate UG must be based solely on empirical observations, now that the argument based on the logical problem of language acquisition has been shown to be invalid.

## Abstract

This project presents a memory-based, analogical model of complex problem solving with a technique of schema formation. Cases in the game of Go are described in a predicate logic representation of spatial stone arrangements near recent moves on the board, and then structure-mapping (Gentner 1983) is used to suggest candidate moves in novel situations based on exemplar cases from expert games. The analogy process is also used to generalise across previous cases to form new schema cases. Problem solving using these prototype schemas is compared with the exemplar-only model. The exemplar run effectively found solutions to about 50% of the problems; schemas performed very similarly, taking half as long and identifying a few useful Go principles. This suggests to us that pure-exemplar models of memory-based processing can be made faster and more compact by introducing schemas. Analysing the model's weaknesses highlights the need for richer board representation and for a reminding stage to select relevant cases. Future work will also focus on using a move evaluation stage to filter spurious generalisations, and using both the evaluation and the generated schemas to enrich the representation.

## Introduction

This paper explores a model of memory-based problem solving to see whether analogical reasoning can be effective at suggesting solutions to complex problems and to see whether schema induction via analogy can serve as a basis for learning useful generalisations. We describe two machine learning experiments designed to test how well exemplars and abstracted schemas perform when used to suggest candidate moves in the game of Go, and review some computational and cognitive implications of this work.

In the memory-based psychological paradigm, experience cases stored in memory are the starting point for solving a target problem, roughly in a three step process.

- (1) *Reminding*: surface features prime cases
- (2) *Matching*: cases analysed to suggest solutions
- (3) *Evaluation*: solutions considered in context

Available features of the problem cue the retrieval of experiences containing similar features, in the first, reminding step. These potentially relevant experiences are then analysed — such as by looking for analogous propositional structure — and if it is a good match, a portion of the remembered experience may be transferred as a potential solution. (In iterative models, the matching step may uncover new surface features which cause new cases to be retrieved.) Potential solutions are evaluated relative to the context and the goals of the target problem, in the third step, and used to form the eventual solution. This approach is closely related to case-based reasoning, and is also apparent in exemplar models of categorisation (Nosofsky, 1984) and some recent work on natural language processing (Daelemans, van den Bosch, & Weijters, 1997).

A schema is a description of general experiences, often formed from a family of episodes with elements in common. They can supplement or organise a simple exemplar model by offering a concise source of the essential factors in many experiences without the incidental details present in episodic memories. Frames, scripts, and model-based reasoning are examples of their use in AI. The theory of pragmatic reasoning schemas (Cheng & Holyoak, 1984) is a clear account of how schemas can combine the best attributes of competing memory-based and rule-based views to model logical reasoning. In the categorisation literature, both prototype and theory (see Komatsu, 1992, for review) models can be considered as relying solely on a schema-definition of categories. Unfortunately in all these theories how to form these schemas is a difficult problem: the second set of experiments below tries a rudimentary method of inducing schemas from analogical matches performed during the memory-based process.

The strategy game Go was selected as a domain for our experiments for three main reasons: it is a plentiful source of difficult problems, many of which computers cannot currently solve; a vast amount of data is available on the Internet Go Server (IGS, 2000); and it does not involve much outside knowledge. The game is played by two players, one with black stones and the other with white, who take turns placing their stones in any unoccupied space on a 19x19 board, with the goal of amassing the greatest amount of territory. Players can capture their opponent's stones, individually or in orthogonally connected groups, by surrounding them in such a way that the captured group is not adjacent to any empty squares of the board. Captured groups are removed from the board, and the newly-unoccupied region typically becomes the capturing player's territory.

Many books can give more information on the rules, the strategy, and the history of the game (Bozulich, 1992, is good for this). Archives for research in Go-playing computer programs are on-line (Reiss, 2000), as are archives for psychological studies in Go (Burmeister, 2000).

One of these psychological studies (Saito & Yoshikawa, 1996) indicates that expert Go players quickly focus on their eventual move, (order of 200 ms in TsumeGo); and that they usually consider the outcome of only one or two possible moves. For these candidate moves, there is a lengthy lookahead evaluation which may go as far as 11 moves deep. Traditional Go-playing programs, even those which have been proposed as cognitive models, perform a broader search on a much greater number of candidate moves, necessarily to a lesser depth and with the result that no Go programs play any better than an amateur. It is fascinating that skilled players are able to focus rapidly — intuitively — on the best moves. In this research, we explore a memory-based model of how this might be done and also whether the abstraction of schemas can benefit performance.

### Experimental Design and Setup

In our view, the expert Go player relies on a large number of case experiences in memory, efficiently represented, and when a new problem is presented, retrieves a small number of possibly-relevant exemplars for fuller evaluation. Schemas may also be involved in representing common, recurring segments of exemplars as easily-accessible, general cases. The major issues involved in developing a computational cognitive model of this view are how the experiences are internally represented, how relevant experiences are selected from memory, and how schemas are formed.

### Representation

As in many machine models of complex problem solving, the representational format used here was a propositional description language recording a small number of perceptually basic, salient features. Specifically, for each problem, this encodes the colours of neighbouring stones around the two previous moves (X and O); the relative position between these two moves (in the format (rel X (rel-1 w 1)), meaning one position to the west of the last move); and, for cases including the expert’s solution, the relative position between the actual response (Q) and the two previous moves.

```

E1 (my-last-move O)
E2 (is-colour white O)
E3 (is-colour black (rel O (rel-1 w 1)))
E4 (is-colour black
    (rel O (rel-1 n 1)))
E5 (is-colour black
    (rel O (rel-1 s 1)))
E6 (is-colour white
    (rel O (rel-1 s 2)))
E7 (make-move Q)
E8 (is-colour white Q)
E9 (equal-position Q (rel O (rel-1 e 1)))

```

Figure 1: A fragment describing an atari opening east

This subset of information was selected because it corresponds generally to the initial observations that a player makes, guided by attentional cues to recent moves and nearby stones, and because as limited and easily-compiled as it is, it already contains enough information to begin drawing conclusions about where to play in certain circumstances. A more complete model of the expert’s initial representation might note a great many more features, symbolising more complicated concepts, but we hoped that this simplification would yet give promising results. The routines we developed to build the description from on-line game records and the routines to evaluate the descriptions as LISP code for visual output are designed to work with a family of vocabularies.

### Analogical Processing

The target problems were compared with cases in memory using the Structure-Mapping Theory of Analogy (Gentner, 1983). We chose this theory because it has been widely examined in the literature on the psychology and computer modelling of analogy, and because the Structure-Mapping Engine program (Falkenhainer, Forbus, & Gentner, 1989) is ideally suited to our representation. Routines in SME can easily read our descriptions, perform the analogy in keeping with a demonstrated psychological theory, score potential matches, and return inferences which correspond to candidate move suggestions.

In the implementation of our model, individual analogies are taken between a target problem and each of 1500 cases in memory. In practice, this is a slow, sequential process that takes between 10 and 30 minutes per problem on a Sun Ultra-10 workstation. In theory, however, each analogy is independent, and this might correspond to a very quick, parallel neural computation done by the brain. It could also be made significantly quicker by incorporating a more diverse description language with a “reminding” approach. A smaller number of cases which seem relevant can be primed by surface features in the target problem, with only those cases containing similar predicates used for the analogical matching (Forbus, Gentner, & Law, 1995). Whether these improvements could get the time per problem down to the order of 200 ms is unclear; up to 30 minutes per problem, though, is not prohibitive at this stage of the experimentation.

### Schema Induction

Once an analogical match has been made between a target problem and a source (base) case, the result can also be used to abstract the common substructure. Instead of looking only at the inferences, the process copies all the matching expressions into a new, schema case. This encodes the essential description elements from pairs of exemplar cases into more compact, abstracted descriptions which can then be used as base cases for solving future problems. Additionally, by repeating the induction on schema cases, the process can

also capture patterns recurring across many experiences in memory. This cognitive model of generalisation learning has been argued for on the basis of order effects by Kuehne, Forbus, & Gentner (1999). A similar algorithm, the Least General Generalisation (Plotkin 1971), has been widely used in AI to induce descriptions in logic, and a related approach has been applied to pattern learning in Go (Stoutamire, 1991). In our model, applying this type of schema induction after analogy has been used to generate candidate solutions has the advantage that the generalisation is returned with very little additional computational effort.

To perform the induction, we developed a LISP module within the SME package that transforms the result of a completed analogy into an abstracted schema. The schema uses the same description language as the parent cases, copying identical predicates exactly and inventing new tokens where the corresponding labels in the parents differ. The resulting schema can be used directly as a base case for analogical reasoning or output to a file. The second set of experiments reviewed below investigates the utility of this induction algorithm in solving complex problems and learning patterns.

### Problem Solving from Examples

The first experiment tried to solve 100 random Go problems by analogy to a library of exemplar cases. We take *solve* to mean that the move chosen by the expert player in the actual game is ranked in the top 50 in the program's list of suggestions (sometimes also top 3 or top 10). In a full-fledged Go-playing model this would be followed by an elaborate evaluation stage which would consider the effects of the candidate moves, typically using some form of lookahead search. Go players perform this lookahead on 1.5 moves on average (Saito & Yoshikawa, 1996), whereas most computer Go programs will evaluate between 20 and 70 moves.

Figure 2: Sample results to a target problem. Numbers indicate ranked suggestions; X and O are the last two moves; and Q is the expert's move.

### Materials

We simulated the human's experience as consisting of 1500 exemplar cases drawn from ten tournament games (freely available on the Internet Go Server, IGS, 2000). These source cases, *ten-games*, are each a LISP-style description in the vocabulary outlined above, recording the neighbourhood of the last two moves with an indication of the move the expert made at that point in the game. One-hundred target problems, *query-random-100*, were compiled from random turns (before the end-game) in other IGS tournament games in the same manner but without any indication of the expert's response.

### Results

Figure 2 illustrates one of the better responses to a target problem. The program's top suggestion (1) is the expert's "right" answer (Q), and is quite close to the opponent's previous move (X). Many of the other candidates were in other sections of the board, reflecting problems locally similar to this one where the expert did play in other areas. (In this situation, playing elsewhere might be better, but as this model attends to stones near X and O, it cannot draw very good conclusions about distal play.)

The program solved 51 of the 100 problems after running for 13 hours (taking the top 50 suggestions). If all suggestions are considered, solutions to 93 problems were found; however, the program made an average of 6791 suggestions per problem. (There are only 361 positions on the board). There were a large number of repetitions — on average, the right answer is suggested 104 times. Looking at different suggestion depths gives a better picture of the program's performance: among the top 3 suggestions, the right answer was found for 7 problems; among the top 10, for 20; and among the top 50, for 51. Figure 3 shows the performance as up to 200 suggestions are considered.

Figure 3: Experiment 1 results. This graph shows the percentage of problems solved by considering the  $x$  highest-scoring suggestions. The heavy line is our program, and the light line a chance player based on the 1970 Zobrist program. The dotted line is the asymptotic percent solved when all inferences were considered.

To put these numbers in perspective, we developed an informed random heuristic on the basis of the 1970 Zobrist program (Burmeister, 2000), also shown in Figure 3. This program selected positions at random, weighted heavily nearby the two prior moves. It took 6 minutes to query the same set, finding solutions to 3 of the 100 problems within its top 3 suggestions; 10 in its top 10; and 35 in its top 50. These numbers are not very sensitive to the precise weights used, so we take this as a baseline for how a rudimentary statistical learning algorithm would perform given only  $X$ ,  $O$ , and  $Q$ .

There were a large number of repeated suggestions in the lists of candidate moves, as well as quite a few invalid moves, either off the board or in an occupied square. A human player would immediately filter these out, and a machine evaluation routine would also quickly eliminate them from the lookahead search; it is interesting to review the effect this has. For our system, after removing these candidates, 13 of the correct solutions were in the top 3 suggestions, 32 in the top 10, and 64 in the top 50. For the informed random player, 5 were in the top 3 suggestions, 14 in the top 10, and 51 in the top 50.

### Analysis

A comparison of our analogical problem solver with the weighted random player shows that, for very small numbers of suggestions, our program performs much better, solving twice as many problems, though taking orders of magnitudes longer. At greater suggestion depths, the chance player improves relative to our program, for the trivial reason that will eventually guess every space on the board; considering more than 50 or 100 suggestions is not very practical either for input to a machine evaluation routine or as even a rough model of human candidate move generation. If we further focus on the source and target problems where the expert played within three stones of one of the last two moves (between 30 and 50 possibilities), the correct answer is in the top 10 different valid suggestions for 67 of the 100 problems. (This compares with 20 for the chance player). This shows that our analogical Go solver performs best on localized problems, which are in fact those instances where our solver has the largest amount of relevant information. This points to the fact that the representation was the biggest weakness when reasoning from exemplars.

### Schema-Based Processing

The second set of experiments was designed to explore the use of schemas in memory-based problem solving. Hundreds of thousands of pairs of cases from the *ten-games* set were passed to our Structure-Mapping Engine schema induction module, and the highest-scoring schemas (after normalisation) were kept as the set *schemas-1500*. This set was then used to solve the same selection of 100 random problems as in the previous experiments, using the same procedure as described above. Next, we examined the schemas which were most effective in solving problems and repeated

the induction process to investigate how well the generalisation technique captures the essential, common aspects in families of cases.

### Comparison with Exemplars

The most significant result with the schema-based run was that the computations took about half as long, achieving approximately the same success rate. On the same problem set (*query-random-100*), this run took 7 hours; in the top three suggestions, the *schemas-1500* source set found answers to 7 of the 100 problems; in the top 10, 23; and in the top 50, 51. In the limit, schemas suggested the solution to 88 problems.

Two main factors explain the speed difference. Firstly, the schema cases are much smaller, about 1/3 the size. Secondly, a much smaller number of suggestions were made per problem, 3204 on average. Nonetheless, the performance at low suggestion depths was about the same. In fact, as a percentage of the total number of suggestions, the correct move was suggested 60 more often by the schemas (77 of 3204) than by the exemplars (104 of 6791). This implies two things:

- When the schema set contained a case which solved the problem, it contained a lot of cases which solved the problem.
- Schemas were more likely to make suggestions to appropriate problems than were exemplars; *i.e.* they were less likely to give wrong answers.

The first point tells us that there was even more repetition in the schema set than in the exemplar set, which might have been expected, considering that the schemas encode common patterns among the exemplar set. The second point was quite surprising, though: one might expect the schemas to be more general, and hence more applicable than the exemplars. What happened, however, was that the exemplars, because they contained so much background information, could match more situations. With many exemplar cases, analogies were based on irrelevant criteria but were still strong enough to form inferences — inappropriately — about  $Q$ . Asymptotically, however, exemplars solved 93 of the 100 problems; in some cases, exemplars appropriately made inferences about  $Q$  based on information that had been lost in the schema formation process.

After filtering out repetitions and invalid moves, the schema-based run was slightly better than the exemplar-based run. The top three suggestions gave solutions to 14 problems (compared to 13 for exemplars); the top 10 solved 39 (versus 32); and the top 50 solved 70 (versus 64). This strengthens our conclusion that in this experiment, the schema induction process was somewhat successful in discarding irrelevant, distracting information from cases and achieving better performance much more quickly.

## The Effectiveness of Schemas

If this conclusion is correct, then many of the schemas should correspond to common Go situations or aphorisms. Figure 4 below shows one schema that was

Figure 4: A particularly good schema. Playing Q to the left of X in a situation like this solved many of the target problems.

particularly useful: it gave correct suggestions to 20% of the posed problems, usually in the top 50 and several times in the top 10. Other effective schemas also helped to solve a large number of problems, to a much greater extent than individual exemplars. On the other hand, there were some problems which no schemas matched but which were matched closely and solved by some exemplars. In summary, it appears that some good schemas can effectively replace a large number of common exemplars, but that in outlying cases, exemplars are important to keep around.

An approach we are currently investigating is to lump exemplars and schemas together, developing new schemas at random (weighted by the SME match score) and adding them to the pool. Some of the high-generation schemas, *i.e.* those formed after multiple generalisations, match patterns in standard Go reference books. One of these is the principle to “hane at the head of two stones”, to jump out in front of an opponent’s line of stones (shown in the left of figure 5 below). Another interesting configuration left out the colour of X and Q, suggesting that whether black or white played X relative to the other two stones, then the other player should set Q down to the lower right of X.

Figure 5: Some very generalised schemas. Interesting schemas found included the “hane”, on the left (play just below X), and the loose rhombi, both on the right (play to the lower right of X).

However, not all the high-generational schemas correspond to nicely stated principles or even to reasonable Go play. Anytime there is a large intersection between cases, even if it is meaningless and accidental, a schema

can form: for reliable, iterable induction, a better technique is needed.

## Conclusion

This memory-based model of the candidate move generation phase of Go has promising and interesting results. One of the three highest-scoring valid suggestions matched the expert’s move in one out of eight problems, and the best 50 suggestions solved more than half the problems despite a simple and locally-confined representation. Still, a large number of problems could not be solved by this model, and in considering future research directions it is useful to analyse these failings.

## Reminding and Richer Representations

Most of the problems that were not solved were ones where the subsequent move was in a different region of the board than either of the two previous moves. In these instances, the source exemplars simply did not store the information to enable our approach to find the answer. It seems likely that human players attend to a much wider range of features; if more of these could be recognised and encoded by the routines that generate the descriptions, we might expect better performance.

On the other hand, it is expensive to keep all this information: the cases would become too large to perform analogies on the entire set. One possible resolution would be to encode initially only the most salient features of the target; a reminding stage, such as in MAC/FAC (Forbus *et al.*, 1995), could select a small number of cases on which to perform the analogical matching. Some inferences would posit the presence of certain features in the target problem, which could be added to the initial representation if they hold, and the analogy could continue iteratively, re-representing, re-reminding, and re-matching, until it flounders or suggests something about where to play.

There is also the question of where these features will come from. Most Go programs have an extensive feature recognition routine, and it would be possible at first just to duplicate some of these. Ideally, these features could then evolve, with better ones developing as the program collects more experience. Schemas might be useful here, to replace common, structured phrases in the representation by a single reference to a schema, similar in a way to chunking. This model would be interesting to test, in Go, or in any domain where expertise might take the form of good feature recognition for case retrieval.

## Evaluation and Improving Abstraction

A major criticism of this particular approach to schema formation is that it only identifies patterns in static input descriptions. It does this without any regard for the significance of stones, and so encodes a lot of useless, coincidental substructures. An interesting AI perspective would be to grade cases and individual description lines according to their performance. A similar, more cognitive approach comes from Riesbeck & Schank (1989) who stress the importance of building logical explanations for generalisations to eliminate this sort of spurious abstraction. This is precisely what is done in the evaluation phase. While we have so

far ignored this phase as distinct and unrelated to representation and matching, it could conceivably be used to build explanations for good schemas; by storing this information as part of exemplar cases, it could also serve to enrich the representation.

### General Discussion

This model gives an example of how experiences and generalisations might be used, by people and by machines, to solve difficult problems. It essentially performs pattern matching using analogy, with good initial results in a very complex domain. Additionally, it embeds some powerful logic and machine learning techniques in a cognitive framework of schema induction. The major weaknesses of our model seem to be in the simplicity of the representation and the absence of the reminding and evaluation stages. These issues, sometimes considered separate from the matching stage, must on the contrary be addressed simultaneously and in depth when developing a memory-based problem solver.

Our approach can also be viewed as finding solution categories for a target problem, as analogical problem solving and categorisation are closely related. In this light, our results suggest that it is more efficient (in terms of time, memory, and to a lesser extent success rate) to define categories on the basis of schemas when there are many similar cases. This offers circumstantial evidence in favour of multiple-prototype and theory-based views of categorisation with the added benefit of describing how schema definitions might be formed from structural and surface features of exemplars. Instead of relying on a complete set of episodic exemplars, a memory-based approach can benefit from the clustering and compression given by analogical induction and the formation of schematic (semantic?) memories.

On the other hand, our schemas did not even suggest solutions to some of the problems that were easily solved by exemplars; forming good schemas, if it is possible in most cases, is more difficult than our technique recognises. No matter what, exemplars will always be needed for those areas where experience is minimal and where categories are not neatly defined. For Go, the data suggest that the best categorisation and problem solving would be achieved by a mixed source set containing a few very general schemas, more specific schemas, and exemplars in areas not well represented by the schemas.

In conclusion, we have implemented and analysed a model of memory-based cognition — in a symbolic architecture — and applied it to complex problem solving in Go, achieving better-than-chance performance with a very limited representation. At this stage, it seems that schemas can assist but not supplant pure exemplars in this type of problem solving. It seems also that the central matching stage may be more intricately dependent on the reminding and the evaluation stage than is typically acknowledged, particularly regarding the representation. This indicates compelling research directions both for Computer Go and for the psychology of problem solving.

## Abstract

Some inferences are seemingly automatic (*reflexive*; Shastri & Ajjanagadde, 1993), whereas others require more effort (i.e., are *reflective*). We present the beginnings of an integrated account of reflexive and reflective reasoning, based on the LISA model of analogical reasoning (Hummel & Holyoak, 1997). The account holds that reflexive inferences are those that can be generated automatically based on existing knowledge in long-term memory, whereas reflective inferences require explicit structure-mapping and therefore demand greater attention and working memory. According to this account, reflexive inferences manifest themselves in the semantic encoding of objects and predicates, whereas reflective inferences manifest themselves as explicit propositions. In contrast to reflexive inferences, which are equally reflexive, reflective inferences may require more or less effort. We present preliminary simulation results demonstrating that both kinds of inference can be modeled in a single architecture for representing propositional knowledge.

## Reflexive vs. Reflective Reasoning

Some inferences are so effortless that we are barely aware of making them. Told that *Bill sold Mary his car*, you will infer that Mary now owns the car so automatically that Shastri and Ajjanagadde (1993) describe the inference as *reflexive*. Even more reflexive is the inference that Bill is probably an adult human male, and Mary an adult human female. Other inferences require more effort. Told that *Bill loves Mary* and *Mary loves Tom*, it is natural to infer that Bill is likely to be jealous of Tom, but this inference arguably requires a bit more reflection (and is less certain) than the inference that Mary is a woman. More effortful still are many kinds of inferences made in the context of scientific and mathematical reasoning, planning, and so forth. What is the relationship between reflexive inferences, such as *Bill is male* or *Mary owns the car*, and more *reflective* inferences, such as *Bill may be jealous of Tom*, or *matter and energy must be special cases of a common physical principle*? And what is the process by which

reflective inferences become more reflexive with experience? To a young child, it may not be immediately obvious that Bill's selling Mary his car implies that she now owns the car; but after a sufficient number of examples, the child will eventually induce a schema that makes the relationship between buying and owning reflexive (if evidenced only by the fact that the inference is reflexive for an adult).

In the literature on human cognition, the study of reflexive and reflective reasoning have been largely separate, with the former more common in the study of (for instance) story comprehension (e.g., Kintsch & van Dijk, 1978; Shastri & Ajjanagadde, 1993; St. John, 1992; St. John & McClelland, 1990), and the latter predominating in the study of problem solving (e.g., De Soto, London & Handel, 1965; Byrne & Johnson-Laird, 1989; Newell & Simon, 1976) and reasoning by analogy (e.g., Forbus et al., 1995; Gentner, 1983; Holyoak & Thagard, 1989; Hummel & Holyoak, 1997). Similarly, computational accounts of reflexive inference (e.g., Shastri & Ajjanagadde, 1993; St. John, 1992) have typically had little to say about more reflective forms of reasoning, and models of reflective (e.g., analogical) reasoning have had little to say about the nature of reflexive reasoning.

The most reflexive form of inference is encoding—inferring, for example, that "Mary" in "Bill loves Mary" is an adult human female. It is this most reflexive form of inference that has been most neglected in models of reflective reasoning. One consequence is that these models must be given, in full detail, the representations they are to use for reasoning. For example, the models of Forbus et al. (1995), Holyoak and Thagard (1989) and Hummel and Holyoak (1997) draw analogies between situations whose representations are fully specified for them. In contrast to human reasoners, who can read a sentence such as "Bill loves Mary, but Mary loves Tom" and infer the details for themselves (e.g., that Bill and Tom are adult human males, etc.), these models must be handed all this information for each analogy they are asked to solve.<sup>1</sup> One reason for this division between models of reflective and reflexive reasoning may be that the two kinds of reasoning obey different computational constraints, and therefore demand different kinds of algorithms. At the same time, however, both kinds of inference take place within the same cognitive architecture, and must operate on the same mental representations.

This paper presents the beginnings of an algorithmic account of the relationship between reflexive and reflective reasoning. In broad strokes the account holds that both kinds of reasoning require the capacity to dynamically bind

---

<sup>1</sup>One notable exception to this generalization is Hofstadter & Mitchel's (1994) CopyCat model, which solves analogy problems of the form X:Y::Z:?, and uses routines to change its representation of X, Y and Z in order to find the best possible analogy. In contrast to other models of analogy, CopyCat is not "stuck" with fixed representations of the elements of its analogies. At the same time, however, this model cannot simulate the kind of encoding discussed here, or the type of reflexive inferences discussed by Shastri & Ajjanagadde (1993).

variables to values (or equivalently, roles to fillers) in order to permit flexible (rule-like) generalization (cf. Shastri & Ajjanagadde, 1993, on the role of variable binding in reflexive reasoning; Holyoak & Hummel, 2000, and Hummel & Holyoak, 1997, on the role of variable binding in reflective reasoning). That is, both reflexive and reflective inferences are operations on symbolic representations. In addition, we propose that what makes reflective reasoning more effortful than reflexive reasoning is, at least in part, that the most reflexive inferences result from a kind of structured memory retrieval (i.e., retrieval that exploits and maintains variable-value bindings), whereas more reflective inferences require explicit structure mapping. That is, as illustrated in the simulations below, we propose that an inference will be fully reflexive when the to-be-inferred information is already available in long-term memory (LTM), and that it becomes progressively more reflective as the to-be-inferred information must be constructed on the basis of mapping large, multi-proposition structures.

The starting point for this effort is Hummel & Holyoak's (1997) LISA model of analogical reasoning, so we will briefly sketch that model's approach to knowledge representation and reflective inference (including memory retrieval, structure mapping, and schema induction). Mapping and retrieval are described in detail in Hummel and Holyoak (1997), and inference and schema induction are described in detail in Holyoak and Hummel (2000).

### The LISA Model

The core of LISA's architecture is a system for representing propositions in working memory (WM) by dynamically binding roles to their fillers, and encoding those bindings in LTM. LISA uses synchrony of firing for dynamic binding in WM (Hummel & Holyoak, 1992; Shastri & Ajjanagadde, 1993). Case roles and objects are represented in WM as distributed patterns of activation on a collection of *semantic units* (small circles in Figure 1); case roles and objects fire in synchrony when they are bound together and out of synchrony when they are not. For example, to represent the proposition *sell-to (Bill, Mary, car)* in WM, semantic units representing the *seller* role of the *sell-to* relation (e.g., *transaction*, *exchange*, etc.) fire in synchrony with units representing *Bill* while units representing the *buyer* role fire in synchrony with units representing *Mary*, and units for the *object* role fire in synchrony with units representing *car*. The three sets of units (*Bill+seller*, *Mary+buyer* and *car+object*) must be mutually de-synchronized with one another.

A proposition is encoded in LTM by a hierarchy of *structure units* (Figures 1 and 2). At the bottom of the hierarchy are *predicate* and *object* units (triangles and large circles, respectively, in Figure 1). Each predicate unit locally codes one case role of one predicate. For example, *seller* represents the first (seller) role of the predicate *sell-to*, and has bi-directional excitatory connections to all the semantic units representing that role; *buyer* and *sell-object*

represents the buyer and object roles, respectively, and are connected to the corresponding semantics. Semantically-related predicates share units in corresponding roles (e.g., *seller* and *giver* share many units), making the semantic similarity of different predicates explicit. Object units are like predicate units except that they are connected to semantic units describing things rather than roles. For example, *Mary* might be connected to units for *human*, *adult*, *female*, etc., whereas *car* might be connected to *object*, *vehicle*, etc.

Figure 1. The LISA LTM representation of the proposition *sell-to (Bill, Mary, car)*.

*Sub-proposition* units (*SPs*; rectangles in Figure 1) bind roles to objects in LTM. *Sell-to (Bill, Mary, car)* would be represented by three *SPs*, one binding *Bill* to *seller*, one binding *Mary* to *buyer*, and one binding *car* to *sell-object*. *SPs* have bi-directional excitatory connections with the object and predicate units they bind together. *Proposition (P)* units (oval in Figure 1) reside at the top of the hierarchy and have bi-directional excitatory connections with the corresponding *SPs*. Complete, multi-proposition analogs (i.e., situations, events or schemas) are represented by collections of structure units (see Figure 2).

The final component of LISA's architecture is a set of *mapping connections* between structure units of the same type in different analogs. Every *P* unit in one analog may share a mapping connection with every *P* unit in every other analog; likewise, *SPs* share connections across analogs, as do objects and predicates. For the purposes of mapping and retrieval, analogs are divided into two mutually exclusive sets: a *driver* and one or more *recipients*. Retrieval and mapping are controlled by the driver. LISA performs retrieval and mapping as a form of guided pattern matching. As *P* units in the driver become active, they generate (via their *SP*, predicate and object units) synchronized patterns of activation on the semantic units (one pattern for each role-filler binding). The semantic units are shared by all propositions, so the patterns generated by one proposition tend to activate one or more similar propositions in LTM (retrieval) or in working memory (analogical mapping). Mapping differs from retrieval solely by the addition of the

modifiable mapping connections. During mapping, the weights on the mapping connections grow larger when the units they link are active simultaneously, permitting LISA to learn the correspondences generated during retrieval. These connection weights also serve to constrain subsequent memory access. By the end of a simulation run, corresponding structure units will have large positive weights on their mapping connections, and non-corresponding units will have strongly negative weights. Hummel & Holyoak (1997) showed that these operations account for a large body of findings in the literature on human analogical reasoning.

Figure 2. LISA LTM representation of *sell-to (Bill, Mary, car)* and *own (Mary, car)* (Situation 1; top) and *sell-to (Beth, Peter, futon)* (Situation 2; bottom).

Augmented with unsupervised learning and intersection discovery, LISA's approach to mapping supports inference and schema induction as a natural consequence (Holyoak & Hummel, 2000). Consider an analogy between two situations (Figure 2): In situation 1, Bill sells his car to Mary (proposition P1), so Mary now owns the car (P2); in situation 2, Beth sells her futon to Peter (P1), but there is no explicit statement that Peter now owns the futon. During mapping, corresponding elements in the two analogs will become active simultaneously. For instance, *sell-to (Bill, Mary, car)* in the driver, will activate *sell-to (Beth, Peter, futon)* in the recipient, so corresponding elements

(such as *Bill* and *Beth*) will fire in synchrony with one another, and non-corresponding elements (e.g., *Bill* and *futon*) will fire out of synchrony. As a result, LISA learns mapping connections from *Bill* to *Beth*, *Mary* to *Peter*, and *car* to *futon*. Likewise, the roles of *sell-to* in situation 1 map to the corresponding roles of *sell-to* in situation 2. However, nothing in situation 2 maps to the roles of *owns* in situation 1. Therefore, when *owns (Mary car)* fires in situation 1, LISA will build units in situation 2 to correspond to the structures in situation 1 representing that proposition: It will build units corresponding to *owner* and *owned*, and connect them to the semantic units representing those roles; it will build SPs corresponding to *owner+Mary* and *owned+car*, and connect them to *owner* and *Peter* and *owned* and *futon*, respectively; finally, it will also build a P unit corresponding to the whole proposition, connecting it to the newly created SPs. (LISA "knows" what to connect to what simply by virtue of which units are firing in synchrony with one another; see Holyoak & Hummel, 2000.) That is, it will infer that Peter now owns the futon.

The same operations permit LISA to perform schema induction in a third "schema" analog. Although we have described the activation of semantic units only from the perspective of the driver, recipient analogs also feed activation to the semantic units. The activation of a semantic unit is a linear function of its input, so any semantic unit that is common to both the driver and recipient will receive input from both and become roughly twice as active as any semantic unit receiving input from only one analog. Shared semantic elements are thus tagged as such by their activations. These shared elements are encoded into the schema by the same unsupervised learning algorithm that performs analogical inference: Units in the schema connect themselves to semantic units and to one another based on their co-activity. Because the learning algorithm is sensitive to the activations of the semantic units, object and predicate units in the schema preferentially learn connections to the semantic that are common to—the intersection of—the corresponding units in the known situations. In the case of the current example, the induced schema would be roughly *sell-to (person1, person2, object)*, and *own (person2, object)*.

## Extension to Reflexive Reasoning

As described above, LISA is a model of reflective reasoning that makes inferences about novel situations based on explicit analogies (i.e., structure-mappings) to familiar situations. However, the operations it uses for analogy, inference and schema induction—most notably, the feedback from the recipient analog to the semantic units (henceforth *recipient feedback*)—suggest themselves as the beginnings of an account of reflexive inference. The basic idea is to use the recipient feedback from structures in LTM (including both general schemas and specific situations) to encode the semantic representation of predicates and objects in the driver. That is, encoding is seen as a collection of reflexive inferences about the properties of the predicates and objects.

Using the recipient feedback in this way solves only one of several problems that must be solved in order to provide a general integrated account of reflexive and reflective reasoning; however, the simulations reported here suggest that it is a useful first step.

Figure 3. Ways to represent the fact that wooden spoons are large in LISA: (a) *large* as a semantic feature connected to the object unit *wooden-spoon*; (b) *large* as a predicate in the proposition *large (wooden-spoon)*.

Consider the concept of a wooden spoon. The statement "wooden spoon" makes exactly two properties of the object *wooden spoon* explicit: it is wooden and it is a spoon. But upon encountering these properties, it is irresistible to infer additional properties, such as that it is large (as spoons go), it is more likely to be used for cooking than for eating, etc. (cf. Medin & Shoben, 1988). These properties may be represented in two qualitatively different ways: as semantic "features" of wooden spoons, or as explicit propositions. In terms of the LISA architecture, these ways of representing the properties of wooden spoons are, respectively, as connections from the *wooden-spoon* object unit to semantic units for *large*, *cooking*, etc., (Figure 3a) and as full propositions, complete with predicates, SPs and P units (Figure 3b). We hypothesize that the former type of (semantic feature) representation is established reflexively, as an automatic part of encoding the representation of wooden spoons, whereas the latter (propositional) form is established more reflectively, by thinking explicitly about the properties of wooden spoons. It is important to note that inferring the properties of wooden spoons (either reflexively or reflectively) it is not a simple matter of replacing the default value of the *material* slot in the spoon schema (i.e., *metal*) with the value *wooden* (e.g., as suggested by Smith & Osherson, 1984; Smith et al., 1988), because the attributes of spoons (i.e., the values bound to the slots of the schema) are correlated: Other attributes such as *size=large* will have to be inferred,

and these attributes will have to replace the corresponding default values in the schema.

We simulated the reflexive form of this inference as follows. We generated five situations (analog), one corresponding to a "new" situation (thinking about a wooden spoon; analog 1), and the other four corresponding to various schemas in LTM. Analog 1 consists of the single proposition *exist (wooden-spoon)*, where the object *wooden-spoon* is connected to a single semantic unit, *wooden-spoon*, which serves to represent the type *wooden spoons*; the predicate *exist* is not connected to any semantic units. (*Exist* is a vehicle for instantiating *wooden-spoon* in a proposition so that it can be activated—it allows LISA to "think about" wooden spoons devoid of any particular context.) Analog 2 is a schema for wooden spoons consisting of two propositions: *wooden (wooden-spoon)* and *big (wooden-spoon)*. The object unit *wooden-spoon* has positive connections to the type semantic *wooden-spoon* and to semantics for *utensil*, *spoon*, *wooden*, and *big*. It has negative (inhibitory) connections to semantics for *metal*. The predicate *wooden* has positive connections to semantics for *material* and *wood*, and an inhibitory connection to *metal*; *big* excites semantics for *size* and *big*, and inhibits *small*. Analog 3 is a schema for metal spoons, and consists of *metal (metal-spoon)* and *small (metal-spoon)*. The semantic representations of *metal-spoon*, *metal* and *small* are analogous to those of *wooden-spoon*, *wooden* and *big*, respectively, except that the appropriate semantics are reversed (e.g., the predicate *small* is connected to the semantic *small* rather than *big*, etc.). Analog 4 is a schema for spoons in general, and consists of the propositions *utensil (spoon)* and *concave (spoon)*. Analog 5 is a schema for horseback riding, consisting of the single proposition *ride (horse)*. Analog 5 serves as a foil to ensure that the model will not simply activate all knowledge in LTM in the course of drawing reflexive inferences about the (semantically empty) wooden spoon in analog 1.

The goal of the simulation is to activate *exist (wooden-spoon)* in analog 1 and observe which schemas it activates in LTM, and whether the recipient feedback from the objects and predicates in those schemas allow *wooden-spoon* in analog 1 to learn an appropriate semantic encoding. We therefore set analog 1 to be the driver, and left analogs 2 - 4 "dormant" in LTM (see Hummel & Holyoak, 1997). The proposition *exist (wooden-spoon)* was then fired, and propositions in LTM were allowed to respond, feeding activation back to the semantic units. When *exist (wooden-spoon)* first fired, both *wooden (wooden-spoon)* and *big (wooden-spoon)* became active in analog 2 (the wooden spoon schema). *Exist* is semantically empty, so the only semantic feature of analog 1 that activated anything in analog 2 is the type semantic *wooden-spoon* (which is shared by the object *wooden-spoon* in analog 2). As a result, *wooden (wooden-spoon)* and *big (wooden-spoon)* became equally active in analog 2. The feedback from these propositions to the semantic units began to activate other schemas in LTM: the semantics *utensil* and *spoon* activated units in analogs 3 (the metal spoon schema) and 4 (the

generic spoon schema). At the same time, the object *wooden-spoon* (in analog 2) *inhibited* the semantics for *metal*. This inhibition propagated into analog 3 (the metal spoon schema), preventing that schema from becoming active and in turn, preventing it from activating its own semantics. When the pattern of activation settled, analogs 2 and 4 were fully active (i.e., both propositions were active in both analogs), along with all the semantic units to which they are connected. As a result, the object *wooden-spoon* in analog 1 learned connections to the semantics for *utensil*, *spoon*, *wooden* and *big* (due to the feedback from the wooden spoon schema), and to *concave* and *utensil* (based on the generic spoon schema): The model reflexively inferred the semantic properties of the wooden spoon.

In a second simulation, analog 1 consisted of the proposition *exist (metal-spoon)*—this time having LISA "think about" metal spoons—and we ran the same operations described above. This time, analog 3 (the metal spoon schema) and analog 4 (the generic spoon schema) became active, and the model inferred the properties of the *metal-spoon* in analog 1: *metal-spoon* learned connections to the semantic units for *utensil*, *spoon*, *metal* and *small* (due to the feedback from the metal spoon schema), and to *concave* and *utensil* (based on the generic spoon schema). In both these simulations, it is interesting to note that LISA assigned each object (the metal spoon or the wooden spoon) to the most general category appropriate (by activating the generic *spoon* schema), but it did not categorize metal spoons as wooden spoons, or vice versa. As a result, it made appropriate inferences about the objects at multiple levels of abstraction (e.g., that the wooden spoon would be big [which is specific to wooden spoons] and that it would be concave [which is general to all spoons]).

In the previous simulations, the inferences were purely reflective, in the sense that we did not allow LISA to retrieve the schemas from memory and map them back onto analog 1. When we allowed the model to reflect on the properties of wooden spoons—by making the wooden spoon schema the driver, the wooden spoon version of analog 1 the recipient, and allowing it to explicitly map the schema onto analog 1—it inferred the explicit propositions *wooden (wooden-spoon)* and *big (wooden-spoon)* in analog 1. (It did do by exactly the same operations described previously in the discussion of LISA's operation.) Similarly, when we allowed it to reflect on the fact that wooden spoons are spoons—by mapping the spoon schema into analog 1—it inferred the propositions *utensil (wooden-spoon)* and *big (wooden-spoon)*. But importantly, it did not infer any of these propositions until it explicitly brought the corresponding schema into WM and mapped it onto analog 1. This property is interesting in combination with the model's ability to reason reflexively to the most generic category applicable (e.g., to assign wooden spoons semantic features that are true of all spoons based on the generic spoon schema): Together, they predict that reflexive inferences—which manifest themselves in the (implicit) semantic encoding of an object or predicate—will automatically take place across multiple levels of category

abstraction, whereas reflective inferences—which cause the construction of explicit propositional structures—will only take place when the reasoner explicitly reflects on the fact that the object belongs to the category (i.e., explicitly maps the category schema onto the object). To our knowledge, no one has yet tested this prediction of the model.

## Discussion

Using simple operations already in place to simulate reflective analogy-based inference—namely, recipient feedback and unsupervised learning—LISA was able to reflexively infer the meaning of "wooden spoon" and "metal spoon" based on examples in LTM. These inferences were reflexive in the sense that they did not require the model to explicitly map the structures in the new example (analog 1) to the structures in LTM. Instead, they were drawn in the course of what is analog retrieval in LISA (i.e., the process of retrieving a source analog or schema from LTM given a novel target as a cue; see Hummel & Holyoak, 1997). By the end of the first two simulations, the objects *wooden-spoon* (in the first simulation) and *metal spoon* (second simulation) had semantic encodings that were richer than what was provided at the beginning of the simulation. In each case, the object unit started with a single semantic feature (*wooden-spoon* or *metal-spoon*) and ended with a semantic encoding specifying its size (*big* or *small*), material (*wooden* or *metal*), shape (*concave*) and use (*utensil*). However, in neither of the first two simulations did analog 1 end up with any new propositions. By contrast, in the third and fourth simulations, when the schemas were called into WM and allowed to map to analog 1, the model inferred propositions that explicitly stated the properties of the wooden spoon. According to the present account, inferring a new proposition (e.g., one stating explicitly that the wooden spoon is big) is a reflective process that requires retrieval of a schema (or specific situation), and an explicit mapping of the structures in that schema to the structures in the new example.

In this respect, our use of the term "reflexive" is somewhat more restrictive than Shastri & Ajjanagadde's (1993). On our account, an inference such as "Mary now owns the car" is not strictly reflexive unless it is represented strictly as features in the *semantic* representation of Mary (i.e., as connections from the unit *Mary* to units representing *ownership*). If instead (or in addition) the inference is represented as an explicit proposition (*own (Mary car)*), we would classify it as "reflective but easy" (as noted previously, some reflective inferences are easier than others). This distinction between our account and that of Shastri & Ajjanagadde stems primarily from the fact that LISA represents objects and predicates as distributed patterns of activation in WM, which precludes binding an object to more than one predicate role at a time (see Hummel & Holyoak, 1997). As a result, LISA makes a strong distinction between properties *qua semantic features* and properties *qua explicit propositions*. By contrast, Shastri & Ajjanagadde's model represents each object or

predicate as a localist unit, making it possible to "stack" predicates on objects, effectively representing multiple predicate-object bindings (i.e., multiple propositions) in parallel (cf. Hummel & Holyoak, 1997). Whether the human mind makes a strong distinction between features and propositions (like LISA), or permits "stacking" of predicates (like Shastri & Ajjanagadde's model) is an empirical question.

## The Origins of Object Features

To this point our discussion of reflexive inference—based on learning connections to features activated by feedback from structures in LTM—has begged a major question: If objects learn the features that describe them by "comparing themselves to" other objects in LTM, then how did the objects in LTM learn the features that describe themselves in the first place? Answering this question "by comparing themselves to objects in LTM when *they* were encoded" is unsatisfying because it brings to mind the infinite regress, "and where did *those* objects learn *their* features?" etc. Although we are far from being able to provide a complete answer to this very difficult question, one aspect of the model that we have not yet discussed may provide a partial answer. Specifically, we allow some semantic features that belong to predicate units to attach themselves to object units during the course of reflexive inference. (In the original LISA, predicate semantics were attached strictly to predicates and object semantics strictly to objects [see Hummel & Holyoak, 1997]; this approach is a departure from that convention.) As a result, roles to which an object is attached in many situations or schemas in LTM (e.g., the role *big*, in the case of *big* (*wooden-spoon*)) can become attached directly to new instances of those objects as semantic features. In this way, an inference like *own* (*Mary*, *car*) can become truly reflexive in the sense of the definition suggested here: If, in several examples in LTM, the buyer of a product is also represented as the owner of that product (i.e., in a separate *own* (*person*, *object*) proposition), then the semantics of the predicate *own* will tend to become attached as semantic features of subsequent objects bound to the *buyer* role of a *sell-to* relation. We have yet to work out fully the details of this proposal, but preliminary simulations have so far been very promising.

## Abstract

Previous research has suggested that human perception of mathematical expressions is based on syntactic structure. Here, we extend our understanding of how humans perceive algebraic equations in two ways. First, we examined the hypothesis that the internal representation used by experienced mathematicians is based on the phrasal structure of the parse tree. This was tested using a memory recognition task, and the results supported the hypothesis. Second, we explored how much experience with mathematics is necessary before such representations become established. Participants were young students with very little experience with algebra. Surprisingly, the students appeared to encode equations in a manner similar to experienced mathematicians.

## Introduction

Mathematical notation and natural language share many common features. Both have a well-defined syntax and semantics, and both allow for the expression of abstract information. However, an important difference is that the layout of mathematical notation is two dimensional in nature, with equations relying on both vertical and horizontal adjacency relationships between the symbols to provide the meaning. It is natural then to ask how humans comprehend mathematical expressions.

The present paper extends our understanding of how humans perceive mathematical expressions in two ways. First we explore the nature of the internal representation used to encode equations. Specifically, we examine whether the information recovered from equations has a parse tree structure similar to that used to represent sentences of natural language. Second, we explore how much experience with mathematics is necessary before such representations become established.

For many years now, phrase structure grammars have been used to understand the way that humans parse natural language sentences (for example, see Akmajian, Demers and Harnish, 1984). This allows the constituent structure of a natural language sentence to be represented diagrammatically by a parse tree, containing various phrases such as noun and verb phrases. Although phrase structure grammars can only

be applied to sequential languages, variations of such grammars have been proposed in an attempt to enable computers to understand mathematical notation (for example, see Anderson, 1977). Analogously to natural language, parse trees for equations can be created based on mathematical syntax. An example parse tree is given in Figure 1.

Figure 1: Parse Tree for  $4 - x^2(y + 7)$

Our previous work on the comprehension of mathematical expressions (Jansen, Marriott and Yelland, 1999) has shown that in a memory recognition task, experienced users of mathematics can more readily identify those parts of a previously seen equation that are syntactically well-formed (that is, which have a coherent mathematical meaning, such as  $y + 7$  in the above example), than those that are not well-

formed (for example,  $-x^2(y$  which is also part of the equation, but does not convey any coherent mathematical meaning on its own). This result provides support for the notion that the internal representation used by mathematicians is based on mathematical syntax. This accords with results by Johnson (1968, 1970) which show that in the context of natural language, chunking of sentences is also guided by syntax. The work of Ranney (1987) also shows that even after only brief exposure, the structure of algebra expressions provide information about the category of the symbols in that expression (whether they are variables, numbers, operators, etc.). This indicates that the parsing of such expressions is based on structural content.

## Experiment 1

It is clear that mathematical syntax plays an important role in encoding equations, however it does not necessarily follow that a parse tree structure underlies the internal representation. The first experiment explores this idea with respect to moderately complex algebra expressions. Our hypothesis is that the internal representation used by experienced mathematicians is based on the phrasal structure of the parse tree. To test this hypothesis, we have set up a recognition task to see if participants can more readily recognize sub-expressions of an equation that form a phrasal node on the parse tree (for example,  $y + 7$  in the previous example) as opposed to sub-expressions that are also syntactically valid, but do not form a phrasal node on the parse tree (such as  $4 - x^2$ ). If our hypothesis is correct, we would expect to see a recognition advantage for the phrasal sub-expressions.

### Method

**Participants** Twenty-four participants successfully completed the experiment. All were staff members, graduate or undergraduate students from the Computer Science department, all competent mathematicians who were experienced with algebra. All participants were volunteers between the ages of 18 and 35 years, with normal or corrected-to-normal vision. Data from an additional 8 participants were not included due to excessive error rates.<sup>1</sup>

**Materials and Design** Seventy-five equations were constructed, all consisting of between twelve and fourteen characters. The equations contained at most one fraction and the variable names were  $x$  and  $y$ , since these are most commonly used. For each equation, sub-expressions of three types were constructed.

- a) A *phrasal sub-expression*, which is a syntactically well-formed component of its equation, which conveys the same meaning on its own that it conveyed in the equation. It is a phrasal node in the equation's parse tree.

- b) A *non-phrasal sub-expression*, which is also a well-formed component of its equation, but does not convey the same meaning on its own that it conveyed in the equation. It is not a phrasal node in the equation's parse tree.

- c) An *incorrect sub-expression*, which was not part of the original equation. It is also a well-formed expression. These act as fillers.

Each of the sub-expressions contained between four and six characters (the average for phrasal sub-expressions was 4.78; for non-phrasal, 4.54; for incorrect, 4.60). See Table 1 for examples of equations and sub-expressions used. As the examples show, a variety of sub-expressions were used, some of which were bracketed, but most of which were not.

In order to present all three sub-expression types for each equation, but ensuring that participants were presented with each equation only once to avoid practice effects, three counterbalanced versions of the experiment were constructed. For each version, there were twenty-five instances of each type of sub-expression. Two additional equations were constructed as practice items. The same practice items were used in each version. Eight participants completed each version, each receiving the items in a different pseudo-random order.

**Procedure** Participants were seated comfortably in an isolated booth. Items were displayed as black text on a white background on a 17" monitor at a resolution of 1024x768, controlled by an IBM compatible computer running a purpose designed computer program. The average width of the equations in pixels was 187 (range 91–244) with an average height of 45 (range 26–59). The average width of the sub-expressions in pixels was 74 (range 25–111) with an average height of 23 (range 16–52).

Participants were given a statement of instructions before the experiment began. Practice items preceded the experimental items, and the participants took approximately fifteen minutes to complete the task. Progress was self-paced, with participants pressing the space bar to initiate the presentation of each trial.

Each item was presented in the centre of the monitor in the following sequence. First, a simple algebra equation was shown to the participant for 2500ms. The equation then disappeared and the screen remained blank for 1000ms. Then the sub-expression was shown, remaining on the screen until a response was made. The participant was required to decide whether the sub-expression was in that equation, responding via a timed selective button press. They pressed the green button, (the '/' key on the right side of the keyboard), to indicate that the sub-expression was part of the original equation, and the red button, (the 'Z' key on the left of the keyboard), to indicate that the sub-expression was not part of the original equation. Participants were instructed to respond as quickly as possible, while taking care not to make too many errors.

The response time recorded was the time between the onset of the sub-expression and the participant's response. After the response, the participant received feedback. If the re-

<sup>1</sup>Data from participants with an overall error rate of over 30%, or making in excess of 50% errors for any given sub-expression type, were excluded from the final analysis.

Table 1: Example equations and sub-expressions used in examining phrasal properties.

Equation	Sub-Expression		
	Phrasal	Non-Phrasal	Incorrect
$y = 8 + \frac{8y - 9x^2}{7y^6}$	$8y - 9x^2$	$8y - 9$	$8x + 9$
$3 - \frac{5}{7 - x^2(8 - y)}$	$(8 - y)$	$7 - x^2$	$2 - x^4$

sponse was correct then the word ‘‘CORRECT’’ appeared on the screen. Otherwise, the word ‘‘INCORRECT’’ appeared on the screen. In both cases, the participant’s response time in milliseconds also appeared on the screen.

**Data Treatment** Two measures were employed to reduce the unwanted effects of outlying data points. Absolute upper and lower cut-offs were applied to response latencies, such that any response longer than 2500ms or shorter than 500ms was excluded from the response time data analysis and designated as an error. Secondly, standard deviation cut-offs were applied, so that any response time lying more than two standard deviations above or below a participant’s overall mean response time was truncated to the value of the cut-off point.

It was necessary to exclude two items from the final analysis due to error rates in excess of 75%. One further item also had to be removed in order to balance the number of items in each version of the experiment. As a result, the final analyses were over twenty-four items per condition, not the original twenty-five. Response time and error data were analysed by a series of analyses of variance (ANOVAs), over both participant and item data. Where both the subject-based and item-based analyses were significant they were combined in the *minF*’ statistic to ensure the generalisability of results over both these domains (Clark, 1973).

## Results and Discussion

The mean correct response time (in milliseconds) and error rate for the three sub-expression types are summarised in Table 2, along with the corresponding standard deviations (in parentheses). Planned comparisons of the data were conducted using two-way ANOVAs (versions  $\times$  sub-expression), carried out separately over subject and item data.

As expected, the participants performed significantly better for phrasal sub-expressions than for non-phrasal sub-expressions. This superior performance was seen in the response times with a 196ms recognition advantage ( $minF'(1, 66) = 33.06, p < .01$ ). This advantage held for error rates also ( $minF'(1, 69) = 8.83, p < .01$ ). This indicates that the equations are perceived in a way that allows for faster and more accurate recognition of phrasal sub-expressions than non-phrasal sub-expressions.

Table 2: Mean correct response times (ms) and error rates (%) as a function of sub-expression type for Experiment 1.

Sub-Expression	RT(ms)	%Error
Phrasal	1153 (178)	14.8 (8.7)
Non-Phrasal	1349 (205)	25.2 (11.2)
Incorrect	1382 (246)	20.3 (9.5)

There was also a significant response time advantage for phrasal sub-expressions over incorrect sub-expressions ( $minF'(1, 57) = 35.97, p < .01$ ). However, there was no corresponding overall advantage for error rates, despite the fact that the item-based analysis was significant ( $F_1(1, 21) = 4.21, p = .053, F_2(1, 69) = 5.46, p < .05$ ). There was no significant difference between non-phrasal and incorrect sub-expressions for either response times or error rates.

The results of Experiment 1 provide support for our hypothesis that the internal representation used by experienced mathematicians is based on the phrasal structure of a parse tree. This comes from the logic of the experiment. Encoding of the equations significantly favours recognition of phrasal sub-expressions, indicating that knowledge of the constituent structure that underlies a parse tree is relied upon in the encoding process.

This outcome and those of previous work (Jansen et al., 1999) indicate that experienced mathematicians use an internal representation based on mathematical syntax and a parse tree structure. One interesting issue is just how much experience with mathematics is necessary before such representations become established. This is the focus of our second experiment.

## Experiment 2

Our hypothesis here is that considerable experience is necessary before humans can parse an equation based on its mathematical syntax. To test this hypothesis, recognition tasks were designed to examine the influence of both syntactic well-formedness and phrasal properties in identifying sub-

Table 3: Example equations and sub-expressions used in examining well-formedness.

Equation	Sub-Expression		
	Well-Formed	Non-Well-Formed	Incorrect
$\frac{9}{x(2y-5)} - 4x^3$	$(2y-5)$	$\frac{\quad}{x(2$	$x(4y+$
$x = 6yx - \frac{2x+2}{x}$	$2x+2$	$= 6yx-$	$\frac{6x+2}{y}$

expressions of equations. The participants in these experiments were students in their first year of high school (Year 7). This year level was chosen because it is one year before algebra becomes a major component of their mathematics syllabus (in Australia). The students had been introduced to the notion of a variable, but had not been introduced to the exponent notation and had dealt only with very simple expressions.

Due to the complex nature of the equations (at least by Year 7 standards), we expect to see no significant performance advantages for one type of sub-expression over another, indicating that the internal representations of the students are not based on mathematical syntax or parse tree structures. However if any advantages are present, this would indicate a predisposition towards encoding equations into syntactically based constituent chunks, even with very little experience.

## Method

**Participants** Eighteen participants successfully completed these experiments. All were Year 7 students, aged 12 to 13 years, with only limited knowledge of algebra. All participants were volunteers with normal or corrected-to-normal vision.

**Materials and Design** Experiment 2 consisted of two parts. Part A looked at syntactic well-formedness, the design of the experiment being similar to the experiment described in Jansen et al. (1999) which was conducted with competent adult mathematicians. Sixty equations were used, and sub-expressions of three types were generated for each.

- a) A *well-formed sub-expression*, which is a component of its equation, and conveys the same meaning on its own that it conveys in the equation.
- b) A *non-well-formed sub-expression*, which is also a component of its equation, but does not convey any coherent mathematical meaning on its own.
- c) An *incorrect sub-expression*, which was not part of the original equation. It can be either well-formed or non-well-formed. These act as fillers.

See Table 3 for examples. The equations consisted of between twelve and fourteen characters, and each of the sub-expressions contained between four and six characters (the average for well-formed sub-expressions was 4.77; for non-well-formed, 4.50; for incorrect, 4.66). Only the variable names  $x$  and  $y$  were used, with at most one fraction being present in any equation.

Part B of Experiment 2 again examined phrasal properties, and was based on Experiment 1. Sixty equations were constructed, along with three sub-expressions per equation (phrasal, non-phrasal and incorrect). The properties of the equations and sub-expressions are the same as described in Experiment 1, with the sub-expressions again containing between four and six characters (the average for phrasal sub-expressions was 4.79; for non-phrasal, 4.50; for incorrect, 4.60). Table 1 contains examples of these. The equations used in part A and part B of this experiment were all different.

For each part of the experiment, three counterbalanced versions were created allowing the presentation of all three sub-expression types for each equation, but ensuring that participants were presented with each equation only once to avoid practice effects. For each version, there were twenty instances of each type of sub-expression. Two additional equations were constructed as practice items. The same practice items were used in each version. The items of each version were presented in a different pseudo-random order for each participant.

Participants did both parts of the experiment in the one sitting, one after the other. Due to the tasks in part A and part B being so similar, the order in which they were done was balanced over all of the participants. Thus half of the participants did part A before part B, with the other half doing the experiment in the reverse order.

**Procedure** The experiments were carried out in a quiet room, with groups of four or five students at a time. Each participant was seated in front of an IBM compatible computer with a 14" monitor, running at a resolution of 800x600. All items were black text on a white background, presented by a purpose designed computer program.

For part A, the average width of the equations in pixels was

178 (range 135–219) with an average height of 47 (range 26–61). The average width of the sub-expressions in pixels was 72 (range 39–179) with an average height of 26 (range 18–51). For part B, the average width of the equations in pixels was 187 (range 97–244) with an average height of 46 (range 26–59). The average width of the sub-expressions in pixels was 72 (range 25–111) with an average height of 24 (range 16–52).

The procedure for each part was very similar to that used for Experiment 1. There was no difference in the display timing of the stimuli or the response mechanism. However, since the students were not expected to perform very well in the task, they may lose confidence in performance if continually reminded of errors. Consequently, no feedback was given. Otherwise, the experimental procedure was the same. Participants were also given a brief rest period between the two parts and took approximately 25 minutes to complete the entire experiment.

**Data Treatment** To reduce the unwanted effects of outlying data points, absolute upper and lower cut-offs were applied to response latencies, such that any response longer than 4000ms or shorter than 500ms was designated as an error. The maximum cutoff time here is longer for the Year 7 students than for the experienced mathematicians in previous experiments.

As expected the participants did not perform well in this task, with the accuracy achieved for many sub-expression types being no better than chance. Given that many students were clearly guessing when presented with these sub-expressions, an analysis of response time data would be meaningless. Analysis was therefore only conducted on error rate data, by a series of analyses of variance (ANOVAs) over both participant and item data. Where these were significant, they were combined in the  $\min F'$  statistic. No participants data was excluded from the analysis.

## Results and Discussion

The error rate for the three sub-expression types in part A (which examined well-formedness) is summarised in Table 4, along with the corresponding standard deviations (in parentheses). Planned comparisons of the data were conducted using two-way ANOVAs (versions  $\times$  sub-expression), carried out separately over subject and item data.

Table 4: Error rates (%) as a function of sub-expression type for Experiment 2A.

Sub-Expression	%Error
Well-Formed	36.1 (21.5)
Non-Well-Formed	51.7 (14.9)
Incorrect	50.6 (19.9)

The results of interest are the performance differences between well-formed and non-well-formed sub-expressions. Participants performed significantly better in recognizing well-formed sub-expressions than their non-well-formed counterparts with an advantage of 15.6% ( $\min F'(1, 37) = 7.50, p < .01$ ). In fact, since in each trial participants had a 50–50 chance of success, it is clear that for both non-well-formed and incorrect sub-expressions, participants were doing no better than random guessing. It is only for well-formed sub-expressions that they were performing better than chance.

Table 5 summarises the error rate data for the three sub-expression types in part B of the experiment (which examined phrasal properties), along with the corresponding standard deviations (in parentheses).

Table 5: Error rates (%) as a function of sub-expression type for Experiment 2B.

Sub-Expression	%Error
Phrasal	34.1 (15.4)
Non-Phrasal	53.6 (16.5)
Incorrect	49.4 (22.9)

The results show a significant 19.4% error rate advantage for phrasal sub-expressions over non-phrasal sub-expressions ( $\min F'(1, 59) = 12.07, p < .01$ ). As in part A, the incorrect and also the non-phrasal results indicate that participants are doing no better than chance in responding to these sub-expression types. However, performance was clearly above chance for phrasal sub-expressions.

Given the limited mathematical experience of the Year 7 students, these results are unexpected. The fact that the overall accuracy of the Year 7 students is far lower than for competent adult mathematicians, indicates that the development of their internal representation still has a long way to go. However, superior performance in recognizing syntactically well-formed and phrasal sub-expressions provides support for the notion that mathematical syntax plays an important role in the way that these students encode equations. This result therefore does not support our hypothesis that considerable experience is necessary before students can parse an equation based on its mathematical syntax.

Despite the significance of these results, it is not clear whether the students represent a heterogeneous or a homogeneous population with respect to their performances in this task. Therefore, a further analysis of the error rate data from this experiment was conducted. For part A of the experiment, a three-way split was carried out based on the difference in accuracy in recognizing well-formed and non-well-formed sub-expressions. The results of participants in each version were divided into three groups. The top group contained participants with the greatest performance advantage in recognizing well-formed sub-expressions over non-well-formed

sub-expressions. The bottom group contained those with the least advantage, or possibly even a disadvantage in recognizing well-formed sub-expressions over their non-well-formed counterparts. The remaining participants formed a middle group, but the results of this group were not of interest. Since there were six participants per version, each group contained the results of two participants from each version. ANOVAs were then conducted to compare the performance of the top and bottom group.

As expected, an even greater performance advantage of 32.5% in identifying well-formed over non-well-formed sub-expressions was found in the top group ( $\min.F'(1, 30) = 19.55, p < .01$ ). However, the performance of the bottom group revealed a slight disadvantage of 1.7% in recognizing well-formed sub-expressions over their non-well-formed counterparts. This result was not statistically significant ( $F < 1$  for analysis by both subject and item).

A similar analysis was conducted for part B of the experiment, with the three way split based on the accuracy difference between recognizing phrasal and non-phrasal sub-expressions. The top and bottom groups reflect the participants with the greatest and least performance advantage respectively, in recognizing phrasal sub-expressions over non-phrasal sub-expressions. The top group again had a significant performance advantage of 32.7% in identifying phrasal over non-phrasal sub-expressions ( $\min.F'(1, 60) = 20.17, p < .01$ ). For the bottom group however, the advantage was only 5.8% which was not statistically significant ( $F < 1$  for analysis by both subject and item).

This result indicates that within the population sample for Experiment 2, there are two distinct groups, one of students who encode equations based on mathematical syntax, and one of those who appear not to. One possible explanation for this result is that some students have more previous experience with algebra and mathematics than others. However, another possibility is that some students might have a stronger predisposition for using knowledge of mathematical syntax to guide construction of internal representations. Certainly more research will be needed before the cause of this result can be resolved.

## Conclusions

Previous research has suggested that adults competent in mathematics encode equations into constituents that have syntactically well-formed structure (Jansen et al., 1999). We have extended upon these results by providing support for the hypothesis that the internal representation used by mathematicians is based on the constituent structure of a parse tree. Evidence has also been presented which indicates that this encoding mechanism is present in young students. This result is surprising given that the students have very little experience in dealing with complex algebraic expressions.

The future direction of this research is to further investigate the encoding mechanisms and internal representations used to process equations, and in particular to examine how the rep-

resentations of equations are used in mathematical problem solving. Also, the positive result with the Year 7 students leads to the question of just how little mathematical experience is necessary before mathematical syntax begins to play a role in encoding equations. Whether or not the students are establishing representations based on mathematical syntax, or their performance reflects a more general encoding mechanism for such complex stimuli, can only be resolved by conducting similar experiments with children who have no experience with algebraic equations.

## Acknowledgements

The authors wish to thank the staff and students at the Prahran Campus of Wesley College in Victoria, Australia, for their helpful co-operation and assistance in conducting the experiments involving the Year 7 students.

## Abstract

We present an experimental design that allows us to investigate the representations and processes used in human multiple-cue judgment. We compare three ideal models of how knowledge is stored and applied in a judgment: A linear additive model (LAM), a heuristic model, Take-the-best (TTB) and a generic exemplar-based model (EBM). The results show that people adaptively change processing depending on what information is present in the learning phase and whether or not the learning situation is compatible with the test. Feedback on a continuous variable provides information sufficient to estimate a LAM that can be used both when learning is and is not compatible with the test. When only dichotomous feedback is provided, the processes differ depending on the learning-test compatibility. At high compatibility, the processing is best described by EBM, but at low compatibility heuristic processes such as TTB become more frequent alternatives to LAM.

## Introduction

In the 1950's and 60's two new research paradigms emerged in cognitive science, categorization research (e.g., Shepard, Hovland, & Jenkins, 1961) and research on multiple-cue judgment (e.g., Hammond, 1955). While the former has continued to flourish, the Brunswikian inspired judgment research quietly left the arena in the 80's, although with a re-emergence in studies on realism of confidence (Gigerenzer, Kleinbölting, & Hoffrage, 1991; Juslin, 1994). The two paradigms have a lot in common, but there is seldom cross-reference between them (but see Kruschke & Johansen, 1999). A major conclusion from research on multiple-cue judgment is that linear models fit judgment data well (Brehmer, 1994) but in regard to knowledge representation and processes, there has been little research. In the categorization literature in contrast, a variety of models with explicit representational and process assumptions have been proposed (see Medin, 1989).

In this article, we bring the two paradigms together by combining multiple-cue learning with theories and methods

from research on categorization. We present an experimental design that allows us to investigate knowledge representations and processes in human judgment. As a point of departure we take research that postulates multiple levels of representation (e.g., exemplars, rules) that compete to control the judgments in a specific task (Ashby et al., 1998; Erickson & Kruschke, 1998; Logan, 1988). The idea is that experience with some domain may lead to co-existing representations at several levels. A general hypothesis is that the process and representation that dominates at the time of judgment is contingent on an interaction between the learning environment and the judgment task to which the knowledge is later applied. We offer some preliminary ideas in regard to the principles that determine this interaction. The crucial question is: In what circumstances will a particular level of representation dominate the judgments?

We compare three ideal models of how knowledge is stored and applied in a multiple-cue judgment task. *Linear Additive Models* (LAM) suggest that we store information in memory about: (a) the weight or *cue validity* attached to each cue in the form of a linear coefficient, and (b) an *algebraic rule* for the combination of the cues, in this case a linear additive rule (Brehmer, 1994). The process at the time of judgment is *cue-integration*. Recently, a simpler and more heuristic alternative has been proposed in terms of the *Take The Best* algorithm (TTB; Gigerenzer & Goldstein, 1996; Gigerenzer, Todd, & ABC Group, 1999). TTB suggests that the single most valid cue that is applicable is used and that no information is integrated. The knowledge in memory are *cue validities* and the process amounts to *cue-substitution*. Finally, *Exemplar-Based Models* (EBM) from the categorization literature (e.g., Medin & Schaffer, 1978; Nosofsky & Palmeri, 1997) assert that the memory traces of each encountered object are stored in memory and that judgments are based on the similarity between the new object and the already stored exemplars. In this case, the representations are *exemplars* and the process is similarity-based *retrieval* from memory.

## Overview of the Experimental Design

The design presented in this article is based on the idea that an object is judged according to cues. The participants learn that there is a species of frogs that vary in degree of toxicity (0 to 100 %). This attribute depends on four characteristics of the frog; color of the back (green or brown), shape of a spot on the back (wedge shaped or round), size of glands above the eyes (large or small) and color of the abdomen (white or light yellow). These characteristics are binary cues that have the weights .4, .3, .2 and .1 respectively, in a linear equation: Toxicity =  $.4 \times \text{Cue 1} + .3 \times \text{Cue 2} + .2 \times \text{Cue 3} + .1 \times \text{Cue 4}$ . The weights can be understood as the proportions of poison that each cue adds to the total amount of poison.

Table 1: The exemplars and total proportion of poison when the weights on Cues 1 to 4 are .4, .3, .2, and .1 respectively.

Exemplar	Cue 1	Cue 2	Cue 3	Cue 4	Total
1	1	1	1	1	1
2	1	1	1	0	0.9
3	1	1	0	1	0.8
4	1	1	0	0	0.7
5	1	0	1	1	0.7
6	1	0	1	0	0.6
7	1	0	0	1	0.5
8	1	0	0	0	0.4
9	0	1	1	1	0.6
10	0	1	1	0	0.5
11	0	1	0	1	0.4
12	0	1	0	0	0.3
13	0	0	1	1	0.3
14	0	0	1	0	0.2
15	0	0	0	1	0.1
16	0	0	0	0	0.0

Adding the weights of all cues with positive cue values (1) gives the total proportion of poison for each frog. For example, if a frog has a green back (1), round spot (0), large glands (1) and light yellow abdomen (0) the total proportion of poison is  $1 \times .4 + 0 \times .3 + 1 \times .2 + 0 \times .1 = .6$ . It is convenient to describe the frogs according to their binary code. The above frog is Exemplar 6 (1010) in Table 1. With four cues, there are 16 possible exemplars. The proportion of poison varies between 0.0 and 1.0 (see Table 1).

In the *learning phase* participants learn to judge whether an exemplar is dangerous or not. Exemplars with a proportion of poison above .5 belong to the category Dangerous, whereas exemplars with a proportion of poison below .5 belong to the category Not dangerous. The participants receive *dichotomous feedback* about the accuracy of their prediction (e.g., “Correct” or “Wrong”). In addition they may or may not receive *continuous feedback* about the exact proportion of poison (e.g., “The amount of poison is 70%”). Exemplars that have a proportion of poison of exactly .5 are randomly assigned as dangerous or not. Three exemplars are omitted in training to test EBM, as described below.

The *single-object test* is the same task as in the learning phase, except that also exemplars that were omitted in the training phase are introduced. In the *pair-comparisons test*, two exemplars are compared in regard to degree of toxicity (i.e., which is the most dangerous one). Feedback is with-

held in the tests. The two tests allow us to investigate how knowledge acquired in one task is applied to a new judgment task, and how this affects the choice of representation.

## Model Specifications

**LAM** The characteristic of LAM is that cue validities and a linear, additive integration rule are retrieved from memory and all four cues are weighed together to calculate a total proportion of poison for each exemplar. Clearly, LAM provides the optimal algorithm for the task: If participants have accurate estimates of the cue validities (linear coefficients) they will categorize all exemplars in the single-object test correctly, except when the proportion of poison is .5. With a correctly estimated LAM the accuracy is .94 (15 out of 16 judgments correct), which provides a ceiling on the accuracy that can be attained.

In the pair-comparisons test, LAM computes an estimated toxicity of each of the two exemplars and decides on the exemplar with the higher estimated toxicity. With a correctly estimated LAM all judgments are correct, except when comparing exemplars with the same poison proportion, where the judgment is a guess (e.g., when comparing Exemplars 4 and 5). When all exemplars are compared to each other once (120 comparisons) the success rate is .98 (5 out of 120 comparisons will be guesses). The representations—the cue validities and the integration rule—and the process of cue integration are the same for all exemplars. Therefore, in the test phase LAM predicts that there should be no difference in the accuracy for (old) exemplars previously presented in the learning phase and (new) exemplars that have not been encountered previously.

**TTB** The characteristic of TTB is that only one of the four cues is used to make a judgment: The cue considered to be the most valid one. In the context of TTB, cue validity is defined as the conditional probability of a correct choice across all cases where the cue is applicable. In the single-object test, TTB implies that an exemplar with cue value 1 on the most valid cue is categorized as dangerous, and an exemplar with cue value 0 as not dangerous. In this application, the most valid cue (Cue 1) has validity .81 when applied to all 16 exemplars. The highest accuracy attainable with TTB in the single-object test is therefore .81.

In the pair-comparisons test, a cue is applicable if one exemplar has cue value 1 and the other 0 on this cue. If the best cue is applicable a judgment can be made, but if the cue values are identical for both exemplars the second to best cue has to be considered, and so on. The most valid cue (Cue 1) has a cue validity of .95 in the application to the pair-comparisons test. The second to best cue (Cue 2) has a validity of .93. In the pair-comparisons test the highest possible accuracy with TTB is .95. This presumes consistent application of the most valid cue that is applicable, correct conception of cue-directions, and correct rank ordering of cue validities. Because the representation and process is the same, TTB predicts that there should be no difference between new and old exemplars.

In addition to these global indices, there are critical exemplars for each cue that discriminate TTB from the other models. In the single-object test, there are two critical ex-

emplars for each cue. If TTB is used, both of these exemplars will be judged incorrectly, whereas if LAM is used they will be judged correctly. Exemplars 8 (1000) and 9 (0111) will be incorrectly categorized if Cue 1 is attended to, because the judgment is based on the binary value of Cue 1 instead of the total poison proportion of the exemplar. Similarly, in the pair-comparisons test there are comparisons that signal the use of TTB. There are three critical comparisons that will be judged incorrectly when Cue 1 is used, because the judgment is based on the binary value of Cue 1 rather than the overall poison proportion of the exemplars. When Cue 2 is used as the best cue, 10 comparisons are critical.<sup>1</sup>

**EBM** With EBM the new exemplar is judged by similarity to retrieved memory traces of previous exemplars. In the single-object test we assume that the process is well-captured by a standard exemplar-based model from the literature, *the context model* (Medin & Schaffer, 1978). On this account, the new exemplar (probe) is assigned to the category Dangerous with a probability equal to the proportion of the summed similarity to the stored exemplars in the category Dangerous, relative to the summed similarity to all stored exemplars. When the context model is applied to the single-object test with parameters that imply extreme specificity (i.e., all similarity parameters equal to 0), the model only retrieves identical exemplars. In this case, the context model produces the same accuracy as LAM, .94.

Application to the pair-comparisons test, where the two objects (probes) are compared in regard to a continuous variable, is more complicated. In a learning environment with only dichotomous feedback, an EBM like the context model can merely differentiate between pair-comparisons that contrast exemplars from different categories. This holds for 50 percent of the comparisons, and for these an EBM can attain perfect accuracy. For the remaining comparisons that involve two dangerous or two non-dangerous exemplars the judgment has to be based on a guess associated with .5 accuracy. Thus: in a condition with only dichotomous feedback an EBM can at most attain an accuracy of .75 ( $.5 \times 1 + .5 \times .5$ ). When feedback is continuous, on the other hand, an EBM can potentially store also the continuous value with the exemplar. An extension of the original context model that applies to estimation of continuous variables is *PROBEX* (for *PROBABILITIES* from *EXEMPLARS*, Juslin & Persson, 1999). When *PROBEX* is applied to pair comparison it makes one estimate of the continuous variable for each of the two probes. Each estimate is a weighted average of the values on the variable that have been stored with previous exemplars, where the weights are the similarities to the probe. The rule for computation of similarity is the multiplicative similarity rule of the context model. In a pair-comparisons task, *PROBEX* decides on the probe with the higher estimated value on the continuous variable. Again, if parameters are set so that only identical exemplars are retrieved (weighted), *PROBEX* allows the same accuracy as

LAM, that is, .98.<sup>2</sup> The reader is referred to Medin and Schaffer (1978) and Juslin and Persson (1999) for a complete specification of the models.

For current purposes, it is sufficient to highlight a general property of many exemplar-based models: Because the judgments are based on similarity to stored exemplars and the multiplicative similarity rule implies a particular sensitivity to identical exemplars, accuracy should be higher for old exemplars that correspond exactly to stored exemplars than for new exemplars. It should thus be easier to categorize exemplars, or compare two exemplars, that have been encountered previously, than new exemplars. EBM can be tested by omitting exemplars in the learning phase and later introducing them in the test phase. If EBM is used, the proportion correct should be higher for old exemplars than for new exemplars.

### Cost-Benefit Considerations and Learning-Test Compatibility

We will concentrate on two principles that determines the representation and process that dominates in a task: *cost-benefit considerations* and *learning-test compatibility*. As a preliminary step to this analysis, we have to make a few additional assumptions about the three models. We interpret both LAM and TTB to involve conscious, controlled and analytical processes constrained by short-term memory. We expect that short-term memory can hold at most a few elements (e.g., cue validities) active at any moment and that the process requires active mental effort. EBM is memory-based and the retrieval processes are assumed to be preconscious, automatic and to require little mental effort. It is possible, however, that EBM requires a longer period of learning to accumulate a sufficient set of exemplars. We assume that these processes are present simultaneously and compete to control a specific judgment.

The principle of cost-benefit consideration implies that the relative gain of applying a process is weighted against the cost of applying it. In the context of a design like the present one, the gain is accuracy and the cost is mental effort. The cost involved in applying a process concerns both investment in the learning phase (e.g., the effort to estimate linear coefficients with LAM), and in the test phase (e.g., cue integration). Payne, Bettman, and Johnson (1993) have studied cost-benefit considerations in choice of decision rules in multi-attribute decision making. This research suggests that as the cost of applying a mental algorithm (e.g., LAM) increases people adapt and turn to heuristic processes (e.g., TTB). The principle of learning-test compatibility implies that for memory-based processes, the conditions for successful retrieval are optimal when the circumstances at test match those at learning. This principle is supported by an extensive literature on memory, and illustrated by concepts such as the principle of encoding specificity (Thomson

<sup>1</sup> The results for Cues 3 and 4 are not reported because analyses of the data show that, if TTB is used Cue 1 and Cue 2 are most frequently used as the best cue.

<sup>2</sup> The limits on accuracy are conditional on complete knowledge of all 16 exemplars. Omitting 3 exemplars in the learning phase constrains the possibility to estimate linear coefficients and cue validities, and to store exemplars. These deviations are minor and have no effect on the conclusions.

& Tulving, 1970) and transfer-appropriate processing (Morris, Bransford, & Franks, 1977).

We apply these principles to three experimental manipulations: (a) *Feedback quality*: Presentation of continuous or dichotomous feedback in the learning phase. (b) *Test format*: Single-object or pair-comparisons test. (c) *Cue order*: Fixed or varied presentation order of the cues.

### Feedback Quality

Presentation of continuous feedback in the learning phase should enhance the use of LAM. Continuous feedback facilitates estimation of linear coefficients for each cue. This decreases the cost required to use LAM and thereby increases its prevalence. Because learning the cue weights with dichotomous feedback is arduous, cost-benefit considerations suggest that participants are likely to resort to a computationally simpler process like EBM or TTB.

### Test Format

In single-object tests, learning and test consist of the same task, whereas in pair-comparisons tests the learning phase and the test differ. The principle of learning-test compatibility implies that EBM should be more common in the single-object test, where the conditions at learning and test are identical. This increases the probability of successful retrieval of stored exemplars. Note that LAM and EBM, in principle, allow the same accuracy, but at different costs: LAM allows rapid learning but requires larger mental effort. EBM requires little mental effort but, presumably, more extended training to attain the same level of performance.

The change of context in the pair-comparisons test should increase the rate of responses guided by LAM or TTB, which are not dependent on episodic retrieval. Participants should have less opportunity to rely on memory (EBM), and turn to the analytic processes implied by LAM and TTB. Moreover, when only dichotomous feedback is provided in the learning phase, EBM provides poor guidance in a pair-comparison that concerns continuous values of the exemplars.

The principles of cost-benefit consideration and learning-test compatibility should interact in a specific way. In pair-comparisons, more mental effort is needed to make the judgment compared to in a single-object test. If LAM is used in a single-object test, four cues are weighted and added. In a pair-comparisons tests, the cognitive effort is doubled. This should make participants who use LAM for single-object judgments swap into a less demanding process in the pair-comparisons test. Because of lower training-test compatibility in the pair-comparisons task, however, they are likely to divert to a heuristic algorithm such as TTB rather than to EBM.

Predictions for the first two manipulations are summarized in Table 2. The provision of continuous feedback should allow the participants to estimate a LAM, and this should be particularly evident in the single-object test where application of LAM demands less effort. With dichotomous feedback, EBM should dominate in the single-object test where training and test conditions match, whereas TTB

should dominate in the pair-comparisons test where this match is lower.

Table 2: Processes predicted to dominate as a function of the manipulation of feedback quality and type of test.

Test format	Feedback quality	
	Continuous	Dichotomous
Single-object	LAM	EBM
Pair-comparisons	LAM/TTB	TTB

### Cue Order

In the experiment, we presented the cues in fixed or randomly varied presentation-order across trials. Our hypothesis was that a fixed cue order should enhance the use of EBM because this should maximize training-test compatibility. This manipulation produced no effects, an observation to which we return in the discussion.

## Method

### Participants

Sixty-four persons (41 women and 23 men, mean age = 24.4) participated. All but 4 were undergraduate students at Uppsala University. Participants received a course credit or a cinema voucher worth approximately 75 SEK for participating.

### Design and Procedure

Each learning trial consisted of presentation of an exemplar of a fictitious frog species with 4 different attributes (described above) with the information presented in written text. Three exemplars were omitted and the remaining exemplars were judged 10 times each in the learning phase, making a total of 130 trials. For half of the participants, exemplars 4, 9 and 10 were omitted, for the other half exemplars 5, 6 and 7. These exemplars are equal in poison percentage (i.e., 4 is equal to 5, 9 is equal to 6 and 10 to 7). The omission was thus counterbalanced.

The participants answered the question “Is the frog dangerous or not?” and received dichotomous feedback “Correct answer“ or “Wrong answer“. Half of the participants also received continuous feedback about the percentage of poison of the frog, for example, “70% poison” The weights, .4, .3, .2 and .1, were randomized to different cues for each participant. For half of the participants cues were presented in fixed order (in the same order and spatial location on the list) and for the other half cues were presented in a varied order.

After the learning phase, participants received a single-object test structurally identical to the learning phase, but without feedback. This phase consisted of 16 trials as all exemplars were judged once. Finally, a pair-comparisons test in which 2 exemplars were contrasted, (also without feedback) was administered. The question was: “Which frog is most dangerous?”. This test consisted of 120 trials (all exemplars were compared to each other once). Each session lasted 45 min to 1h and 30 min.

## Results

### Proportion Correct

In the single-object test, the use of LAM and EBM was predicted and the results support these predictions. Table 3 displays the mean proportions correct (M) and 95 % Confidence Intervals (CI) for each condition.

Proportions correct clearly refute the use of TTB in the continuous feedback condition since the confidence intervals do not include .81, the maximum performance possible for TTB. The proportion correct is significantly higher in the continuous feedback condition than in the dichotomous feedback condition,  $t(62) = 2.04$ , (*one-tail*)  $p = .03$ . This is expected if participants, to some extent, rely on LAM but not if they uniformly rely on EBM. In the continuous feedback condition it is easier to estimate cue validities and therefore the proportion correct is expected to be higher in this condition if LAM is used.

Table 3: Proportions correct (M) and 95 % Confidence Intervals (CI) for each condition of the single-object test.

Feedback	Cue order		Total
	Varied	Fixed	
<b>Continuous</b>	M=.86 * (CI: .81-.91)	M=.88 (CI: .80-.88)	M=.87 * (CI: .83-.92)
<b>Dichotomous</b>	M=.82 (CI: .78-.87)	M=.79 (CI: .70-.88)	M=.80 (CI: .76-.85)
<b>Total</b>	M=.84 (CI: .77-.89)	M=.84 (CI: .80-.87)	M=.84 (CI: .80-.87)

\*The CI does not include .81, the maximum performance possible for TTB.

In pair-comparisons, the participants were predicted to use LAM in the continuous feedback condition and TTB in the dichotomous feedback condition. The mean proportion correct is .90 (CI: .87-.94) in the continuous feedback condition and .80 (CI: .75-.85) in the dichotomous feedback condition. The proportions correct are consistent with TTB. In sum: The proportions correct falsify TTB in the single-object condition with dichotomous feedback, but the proportions correct are compatible with LAM and EBM in all conditions. Presentation order of the cues had no effect on accuracy.

### Old and New Exemplars

The differences in proportions correct for old and new exemplars are presented in Figure 1. The only condition in which there is a substantial advantage for old exemplars over new exemplars is the single-object/dichotomous feedback condition, where EBM is predicted to dominate. In the other three conditions in Figure 1, EBM is not supported. When feedback quality is high and the cost of applying a complex algorithm is low, participants can rely on the powerful (but choosy on data) LAM. When feedback is of poorer quality, the cost of applying LAM is too high and the participants resort to the less demanding EBM. This is particularly likely to occur when learning-test compatibility is high (i.e., in the single-object/dichotomous condition).

In Figure 2, proportions correct are displayed separately for new, mixed (comparing 1 new and 1 old exemplar) and

old exemplars in the pair-comparison test. In the continuous feedback condition, there is no difference between new, mixed or old exemplars, supporting LAM (TTB is refuted by the proportion correct, see Table 3). More perplexing, in the dichotomous feedback condition there is no difference between old and new exemplars, but the proportion correct on mixed exemplars is significantly lower. This effect reflects a bias to choose the old exemplar, resembling the *recognition principle* discussed in the context of TTB (Gigerenzer & Goldstein, 1996). This principle states that when presented with a pair comparison between two objects, only one of which is recognized, the participants will guess on the recognized object. In sum: In the dichotomous feedback condition, the comparison of old and new exemplars supports EBM in single-object tests and, potentially, TTB in the pair-comparison tests. In the continuous feedback conditions, the results support LAM.

Figure 1: Mean difference between proportion correct for old and new exemplars and 95 % Confidence Intervals for the continuous (filled squares) and dichotomous (open squares) conditions.

Figure 2: Mean proportion correct and 95 % Confidence Intervals of pair comparisons with new, mixed and old exemplars for the continuous (filled squares) and dichotomous (open squares) feedback conditions.

### Critical Exemplars

The critical exemplars do not provide much support for TTB in the single-object conditions. TTB with Cue 1 as the best

cue, should yield wrong judgments on Exemplars 8 (1000) and 9 (0111) in the single-object test. The proportion correct on these Exemplars is well above 0 in both conditions, specifically .83 (CI: .72-.94) in the continuous feedback condition and .73 (CI: .62-.85) in the dichotomous feedback condition. On individual level, five participants (7.8%) used TTB, four judged both critical exemplars of Cue 1 incorrectly and one the critical exemplars of Cue 2. These participants were equally distributed in the dichotomous and continuous feedback conditions. In the pair-comparisons test, TTB receives some support from the critical comparisons. Although a group level analysis shows no consistent use of TTB, on an individual level 16 participants (25%) used TTB: Nine with Cue 1 as the best cue and, surprisingly, seven with Cue 2 as the best cue.

### Discussion

We have introduced a design in which the knowledge representations and processes in a multiple-cue learning task can be studied. The results suggest that humans change cognitive processing, as a function of the information present during learning and the compatibility of learning and test, in a way that is consistent with the principles of cost-benefit and learning-test compatibility derived from previous research.

Specifically, the presentation of continuous feedback in the learning phase provided participants with information that allowed them more easily to estimate a LAM. A LAM is applicable both when learning is, and is not, compatible with the test, but the application is more demanding in the pair-comparisons test. Thus, there was more support for the domination of LAM when continuous feedback was provided, but less so in the pair-comparisons than the single-object test.

When only dichotomous feedback is available, the estimation of LAM becomes demanding and other processes come to dominate the judgments. The other processes correspond to the two classical ways of circumventing the limited capacity of controlled thought processes: memory-based performance, or automatization, and heuristic processing. When the test is similar enough to the learning task, processing is memory-based and relies on exemplar representations. When the test is different from learning, heuristic processes, such as TTB, increase in frequency. Overall, however, we found little evidence in support of TTB (i.e., a minority of participants in the pair-comparisons task seemed to rely on it). This may perhaps be explained by the relatively simple task used in the experiment and, indeed, as the task became more complex, evidence in favor of TTB seemed to increase. Nonetheless, at present there is little empirical data that provide support for the empirical validity of TTB.

To our surprise, the manipulation of fixed or varied order of the cues had no effect. Together with the clear effect of old and new exemplars in the dichotomous/single-object condition, this suggests that the judgments are sometimes guided by exemplar-memory, but the representation of the exemplars may be more conceptual than visual in its character.

# Influences on Attribute Selection in Redescriptions: A Corpus Study

Pamela W. Jordan (jordan@isp.pitt.edu)

Intelligent Systems Program

University of Pittsburgh

Pittsburgh PA 15260

## Abstract

We report on the results of the first stage of a corpus analysis that tests five hypotheses about how domain and discourse goals and the functions of repetition can influence the content of redescrptions in dialogue. We found a positive correlation between the attributes expressed in redescrptions and contexts in which three of these types of goals are predicted. These results provide us with guidance on the selection strategies we will test in the next stage of analysis.

## Introduction

In an extended discourse, speakers often redescribe objects that were introduced earlier in order to say something more about the object or the event in which it participates. The main goal when redescribing an entity is to re-voke the appropriate discourse entity. However, a goal-directed view of sentence generation suggests that speakers can attempt to satisfy multiple goals with each utterance [Appelt, 1985] and that a single linguistic form can opportunistically contribute to the satisfaction of multiple goals [Stone and Webber, 1998]. The possibility that goals besides identification could influence the content of a nominal expression<sup>1</sup> have not been fully addressed in computational work on generating nominal expressions.

The many-one mapping of goals to linguistic forms is more generally referred to as *overloading intentions* [Pollack, 1991]. Overloading can involve tradeoff across linguistic levels [Di Eugenio and Webber, 1996, Stone and Webber, 1998]. For example, an intention which is achieved by complicating a form at the semantic level may allow the speaker to simplify at the syntactic level by omitting important information [Stone and Webber, 1998].

Although we have learned that overloading is natural and perhaps even necessary, we have no well supported account of what degree of overloading is reasonable and what forms can more readily address multiple goals in dialogue. Without such an account, we have no principled way to deploy overloading in the automatic generation of natural language. Without well supported constraints on overloading, we are liable to create overloads in unnatural ways which will actually impede effective communication.

To investigate whether overloading applies to redescrptions, we examined 166 non-pronominal redescrptions found in 13 dialogues of the COCONUT

corpus [Di Eugenio et al., 2000]. This corpus contains computer-mediated dialogues in which two people collaborate on a simple design task, buying furniture for two rooms of a house. The participants' main goal is to negotiate the purchases; the items of highest priority are a sofa for the living room and a table and four chairs for the dining room. The participants also have specific secondary goals which further complicate the problem solving task. Participants are instructed to try to meet as many of these goals as possible, and are motivated to do so by associating points with satisfied goals. The secondary goals are: (1) Match colors within a room, (2) Buy as much furniture as you can, (3) Spend all your money. Each participant is given a separate budget and inventory of furniture and must decide what to make mutually known. Every furniture item in the inventory is described by five attributes; type, color, price, owner, and quantity.

In this article, we report on the results of the first stage of a corpus analysis that tests five hypotheses about how domain and discourse goals and the functions of repetition can influence the content of redescrptions in dialogue. We found a positive correlation between the attributes expressed in redescrptions and contexts in which three of these types of goals are predicted. The positive correlations will guide us in implementing and testing selection strategies for generating nominal expressions.

## Hypotheses about influences on redescrptions

Our hypotheses reflect non-identification goals that could influence the choice of attributes for a redescription. These goals are derived from work on the functions of repetition at the utterance or propositional level [Walker, 1993, Johnstone, 1994] and from observations about task intentions and constraint changes (e.g. matching colors) that were not directly communicated by the dialogue participants.

Our first hypothesis is based on the observation that in the COCONUT corpus, people often adjusted task constraints with no explicit discussion (38%).<sup>2</sup> Similarly to [Walker, 1993] for the propositional level, we suggest that the hearer is inferring changes from the redundancies in the redescription. So the repeated property could

<sup>1</sup>Identification being satisfied by more than a nominal expression also deserves consideration.

<sup>2</sup>Constraints are found in planning and scheduling tasks as well as design tasks [Di Eugenio et al., 2000, Jordan, 2000].

both help uniquely identify the intended discourse entity and enable the hearer to infer constraint changes.

To illustrate this possibility for COCONUT, assume that there is an initial constraint setting to match colors, that the speaker just discussed using a red table and prior to that introduced tables of various colors, four \$100 red chairs, and four \$75 green chairs. Finally, assume that she has decided to drop the color match constraint and suggest the cheaper \$75 chairs. When she communicates her suggestion, we hypothesize that she will prefer saying *green chairs* or *\$75 green chairs* over the more economical *\$75 chairs*. By choosing “green,” she adequately identifies the target chairs while also enabling the hearer to infer that she intends to drop the color match constraint. She has eliminated having to explicitly communicate the information [Walker, 1993] and reduced the risk of the hearer missing the inference [Carletta, 1992].

DOMAIN CONSTRAINT CHANGES HYPOTHESIS: Properties related to constraint changes are expressed in a context where the change must be inferred by the hearer.

Intentional relations indicate that an utterance, for example, elaborates or motivates other utterances, helping to bind together utterances to form a coherent discourse [Mann and Thompson, 1987]. Since the relations between utterances can influence the content and form of utterances [McKeown, 1985, Moser and Moore, 1995], we suggest that they could influence redescriptions as well. For example, in a context where all the object information is mutually known, a table needs to be chosen and red chairs have already been selected, (1b) can be considered motivation for the choice made in (1a).

- (1) a. Let’s use my table.  
b. It is red.

We know that it is beneficial under certain cognitive resource limitations to make motivations explicit even when the motivation is mutually known [Walker, 1993]. When we replace (1) with (2), the redescription may subsume the motivation and do the same thing.

- (2) Let’s use my red table.

PERSUASION HYPOTHESIS: Property values that are pivotal for deliberation are expressed in the context of goals to communicate a proposed action.

If a speaker repeats an utterance and provides no new information, this can show that a stage of the interaction is complete [Whittaker and Stenton, 1988, Jordan and Di Eugenio, 1997]. Repeating properties for a recently evoked item could show that the current stage has just been completed while doing so for an

older item could indicate that a higher level subproblem has been completed. In (3), S’s second utterance appears to end a stage in the interaction, in this case the end of the agreement process for a *select sofa* action [Di Eugenio et al., 2000].

- (3) S: ...I have a \$300 yellow sofa...

G: My sofa’s are more expensive so buy *your \$300 yellow sofa*. Also...

S: ... I will go ahead and buy *the \$300 yellow sofa*.

COMMITMENT HYPOTHESIS: In the context of a commitment to a proposal, all the properties expressed in the proposal will be repeated.

The second case of indicating that a higher level subproblem has been completed is a summary. Given the goals for the COCONUT design problem, the participants need to agree on the furniture items selected, whether colors should match in a room and whether they have selected as many different items as they can. In addition they have the hard constraint of not overspending. We suggest that a speaker would need to review all of these decisions in order to summarize the currently agreed upon solution state. Since the furniture items all have attributes related to each of these decisions, we hypothesize that a speaker will economize his summarization by including all the attributes that relate to decisions when listing the agreed upon items in the current solution. For example, in (4), the participants have previously decided on the dining room items and are completing their selections for the living room. Note that when G requests a summary of the living room, D includes all the attributes that relate to decision making for the task. D also decides to review all the items that they had previously decided upon for the dining room.

- (4) G: I got the rug. What do you have in the living room and what are the prices of the items

D: the green sofa in the living room 350. dining room—> 3 yellow chairs 75 each, 1 high-table yellow, 1 yellow rug

SUMMARIZATION HYPOTHESIS: In the context of a previously completed problem or subproblem, all decision relevant, mutually known properties for an item will be repeated.

Finally, a speaker might also repeat an utterance to show that it was understood [Clark and Schaefer, 1989, Brennan, 1990, Walker, 1992, Walker, 1993]. In the COCONUT corpus, the hearer sometimes repeats the description in the turn immediately following. For example, in (3), G repeats S’s description of the sofa, although the sofa was introduced by S. We claim that this type of redescription could help verify that the property information was correctly understood.

VERIFICATION HYPOTHESIS: In the context of a newly introduced entity, all the properties expressed will be repeated by the hearer in his/her next turn.

### Analyzing the Corpus

To identify the contexts and attribute usages we described in the hypotheses we used annotated features<sup>3</sup> and other easily extractable features of the corpus (e.g. the utterance speaker and the proximity of a redescription to its last mention). We used two types of corpus annotation features to support our study: (1) discourse entity level annotations that capture (a) the definitions and updates for discourse entities as a dialogue progresses and (b) the properties selected to redescribe discourse entities, and (2) utterance level annotations that capture (a) the problem solving state in terms of goals and constraint changes, and (b) discourse features such as commitments and offers. All of the features we used were found to have good intercoder reliability [Di Eugenio et al., 1998, Jordan, 1999]. The annotation features are described in detail in [Jordan, 2000].

Of these feature, the discourse features are the most complicated. They are based on elements of the agreement process described in [Di Eugenio et al., 2000]. The high-level definitions for these features are:

- propose: The speaker offers an item in a context where he already knows the hearer’s alternatives.
- partner decidable option: The speaker describes or offers an item but does not know the hearer’s alternatives.
- unconditional commit: The speaker indicates his commitment to using an item.
- unendorsed option: The speaker offers an item in a context where he knows the hearer’s alternatives and indicates an alternative is better.

Next we will describe how we used the annotation features to identify the contexts and redescrptions indicated in our hypotheses.

### Results of Corpus Analysis

We used chi-square and the Fisher exact tests<sup>4</sup> to check for correlations between factors. Although these tests assume independence, we feel we can violate this assumption given that the dependencies between redescrptions aren’t necessarily direct and obvious.<sup>5</sup> In all of the contingency tables, the counts are restricted to utterances

<sup>3</sup>The annotators for the corpus only knew the high-level goal of the study. Because of this, their annotation decisions were not influenced by the hypotheses we are studying here.

<sup>4</sup>We use the Fisher exact test when  $N < 20$  and an expected frequency is  $\leq 5$ .

<sup>5</sup>On average, the dialogues have 42 utterances, 25 discourse entities, and 6 utterances between redescrptions.

Changes	Related Properties
Room Color Limit	color
Price Upper Limit	price
Price Evaluator	price
Property Limit	color, price

Table 1: Associated Properties and Changes

that contain redescrptions. Finally the counts were all done automatically using software that interpreted the annotation features since the contextual factors generally involved multiple annotation features.

**Domain Constraint Changes Hypothesis** For this hypothesis we test whether there is a difference in property usage when a constraint change is communicated implicitly or explicitly. COCONUT is annotated with features indicating (1) whether a constraint change was communicated and whether this was accomplished implicitly or explicitly (2) which properties were included in the redescrptions. We examined each utterance for every constraint change that is generally possible for the domain when populating the cells of the contingency table.

We only count properties that relate to constraints. For example, we only look at the usage of the color property for the color match constraint or price for placing price limits. In Table 1, we list each of the constraint types that we examined and the property that we expected would be useful for inferring that change.<sup>6</sup> Our expectations derive from the instructions given to the COCONUT dialogue participants.

	Property Used	Property not Used
Implicit change	9	0
Explicit change	2	11

Table 2: Contingencies for Domain Constraint Changes Hypothesis

Table 2 shows that in the context of an implicit constraint change, properties related to the change are more likely to be used in the description than when the change is explicit (Fisher Exact Test,  $p < 0.0002$ ).

**Persuasion Hypothesis** For the Persuasion hypothesis, we wish to test whether expressing a property in a redescription is related to whether the expressed property makes the redescrbed item more desirable as a solution for a goal than the alternatives. For example, the cost of the item being redescrbed might be lower than any of the alternatives that have been discussed so far.

<sup>6</sup>The relevant property for the property limit constraint is indicated in the annotation for the constraint change.

A persuasion context exists when a proposal is to be made and alternate solutions exist and there is a contrast between the colors or prices that make the proposed item clearly a better choice. Given the analysis of the agreement process in [Di Eugenio et al., 2000], we first look for either a propose utterance, or an unconditional commitment utterance where the previous state is an unendorsed option, a partner decidable option or a list of options in which the speaker intentions are unclear.

For each of the unconditional commitment cases, we present examples. First, in (5), A’s partner decidable option is followed by B’s unconditional commitment.

(5) A: I have a blue sofa for \$200.

B: I have a yellow sofa for \$250. Let’s go with your \$200 sofa.

In (6), B does not endorse the option he presents but A overrides his objection with an unconditional commitment to it.

(6) A: We have \$100 left. I still have that \$50 blue chair.

B: I have a rug for \$100, but it is yellow.

A: We don’t need to match. Let’s get your \$100 rug.

Finally, in (7), A lists all of the items he has available. From the perspective of the agreement structure, lists such as this have no high-level task goals associated with them. However, the items do become part of the dialogue participants shared knowledge allowing all the items to be considered during problem solving so that they can become alternative options for the goals they are implicitly associated with. Because B is a position to deliberate<sup>7</sup>, his second utterance is annotated as an unconditional commitment. In this case there are two possibilities for what sofa to select, a persuasion context arises.

(7) A: I only have 2 red tables for \$200, 1 green table for \$350 and 4 \$50 blue chairs. I don’t have any rugs or lamps but I have 1 yellow sofa for \$200.

B: I have yellow rug for \$75 and a blue sofa for \$200. Let’s buy your yellow sofa and my rug.

Once we have identified possible persuasion contexts, we need to check for contrasts with alternatives. The alternatives are approximated by accumulating a list of the items evoked for each action. After a propose or unconditional commitment, all the items in the list for an action get flushed before starting over with the proposed item.

<sup>7</sup>This deliberation requirement for unconditional commitment is related to the problem solving architecture and is justified in [Di Eugenio et al., 2000].

Contrast	Related Property
Matches room but not alternatives	color
Cheaper than alternatives	price
More expensive than alternatives (near end of problem)	price

Table 3: Associated Properties and Contrasts

Next we check for contrasts. The contrast possibilities are shown in table 3 and arise from the COCONUT problem description. We were unable to accurately model the goal of buying as much as possible with the annotations available. For color we compare the color of the proposed item to those items already selected for the room and the alternate items. If the proposed item matches items already selected for the room while none of the alternates do, then a persuasion context exists. For prices there are two possibilities that depend on whether or not the end of the problem solving effort is nearing. An item may be a better choice when either (1) the price of the proposed item is greater than that of each alternate (i.e. it may be helping to spend out the budget) or (2) the price of the proposed item is less than that of each alternate (i.e. the cheaper item may be preferred since it leaves some money for other purchases).

Table 4 shows support for the persuasion hypothesis ( $\chi^2 = 5, p < .05, df = 1$ ).

	Property Not Used	Property Used
no contrast	18	9
contrast	13	24

Table 4: Contingencies for Persuasion Hypothesis

**Commitment Hypothesis** Here we test whether in the context of a commitment to a proposed action all the properties expressed in the proposal are more likely to be repeated. A commitment context exists when either (1) there is a previous proposal or unconditional commitment for the action involving the entity in the immediately previous turn and no other items must have been discussed for the action in the interim or (2) a speaker unconditionally commits again after doing so in his previous turn.

When determining repeated properties, we discount the type and owner properties. The type property is excluded because it involves pronominalization and zero anaphora; issues we are not addressing in this research. We exclude the owner property because its only function is identification in this domain.

Table 5 indicates that in contexts where a commitment is predicted, all mutually known properties are more likely to be included in redescrptions (Fisher Ex-

act Test,  $p < .0171$ ).

	Not Repeat Properties	Repeat Properties
No Commitment	7	8
Commitment	2	20

Table 5: Contingencies for Commitment Hypothesis

**Summarization Hypothesis** Here we test if the previous completion of a problem or subproblem correlates with expressing all the decision related, mutually known properties in a redescription. First, we must isolate redescriptions that occur after an agreement has been reached for the action.

A summarization context exists when an agreement has been reached for the action without the action being readdressed between the agreement and the current turn. The achievement of an agreement state is approximated when either (1) a propose or partner decidable option was the last state for the action and it happened more than two turns ago or (2) an unconditional commit was the last state and it happened two or more turns ago. In the first case, the agreement must be inferred and in the other the agreement is more explicit.

For the agreement state under condition (1), we require more than two turns to intervene because we want to allow for the cases where the partner left the decision pending by moving on to a dependent action (e.g. a final table decision may be left pending until the chair options are explored). We are estimating that if the action is not revisited after three turns, then it was not put on hold pending work on another action and that the partner agreed by moving on to another independent action.<sup>8</sup> This test for agreement takes into consideration that the initiation of the relevant next contribution shows evidence of understanding [Clark and Schaefer, 1987] and possibly joint commitment. For condition (2), we require that there be an intervening turn so that the partner is able to show that he has moved on to some other problem.

As with the commitment hypothesis, the type and owner properties are excluded when determining whether mutually known properties are repeated.

Table 6 indicates there is no correlation between a summarization context as we have characterized it and whether all the mutually known properties that relate to decisions get repeated ( $\chi^2 = 1.49, df = 1, NS$ ).

**Verification Hypothesis** With this hypothesis we test whether the repetition of all the properties presented in a previous description correlate with a con-

<sup>8</sup>In the initial version of the annotation scheme, there was a feature for indicating dependent actions but it was dropped because of poor intercoder reliability.

text in which the entity was just introduced. In this case we collect all the properties that were presented in the turn where the item was first described and check whether this mention of the item was in the immediately previous turn or further back in the dialogue. As with the commitment and summarization hypotheses, the type and owner properties are excluded when determining whether properties are repeated. Table 7 shows no correlation between the verification context and the choice of attributes ( $\chi^2 = .06, df = 1, NS$ ).

## Conclusion

Our analysis of the COCONUT corpus, shows positive correlations between the content of redescriptions and three of the contexts in which the repetition and domain and discourse goals we considered are expected. In particular, the contexts in which constraint changes, reasons for proposing, and commitment to proposals are predicted, positively correlated with the attributes expressed in the redescriptions of discourse entities. Finally, we found no support for the hypotheses that the properties expressed in a redescription correlate with verification or summarization contexts. In the case of the verification context, it is possible that the non-interruptibility of the COCONUT communications setting makes this sort of repetition function unnecessary. In the case of the summarization context, our ability to accurately detect this context may have been hampered by the estimates we had to make about the current state of the problem solving. Furthermore, there may be additional influences that depend on the reason for the summarization or the point at which it occurs during problem solving.

In future work we will test an attribute selection algorithm that embodies these hypotheses and compare

it against human performance and baseline algorithms that only consider the identification goal for redescrptions (e.g. IDAS [Dale and Reiter, 1995]).

## Abstract

There has traditionally been significant interest in the role of verb semantic restrictions in both psycholinguistic and computational theorizing about language interpretation (e.g., McRae, Spivey-Knowlton, & Tanenhaus, 1998; Resnik, 1996; Trueswell, Tanenhaus, & Garnsey, 1994). The bulk of this research has focused on how such information influences syntactic choices during parsing. The current paper explores in detail the time-course of, and mechanisms for, on-going referential processing. While their eye movements were recorded, subjects acted upon spoken instructions such as "Now I want you to fold the napkin." The verb was either highly constraining (e.g., "fold") or weakly constraining ("pick up"); the array contained either just one object with the appropriate affordances (the target) or two such objects (the target and a competitor). We provide evidence that listeners are capable of rapidly constraining the domain of reference of upcoming constituents to multiple objects with appropriate semantic affordances, which compete for referential consideration. Moreover, in relation to computational theorizing on this topic, the eyemovement patterns suggest that a verb's informativeness (i.e., the "tightness" of the semantic space of possible constituents, Resnik, 1996) affects the speed with which listeners can compute the domain of reference of upcoming constituents.

## Introduction

Psychologists have been interested in the process of language comprehension since the earliest days of generative grammar (Fodor & Bever, 1965; Miller & Isard, 1963; Slobin, 1966). Most comprehension studies have focused on the problem of syntactic ambiguity resolution – how listeners or readers decide among competing structural analyses (Caplan, Baker, & Dehaut, 1985; Crain & Steedman, 1985; Ferreira & Clifton, 1986; Frazier & Fodor, 1978; MacDonald, Pearlmuter, & Seidenberg, 1994; Trueswell et al., 1994, among many others). In the last several years, however, there has been a growing interest in on-line *semantic* interpretation – in particular, the extent to which listeners can use combinatory semantic information to determine the reference of words and phrases in a rapid, incremental fashion. Much of this work has been conducted in the so-called visual world paradigm, in which listeners manipulate the

contents of a miniature world as their eyes are tracked by a head-mounted visor (Sedivy, Tanenhaus, Chambers, & Carlson, 1999; Tanenhaus, Spivey-Knowlton, & Sedivy, 1995). In this paper we provide evidence, using this paradigm, that the meanings of verbs become available to listeners rapidly enough to constrain the domain of reference for the upcoming direct object.

By virtue of what they mean, words often impose restrictions upon the semantics of other words that appear with them. Many prepositions impose restrictions on the geometric properties of their objects (see especially Landau & Jackendoff, 1993); *through*, for instance, requires that its object have some kind of hole. Verbs are especially picky in this regard: The subject of a verb must be the sort of thing that can perform the denoted action, and the direct object must be the sort of thing that can be sensed, manipulated, or changed in the relevant way. The verb *drink*, for instance, requires a subject capable of drinking, and a direct object capable of being drunk. Hence while *John drank the juice* sounds perfectly natural, both *The table drank the juice* and *John drank the table* register as distinctly odd. Although semantic restrictions have long played a role in linguistic theory (e.g., Chomsky, 1965; Jackendoff, 1972) and in the study of syntactic processing (Boland & Boehm-Jernigan, 1998; McRae et al., 1998; Tabossi, Spivey Knowlton, McRae, & Tanenhaus, 1994; Trueswell et al., 1994) little research has been done until recently to examine their potentially important role in on-line referential processing.

Using the visual world paradigm, Chambers, Eberhard, Carlson, and Filip (1998) have demonstrated rapid access to the meaning of the preposition *inside* and its use to restrict the referential domain of definite noun phrases. Participants in their experiment sat before an array of objects including a duck, a rope, a napkin, a can, and a whistle. When they were instructed to "Put the whistle inside the can," participants launched eye movements to the can even before the onset of the noun. The meaning of *inside* provided enough information for listeners to limit the referential domain of the upcoming noun phrase to the one object with the appropriate physical properties (or *affordances*, in the terms of Gibson, 1977). Crucially, such movements were not found when the preposition was *below* – which does not constrain the affor-

dances of its object – or when the array contained two additional objects with an interior volume (a bowl and a glass).

While highly suggestive, these results are limited in two ways. First, Chambers et al. used only one lexical item (*inside*), and so it is unclear whether semantic restrictions are rapidly available across a range of lexical items. Second, prepositions are generally considered to be closed-class items (Talmy, 1988), which differ from open-class items in a number of important ways, including frequency and semantic richness (Friederici, 1985; Gordon & Caramazza, 1985; Neville, Mills, & Lawson, 1992; Van Petten & Kutas, 1991). Perhaps it is the status of *inside* as closed-class that makes its semantic restrictions so readily available.

Evidence that bears on both of these concerns comes from a recent study by Altmann & Kamide (1999), who used a modified version of the visual world paradigm to explore the online processing of verbs. In their experiment, participants sat before a computer screen displaying several pieces of clip art: for example, a boy, a toy train, a toy car, a birthday cake, and a balloon. Listeners heard the scene described with one of two sentences: "The boy will move the cake," or "The boy will eat the cake." In the first case, multiple objects in the scene satisfied the semantic restrictions of the verb; in the second case, only the cake did so. Altmann and Kamide found that eye movements to the target were launched more rapidly after *eat*-type verbs (where the verb picked out only one object in the array) than after *move*-type verbs (where the verb picked out multiple objects). Looks to the target object were always delayed for *move*-type verbs until after hearing the definite NP *the cake*. These results suggest that semantic restrictions are rapidly available for open-class verbs as well as for closed-class prepositions, and across a range of lexical items.

Like the Chambers et al. (1998) experiment, the Altmann and Kamide study also has some features that limit what we can conclude about the on-line use of semantic restrictions. First, participants in one of their experiments had to indicate (with a button press) whether the sentence matched the visual scene (in half of all trials, the sentence did *not* match the scene). This metalinguistic judgment might have caused participants to process the incoming sentences in a strategic, non-natural fashion, perhaps encouraging them to focus more closely on verb information than they otherwise might have.<sup>1</sup>

More importantly, the two experiments reported in Altmann and Kamide provide conflicting evidence for the use of semantic restrictions to constrain referential domains. If listeners rapidly exploit the semantic restrictions of verbs to constrain the domain of reference, they should spend less time looking at inedible objects following *eat* than following *move*. Their graph of data from Experiment 1 confirms this prediction. But their graph of data from Experiment 2 re-

veals the opposite pattern: Participants spent more time fixating non-target objects after *eat* than after *move*. Further complicating interpretation of their results, Altmann and Kamide include in the category "Other" both non-target objects that meet the restrictions of the verb and non-target objects that do not meet those restrictions. It is therefore impossible to judge whether participants excluded incompatible objects from consideration altogether, as would be predicted by a model in which listeners restrict the referential domain rapidly and incrementally.

In reporting their data, Chambers et al. (1998) separate looks to other containers from looks to non-containers. Their data show some signs of early temporary consideration of the cohort of objects with the appropriate affordances (the target plus the other two containers). However, the proportion of early looks to each of these objects was only slightly greater than the proportion of early looks to an unrelated object. The fragmentation of attention among several objects in the multiple containers condition may have made it difficult to distinguish looks to the competitors from (presumably random) looks to unrelated objects. The precise time-course of referential restriction therefore remains uncertain.

In what follows, we report an experiment on the semantic restrictions of verbs using the visual world paradigm, with multiple lexical items and a condition with a single competitor. In this study, participants acted out spoken instructions like "Now I want you to fold the towel." On half of trials, the array contained just one object with the appropriate affordances (the target). On the other half, it contained both a target and one competitor (in this case, a napkin). Participants also acted out instructions like "Now I'd like you to pick up the towel" with precisely the same manipulation of competitor presence. While some verbs (e.g. *fold*) imposed strong semantic restrictions relative to the scene (picking out just one or two objects), other verbs (e.g. *pick up*) imposed only weak restrictions (potentially picking out all four objects).

Two aspects of our experiment should help to illuminate further both the time course and the causes of rapid referential restriction. First, we separate looks to compatible non-target objects from looks to incompatible non-target objects. Second, we include only one competitor in our trials, making it easier to distinguish looks to the competitor from random looks to unrelated (incompatible) objects in the display.

## Methods

### Participants

Sixteen undergraduates from the University of Pennsylvania participated in this study. They received either course credit or \$6.00. All were native speakers of English and had uncorrected vision or wore soft contact lenses.

### Stimuli

All critical instructions had the form "Now I want you to *verb* the *noun*" (followed in some cases by an additional phrase, such as "into the box"). We chose eight verbs with strong semantic restrictions, and four verbs with weak semantic restrictions (meaning that each weak verb was pre-

<sup>1</sup> Another version of the experiment eliminated the explicit metalinguistic component. But in that experiment, the participants – who did not participate in the prior version – were told that "in this version of the experiment, we aren't asking you to pay any particular attention to the sentences." This allusion to the prior study might have encouraged participants to strategize metalinguistically.

sented twice). As outlined in the Introduction, the experiment had a 2 (Restriction Strength: Strong versus Weak) x 2 (Competitor: Present versus Absent) design. Note that when the verb was Weak, the Competitor acted as such in name only, as the verb lacked the restrictions necessary to pick out a subset of the objects in the array.

Each list contained sixteen target trials; eight with Strong Verbs and eight with Weak Verbs. The design was such that subjects heard each Strong Verb only once, and manipulated each target object only once. The target trials in a list were evenly divided between the four conditions (with four trials per condition); conditions were rotated across lists, resulting in four lists. All trials consisted of two instructions: the critical sentence followed by a second instruction, which asked participants to further manipulate the Target (e.g., "Now I want you to fold the towel. Now cover the box with it").

Target trials were accompanied by sixteen filler trials that used other verbs and involved the manipulation of other objects. Order of target and filler trials within a list was determined by random assignment, with two constraints: first, that there be no more than two consecutive target trials using the same verb type; and second, that critical trials and filler trials alternated. To control for order of presentation, each list was presented in one of two orders, one the reverse of the other.

Prior to each instruction, participants were told to "Look at the cross" (the central fixation point on the table). Instructions were digitally recorded and played from a laptop computer connected to a pair of external speakers. Post experiment interviews revealed that subjects were unaware of the manipulation or intent of the experiment.

## Procedure

Eye movements were monitored with an ISCAN head-mounted eye-tracker. The device had two cameras: One recorded the visual environment from the perspective of the participant's left eye, and the other recorded a close-up image of the left eye. A computer analyzed the eye image in real time, superimposing the horizontal and vertical eye position on the scene image; this composite image was recorded to tape using a frame-accurate digital video recorder. The tracker determined eye position by following the relative positions of the pupil and the corneal surface reflection, thereby canceling out errors in eye position that might result from slippage of the visor. Moreover, because the scene and eye cameras were attached to the visor, tracking accuracy was not affected by movements of the participant's head.

Participants were asked to carry out the instruction as quickly as they could. The entire experiment lasted approximately half an hour.

## Results

The digital videotape of each participant's scene and eye-position was analyzed by using the slow motion and freeze frame viewing on a digital VCR. For each trial, the frame number corresponding to the onset of the spoken instruction was noted. Then, the location and onset time of each successive fixation on an object was recorded by inspecting the video frame images until 1 sec after the offset of the instruc-

tion. Trials were not included in the analysis if the tracking signal became degraded during the critical portion of the sentence, which was defined as lasting from the onset of the verb until 1 sec after the offset of the instruction. Of the 256 trials, 16 (6.25%) were not included in the analyses.

Figure 1 presents the fixation probabilities over time in 33-ms intervals (the sampling rate of the VCR), for the Target (the upper graph) and the Competitor (the lower graph). The data are plotted relative to the onset of the noun, corresponding to zero milliseconds on the X-axis. The onset of the verb occurred an average of 485 milliseconds prior to the noun, and is marked by a vertical bar above the X-axis. The probabilities do not sum to zero because the plot omits the probabilities of fixating the cross or the other two objects. The probability of fixating either the cross or the other two objects did not differ across conditions.

**Figure 1:** Proportion of trials with fixations to target (top) and competitor (bottom).

In the Strong Verb, Competitor Absent condition, there were early looks to the Target (the open circles in the upper graph) and essentially no looks to the Competitor Replacement (the open circles in the lower graph). Early consideration of the Target begins in this condition prior to the onset of the noun, and rises rapidly during the first 250 msec of the noun. By contrast, in the Strong Verb, Competitor Present condition (e.g., when the array contained both a towel and a napkin), looks to the Target (the filled circles in the upper graph) were reduced, as participants temporarily considered the Competitor (the filled circles in the lower graph). Interestingly, participants evenly distributed their early inspection of the scene between the objects that had the appropriate affordances (e.g., the two foldable objects).

Instructions containing Weak verbs (e.g., "pick up") exhibited a different pattern of fixations. Fixations on the Target (the triangles in the upper graph) were delayed until after the onset of the noun. The greatest delay occurred in the Weak Verb, Competitor Present condition (the filled triangles in the upper graph). This time period was marked by some temporary consideration of the Competitor (the filled triangles in the lower graph). This competition presumably reflects minor confusion arising from perceptual similarity between the Target and Competitor. For instance, a few "accidental" looks to the towel ought to be expected upon hearing "napkin" in the instruction "Now I'd like you to pick up the napkin...". Consistent with this explanation, competition in this condition is small and appears after onset of the noun.

### Early Looks to the Target

In order to assess whether early looks to the Target occurred more often in the Strong Verb, Competitor Absent condition than in the other three conditions, we averaged the proportion of time spent fixating the Target during a time slice corresponding to 233 ms after the onset of the verb until 233 ms after the onset of the noun (see Table 1). Because it takes approximately 200-250 ms for the eyes to respond to phonemic input in word recognition studies using this paradigm (e.g., Allopenna, Magnuson, & Tanenhaus, 1998), any significant differences during this portion of the speech are unlikely to be attributable to the perception of the noun (e.g., Allopenna et al., 1998). To test differences, subject and item means were entered into separate Analyses of Variance (ANOVAs) with three factors: Verb Type (Strong, Weak); Competitor (Absent, Present) and Presentation List/Item Group (4 lists in the subject analysis and 4 item groups in the item analysis).<sup>2</sup> These analyses revealed a reliable effect of Verb Type ( $F(1,12)=24.70$ ,  $p<0.001$ ;  $F(1,12)=15.15$ ,  $p<0.005$ ) with Strong verbs showing more early looks to the Target than Weak verbs. There was also a marginal effect of Competitor Presence ( $F(1,12)=3.27$ ,  $p<0.1$ ;  $F(1,12)=3.91$ ,  $p<0.1$ ). There was an interaction between Verb Type and Competitor Presence that was significant in the subject analysis and marginally significant in the item analysis ( $F(1,12)=5.65$ ,  $p<0.05$ ;  $F(1,12)=4.32$ ,  $p=0.06$ ). Simple effects tests showed that Strong verbs had an advantage over Weak verbs when the Competitor was Absent ( $F(1,12)=16.28$ ,  $p<0.005$ ;  $F(1,12)=14.30$ ,  $p<0.005$ ) but not when it was Present ( $F(1,12)=1.64$ ;  $F(1,12)=0.89$ ).<sup>3</sup>

<sup>2</sup> All ANOVAs were conducted on an arcsine transformation of the data, arcsine  $((2*p)-1)$ . This was done to adjust for the fact that the proportion  $p$  is bounded at 0 and 1. ANOVAs conducted on untransformed data yielded similar statistical patterns.

<sup>3</sup> For looks to Target only, there were some uninterpretable interactions with the List factor.

**Table 1A:** Proportion of Looks to the Target

Time Slice 1: (Verb + 233ms) to (Noun+233ms)		
	Competitor Present	
	YES	NO
Strong Verb	0.07	0.17
Weak Verb	0.05	0.04

Time Slice 2: (Noun + 233ms) to (Noun+767ms)		
	Competitor Present	
	YES	NO
Strong Verb	0.39	0.56
Weak Verb	0.29	0.44

**Table 1B:** Proportion of Looks to the Competitor

Time Slice 1: (Verb + 233ms) to (Noun+233ms)		
	Competitor Present	
	YES	NO
Strong Verb	0.09	0.01
Weak Verb	0.03	0.01

Time Slice 2: (Noun + 233ms) to (Noun+767ms)		
	Competitor Present	
	YES	NO
Strong Verb	0.16	0.00
Weak Verb	0.09	0.03

### Early Looks to the Competitor

Similar ANOVAs were conducted on the mean proportion of early looks to the Competitor during this time slice (see Table 1). As can be seen in the table, most looks to the Competitor occurred in the Strong verb condition when the Competitor was Present. The analysis revealed a reliable interaction between Competitor presence and Verb Type ( $F(1,12)=7.97$ ,  $p<0.05$ ;  $F(1,12)=18.99$ ,  $p<0.005$ ), a marginal effect of Competitor Presence ( $F(1,12)=3.98$ ,  $p<0.07$ ;  $F(1,12)=9.79$ ,  $p<0.05$ ) and no effect of Verb Type ( $F(1,12)=3.25$ ;  $F(1,12)=3.06$ ). Simple Effects showed an effect of Verb Type when the Competitor was Present ( $F(1,12)=6.50$ ,  $p<0.05$ ;  $F(1,12)=10.16$ ,  $p<0.01$ ) but not when it was Absent ( $F(1,12)=2.77$ ;  $F(1,12)=2.87$ ).

To assess any preference for looking at the Target over the Competitor during this time slice, two-tailed t-tests on subject and item means were done comparing looks to the Target with looks to the Competitor. To avoid Type I errors, we corrected for the number of tests by dividing the alpha by four. As expected, the only reliable difference arose in the Strong Verb, Competitor Absent condition, where there were significantly more looks to the Target than to the Competitor Replacement (e.g., a Coke can) ( $t(15)=3.48$ ,  $p=0.003$ ;  $t(15)=3.96$ ,  $p=0.001$ ).

### Later Looks to the Target.

We also quantified looks to the Target and Competitor in a second time slice, corresponding to approximately 500 ms after the first time slice (i.e., from 233 ms after the onset of the noun until 767 ms after the onset of the noun; see Table

1). Differences in this region are more likely to be affected by the perception of the target noun phrase. ANOVAs revealed a main effect of Competitor Presence ( $F(1,12)=10.71$ ,  $p<0.01$ ;  $F(1,12)=11.60$ ,  $p<0.01$ ), with more looks to the Target when the Competitor was Absent. In addition, there was a marginal effect of Verb type ( $F(1,12)=9.15$ ,  $p<0.05$ ;  $F(1,12)=3.91$ ,  $p<0.08$ ) with more looks to the Target when the sentence contained a Strong verb. There was no interaction between these factors ( $F_s<1$ ).

### Later Looks to the Competitor

ANOVAs on the mean proportion of time spent looking at the Competitor in this region revealed a main effect of Competitor ( $F(1,12)=11.48$ ,  $p<0.01$ ;  $F(1,12)=39.10$ ,  $p<0.001$ ), no effect of Verb Type ( $F(1,12)=0.38$ ;  $F(1,12)=1.52$ ) and a weak interaction between these factors that was significant only in the item analysis ( $F(1,12)=2.72$ ;  $F(1,12)=6.64$ ,  $p<0.05$ ).

### Discussion

We have presented evidence that the semantic restrictions of verbs become available rapidly enough during comprehension to permit listeners to make predictions about the likely reference of the upcoming direct object. Participants looked more rapidly at the referent of the direct object when the verb had Strong restrictions than when it had Weak ones. For instance, they looked more rapidly at the towel when told to fold it than when told to pick it up. When the scene included a second foldable object, the use of a Strong restrictions verb resulted in early temporary consideration of this second object, which competes with the target object. This pattern replicates the one reported both by Chambers (1998) and by Altmann and Kamide (1999), with several improvements: We used multiple lexical items, a task less likely to induce listener strategies<sup>4</sup>, and a single competitor. The last improvement allowed us to show that listeners rapidly eliminated incompatible non-target objects from consideration.

While it seems clear that semantic restrictions are rapidly available for referential restriction, the precise mechanism of this restriction remains unclear. There are two explanations for the source of this restriction. Listeners might launch eye movements after hearing a strongly constraining verb because they have already assessed the properties of the objects in the display and recognize that only a subset of those objects is compatible with the verb's restrictions. By con-

trast, listeners might launch eye movements simply because a strongly restricting verb is more likely than a weakly restricting *in any context* to pick out a unique referent (or subset of referents). We will refer to these possibilities as *affordance matching* and *informativeness*, respectively. In fact, the notion of informativeness has been quantified in recent computational theorizing by (Resnik, 1996), who also provides evidence that verb informativeness has very real psycholinguistic consequences.

These two possibilities make different predictions about the likelihood of launching an eye movement just after hearing the verb. If listeners actively match affordances, they should launch eye movements as soon as they determine that one or more objects in the scene satisfy the restrictions of the verb. Thus, they should be equally likely to launch eye movements following a weak verb as following a strong verb, because in both cases, at least one object in the array satisfies the restrictions of the verb; in both cases, interrogation of the array can begin immediately. If, on the other hand, eye movements are triggered by a verb's informativeness, listeners should be more likely to launch eye movements following a strongly constraining verb than following a weakly constraining one, as informative verbs carry enough information to identify their direct objects, whereas weakly informative verbs do not.

To test between these possibilities, we examined the proportion of fixations on any object in two time slices: from 233 ms after the onset of the verb until 233 ms after the onset of the noun, and from 233 ms after the noun to 767 ms after the noun (the same slices used in the analyses presented in the Results section). As Table 2 indicates, listeners were more likely to launch a fixation to any object following a Strong verb than following a Weak verb. In Time Slice 1, the effect of verb type was reliable in the subject analysis, and marginal in the item analysis ( $F(1,12)=9.71$ ,  $p<0.01$ ;  $F(1,12)=4.36$ ,  $p<0.06$ ). In Time Slice 2, the effect of verb type was reliable in both analyses ( $F(1,12)=8.28$ ,  $p<0.02$ ;  $F(1,12)=7.96$ ,  $p<0.02$ ).

**Table 2:** Proportion of looks to any object

Time Slice 1: (Verb + 233ms) to (Noun+233ms)		
	Competitor Present	
	YES	NO
Strong Verb	0.22	0.22
Weak Verb	0.16	0.12
Time Slice 2: (Noun + 233ms) to (Noun+767ms)		
	Competitor Present	
	YES	NO
Strong Verb	0.60	0.63
Weak Verb	0.46	0.52

While these data are somewhat preliminary, they suggest that a verb's informativeness, independent of context, contributes to the speed with which listeners can compute the domain of reference of upcoming constituents. Because a Strong verb is highly informative about its upcoming direct object, listeners can begin to interrogate the visual scene for

<sup>4</sup> It is of course possible that listeners in our task developed strategies that resulted in them unnaturally focusing on particular classes of information (see Tanenhaus & Spivey-Knowlton, 1996 for a discussion of this issue). However, if strategies were developed to use verb restrictions, we might expect their effects to emerge over the course of the experiment. We tested this possibility in two ways. We inspected the first half of the trials in the experiment, and we inspected the first of paired items in the experiment. In both cases, the pattern of eye movements was similar to the overall pattern, i.e., early looks to the Target in the Strong Verb Competitor Absent condition, and some early looks to the Competitor in the Strong Verb Competitor Present condition.

an object with the appropriate affordances before they have heard the noun phrase.

Whether early eye movements are driven by informativeness or affordance matching, it is clear that verb meanings can be accessed rapidly enough to make predictions about the reference of an upcoming direct object, and to constrain the set of entities to which the direct object might refer. The current findings contribute to a growing body of data that support a view of semantic interpretation as both incremental and predictive. Words not traditionally thought to carry reference – prepositions (Chambers et al., 1998), adjectives (Sedivy et al., 1999), and verbs (Altmann & Kamide, 1999, the present study) – can be exploited by listeners to predict the reference of upcoming nouns. Indeed, the linking of speech to a mental model of the world appears to be an active, continuous process.

## Abstract

Usage of discourse markers in tutorial language can make the difference between stilted and natural sounding dialogue. In this paper we describe some simple rules for selection of discourse markers. These rules were derived for use in an intelligent tutoring system by applying decision-tree machine learning to human tutoring language. The fact that these selection rules operate within the environment of an intention-based planner encouraged us to derive our decision tree partly based on intention-based features. The resulting tree, when applied to the generation task, is relatively easy to understand because it can be referred to traditional intention-based linguistic explanations of discourse marker behavior.

## Introduction

CIRCSIM-Tutor (CST) is a natural language-based intelligent tutoring system that engages the student in Socratic-style dialogue. The goal of the CST project is to imitate fluent simplified human tutoring language, both in the choice of tutorial dialogue strategies and in the use of language.

One feature of fluent dialogue is the use of discourse markers such as “so,” “and,” and “now,” which often occur at structural boundaries in the discourse. Discourse markers, also known as cue words, have as many different descriptions as people describing them. In Grosz and Sidner's (1986) procedural description of discourse, discourse markers flag changes in both attentional and intentional state. In Rhetorical Structure Theory, discourse markers mark rhetorical relations between segments (Mann and Thompson, 1988). The grammar of Quirk et al. (1985, pp. 632 *ff*) subsumes most discourse markers within conjunctions. Stenstrom's (1994) manual on analyzing

discourse emphasizes their use as marking boundaries of topics and digressions and describes them in concert with interpersonal “interactional signals.” Schiffrin (1987) provides a detailed accounting of the behavior and purpose of eleven discourse markers without being tied to a particular theory of discourse or syntax. Schiffrin also provides an operational definition of discourse markers, giving evidence that discourse markers have functions such as aiding coherence and cohesion in text. Halliday and Hassan (1976) in their book on cohesion describe the function of quite a number of discourse markers in detail.

Recently there have been attempts to describe the behavior of discourse markers in computationally useful ways by applying methods of machine learning and corpus linguistics. Litman (1996) devised rules for distinguishing between semantic and structural uses of discourse markers in transcribed speech. In sharp distinction to the more traditional linguistic accounts, the rules are based largely on observable features such as the length of phrases, preceding and succeeding cue words, and prosodic features. Moser and Moore (1995) divided instructional dialogue into discourse segments and coded various relationships between them according to Relational Discourse Analysis, which combines Grosz and Sidner's type of analysis with Rhetorical Structure Theory. They derived rules for a number of aspects of discourse marker usage, including placement and occurrence vs. omission. Di Eugenio, Moore, and Paolucci (1997) studied the same dialogues toward similar ends. Nakano and Kato (1999) studied Japanese instructional dialogue, using machine learning to derive rules for occurrence of three categories of discourse markers. They divided their text into segments in the same manner as RST, but also coded the instructional goals for

each segment in addition to coding the kinds of features used in previous studies.

The addition of instructional goals in Nakano and Kato's study is important to the CIRCSIM-Tutor project, and should be encouraging from the standpoint of trying to generate (as opposed to analyze) instructional dialogue. One reason is that instructional goals proved to be explanatory. A common feature of the machine learning studies is that the text is coded for a large number of features, of which only a few are incorporated by the machine learning process into the eventual rules or decision tree. In Nakano and Kato's study instructional goals were so incorporated, meaning that they were more explanatory than many of the other features. This is congruent with non-corpus-based linguistic theories that explain discourse markers in terms of the speaker's intentions.

The speaker's intentions are rarely explicit in text; for purposes of analysis intentions are divined by coders. However when the machine tutor is generating dialogue, the machine speaker's "intentions," i.e. the tutorial goals, can be given in the form of planning goals, see for example (Young, Moore & Pollack, 1994). Nakano and Kato have shown that having the tutorial goal structure in hand can potentially lead to better discourse marker selection.

In this paper we use attribute-based machine learning of decision trees, specifically the C4.5 algorithm (Quinlan, 1993), to investigate discourse marker selection. We make use of both structural features and aspects of the sequence of tutorial goals—the "intention" of the machine tutor. Although we learn rules from transcripts of human dialogues, we concentrate on features that are available within the CIRCSIM-Tutor generation environment.

The machine tutor does not reason about rhetorical relations such as are usually used to explain discourse markers. Instead it has planning goals that produce schemata containing patterns of dialogue. These schemata define the dialogue segments. Rhetorical relations are implicit in the patterns, so it is possible to relate goal-structure explanations of discourse markers to the rhetorical relation-based theories.

## The Experiment

We recorded the features surrounding instances of discourse markers in human tutorial dialogue, then derived a decision tree to predict discourse marker selection.

The users of CIRCSIM-Tutor are medical students in a first-year physiology class studying the reflex control of blood pressure. Students are required to predict the changes in a set of physiological variables, after which the tutor endeavors to elicit corrected predictions via Socratic-style dialogue, asking questions and giving hints. CST's conversation can be largely segmented into the correction of individual variables.

The CIRCSIM-Tutor project has transcripts of one- and

two-hour keyboard-to-keyboard tutoring sessions between physiology professors and medical students. Our construction of the computer tutor's planning operators and tutorial language is informed by these transcripts. The transcripts were previously marked up with tutorial goals and language phenomena for this purpose (Kim, Freedman & Evens, 1998a, b; Freedman et al., 1998; Zhou et al., 1999). Tutorial goals consist of global goals for tutoring and local goals for maintaining coherence of dialogues. The global goals used in this study are hierarchically arranged into *method* and *topic* levels. A *method* goal describes one way to remediate a student's incorrectly predicted physiological variable. Within one method, a sequence of *topic* goals describes individual concepts to be expressed. A topic can be expressed by either telling the information to the student or eliciting it from the student. A typical dialogue pattern for the correction of one individual variable is as illustrated in Figure 1. The sequence of tutorial goals is as follows:

- The variable to be corrected is introduced into the conversation.
- Various topic goals are realized by telling them to the student or eliciting them from the student.
- The corrected prediction is elicited from the student.

The discourse markers we study in this paper occur at the boundaries between topic goals, as shown in italics in Figure 1. We are concerned with the selection of these discourse markers in human tutorial dialogues in order to generate them correctly. Placement of discourse markers is not an issue, we ignore discourse markers which occur elsewhere.

It will be noted that in our dialogues the junctures between topic goals do not always coincide with the turn boundaries; in fact in our illustration one topic is spread among three turns and one turn encompasses parts of three topics. One typical tutor turn contains:

- An optional acknowledgment of the student's answer
- Possibly an elaboration on that answer
- Possibly some new information
- A question or instruction to the student

(Freedman & Evens, 1996)

The context of a discourse marker therefore includes not only the structure of topic goals, but also information from the turn structure. Preceding the first discourse marker in a tutor's turn is a possible tutor's acknowledgment to the student and possibly some elaboration. Furthermore there is the student's immediately preceding turn, which usually consists of the answer to the tutor's previous question. Some examples of these features, including our characterization of the correctness of the student's answer, are also annotated in Figure 1.

The human transcripts also contain dialogue that is too complex for us to mark up according to our goal hierarchy

and is therefore excluded from our sample.

We further restricted ourselves to exchanges where the student gave answers that were correct or “near misses.” A near miss is a student answer that is true but not expected, and can be repaired without contradicting the student (Zhou et al., 1999). In the dialogue in Figure 1, the tutor repaired the student’s overly specific answer by echoing back the more general answer. Sometimes the tutor temporarily suspends the current topic goal and interpolates a tutoring schema to repair the unexpected answer. In that case the goal hierarchy would show an inner sequence of topic goals devoted to remediating one outer topic. These instances are included in our sample. The tutor’s responses to incorrect student answers (as opposed to near misses) are too varied for us to obtain any regularities in discourse marker usage, so we excluded them.

We extracted instances of the discourse markers “and,” “so,” and “now” because these are the most frequently used ones in our transcripts. Each instance consists of the context around one discourse marker coinciding with a topic change, coded for the following five attributes:

- Category of the student’s answer preceding the marked topic boundary: correct, near miss, or N/A. The N/A case occurs when the tutor covers several topics within one turn, so the topic preceding the discourse marker does not contain a student answer.
- Presence or absence of acknowledgment preceding the topic boundary: ack, no-ack, N/A.
- Discourse marker: “and,” “now,” “so.”
- Position within the sequence of topic goals of the topic following the discourse marker: introduce, initial, middle, or final.
- Presentation of the topic following the discourse marker: inform or elicit.

Thus the sentence “and the reflex hasn’t started to operate yet” from turn 3 of Figure 1 is coded as:

- Student’s answer category = “near miss”
- Acknowledgement = “present”
- Discourse marker = “and”
- Position in sequence = “middle”
- Type of presentation = “inform”

We supplied 60 cases of these feature-annotated discourse marker occurrences to the C4.5 machine learning program. It produced the following rules for selection of the discourse marker:

- If the topic position is introduce then use “now”
- If the topic position is middle then use “and”
- If the topic position is final then use “so”
- If the topic position is initial  
and if the presentation is inform then use “so”  
else {presentation is elicit} use “and”

These rules misclassified 8 of the 60 cases, for an error rate

of 13.3%.

These rules describe our expert tutors’ linguistic behavior, predicting which discourse marker will be selected in certain contexts. We start with this description in order to produce rules for text generation.

## Discussion

Most of the predictions of the derived rules can be explained by existing discourse marker theories. The “now” on the introduction topic is consistent with the explanation by Grosz and Sidner (1986) of marking an attentional change, creating a new focus space of salient objects and topics. Schiffrin (1987, p. 230) says “...‘now’ marks a speaker’s progression through discourse time by displaying attention to an upcoming idea unit.” In fact, this reading of “now” explains some of the cases of “now” that are misclassified by the derived rules. These are cases where the tutor does not explicitly utter an introduce topic at the beginning of the segment, with the result that the attention-shifting “now” is attached to the initial topic. Here is one example:

Now, what two parameters in the prediction table together determine the value of SV?

Although the derived rules misclassify our marked-up transcripts in these cases, for the purpose of generating sentences in the machine tutor this is a useful discovery. The intention to shift tutoring to a new variable is available in CIRCSIM-Tutor’s tutorial goal structure, even if not always expressed in text, so the text generator can plausibly know to emit “now.”

Most of the remaining predictions of the derived rules can be explained by existing discourse marker theory. Shiffrin (1987) and Halliday and Hassan (1976) and Quirk et al. (1985, p. 638) all describe “so” as indicating a result. In our derived rules, the “so” attached to the final topic is used in this fashion. The final sentence of turn 3 in Figure 1 illustrates this point.

When the rules predict “so” attached to the initial topic it has a different role. It is found in what we call the *present-anomaly* tutoring method used to point out the inconsistent appearance of reported facts, viz:

So, in DR heart rate is up, cardiac output is up, but stroke volume is down. How is this possible?

This “so” is explained by Halliday and Hassan as “a statement about the speaker’s reasoning process” meaning it is logical to be having this thought right now.

The discourse marker “and” usually occurs on medial topics to “coordinate and continue” the topics (Schiffrin, 1987, p. 152), and needs no explaining. The discourse marker “and” occurring on the initial topic seems anomalous, but it occurs in the context of a tutorial schema we call *move forward*. This schema attempts to persuade the

student of the correct value of a new physiological variable based on the result of the immediately preceding discussion of a different variable. Here is an example:

Tu: ...That being the case, what will happen to right atrial pressure in this situation?

St: Increase.

Tu: *And* if right atrial pressure increases, what would happen to stroke volume?

In this example, the final topic in the first segment occurred when the student produced the correct value for right atrial pressure. The tutor skipped introducing the next variable, stroke volume, and proceeded directly to the initial topic of the tutoring schema for its correction, which moves forward in causal physiological reasoning from the final topic in the preceding segment. In this case “and” is warranted, it would seem that “so” would be equally appropriate. This is another instance where the CIRCSIM-Tutor text generator makes use of the discourse goal being processed. Even though tutoring of a new variable usually starts with the discourse marker “now,” when the new variable is taught by the *move forward* method goal then the generator emits “and” instead.

Except for the initial discourse marker (usually “now”) at the beginning of a tutoring method schema, it is possible to apply to our own data Di Eugenio et al.’s (1997) discoveries relating rhetorical structure to discourse marker occurrence. Although we did not perform any rhetorical structure analysis on our texts, most of our method schemas fit one of their patterns, as described next.

Here is an idealized realization of a typical CIRCSIM-Tutor method schema for teaching a variable, called *tutoring via determinants*:

Tu: What are the determinants of cardiac output?

St: Heart rate and stroke volume.

Tu: And what is the relation of stroke volume to cardiac output?

St: Direct.

Tu: And we have already seen that heart rate is unchanged. So what happens to cardiac output?

St: It goes up.

In order to analyze this in terms of rhetorical relations, we write down all the propositions in the sequence they occur as if it were a monologue, thereby exposing the argument in simplest form. Since the intention of each of the tutor’s questions is to cause the student to believe the corresponding assertion, we think this is a reasonable model.

- a) The determinants of cardiac output are heart rate and stroke volume,
- b) And stroke volume affects cardiac output directly,
- c) And heart rate is unchanged,
- d) So cardiac output goes up.

In the terms of Relational Discourse Analysis, proposition d) is the *core* while a), b), and c) are *contributors*. The intentional relationship between each contributor and the core is *convince*. In fact, most of our methods have the same structure: the core is the last statement, where the value of the variable is finally understood, and the contributors all argue for the truth of the core. In (Di Eugenio et al., 1997) these relations are all analyzed in the “core2” class, meaning that the core follows the contributor in the text. Their decision tree on discourse marker occurrence yields a simple answer for these cases: the discourse marker should ordinarily appear.

## Conclusions

We have applied decision tree learning to transcripts of expert tutors in order to learn rules that predict discourse marker selection. Our purpose in this endeavor is not to find rules for analyzing texts, but to produce rules for text generation in CIRCSIM-Tutor. Discourse marker usage has traditionally been explained partly in terms of the intention of the speaker and partly in terms of the rhetorical structure of the text. Neither is explicit in transcripts of discourse, but must be imputed by researchers before analyses of discourse markers can proceed. Recent work in using machine learning to explain discourse marker usage has thus shied away from using intention-based explanations.

However within the context of the machine tutor the generation algorithm has access to the speaker’s intentions. In CIRCSIM-Tutor these intentions are the pedagogical goals. The structure of these goals implies the rhetorical structure of the text to be generated. So without explicit reasoning in the rhetorical terms that usually explain discourse markers, simply examining the current goals enables the text generator to select the correct discourse marker.

Our machine-derived decision tree analysis of discourse marker selection is quite successful. The features that drove the machine learning process included the same pedagogical goal analysis as is used by the machine tutor. The decision tree that results was examined by hand; where it incorrectly predicts observed data the decisions can be enhanced by applying traditional linguistic explanations. The fact that this decision tree is intention-based enables us to correlate it to existing linguistic descriptions of discourse marker usage.

## Acknowledgments

# Are Structural Principles Useful for Automatic Disambiguation ?

**Alexandra Kinyon** (Alexandra.Kinyon@linguist.jussieu.fr)  
TALANA-Université Paris 7 / CIS Dpt University of Pennsylvania  
Case 7003 2 Pl Jussieu 75005 Paris. France

## Abstract

In this paper we discuss how structural Preferences can be expressed within an LTAG framework on dependency like structures. We argue that the use of psycholinguistically motivated criteria is useful for building practical parse-ranking applications.

## Introduction

On the one hand computational linguists aim at parsing real texts : it is a difficult task, essentially because of spurious ambiguity. The goal is then to find a single preferred overall analysis for each sentence, either by resorting to general principles or to statistical methods, most of the time by focussing on the efficiency of the technique used, rather than on its theoretical relevance. So most of these disambiguation techniques do not take into account theoretical (i.e. cognitive) relevance, especially the incremental nature of human sentence processing.

On the other hand, psycholinguists aim at modeling the very early preferences which people employ in ambiguity resolution during an incremental parse of a sentence, without being concerned with the development of wide-coverage parsing systems or the integration of their principles in wide-coverage grammars. Importantly, these early decisions that people make may or may not eventually be compatible with the overall analysis of the sentence.

In this paper we argue that the two approaches are not antagonistic : wide-coverage disambiguation systems can integrate psycholinguistically motivated principles and yet be efficient. We present structural preferences which are expressed on dependency structures instead of constituent trees, within the framework of Lexicalized Tree Adjoining Grammars (LTAGs). In the first part of this paper, we briefly introduce the LTAG formalism. Then we present the preference principles used, and show that they work well in practice on large data. In a third part, we show why "pure" lexicalist approaches seem insufficient. In a fourth part, we discuss the interaction between our preference principles.

## 1. Brief overview of LTAGs

A LTAG consists of a finite set of **elementary trees** of finite depth. Each elementary tree must "anchor" one or more lexical item(s). The principal anchor is called "head", other anchors are called "co-heads". All leaves in elementary trees are either "anchor", "foot node" (noted \*) or

"substitution node" (noted  $\downarrow$ ). These trees are of 2 types : **auxiliary** or **initial**<sup>1</sup>. An auxiliary tree has exactly one distinguished leaf, called "foot node" and marked \*. Trees that are not auxiliary are initial. Elementary trees combine with 2 operations : **substitution** and **adjunction**. Substitution is compulsory and is used essentially for arguments (subject, verb and noun complements). It consists in replacing in a tree (elementary or not) a node marked for substitution with an initial tree that has a root of same category. Adjunction is optional (although it can be forbidden or made compulsory using specific constraints) and deals essentially with determiners, modifiers, auxiliaries, modals, raising verbs (e.g. seem) and sentential complements (e.g. object sentential complements). It consists in inserting in a tree in place of a node X an auxiliary tree with a root of same category . The descendants of X then become the descendants of the foot node of the auxiliary tree. Contrary to context-free rewriting rules, the history of derivation must be made explicit since the same derived tree can be obtained using different derivations. This is why parsing LTAGs yields a **derivation tree**, from which a **derived tree** (i.e. constituent tree) can be obtained. Figure 1 shows the elementary trees anchored when parsing "Yesterday John kicked the bucket"<sup>2</sup>, as well as the derivation trees obtained both for the "literal interpretation" and for the "idiomatic interpretations" of the sentence. It also shows that both derivation trees yield the same derived tree<sup>3</sup>. The derivation tree is close to a dependency structure (cf Candito & Kahane 98).

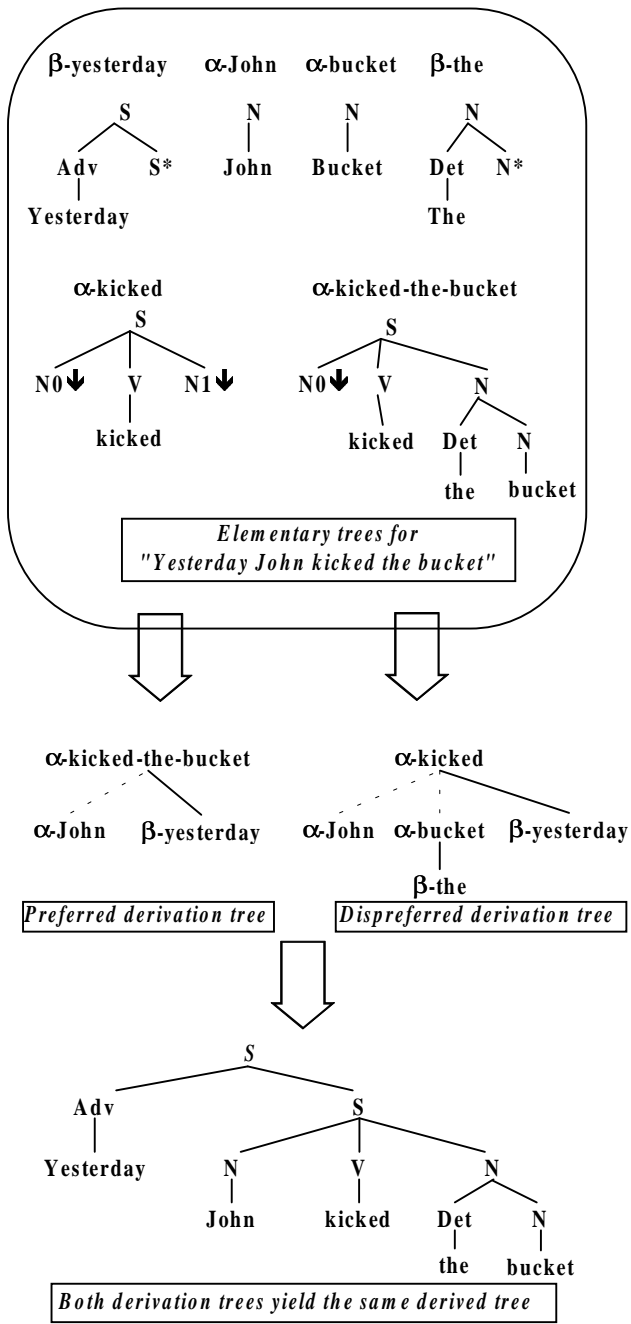

Moreover, linguistic constraints on the well-formedness of elementary trees have been formulated (Abeillé 91) (Frank 92) :

- Predicate Argument Cooccurrence Principle : there must be a leaf node for each realized argument of the head of an elementary tree.

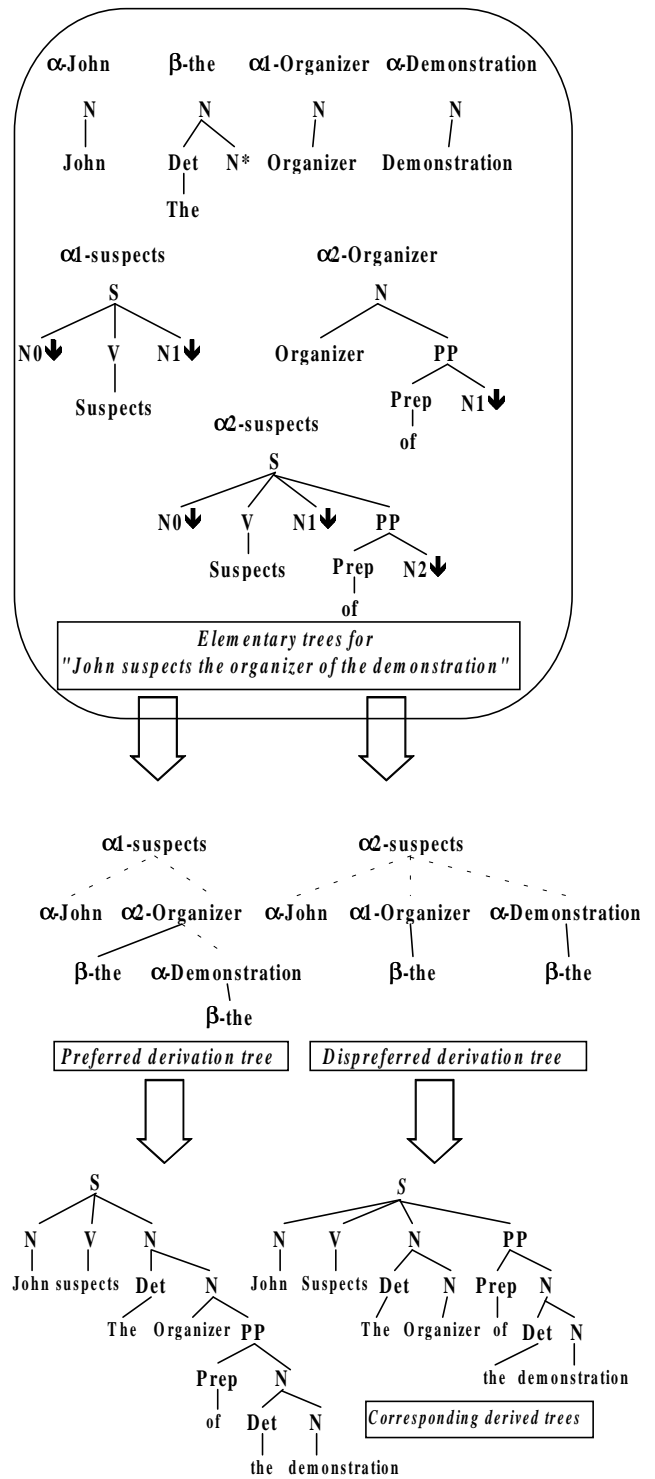

<sup>1</sup> Traditionally initial trees are called  $\alpha$ , and auxiliary trees  $\beta$

<sup>2</sup> All our examples follow linguistic analyses presented in [Abeillé 91]. Thus we use no VP node and no Wh nor NP traces. But this has no incidence on the application of our preference principles.

<sup>3</sup> Dotted lines in derivation trees indicate a substitution, plain lines an adjunction. The number at each node represents the address at which the operation took place, following Gorn convention.

**FIGURE 1 : Illustration of LTAG and of Principle 1**

**FIGURE 2 : Illustration of Principle 2**

- Semantic consistency : No elementary tree is semantically void
- Semantic minimality : an elementary tree corresponds at most to one semantic unit

## 2. Three preference principles expressed on derivation trees

A vast literature, going back as early as (Kimball 73), addresses structural parsing preferences. Older principles, such as right association (RA) and minimal attachment (MA) have been criticized : Among other things, the interaction between these principles is unclear. These principles lack provision for integration with semantics and/or pragmatics (Schubert (84)), do not clearly establish the distinction between arguments and modifiers<sup>4</sup> (Ferreira & Clifton (86)) and are English-biased : evidence against RA has been found for Spanish (Cuetos & Mitchell (88)) and Dutch (Brysbaert & Mitchell (96)). Newer structural principles, on the other hand, such as "Attach anyway" (Fodor & Inoue 98), are not integrated nor implemented into wide-coverage grammars.

So, to account for widely accepted preference principles, which are difficult to formulate in terms of constituents trees (idiomatic interpretation of a sentence favored over its literal interpretation (Abeille 95) (Gibbs 85) (Gibbs & Nayak 89)., arguments favored over adjuncts (Abney 89), (Britt & al. 92) and attachment to closest potential governor), (Kinyon 99a) has formulated the three following principle on dependency-like structures within the LTAG framework :

- 1-Prefer the derivation tree with the fewer number of nodes
- 2-Prefer to attach an  $\alpha$ -tree low in a derivation tree
- 3-Prefer the derivation tree with the fewer number of  $\beta$ -tree nodes<sup>5</sup>

A discussion on the linguistic adequacy of these principles, as well as on why LTAGs are better than other lexicalized formalisms such as LFG to formulate these principles can be found in Kinyon (99b).

Principle 1 accounts for the preference we have for the idiomatic interpretation of a sentence. In LTAGs, all the set elements of the expression are present in a single elementary tree. We have shown in Figure 1 the derivation trees obtained when parsing "Yesterday John kicked the bucket". The derivation tree for the idiomatic interpretation, which is preferred, has fewer nodes than the derivation tree for the literal interpretation..

<sup>4</sup> It is argued that MA and RA do distinguish arguments from modifiers, since arguments will yield a constituent tree with fewer nodes, but this relies very heavily on the underlying syntactic framework : it may be true for an X-bar theory, not necessarily for a more "surfastic " theory of syntax.

<sup>5</sup> This principle was initially presented in (Srinivas & al 95), formulated as "prefer to substitute rather than to adjoin".

Principle 2 captures the preference for an argument to attach to its closest potential governor. So in (a1), "of the demonstration" is preferably attached to "organizer" rather than to "suspect". Similarly, in (a2), "To whom" attaches to "say" rather than to "gives". Figure 2 shows how principle 2 yields the preferred derivation tree for sentence.(a1).

- (a1) John suspects the organizer of the demonstration
- (a2) To whom does Mary say that John gives flowers

Finally, principle 3 accounts for the preference of arguments over adjuncts. So it will allow to retrieve the right attachment in (b1), where "le matin" (the morning) is argument of "regarde" (watches) rather than modifier. It also allows to retrieve the correct attachment in (b2) where "to be honest" is argument of prefer, rather than sentence modifier.

- (b1) Jean regarde le matin (John observes the morning / John watches in the morning)
- (b2) John prefers his daughter to be honest

These principles are easy to implement, so they have yielded practical results<sup>6</sup> : A parse-ranker has been implemented for French within the FTAG project (cf Abeille & al 99,00), using a semi-automatically generated wide coverage grammar of 5000 elementary trees (Candito 96). This parse ranker, tested on 1000 TSNLP sentences, allows to go down from 2.85 derivations trees / sentence to 1.4 derivation trees / sentence without degrading the quality of parsing (i.e. without discarding "correct" parse trees). These results hint that the three principles are well-motivated from a cognitive point of view. This parse ranker is currently being ported to English and tested on the WSJ.

It is important to note that the distinction between arguments and modifiers can be easily expressed within LTAGs, because in derivation trees elementary trees for arguments are essentially initial ( $\alpha$ ), while elementary trees for modifiers are auxiliary ( $\beta$ ).

It is also important to note that (contrary to RA) these structural preferences are language independent, again because they are formulated on dependency-like structures and not on constituent structures : we have just seen that they work well for French, although French is argued to be an "early closure" language (Zagar & al 97).

## 3. Antagonism with lexicalist approaches ?

It has been shown that humans do exhibit frequency effects in language comprehension (Truwell 96), but this does not mean that structural principles are unsound and especially it does not demonstrate that disambiguation systems should resort only to "pure" lexicalist approaches :

One argument against the structural principles presented in 3 would be to say that these structural principles do not

<sup>6</sup> We do not claim, however, that these principles have yielded better results in automatic disambiguation than statistical parsers which integrate lexical information (e.g. Collins 96). Clearly though, our technique is easier to put to use, esp. for languages for which no training data is available.

exist (i.e. are not observable once frequency effects are taken into account). We disagree for the following reasons :

If the use of such principles was just a mere approximation, it would make it hard to explain that the empirical results are so good. Pure lexicalist approaches have not yielded such results to our knowledge on large real-world data (very little data about lexical preferences are available on a large scale esp. for languages other than English).

Also, lexicalist approaches do not allow to explain how two preferred subcategorization frames interact. For example, if "suspect N of N" and "organizer of N" are two preferred realization frames for respectively "suspect" and "organizer", one still needs to account for the fact that "demonstration" will be attached to "organizer" rather than to "suspect" in "John suspects the organizer of the demonstration"<sup>7</sup>. With the same type of reasoning, although "put N in N" is a common realization frame for arguments of "put", the sentence (c) nonetheless seems incomplete. This can also not be accounted for with a pure lexicalist approach

(c) I've put the book that you were reading in the library

Moreover, lexicalist approaches also do not necessarily account for unknown words<sup>8</sup> : in a sentence like (d) "at the man" will most likely be preferred as argument of "plups" rather than modifier, although we know nothing about the preferred subcategorization of "plups". So when considering language acquisition, unknown words are still processed, although no data is available regarding the preference of realization of their arguments. Structural preferences thus appear as a much more economical way to acquire new words : here "at the man" is argument of "plups" so "plups" subcategorizes a PP introduced by "at", whereas if one had to rely on frequency effect, it would take much longer to encounter "plups" many times before formulating a hypothesis about its subcategorization, and verifying it. Also, resorting to very few structural preferences for disambiguation seems much more economical and practical than storing huge quantities of frequency information about the lexicon, especially since contrary to structural preferences, information on the lexicon has to change from language to language.

(d) He plups at the man

Finally, to oppose lexicalist approaches and support the structural principles presented in 3, (Kinyon 00) formulated the following hypothesis :

Regardless of which realization of arguments a verb favors, if it can subcategorize a PP introduced by a given Preposition P, then in practice when the verb and a PP introduced by P appear in the same sentence, the PP is either an argument of the verb, or in a position where it can not be argument (i.e. argument of a closer potential governor, or located

in another clause such as inside a relative, or modifier only if the verb is already saturated).

This hypothesis was validated on LeMonde, a one million words annotated and shallow-parsed corpus for French (Clément & Kinyon 00, Abeillé & al 00b). The 100 most frequent verbs were extracted. 56 of these verbs could subcategorize PPs introduced by one or several prepositions, for a total of 71 subcategorization frames. Then, for each of these subcategorization frames, all the sentences where Verb and Prep co-occur were extracted and examined manually. The main findings are the following :

1- Cases of possible ambiguous attachment remain (13.86 % of the sentences examined)

2- 39% of these ambiguous cases are solved when attaching the PP to the closest potential governor. Moreover, the attachment is deemed correct in all cases.

3- The probability for a verb to realize as an argument a PP introduced by a given Preposition P does not help disambiguation and does not predict the proportion of ambiguous attachments encountered when examining sentences where Verb and P co-occur.

4- Rather, the preposition itself is important : "à" yields much more ambiguity than other prepositions such as "avec" or "pour" because it often introduces a temporal or locational expression (e.g. "à l'assemblée nationale" (*in parliament*) / "à 3 heures" (*at 3 o'clock*)). In fact, 46% of the ambiguous cases remaining after applying structural principles 2 and 3 are solved by resorting to very simple semantic information : à + location nouns , à + time nouns are overwhelmingly adjuncts and not arguments.

Therefore, only 4.6 % of ambiguous attachments remain (mainly set phrases such as "lancer un appel au calme"), which could be disambiguated by refining semantic disambiguation. Thus the hypothesis is validated, which indicates that the use of structural principles + basic semantic information allows very efficient disambiguation and again, in a more economical manner than lexical approaches.

As discussed in (Kinyon 99b) though, some lexical preferences seem useful, but formulated not at the level of lexical items, but rather at the level of parts of speech. So for instance, grammatical categories are preferred over lexical categories. So in (e1) clitic will be preferred over noun for "elle", in (e2) "être" (be) will be an auxiliary rather than a lexical verb, and in (e3) "deux" will be a determiner rather than a noun. General lexical preferences of this type have been incorporated in the parse-ranker discussed in 3. Expressing lexical preferences in such general terms is also economical and allows to eliminate some cases of spurious ambiguity.

(e1) Elle court (She runs / It is her who runs)

(e2) Elle est venue (She has arrived / She is an arrival)

(e3) Je vois deux hommes (I see two men)

<sup>7</sup> Whereas claiming that arguments prefer to attach to their closest potential governors solves this problem.

<sup>8</sup> One may say that more general information is used when encountering unknown lexical items, but this general idea is not implementable as such.

#### 4. Conflicts between structural principles

One of the main argument against "traditional" structural principles is that the interaction between them is unclear. It has been said for example that in case of conflict, minimal attachment prevails over right association in a sentence such as "He repaints the wall with cracks" thus allowing to account for the garden path effect. Of course, this suffers numerous counter-examples.

With the structural principles presented in 3 and expressed on dependency like structures, it is striking that zero conflicts were encountered, both on the 1000 sentences for French, and on 3000 sentences from the wall street journal for English.

This strongly suggests that these principles are relevant from a cognitive point of view.

#### Conclusion

We have presented three parsing preference principles expressed on dependency like structures, and shown that these language-independent principles are both psycholinguistically relevant and useful to disambiguate real-word data on a large scale (which has led to the development of a parser-ranker). We also came to the conclusion that an efficient disambiguation scheme involving these structural preferences as well as limited semantic information and "simplified" lexical principles (i.e. expressed in terms of parts of speech) was more economical than acquiring large amounts of lexical data, thus being more appealing both from a practical and from a cognitive point of view. In fact, these structural preferences are a first step towards a psycholinguistically relevant processing model for LTAGs, which allows among other things to predict garden-path phenomena (cf Kinyon 99c, Kinyon 00b).

## Abstract

Models that rely exclusively on static representations cannot account fully for the flexibility of human analogy-making. More sophisticated models should provide mechanisms for dynamic extension, elaboration, and re-representation of episodes. One such mechanism—the *instantiation* mechanism—is described. It uses the target problem as a template for extending the source and vice versa. These extensions are driven and constrained by semantic knowledge about general regularities in the domain. The instantiation mechanism has been developed within a model of analogy-making called AMBR. It relies on AMBR's support for parallel, decentralized, and interactive computation. The instantiation mechanism runs in parallel with the mechanisms for analog access and mapping. Thus, these latter mechanisms guide the instantiation mechanism as to which facts in the large semantic memory are relevant to the specifics of the current situation.

## Re-Representation in Problem-Solving

A substantial body of evidence suggests that people can change their mental representations dynamically during various cognitive tasks. Yet, despite the widespread agreement that human representations are dynamic and flexible, the mechanisms behind these re-representation abilities are not well explored and understood. This paper suggests some mechanisms that can serve that purpose.

In the context of problem solving, there are at least two complementary aspects of re-representation: re-representation of the target problem and re-representation of prior knowledge. These two aspects correspond to Jean Piaget's complementary and related processes of assimilation and accommodation. Re-representation of the target is a process of assimilation because the new information is transformed to comply with the existing knowledge. Conversely, re-representation of the existing knowledge in the face of new experience is a process of accommodation.

*Re-representation of the target problem* has received more attention although it is still not fully understood. Gestalt psychologists (Maier, 1931; Dunker, 1945) demonstrated the importance of dynamic changes of

the target representation for successful problem solving. However, the mechanisms behind this remained unclear and somehow mysterious. Unfortunately, contemporary cognitive science has not been particularly successful to fill this gap, although some progress has been made. Douglas Hofstadter and his group have worked for many years on the integration of analogy-making and what they call high-level perception (Hofstadter, 1995; French, 1995; Mitchell, 1993; Chalmers, French & Hofstadter, 1992). They have proposed a number of mechanisms that work together to build several alternative representations simultaneously, settle gradually on one of them, and radically restructure the representation and settle on an alternative one if necessary. Lange & Wharton (1992) have worked on a similar problem—integrating language comprehension with analogical reminding. They suggested a mechanism for parallel processing of several possible interpretations of an ambiguous phrase. This mechanism would allow for re-interpretation of the phrase if necessary.

The issue of *re-representation of existing knowledge* during the problem solving process has been systematically ignored in the problem solving literature. Unfortunately, most classical models of problem solving take the existing knowledge as constant<sup>1</sup>. Long-term memory structures only have to be retrieved and applied (Ernst & Newell, 1969; Newell, 1990; Anderson, 1983; Anderson & Lebiere, 1998). The same is true for models of analogy-making: they retrieve a ready-made representation of an old episode when looking for a base for analogy (Gentner, 1989; Thagard, Holyoak, Nelson & Gochfeld, 1990; Kokinov, 1994a; Forbus, Gentner & Law, 1995; Hummel & Holyoak, 1997).

The idea that there are ready-made representations of episodes formed during the encoding stage has been challenged by researchers of human memory for quite some time. There is much evidence for the constructive nature of the “retrieved memory traces”. Thus Loftus (1977, 1979) and Neisser and Harsch (1992) demonstrate that people can have vivid “memories” of nonexistent episodes which are clearly constructed during the “retrieval” process. Bartlett

---

<sup>1</sup> We do not discuss learning here—it involves gradual long-term knowledge change rather than short-term accommodation.

(1932) has shown that episode representations are distorted and enriched with information inherited from the schema for the typical event.

The purpose of this paper is to show how episodic representations can be dynamically extended with information derived from general semantic knowledge. AMBR is among the few models of analogy-making which use both semantic and episodic knowledge (Kokinov, 1994a). However, the version reported in (Kokinov, 1994a) used them for different purposes. Episodic memory was a repository of ready-made representations of episodes that might be used as bases for analogy-making. Semantic memory served only to establish semantic similarity between the relations, attributes, and objects participating in the episodes. In the new version of AMBR described in this paper, the boundaries between semantic and episodic memory are blurred and general statements from semantic memory are instantiated to complement and extend the representations of episodes.

## **Main Assumptions of the AMBR Approach to Episode Re-representation**

### **Flexible Dynamic Representations**

The first assumption is that episodes and concepts are not represented by fixed and static complex memory structures such as schemas, lists of propositions or lists of rules. Rather, there are fuzzy and overlapping *coalitions* of simple memory elements. The key distinction is that complex memory structures are retrieved in an all-or-none fashion, while flexible dynamic representations are retrieved and/or constructed element by element. Each element has an activation level associated with it. Depending on the specific pattern of activation over the coalition, various partial representations of the same episode or concept can be retrieved. Some elements of the coalition might be strongly connected with each other and thus tend to be retrieved together, while others might be retrieved only rarely and under specific retrieval conditions. There is also a possibility for *blends* to emerge. This happens when elements belonging to more than one coalition become active together. All this flexibility is important for making re-representation possible.

### **Flexible Dynamic Computation**

The second assumption is that computations are also flexible, parallel, and interactive. There are multiple processes running in parallel and interacting in complex ways that are not specified in advance. Thus, re-representation results from the interplay of many processes including: (i) retrieval of past episodes, (ii) retrieval of generic knowledge, (iii) instantiation of the generic rules or facts, (iv) attempt to build the representation of the past episode in a form that makes it alignable with the representation of the problem at hand, and (v) attempt to build the representation of the target problem in a form that makes it alignable with the representation of the past episode. As stated earlier, it is believed that all these processes should run in parallel and influence each other's

work. In addition, each of the processes described above is quite complex in itself and in turn has to be considered as the result of the interplay of many simpler and more local processes. These requirements lead to a view that complex computation is an emergent interactionist phenomenon rather than pre-specified sequence of algorithmic steps.

### **Integrated Semantic and Episodic Memory**

Semantic memory contains information about concepts and statements about classes of instances. Episodic memory contains information about instances, episodes, and statements about instances. There has been a long-lasting discussion for and against the distinction between these two memories (see, for example, Anderson & Ross, 1980, Herrmann & Harwood, 1980). The third assumption of AMBR is that semantic and episodic memories are integrated so as to allow for coordinated search in both memories. Whenever a cue is provided, both semantic and episodic memory elements can potentially be retrieved. Thus, when a past episode is *recalled* from memory, both specific and general knowledge is used in the recollection process. In this way semantic knowledge can extend the episodic knowledge.

### **Integration of Memory and Reasoning**

The process of re-representation requires that the process of memory access, on one hand, and the processes of mapping and instantiation, on the other, run in parallel and interact with each other. Thus the fourth assumption is that memory and reasoning are highly integrated.

## **AMBR: An Analogy-Making Model Based on the Cognitive Architecture DUAL**

An analogy-making model with re-representation capabilities needs the support of a full cognitive architecture that implements all the assumptions above. The cognitive architecture DUAL is specifically designed to support this decentralized and interactive style of computation (Kokinov, 1994b, 1994c, 1997). The AMBR model of analogy-making (Kokinov, 1994a) is based on this architecture. This paper describes the re-representation extensions that have been added to the model after the original publication. Before explaining how the assumptions are implemented and how they contribute to re-representation, a brief and more general description of DUAL and AMBR is needed.

DUAL is a cognitive architecture based on the *society of mind* idea (Minsky, 1986; see also Hofstadter, 1995). Every DUAL-based system consists of many micro-agents, each of which is quite simple. The micro-agents do not have goals and do not plan their activities; they are simple representation and computation devices. They can establish new links with other agents and some of them can construct new agents. DUAL-agents form coalitions that collectively represent an episode or a generalized concept, or dynamically form coalitions that collectively produce an emergent computation process. Each agent can participate in many coalitions to a various extent depending on the weights of the links connecting that agent to other agents in the coalition.

Knowledge representation in DUAL is highly decentralized. Each episode, concept, general theory, etc. is represented by a coalition of many agents, each of which represents just a small piece of knowledge. Thus a simple episode such as boiling water in the kitchen would be represented by a quite big coalition of agents: an agent for every *concept* related to the situation such as “water”, “kitchen”, “boiling”, “plate”, “pot”, “on”, “in”, “hot”, “cold”, “cause”; an agent for every *instance* of these concepts involved in the particular situation, i.e. “water-1”, “kitchen-3”, “boiling-2”, “plate-3”, “pot-3”; as well as for every single statement such as “on-1(pot-3,plate-3)”, “in-1(water-1,pot-3)”, “hot-1(plate-3)”, “red-1(pot-3)”, etc. However, it should not necessarily be the case that all elements of a coalition become members of the working memory (WM) at certain moment. On the contrary— typically only part of the coalition is activated. Thus each episode is almost always only partially available. Moreover, different subsets of the coalition are active in different contexts. The long-term memory (LTM) of DUAL is the population of all permanent agents, active or inactive. The working memory is simply the active part of LTM plus some newly created temporary agents.

Each agent is a DUAListic computational and representational device: it has a symbolic and a connectionist part. While the symbolic part represents a piece of knowledge (as described above), the connectionist part represents the relevance of this piece of knowledge to the current context. The relevance is represented by the graded activation level computed by the connectionist processor associated with the agent. All the inferences based on the knowledge represented by the agent are computed by the symbolic processor associated with the same agent. These computations are also based only on local interactions with neighboring agents. If necessary, the agents are able to establish new temporary links (and interactions) with other agents. The speed of symbolic processing of a given agent depends on the activation level. In this way the computations are faster if the corresponding knowledge structures are considered relevant to the context and slower or even impossible if they are less relevant or irrelevant.

AMBR is a model of analogy-making based on DUAL, which integrates memory and reasoning. The mechanisms for memory access, mapping, inference, re-representation, etc. are based on emergent computations implemented over a large set of DUAL agents. Memory access is based mainly on the spreading activation mechanism of the connectionist aspect of DUAL. Mapping is based on a number of mechanisms such as marker passing for establishing semantic correspondence, temporary-agent constructors for establishing hypotheses about possible correspondences, link constructors for establishing positive or negative links among hypotheses and existing long-term agents based on structure correspondence, etc. All these mechanisms are running in parallel and influence each other, thus giving rise to various interaction effects.

## AMBR Mechanisms for Dynamic Extension of Episode Representation

Episode representation is dynamically extended in AMBR by the interplay of three processes running in parallel: (i) gradual and partial retrieval of episodic and semantic memory elements, (ii) gradual and partial mapping the retrieved episode and semantic elements onto the target elements, and (iii) gradual and partial instantiation of general statements from semantic memory.

*The gradual retrieval process* is based on the spreading activation over the links between the neighboring agents. When the activation level of certain agent exceeds a given threshold, the agent becomes part of the working memory<sup>2</sup>. It is possible that only part of the coalition passes the threshold, which means that it is possible that only part of the encoded episode elements are retrieved. Thus different representations of the past episode are “constructed” or “retrieved” in different contexts. This differs from other analogy models. Most of them use centralized episode representations (Forbus, Gentner, & Law, 1995, Thagard et al., 1990). Even in LISA (Hummel & Holyoak, 1997) where the episodes are represented in a decentralized way and where the retrieval process is a gradual one, there is a final decision about which episode has won the competition. This decision is done centrally and all elements of the winner are switched from “dormant” into “active” state. Therefore, no partial retrieval of episodes is possible. In AMBR there is even no in-principle possibility to do this form of forced retrieval of whole episodes because the system does not keep any central registry of rosters enumerating the affiliation of elements to episodes.

Since there are tight links between the elements of semantic and episodic memory, activated agents do not necessarily represent elements of an episode. They can also represent pieces of semantic knowledge. Thus, contrary to other models, the retrieval process in AMBR brings both elements of episodic and semantic memory into the WM. Since semantic knowledge is also represented in a decentralized manner, it has the same degree of flexibility. Two scenarios are worth mentioning. The spreading activation mechanism can retrieve (i) a coalition representing schematic knowledge about a typical situation (e.g. “boiling water in the kitchen”) or (ii) single generic statements (such as “a pot is made of metal”). Because the process of instantiation of a schema is much more traditional and well studied, we will focus on the instantiation of single generic statements.

*The gradual mapping process* starts as soon as the first elements from episodic or semantic memory pass the working-memory threshold. An attempt is made to map them onto elements from the target description. An external observer monitoring the behavior of the system as a whole can ascribe different labels to this process depending on the particular kind of prior knowledge that the system happens to use in each particular case. If a past episode is retrieved and mapped to the target, this could be labelled “analogy”. If a general schema is retrieved and used as a source for the

---

<sup>2</sup> After entering the WM, the graded activation continues to play an important role since the speed of symbolic processing performed by the agent depends on its activation level.

mapping, the “analogy-making” mechanism produces an inference that we might prefer to call deductive<sup>3</sup>. The prevailing number of cases will be mixed, however: both episodic and semantic elements will be mapped. These are the cases considered in more detail in this paper. The process of analogy-making is an emergent process. What actually happens in the system at the micro-level is that individual elements of the descriptions try to find their “mates”, i.e. to form correspondence hypotheses between target elements and retrieved elements regardless of whether these elements are originating from episodic or semantic memory. At the same time all the agents participating in this process establish temporary links among themselves in order to cooperate in finding a structurally consistent mapping (Gentner, 1983).

The details of how retrieval and mapping are performed in a decentralized and emergent way will not be presented here because of lack of space. Interested readers can find such descriptions elsewhere (Kokinov, 1994a, Kokinov, Nikolov, & Petrov, 1996). The focus here is on the processing that takes place after a mapping between elements of semantic memory and target elements is established. For example, when an isolated generic statement from semantic memory, such as “made-of-1(teapot,metal)” or “is-hot-1(plate)”, is retrieved it can be mapped onto elements of the target description such as “made-of-2(vessel-1,wood-3)” or “is-burning-2(fire-1)”, respectively.

After the initial correspondence is established, which might be based on the semantic similarity between the predicates (established by the marker-passing mechanism), a generic hypothesis is formed (i.e. a new agent is created) which puts the target proposition—“made-of-2(vessel-1, wood-3)” —in correspondence with the general statement coming from semantic memory that teapots are typically made of metal: “made-of-1(teapot,metal)”. In case that the retrieved episode representation already contains a statement “made-of-3(teapot-1,metal-1)” then most probably it will win the competition and the generic hypothesis will be rejected. However, if such statement is not encoded in the long-term memory since the material of the teapot was not important at the time of experiencing the event, or it was encoded but for some reason it is now not retrieved in WM and therefore does not exist in the current representation of the episode, then it might happen that the generic hypothesis wins the competition or at least is strong enough to start an instantiation process.

**The instantiation process** builds up a new proposition where all the universally quantified variables will be replaced by specific instances-constants, e.g. “made-of-1(teapot,metal)” goes into “made-of-4(teapot-1,metal-prototype)”. How are the constants chosen? If there is a constant (object) of the same type in the retrieved episode, it should be used. In the example above, the episode representation involves such an instance—“teapot-1”. Then the new proposition will use it as an argument. If the episode contains no specific instance of that type then a new instance is constructed which has the properties of the

prototype of the corresponding class. In this example, there is no instance of metal in the episode representation and therefore a new instance is formed—“metal-prototype”. Thus the instantiation mechanism tries to reuse existing instances whenever possible. The DUAL marker-passing mechanism provides information about which instances of the concept “teapot”, if any, are active in the current representation of the episode and hence are available for instantiation.

Instantiation has been used in analogy-making models so far only for adding new objects and propositions to the target problem, i.e. for making analogical inferences (Holyoak & Thagard, 1989, Falkenhainer, Forbus, & Gentner, 1989). In AMBR it is used for extending episode representation and relies heavily on the semantic knowledge of the system.

In summary, the process of extending the representation of the episode emerges from the interaction of several processes that are themselves emergent: the retrieval process which continuously brings up new episodic and semantic memory elements into WM, the mapping process which continuously builds hypotheses about possible correspondences between the retrieved elements and elements from the target description, and the instantiation process which continuously constructs new specific propositions based on generic propositions retrieved from semantic memory.

Why is the continuous interplay between these three processes important? The interactions guide each of the processes and therefore make each of them more effective. They preclude the model from doing exhaustive search. The influence of retrieval on mapping and instantiation is obvious since nothing can be mapped or instantiated if it is not activated (retrieved). The role of mapping is unusual compared to other models of analogy-making. Since the retrieval process in AMBR is a piece-by-piece process that runs continuously and in parallel with the mapping, the latter can influence the former. It is always the case that the retrieved elements of the episode send out activation to the rest of the elements of the episode representation and thus constantly try to activate the whole coalition. However, if the coalition is not tight enough (which is the typical case) they would be able to retrieve only some of their coalition partners. Exactly which elements will be retrieved depends not only on the initial set of elements but also on their mapping status, i.e. which of them are mapped onto target elements and which are not. Elements that are mapped receive abundant activation from the target and therefore will play important role in any further retrieval. In this way the mapping influences the retrieval process.

The importance of this interaction between processes can be demonstrated by contrasting two runs of the system: one with parallelism and interaction and one without. Figure 1 presents such a comparison from a simulation experiment. In the “parallel condition” (thick lines in the figure) all processes are running in the way they have been described so far. In the “retrieval only condition” the mapping process has been intentionally switched off. The important result is that, although the target and the background knowledge were exactly the same in the two runs, two different episodes are retrieved—a more structurally similar one in the first case and a more superficially similar one in the second case.

---

<sup>3</sup> AMBR has been proposed as a unifying mechanism for deductive, inductive, and analogical reasoning (Kokinov, 1988, 1990, 1992, 1994a).

Figure 1. Retrieval indices for two episodes, A and B, in two different conditions as a function of time. The thick lines correspond to the parallel condition in which mapping influences retrieval, the thin lines show 'pure' retrieval.

The mapping influences the instantiation process as well. If there were no such influence, the model would have to build up unrealistically many instantiations—one or more for each generic proposition retrieved from semantic memory. However, the instantiation process is guided by the mapping process—only general propositions that are mapped onto target propositions will be instantiated. On the other hand, once an instantiation is built it supports the mapping and helps in further retrieval of memory elements.

### Conclusions

The mechanisms described above allow for dynamic re-representation of the episodes by: retrieving additional information from episodic memory based on the established mappings; by constructing new memory elements and integrating them into the episode representation based on instantiation of generic statements retrieved from semantic memory and mapped onto the target description; and by retrieving elements from other episodes thus producing a blending between episodes.

In this way AMBR makes the following predictions which can be tested experimentally. The first prediction is that the partial mapping established up to a point influences the further retrieval process. This prediction can be tested by analysing thinking-aloud protocols. Actually, such results have been obtained by Ross and Sofka (1986) as a side effect in a thinking-aloud study. They are summarized in (Ross, 1989) as follows: "... other work (Ross & Sofka, 1986) suggests the possibility that the retrieval may be greatly affected by the use. In particular, we found that subjects, whose task was to recall the details of an earlier example that the current test problem reminded them of, used the test problem not only as an initial reminder but throughout the recall. For instance, the test problem was used to probe for similar objects, and relations and to prompt recall of particular numbers from the earlier example. The retrieval of the earlier example appeared to be interleaved with its use because subjects were setting up correspondences between the earlier example and the test problem during the retrieval." The simulation data described here are obtained

absolutely independently and are based only on the theoretical assumptions of DUAL and AMBR and exhibit exactly the same pattern of interaction.

A second prediction is that people would instantiate generic knowledge in cases where there is missing information from the episode representation and where this information is needed for the mapping, i.e. there is a corresponding piece of information in the target which needs to be mapped onto something from the base. An experiment is currently being prepared to test this hypothesis. McKoon and Ratcliff (1981) demonstrated that people make inferences and extend episode representation during the encoding process, e.g. after listening to a sentence such as "Alice pounded in the nail until the board was safely secured." listeners would infer and encode that "Alice used a hammer." Our prediction is that they would further extend the representation during the recall process when they use that episode in order to map it to the target.

Finally, a third prediction is that people will tend to blend episodic information if the information needed for mapping is missing in the best retrieved episode, but is present in another episode that is also partially retrieved. Another experiment is under development to test this prediction.

# Controlled Exploration of Alternative Mechanisms in Cognitive Modeling

Rita Kovordányi (ritko@ida.liu.se)

Department of Computer and Information Science  
Linköpings Universitet, SE-581 83 Linköping, Sweden

## Abstract

Overt cognitive behavior arises through a complex interaction between internal, not directly observable, cognitive mechanisms. As there may be several ways of achieving the same overt behavior, it is intrinsically difficult to find the “correct” model. One way to proceed however is to uncover the causal dependencies between a particular configuration of cognitive mechanisms and simulated overt behavior. This can be achieved in controlled simulation experiments where every combination of potentially important cognitive mechanisms is systematically tried out. To illustrate this point, we briefly describe an application of the two-level factorial simulation design on a modeling project in mental imagery. We conclude by discussing the potential of the method as a tool for reliable incremental model development.

## Introduction

The general objective of modeling and simulation is often to correctly predict real-world system performance. In addition to this, cognitive modeling aims at discovering the true nature of cognition (Kieras, 1987; Anderson, 1993; Newell, 1990; Kosslyn, 1980, 1994; Kosslyn et al., 1979). Ideally, this would presuppose either that a cognitive model can be rejected as invalid with respect to empirical data, or that a cognitive model, or a particular cognitive mechanism, can be singled out as being valid within a given theoretical setting.

However, behavioral data often do not cover every necessary aspect of a cognitive phenomenon or are qualitative in nature, and may thus be consistent with a range of possible accounts. This open-endedness poses a severe problem in cognitive theory construction and model building, a problem which is commonly known as the identifiability problem: “The thorny issue of how we can know [that we have arrived at] the correct theory” (Anderson, 1993, p. 10).

Several ways of dealing with this problem have emerged during decades of modeling practice. First, the empirical basis for model construction can be broadened to increase the number of constraints and thereby pin down the gross structure of possible cognitive models. Within the space of possible models which is left, often ad hoc or heuristic search is employed to find a model which satisfies the full range of data (Kieras, 1985). In general, this method increases the probability that the model found is also “correct” in a broader sense.

Second, unified architectures of cognition are incrementally constructed in a team effort and evolve through years of development to accumulate a wide range of empirical data. These architectures outline the main processing subsystems

and the flow of processing in the cognitive system, and in this way support the development of specific, lower-level models (Rosenbloom et al., 1993; Anderson, 1993).

Overt cognitive behavior arises from a complex interaction between internal cognitive mechanisms. Even when model development is guided by assumptions about the overall cognitive architecture, it may be difficult to pin-point which of several possible mechanisms is responsible for a set of empirical observations. For example, should the empirically observed reaction time and error-rate effects of “attending” to visual stimuli be attributed to early or late selection in the visual system, assuming that visual perception is implemented in a hierarchy of mutually interacting stages of processing?

In general, there is a need to untangle the complex interaction between hypothetical cognitive mechanisms. On the one hand, one would like to establish a causal link between central mechanisms and their contribution to overall model behavior. On the other hand, one would like to identify those mechanisms, which either give rise to invalid behavior, or do not significantly contribute to overall model performance. Strictly speaking, this entails an experimentation with cognitive models using an experimental design where every cognitive mechanism in the chain or network of mechanisms involved in a cognitive task is systematically varied so that alternative implementations of individual mechanisms can be fully cross-combined.

For practical reasons, high-dimensional experimental designs are avoided in real-world, psychological experiments. However, in general such practical limitations do not apply to a computer simulation environment. Yet, the full factorial design (cf. section on ‘The two-level factorial design’ below) is not employed in cognitive modeling.

In a modeling project on mental imagery (Kovordányi, 1999b), we have adopted this approach and have systematically simulated alternative embodiments of a generic interactive activation model (McClelland, 1979; McClelland and Rumelhart, 1981, 1994/1988; Rumelhart and McClelland, 1982). Based on our experience with this project, we would like to point to the potentials of this method.

## Simulating cognitive models in a controlled experimental setting

The advocated method for exploring cognitive models may be conceived of as the equivalent of running a high-dimensional real-world experimental design with a multi-way analysis of co-variation (multi-way ANOVA). In this sense, the space of cognitive models is used as a virtual en-

vironment for experimentation: The structure of this environment is partially fixed by what we call the model framework. “The independent variables” correspond to those aspects of the cognitive model which cannot be specified in advance, but which may be potential determinants for the model’s overall behavior. “The dependent variable” constitutes a measure of model performance which, for purposes of model validation, should correspond to experimentally observed behavior in human subjects. Experimentation through systematic model simulation aims to shed light on how some of the “a priori” unknown aspects of the partially specified model interact in affecting the model’s behavior, and most importantly, whether a specific combination of model properties produces valid model behavior.

### The two-level factorial design

Systematic exploration of alternative model instances can be organized according to a full two-level factorial design (Law and Kelton, 1991; Box et al., 1978). This design emphasizes that the question of which model parameters are causally involved in a particular type of simulated behavior can be answered only if all parameters have been fully cross-combined. In order to keep down the computational cost of exploring all parameters, parameter values are varied between a predetermined min- and max-value, in what is called a two-level factorial design.

Note that, for the above reasons, if some model parameters were to be fixed at a given “reasonable value” in order to keep down simulation complexity, the power of the simulation design would diminish. Strictly speaking, such simulations cannot validate conclusions about which model properties are causally involved in the simulated behavior. Simply expressed, parameters may have been fixed at a value where they in fact interact with the central parameters of the model. Hence, for example, if no effect is obtained when the value of one of the central parameters is varied, this could in fact hide a significant negative effect, which is positively modulated by a peripheral parameter, which has been fixed.

Ideally, for a problem with  $k$  degrees of freedom, the minimal number of simulations which needs to be run in order to detect causal dependencies between model parameters is  $2^k$ . However, if the number of simulations turn out to be unmanageably large, a fractal two-level factorial design may be used instead of a full design (cf. Law and Kelton, 1991; Box et al., 1978). In these designs, peripheral parameters are not fixed at an ad hoc value, but are instead defined dynamically to be a function of other, more central parameters.

In addition to providing a minimally sufficient basis for detecting causal relationships in the simulation results, using a two-level factorial design renders the analysis of simulation results computationally simple. A simulation where  $k$  parameters are varied is captured in a design matrix of size  $2^k \times k$  containing +s and –s representing low and high parameter values (cf. Law and Kelton, 1991; Box et al., 1978). The way the matrix is set up, each row will represent a unique combination of parameter values, which in turn corresponds to a particular simulation run. As the design matrix

is regular, it is easy to set up. In addition, once it is computed, the same matrix can be used to control the simulations and to conduct data analysis.

To illustrate the latter case, if the possible interaction between parameters  $p_1$ ,  $p_3$ , and  $p_7$  are inquired, columns 1, 3, and 7 of the design matrix are multiplied value-by-value, and then multiplied with the set of simulation data. The effect of these multiplications is that the correct signs will be added to the data column. A final summation of all the signed entries in the data column, divided by  $2^{k-1}$ , where  $k$  denotes the number of model parameters, yields the desired mean interaction of the parameters involved (cf. figure 1).

Figure 1: Example of a two-level full factorial simulation design matrix for three parameters. Each row in the matrix denotes a unique combination of parameter values. The last column in the design matrix designates the outcome of simulating a model (instance) for that particular parameter combination.

### Our modeling project

In our investigation of mental imagery, a full two-level factorial design was used where all parameters not inherently dependent on each other were cross-combined (Kovordányi, 1999b, 2000). While variations in the effect of several possible factors, such as the effect of mental image fading, were taken into account, simulation data analysis was centered around uncovering the effect of focusing early versus late selective attention on part of a mental image in a mental image reinterpretation task. As the empirical results of Finke and colleagues (Finke et al., 1989) and Peterson and colleagues (Peterson et al., 1992) used for model validation were qualitative, no attempt was made to optimize the models towards these data (Kovordányi, 2000). Model validity was instead defined qualitatively, and served as a means for “filtering out” invalid model instances.

### Parameterization of the model design space

The interactive activation model used in our project (cf. Kovordányi, 1998, 1999a) drew its main architectural components from the comprehensive model of mental imagery

forwarded by Kosslyn (1994; Kosslyn et al., 1979; Kosslyn et al., 1990). This model framework enabled us to capture all basic assumptions made at a higher, theoretical level, while enabling a systematic search for algorithmic details, which were left open by the theoretical and empirical basis.

How should an underconstrained model be partially specified so that it allows for a natural variation of model properties? One approach, used in our modeling project, is to set up a generic model framework as a localist network, and let each node in this network encode a holistic property or feature of the modeled phenomenon. In the case of visual perception, one kind of holistic property would be, for example, the individual line segments, which make up more complex line drawings.

One example of localist networks is the interactive activation model developed by McClelland and Rumelhart (McClelland, 1979; McClelland and Rumelhart, 1981, 1994/1988; Rumelhart and McClelland, 1982). In these models, the localist nodes are arranged into reciprocally connected layers of processing, thereby further increasing the structure and penetrability of the model. Units within the same processing layer are assumed to have the same inhibitory/excitatory connection weights. In such a model framework, model parameters can be naturally expressed as connection weights, activation thresholds, resting levels, or simply as “control flags”. These flags could, for example, control whether an individual simulation run should be initiated top-down or bottom-up in the interactive network.

Model parameters can arise naturally also in symbolic

models. Parameters in these models could be represented as alternative (sets of) production rules, or simply alternative definitions (fnc1 – fnc2) of a cognitive mechanism together with some means for activating them at run-time. Hence, in essence, any modularly built computational model can be parameterized with a minimal overhead cost.

## Simulations

Our model framework for mental imagery encompasses three mutually interacting layers of processing (figure 2). At the lowest level, the visual buffer contains detectors for oriented line segments. At the next stage, these feature detectors can evoke (and get feedback from) simple geometric patterns, such as composite lines or triangles, which are stored in visual long-term memory. At the highest level of processing, geometric patterns are combined into abstract concepts stored in amodal, associative long-term memory. In addition to between-layer connections, there is lateral, within-processing-level inhibition between mutually inconsistent (groups of) units. Interpretation in this system entails the dynamic establishment of a correspondence between low-level and higher-level representations.

We simulated mental and perceptual reinterpretation of two composite line drawings from Finke and colleagues (1989, exp. 1). Possible interpretations of these figures were limited to a small set of predefined geometric forms and abstract concepts. For example, possible interpretations of the first figure, formed from an upper case ‘H’ superim-

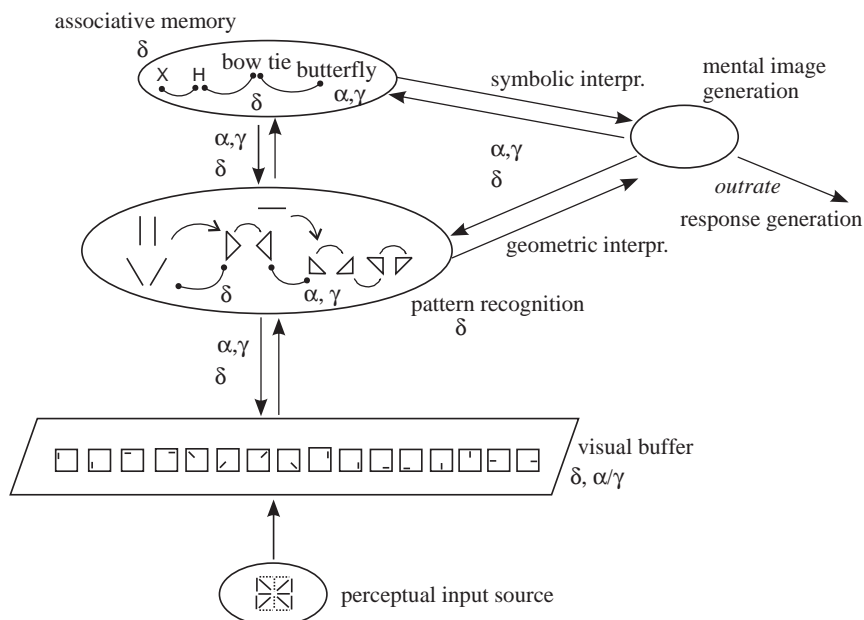

Figure 2: Communication and control structure of our model. Model parameters are shown as tags attached to the corresponding connection or subsystem. Note that model performance is expected to depend not only on how parameters are set, but also on whether the system is initiated top-down or bottom-up. These the two ways of initiating the system correspond to mental imagery and visual perception, respectively.

posed on an upper case 'X', were limited to "four small equilateral triangles", "two large isosceles triangles", "a butterfly", "a tilted hourglass" and "a bow-tie".

As layers in the system were reciprocally interconnected, simulations could be initiated either top-down or bottom-up. This made it possible to compare reinterpretation

performance in visual perception and in mental imagery. When simulations were run in mental mode, a chosen symbolic concept was activated in associative long-term memory, and this activation was projected into the visual buffer, where an activation pattern emerged which represented a visual mental image. When simulation was run in perceptual mode, visual input entered the system at the visual buffer, and was forwarded through consecutive stages of processing, and matched to geometric patterns and abstract concepts. One of these patterns or concepts was selected for verbal report.

Simulations were run through four phases: Mental image generation, followed by mental image reinterpretation, continued with a corresponding perceptual image build-up of the same line-figure, followed by perceptually based reinterpretation. Each simulation was run for 10 simulated seconds, in discrete simulation steps of 50 ms.

Two configurations of the model framework were scrutinized: One where attentional selection occurred late, affect-

ing processing at the level of associative long-term memory, and one where selection occurred early and directly affected the contents of the visual buffer. For these model configurations, the effect of focusing attention (versus not focusing attention) was investigated, taking into account the interaction effects that arose between this central, and other peripheral model parameters.

### Data analysis

In our project, data analysis was based on semi-automatic preparation of the raw simulation data. The prepared data were then visualized. The aim was to facilitate the discovery of significant parameter interactions, and in addition provide a basis for estimating model validity for the different parameter combinations. Below we briefly describe the key stages of this process.

### Identification of interacting parameters

Activation levels of all response units in the interactive activation network were measured for each simulation run, that is for each parameter combination (cf. Kovordányi, 1999b). From these activation values the corresponding probability for mental reinterpretation was calculated. Mental reinterpretation rates were considered valid if they qualitatively matched the reinterpretation rates obtained by Finke and

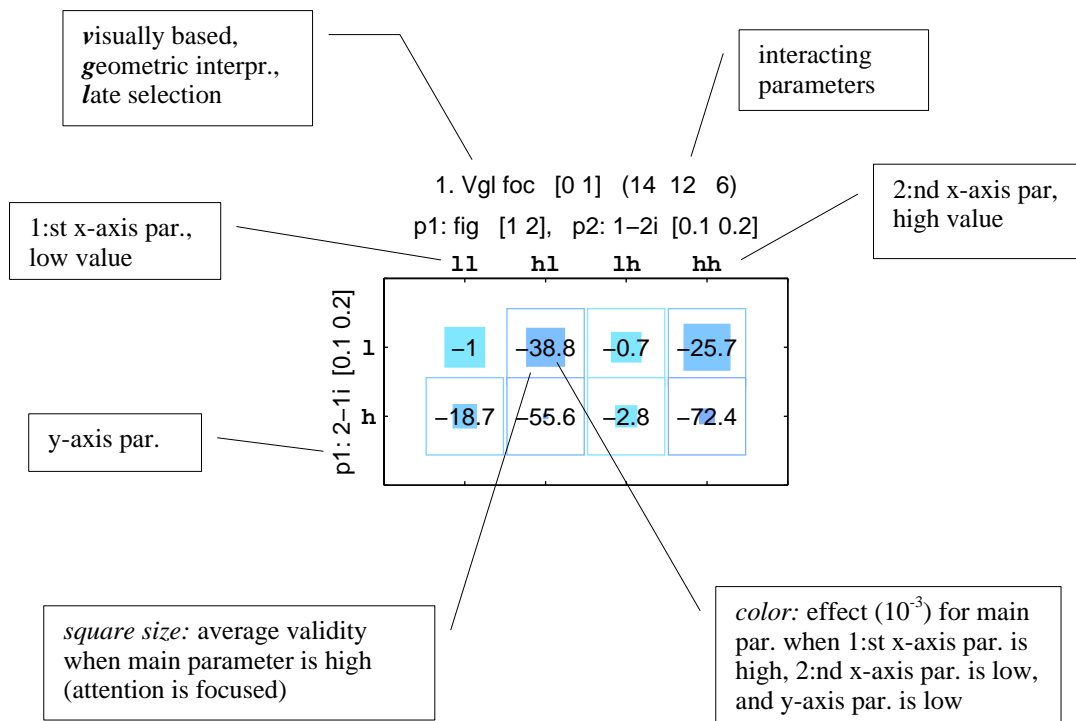

Figure 3: Example visualization of the simulation data. Data values are color-coded to support the understanding of interaction patterns. The area of the square markers reflects the validity of the underlying parameter combinations.

colleagues (1989, exp. 1), and Peterson and colleagues (1992). This amounted to the satisfaction of the following constraints: First, reinterpretation rates were required to be lower for abstract, conceptual interpretations than for geometric interpretations (cf. Finke et al., 1989). In addition, interpretations obtained during mental imagery had to be below those obtained during visual perception.

Second, reinterpretation rates were required to be qualitatively consistent with the findings of Peterson and colleagues (1992), which indicate that reinterpretation rates increase after a de- and refocus of attention.

### Calculation of parameter effects

The calculation of individual parameter effects and parameter interactions was based on a design matrix of  $-s$  and  $+s$ , representing high- and low parameter values (cf. figure 1). In this matrix each column denoted a model parameter and each row represented a specific parameter combination. A measure of model performance, that is simulated mental reinterpretation probability, was associated with each row in the design matrix. In general, in order to obtain a parameter's average effect on overall model performance, those rows in the model performance column of the design matrix which correspond to a low parameter value are summed and subtracted from those rows which correspond to high values. Higher-order interaction effects can be obtained in a similar manner (Law and Kelton, 1991; Box and Hunter, 1978). Given the simulation design matrix, these calculations can be expressed as a sequence of simple matrix operations.

### High-dimensional visualizations

Those groups of interacting parameters whose modulating effect exceeded 20% of the central parameter's effect—in our project this parameter denoted the focusing of attention—were prepared for subsequent visualization. Simulation data was prepared in such a way that parameters which exhibited a stronger mutual interaction with the central parameter would also be visualized closer to each other. This grouping of more related parameters turned out to enhance the understanding of interactions, since stronger interaction patterns emerged as salient color-patches.

The visualizations (illustrated in figure 3) can be conceived of as a high-dimensional cube of changes in model performance, each dimension representing changes caused by one of the interacting parameters. This cube can be sliced and stacked recursively onto a two-dimensional plot (cf. Bosan and Harris, 1996; Harris et al., 1994). Each x-y coordinate in these plots denotes a specific combination of interacting parameters. In our project, the direction of change in model performance was coded along two different color scales, and the magnitude of change was indicated by variations in hue within these scales, with deeper colors depicting a larger change.

The amount of information contained in the visualizations was further increased by the addition of information on model validity. We let the relative area of each colored square reflect the average validity of models corresponding to the central parameter's high value. In our case, this amounted to selective attention being focused. As a result of

including model validity in the visualizations, simulation data contributed to the visual appearance of the plot only to the extent to which they were valid.

### What type of results can be obtained?

Two categories of questions can be addressed using this method. First, simulation results can be approached with a particular hypothesis in mind, as was done in our project. In this case, one would like to make sure that the main effect of a particular embodiment of a cognitive mechanism,  $x_+$  (corresponding to parameter  $x$  at its high value), is as was predicted. For example: Do any of the interactions observed in the simulation results change the fact that parameter  $x$  is generally inhibitory? In addition, one would be interested in mapping out the validity of models where cognitive mechanism  $x_+$  is operating.

Second, simulation results can be openly explored, perhaps focusing on the role of a few central parameters. In this situation, one could, for example, be interested in finding out which cognitive mechanisms work in concert and which work against each other. In the first case the mechanisms would affect model performance in the same direction. In the latter case they would work in opposite direction, canceling out each other's effect. In addition to mapping out such interactions, one would be interested in which combination of mechanisms constitute valid models. This search for valid models can be a powerful way of constraining the space of possible models when several sources for validation are used (for example, a small set of seemingly contradictory experimental results).

### Concluding discussion

The use of distinctive colors, the organization of the visualizations' layout according to the strength of interactions, together with the technique described above for indicating model validity, turned out in practice to facilitate the understanding of the interaction patterns. Strong interactions which also gave rise to valid performance tended to visually coagulate into contiguous color-patches, which "popped-out" from the background of empty squares, marking non-valid cases.

The virtues of this combination of factorial simulation, analysis and visualization method are, in our view, compelling: Although the modeling framework is assumed to be based on a firm empirical basis, model properties which are not well-founded need not be specified in an ad hoc manner.

From a more theoretical perspective, conclusions which can be drawn from a full-factorial investigation will approach the stringency of appropriately conducted "real-world" experiments, with an inevitable difference: The validity of any results obtained will ultimately depend on the validity of the modeling framework itself. Within this framework, causal dependencies between hypothetical cognitive mechanisms and overall model behavior can be correctly mapped out. As a result, the development of subsequent models and/or the construction of cognitive theories can be guided in a stringent way.

As the method itself is qualitative in nature (parameters are varied coarsely between a high and a low value), models

can be validated on the basis of qualitative empirical data. Note that the objective with using this method is not primarily to quantitatively adjust a model's overt performance to empirical data by manually tuning parameters, but instead to single out a combination of internal cognitive mechanisms as the probable cause of empirically observed human behavior.

In a longer perspective, this method can contribute to the incremental development of more and more finely tuned cognitive models. Starting with a firmly based, minimally specified initial model framework, valid cognitive mechanisms can be singled out and subsequently embedded into the framework. Given these additional mechanisms, and/or having refuted some peripheral model properties, the next round of search can be narrowed down, and targeted at a more detailed level. As each increment is reasonably well-founded (validation is based on average simulation results), model development can be more directed.

### Acknowledgments

We would like to thank Sture Hägglund, and two anonymous reviewers for suggestions and valuable comments on an earlier version of this article. We would also like to thank Yvonne Wærn, and Jonas Barklund for fruitful discussions during the development of this project. This work was supported by the Swedish National Board for Industrial and Technical Development and the Swedish Council for Research in the Humanities and Social Sciences.

## Abstract

Understanding the mechanisms of learning is one of the central questions of Cognitive Science. Recently Marcus et al. showed that seven-month-old infants can learn to recognize regularities in simple language-like stimuli. Marcus proposed that these results could not be modeled via existing connectionist systems, and that such learning requires infants to be constructing rules containing algebraic variables. This paper proposes a third possibility: that such learning can be explained via structural alignment processes operating over structured representations. We demonstrate the plausibility of this approach by describing a simulation, built out of previously tested models of symbolic similarity processing, that models the Marcus data. Unlike existing connectionist simulations, our model learns within the span of stimuli presented to the infants and does not require supervision. It can handle input with and without noise. Contrary to Marcus' proposal, our model does not require the introduction of variables. It incrementally abstracts structural regularities, which do not need to be fully abstract rules for the phenomenon to appear. Our model also proposes a processing explanation for why infants attend longer to the novel stimuli. We describe our model and the simulation results and discuss the role of structural alignment in the development of abstract patterns and rules.

## Introduction

Understanding the mechanisms of learning is one of the central questions of cognitive science. Recent studies (Gomez & Gerken, 1999; Marcus, Vijayan, Rao & Vishton, 1999) have shown that showed that infants as young as seven months can process simple language-like stimuli and build generalizations sufficient to distinguish familiar from unfamiliar patterns in novel test stimuli. In Marcus et al's study, the stimuli were simple 'sentences,' each consisting of three nonsense consonant-vowel 'words' (e.g., 'ba', 'go', 'ka'). All habituation stimuli had a shared grammar, either ABA or ABB. In ABA-type stimuli the first and the third word are the same: e.g., 'pa-ti-pa.' In ABB-type stimuli the second and the third word are identical: e.g., 'le-di-di'. The infants were habituated on 16 such sentences, with three repetitions for each sentence. The infants were then tested on a different

set of sentences that consisted of entirely new words. Half of the test stimuli followed the same grammar as in the habituation phase; the other half followed the non-trained grammar. Marcus et al. found that the infants dishabituated significantly more often to sentences in the non-trained pattern than to sentences in the trained pattern.

Based on these findings Marcus et al. proposed that infants had learned abstract algebraic rules. They noted that these results cannot be accounted for solely by statistical mechanisms that track transitional probabilities. They further argue that their results challenge connectionist models of human learning that use similar information, on two grounds: (1) the infants learn in many fewer trials than are typically needed by connectionist learning systems; (2) more importantly, the infants learn without feedback. In particular, Marcus et al. demonstrated that a simple recurrent network with the same input stimuli could not model this learning task.

In response, several connectionist models have attempted to simulate these findings. Unfortunately, all of them to date include extra assumptions that make them a relatively poor fit for the Marcus et al experiment. For example, Elman (1999; Seidenberg & Elman, 1999) use massive pre-training (50,000 trials) to teach the network the individual stimuli. More importantly, they turn the infants' unsupervised learning task into a supervised learning task by providing the network with external training signals. Other models tailored to capture the data of the study seem unlikely to be applicable to other similar cognitive tasks (Altmann & Dienes, 1999). Using a localist temporal binding scheme, Shastri and Chang (1999) model the infant results without pretraining and without supervision, but still require an order of magnitude more exposure to the stimuli than the infants received.

We propose a third alternative. There is evidence that structural alignment processes operating over symbolic structured representations participate in a number of cognitive processes, including analogy and similarity (Gentner, 1983), categorization (Markman & Gentner, 1993), detection of symmetry and regularity (Ferguson, 1994), and learn-

ing and transfer (Gentner & Medina, 1998). Although these representations and processes are symbolic, they do not need to be rule-like, nor need they involve variables. Instead, we view the notion of correspondence in structural alignment as an interesting cognitive precursor to the notion of variable binding<sup>1</sup>. Correspondences between structured representations can support the projection of inferences, as the analogy literature shows, and therefore a symbolic system can draw inferences about novel situations even without having constructed rules. Moreover, as discussed below, comparison can be used to construct conservative generalizations. Across a series of items with common structure such a process of progressive abstraction can eventually lead to abstract rule-like knowledge. The attainment of rules, in those cases where it occurs, is the result of a gradual process. As we will show, symbolic descriptions can be used with structural alignment to model learning that is initially conservative, but which occurs fast enough to be psychologically realistic.

We first describe our simulation model of the Marcus et al task, which uses a simple combination of preexisting simulation modules, i.e., SME, MAGI, and SEQL. All of these modules have been independently tested against psychological data and independently motivated in prior modeling work. With the exception of domain-specific encoding procedures, no new processing components were created for this task. We then describe the results of our simulation of the Marcus et al data, showing that our simulation can learn the concepts within the number of trials that the infants had, without supervision and without pre-learning. We also show that the simulation can exhibit the same results with noisy input data. Finally, we discuss some of the implications of the symbolic similarity approach for models of cognitive processing.

### Modeling infant learning via structural alignment

A psychological model of the infants' learning must include the kind of input, the way the infants are assumed to encode the individual sentences, and the processes by which they generalize across the sentences. The architecture of our simulation is shown in Figure 1. We first describe our assumptions concerning the infants' processing capacities. Then we describe each component in turn.

**Processing Assumptions:** We assume that infants can represent the temporal order within the sentences (Saffran, Aslin & Newport, 1996). We further assume that the infants notice and encode identities within the sentences: for example, the fact that the last two elements match in an ABB sentence. This assumption is consistent with evidence that human infants, as well as with studies of nonhuman primates (Oden *et al*, in press), can detect identities. We also assume that infants can detect similarities between sequentially presented stimuli, consistent with studies of infant habituation, which demonstrate that infants respond to sequential sameness (e.g., Baillargeon, 1994).

Figure 1: Simulation Architecture

**Input stimuli:** To make our simulation comparable with others, we use a representation similar to that of Elman (1999), namely, Plunkett & Marchman's (1993) distinctive feature notation. Each word has twelve phonetic features, which can be either present or absent. The presence or absence of each feature for each word is encoded by symbolic assertions. If feature  $n$  is present for word  $w$ , the assertion  $(Rn\ w)$  is included in the stimulus, and if absent, the assertion  $(Sn\ w)$  is included. Thus the acoustic features of each word are encoded as twelve attribute statements.

We modeled the Marcus et al experiment both without noise (Experiment 1) and with noise (Experiment 2). Marcus et al. used a speech synthesizer to control the pronunciation of the stimuli, but while this reduces variability, it cannot eliminate the possibility that the infant might encode something incorrectly.

**Temporal encoding:** We assume that the infant encodes the temporal sequence of the words in a sentence in two ways. First, each incoming word has an attribute associated with it, corresponding to the order in which it appears (i.e., FIRST, SECOND, or THIRD). We further assume that the infant encodes temporal relationships between the words in a sentence; to code this, an AFTER relation is added between pairs of words in the same sentence indicating their relative temporal ordering. The particular labels used in this encoding step are irrelevant – there are no rules in the system that operate on these specific predicates – the point is simply that infants are encoding the temporal order of words within sentences.

**Regularity Encoding:** We assume that the infants notice and encode identities within the sentences: for example, the fact that the last two elements match in an ABB sentence. Thus the simulation must incorporate a process that detects when words are the same. We use the MAGI model of symmetry and regularity detection (Ferguson, 1994) to automatically compute these relationships. MAGI treats symmetry as a kind of self-similarity, using a modified version of structure-mapping's constraints to guide the self-alignment process. MAGI has been successfully used with inputs ranging from stories to mathematical equations to visual stimuli,

<sup>1</sup> That structure-mapping algorithm neither subsumes, nor is subsumed by, traditional pattern matching such as unification is shown in Falkenhainer, Forbus, & Gentner (1988).

and it has done well at modeling certain aspects of visual symmetry, including making new predictions (Ferguson *et al* 1996). Here MAGI is used on the collection of words in a sentence. For any pair of words  $w1$  and  $w2$  that MAGI finds sufficiently similar, this module asserts (SIM  $w1$   $w2$ ), and a DIFF statement for every other pair of words in the sentence. (If MAGI does not find any pairs similar, DIFF statements are asserted for every pair of words.) This module also asserts (GROUP  $w1$   $w2$ ) for pairs of similar words, to mark that they form a substructure in the stimulus, and adds DIFF statements between groups and words not in the group. This use of MAGI is an example of what Ferguson (1994, in preparation) calls *analogical encoding*.

## SEQL

Once each sentence is encoded, we assume infants can detect the similarities between sequential pairs of sentences. The detection of structurally parallel patterns across a sequence of examples is modeled by SEQL (Skorstad, Gentner & Medin, 1988; Kuehne, Forbus, Gentner & Quinn, 2000), a model of the process of category learning from examples. SEQL constructs category descriptions via incremental abstraction. That is, the representation of a category is a structured description that has been generated by successive comparison with incoming exemplars. If the new exemplar and the category are sufficiently similar, the category description is modified to be their intersection -- i.e., the commonalities computed via structural alignment by a generalization algorithm. If the new exemplar is not sufficiently similar, it is stored separately and may later be used as the seed of a new category.

The structural alignment process is implemented via SME, (Falkenhainer *et al* 1988; Forbus *et al* 1994) a cognitive simulation of analogical matching. Here the base description is a category description, and the target description is the new exemplar. The structural alignments that SME computes are used in three ways by SEQL. First, the numerical structural evaluation score it computes<sup>2</sup> is used as a similarity metric, a numerical measure for deciding whether or not two descriptions are sufficiently similar. Second, the candidate inferences it computes serve as a model for category-based induction (c.f. Blok & Gentner, 2000; Forbus, Gentner, Everett, & Wu, 1997). Third, the correspondences in the best mapping SME produces serves as the basis for SEQL's generalization algorithm.

SEQL maintains a set of generalizations and a set of singular exemplars. When a new exemplar comes in, it is compared against existing generalizations to see if it can be assimilated into one of them. Otherwise, it is compared with the stored exemplars to see if a new generalization can be formed. If it is insufficiently similar to both the generalizations and the stored exemplars, it is stored as an exemplar itself.

SEQL begins with no generalizations; it simply stores its first exemplar. If the next exemplar is sufficiently close to the first, their overlap is stored as the first generalization. A

<sup>2</sup> Although SME can compute multiple mappings, we use the structural evaluation score of the best mapping, normalized by the size of the base description.

generalization consists of the overlap between the two input descriptions: that is, the shared structure found by alignment. Thus generalizations are structured descriptions of the same type as the input descriptions, although containing fewer specific features. If a new exemplar is sufficiently similar to a generalization (as determined comparing the structural evaluation score to a set threshold), then (a) the generalization is updated by retaining only the overlapping description that forms the alignment between the generalization and the exemplar; and (b) candidate inferences are projected from the generalization to the exemplar. Non-overlapping aspects of a description (e.g., phonetic features or relations that aren't shared) are thus "worn away" with each new assimilated description. (The threshold that determines when descriptions are sufficiently similar to be assimilated helps prevent descriptions from diminishing into vacuity.)

Returning now to the infant studies, we assume that babies are carrying out an ongoing process of comparing and aligning the incoming exemplars with an evolving generalization. We further assume that the relational candidate inferences from the general pattern to a new exemplar represent expectations on part of the infant.<sup>3</sup> When these expectations are violated by an incoming stimulus that does not fit the generalized pattern (e.g., an ABB test sentence after the ABA generalization has been formed), we assume the infant requires extra time to process the inconsistent stimulus.

## Simulation Experiments

In both experiments, we followed the procedure of Marcus *et al*. Each stimulus was a simple three-word sentence, encoded as described earlier. There were two sets of training stimuli, one following the ABA pattern and one following the ABB pattern. The training stimuli were (ABA) de-di-de, de-je-de, de-li-de, de-we-de, ji-di-ji, ji-je-ji, ji-li-ji, ji-we-ji, le-di-le, le-je-le, le-li-le, le-we-le, wi-di-wi, wi-je-wi, wi-li-wi, wi-we-wi and (ABB) de-di-di, de-je-je, de-li-li, de-we-we, ji-di-di, ji-je-je, ji-li-li, ji-we-we, le-di-di, le-je-je, le-li-li, le-we-we, wi-di-di, wi-je-je, wi-li-li, wi-we-we. The test stimuli in both experiments were four descriptions representing two novel ABA-type (ba-po-ba, ko-ga-ko) and two novel ABB-type sentences (ba-po-po, ko-ga-ga). The threshold value for SEQL was set to 0.85 in both experiments.

### Experiment 1

This experiment is most comparable to previous simulation models of the phenomena, in that we assume noise-free encoding of the stimuli. A simulation run consists of exposing SEQL to all of the stimuli from a particular training set (either ABA or ABB) once and then seeing the response given the four test sentences. To avoid possible biasing due to sequence effects (See Kuehne *et al.*, 2000), 20 simulation runs were made for each training set using different random

<sup>3</sup> SME can also produce attribute-level candidate inferences, and does so on these stimuli. We assume that, since these inferences concern directly perceivable features, testing them takes very little time.

orders. Identical match score and relational candidate inferences were produced for all sequences with a given stimulus set. In each case, SEQL produced a single generalization during the learning phase. For the test phase we used encodings of the corresponding stimuli used with infants, as noted above. Tables 1a and 1b show the results of this series for two generalizations paired against the four test sentences.

**Table 1a: ABA training stimuli**

Test Stimulus	Match Score	Candidate Inferences
<b>Ba-po-ba</b>	<b>0.658</b>	<b>None</b>
<b>Ko-ga-ko</b>	<b>0.689</b>	<b>None</b>
Ba-po-po	0.486	(DIFF po1 ba1) (DIFF po1 po2) (SIM ba1 po2)
Ko-ga-ga	0.455	(DIFF ga1 ko1) (DIFF ga1 ga2) (SIM ko1 ga1)

**Table 1b: ABB training stimuli**

Test Stimulus	Match Score	Candidate Inferences
Ba-po-ba	0.328	(SIM po1 ba2) (DIFF ba1 (GROUP po1 ba2))
Ko-ga-ko	0.350	(SIM ga1 ko2) (DIFF ko1 (GROUP ga1 ko2))
<b>Ba-po-po</b>	<b>0.776</b>	<b>None</b>
<b>Ko-ga-ga</b>	<b>0.753</b>	<b>None</b>

The in-grammar (bold) and out-of-grammar (plain text) matches show clear differences in their match scores. In-grammar matches are above 0.64 and do not generate relational candidate inferences. Out-of-grammar matches have match scores below 0.5, and lead to relational candidate inferences. Thus out-of-grammar test sentences lead to longer looking behavior, as predicted.

## Experiment 2

As noted earlier, we believe that noise-free stimulus encodings are unrealistic. Consequently, we used the same procedure as Experiment 1, but this time introducing noise into the representations for the training and test stimuli. For each sentence, one of the words was randomly picked, and one of its attributes (also chosen at random) was dropped or flipped, with the rest of its description being unchanged. Such changes can be significant: for example, flipping a single phonetic feature turns the word ‘de’ into the word ‘di’. Again, 20 simulation runs were made for each training set using different random orders. Naturally the match scores and, to a lesser degree, the generated candidate inferences, did vary across the individual runs. Tables 2a and 2b show the results. The scores were averaged over all 20 runs.

Although the noise affected the details of the computations, the overall pattern of results remains the same. The in-grammar (bold) match scores are far higher than the out-of-grammar (plain text) scores; and the out-of-grammar

stimuli produce relational candidate inferences while the in-grammar stimuli do not.

**Table 2a: ABA training stimuli**

Test Stimulus	Average Match Score	Candidate Inferences Min, Average, Max
<b>ba-po-ba</b>	<b>0.647</b>	<b>0, 0, 0</b>
<b>ko-ga-ko</b>	<b>0.682</b>	<b>0, 0, 0</b>

## Comparison with other models

The results of Marcus et al. (1999) have sparked an active debate focused on two issues: (1) Can current connectionist models (e.g., simple recurrent networks) model these results? (2) Do infants generate abstract rules that include variables?

Regarding the adequacy of simple recurrent networks, Marcus et al. state “Such networks can simulate knowledge of grammatical rules only by being consequently trained on all items to which they apply; consequently, such mechanisms cannot account for how humans generalize rules to new items that do not overlap with the items that appeared in the training.” Elman’s (1999) response describes his use of a simple recurrent network to model this task. Elman’s model requires tens of thousands of training trials on the individual syllables, and treats the problem as a supervised learning task, unlike the task facing the infants. By contrast, our simulation handles the learning task unsupervised, and produces human-like results with only exposure to stimuli equivalent to that given to the infants. Moreover, our model also continues to work with noisy data, something not true of any other published model of this phenomenon that we know of.

The learning in our model is due to the “wearing away” of non-identical phonetic attributes through subsequent comparisons. Although SEQL’s learning proceeds faster than connectionist models, it is still slower than systems that generate abstractions immediately (e.g., explanation-based learning (DeJong & Mooney, 1986)). In SEQL’s progressive alignment algorithm, the entities in the generalizations lose their concrete attributes across multiple comparisons, leaving the relational pattern of each grammar as the dominant force in the generalization only after a reasonable num-

ber of varied examples are seen.<sup>4</sup> There is considerable evidence for this kind of conservative learning (Forbus & Gentner, 1986; Medin & Ross, 1989).

Turning to the second issue, whether infants have variables and generate abstract rules, Marcus et al (1999) claims “[I]nfants extract abstract algebra-like rules that represents relationships between placeholders (variables), such as ‘the first item X is the same as the third item Y,’ or more generally that ‘item I is the same as item J.’” But our simulation does not introduce variables, in the sense commonly used in mathematics or logic. The generalizations constructed by SEQL do indeed include relational patterns that survive repeated comparisons because they are shared across the ingrammar exemplars. Furthermore, the entities (words) in the generalizations have many fewer features than the original words, as a result of the wearing away of features in successive comparisons. One could consider these patterns as a form of psychological rule, as proposed by Gentner and Medina (1998), with the proviso that the elements in the rule are not fully abstract variables, although they might asymptotically approach pure variables.

## Discussion

This paper proposes a third kind of explanation for the infant learning phenomena of Marcus et al (1999): incremental abstraction of symbolic descriptions via structural alignment. We believe our explanation is currently the best one for three reasons. First, it models the infant data with fewer extra concessions than previously published models (i.e., no pre-training, no supervision, and noisy data). Second, the processes we postulate are cognitively general; they apply to a large set of phenomena. Third, the abstraction processes we propose are consistent with research demonstrating that human learning is initially conservative (Brooks, 1987; Forbus & Gentner, 1986; Medin & Ross, 1989). Interestingly, there is ongoing research in developing symbolic connectionist models consistent with these processes (e.g., Holyoak & Hummel, 1997).

Many issues remain to be explored. For example, although our system does not introduce variables in its generalization process, there is a sense in which the entities in the generalization are on their way to becoming variables. Gentner and Medina (1998) have proposed that the process of progressive alignment can lead to rules. They further suggested that the application of rules to instances can be accomplished using the same general processes of structural alignment and projection that are used in analogy. The difference is that the base domain is an abstraction, the entities are ‘dummies’ with no features to either help or impede the match with the specific entities in the exemplar. Another issue concerns the incorporation of statistical notions in SEQL. Although SEQL is to a certain degree noise-resistant,

---

<sup>4</sup> SEQL learns with only one exposure to the 16 learning sentences, whereas Marcus’s infants received three exposures for each sentence. It is possible that the infants would have learned with only one pass; however it is also possible that the infants were less consistent in detecting the similarities than our simulation with its current parameters.

we suspect that to model large-scale learning, it will need to keep track of more statistical information than it does currently, so that properties wear away more slowly.

We note that it is common to conflate symbolic processing with rule-based behavior, and parallel processing with connectionist models. The model described here is symbolic, but it need not involve variables or rules. Further, it involves extensive parallel processing (most of SME and MAGI’s computations are parallel). Given the complexity of the phenomena, such confluations seem unwise.

The debates stirred by the Marcus et al. results bear on a critical issue in human learning and development: namely, what knowledge or mechanisms must be assumed to account for the rapid and powerful achievements demonstrated by infants in both cognition and language. Our results suggest that the general learning mechanism of structure-mapping theory may go a long way in accounting for these accomplishments.

### Abstract

We present a novel theoretical model of multiple stages in the acquisition of tense and agreement in Child French. First, we show that tense and agreement inflection follow independent courses of acquisition. Over the three stages of development attested in the data, tense production starts and ends at near-adult levels, but suffers a “dip” in production at the second stage. Agreement develops linearly, going roughly from none to 100% over the same time. This profile suggests a *competition* between tense and agreement at the second stage which is naturally expressed in terms of constraint violability and constraint re-ranking (Optimality Theory, Prince & Smolensky, 1993). By incorporating the further mechanism of partial rankings of constraints, our analysis successfully predicts, over three stages, the frequency with which children use tensed, agreeing, and nonfinite verbs.

### The Attested Development of Tense and Agreement in French

It is cross-linguistically well-attested that young children (around the age of 2) often produce simple sentences with a non-finite root (verb) form (NRFs), ungrammatical in the adult language, while also producing adult-like finite verbs with tense and agreement marking (Wexler, 1994, 1998, *inter alia*). What has been previously overlooked, however, is whether the distinct inflectional categories of tense and (person/number) agreement develop independently over time. A detailed analysis of spontaneous speech production data from three French children from the CHILDES Database (MacWhinney & Snow, 1985) provides strong evidence that the two categories indeed follow a different path of development.<sup>1</sup>

As a preliminary step of analysis the relevant files were analyzed by hand and classified into PLU (Predominant Length of Utterance) stages (Vainikka, Legendre & Todorova, 1999). This independent measure refines the traditional observation that children progress through one-word, two-word, and multi-word stages and has proven better suited to capture syntactic development than the well-known MLU measure (Brown, 1973).

French presents specific challenges for a study of the development of finiteness because the overwhelming majority of verbs used by young children belong to the first conjugation class (‘-er verbs’) which displays considerable homophony across morphological person inflections. In the absence of an overt subject (which is frequently omitted by young children) it cannot be determined whether a given phonetic form like [dās] *danse* ‘dance’ in the present tense carries correct agreement in person and number. However, clitic subject pronouns in French (e.g., *je* ‘I’) provide a diagnostic

---

crosslinguistically (Vainikka, Legendre & Todorova 1999). We have done in-depth work on transcripts from eight different children at this stage of development, covering English, French, Polish, Russian, and Swedish. Further analyses are underway as well. We should point out that while the conclusions drawn in this paper are made on the basis of data from (only) three children, we believe (following well-established tradition in the study of the acquisition of syntax by children) that examining a small number of subjects in detail allows us to uncover complexity that would be missed in a necessarily less detailed overview of a larger group of subjects. Furthermore, there is strong evidence to suggest that syntactic acquisition proceeds in a highly constrained and species-universal manner. Given this, we do not expect to find a great deal of variation from child to child, increasing the likelihood that the results reached on the basis of these three children will generalize across French-speaking children.

<sup>1</sup> The data we report on in this paper is part of a larger project aimed at studying the acquisition of tense and agreement

for agreement marking: Following Lambrecht (1981), Suñer (1988), Legendre (1999), and others, we take subject clitics to be an overt realization of agreement, rather than considering them to be overt subjects. Agreeing with Pierce (1992), we consider them to provide a reliable diagnostic for finiteness in child French. We also count verbs with a finite morphological shape which occur with an appropriate overt subject as agreeing.

The widespread tendency of young children to omit auxiliaries raises another issue with respect to coding. A past participle with no auxiliary has an adjectival use in adult French, and in the absence of an auxiliary it is nearly impossible to determine which use was intended by the child (adjective, main verb, or past tense). Similarly, a bare infinitive might represent either the future tense with no auxiliary, or a true NRF. We have coded only forms of the verb consisting of both the auxiliary and the participle/infinitive as instantiations of tense. Participles and infinitives used without the auxiliary were coded as non-finite forms.

We calculated the proportions of forms morphologically inflected for tense and/or agreement out of the total number of verbs produced by each child at each attested PLU stage. It is well-known that the third person singular and present tense forms are the first to appear in child productions, and for a time may be the only finite forms produced by the child. Furthermore, young children tend to overuse third person singular and present tense forms. This suggests that these serve as “default” forms, making it unclear whether a third person singular (3sg) verb is truly agreeing with a 3sg subject or whether it lacks agreement and is taking on an “elsewhere” form (see also Ferdinand, 1996). To determine the proportion of children’s verbs which actually show

agreement (and not a default form), we have counted only non-3sg and non-present forms as unambiguously showing agreement, and we present our results in these terms.

Tables 1–2 below summarize our findings relating to the use of tense and agreement, respectively, by each child. The numbers in Table 1 show the proportion of tensed verbs which had non-present forms, those in Table 2 show the proportion of verbs which appeared with non-3sg agreement. Of the verbs showing present tense or 3sg agreement, some presumably reflect a default form, while others reflect correct 3sg agreement or present tense. We will estimate the proportion of correct vs. default tense/agreement marking following the discussion below.

The combined results are graphed in Figure 1 to illustrate the development of tense and agreement across the attested PLU stages.

Because the figures in Table 1 are the percentages of overall utterances that contain *non-present* tense forms in Table 1, we do not ever expect these figures to reach 100%. To understand what level of production these percentages correspond to, we need to know what *adult-like* production of non-present tense forms is. To determine this, we ran a similar count on the adult utterances in two of the CHILDES files (Philippe 11 and Grégoire 9) in order to get at least a reasonable estimate of what adult use of non-3sg and non-present forms is. These results are given in Table 3.

Assuming that adults always produce finite verbs and given that they produce non-present tense verbs roughly 31% of the time, we can reasonably take the children’s 35% production of non-present tense (out of unambiguously tensed verbs) at stage 3b to be an adult-like level of production. On the other hand, we can also reasonably assume that the 4% production of non-3sg (of agreeing verbs) at stage 3b indicates that the children are not realizing agreement and are using a default (3sg) form.

As we can see from Tables 1–2 and Figure 1 below, tense and agreement undergo distinct patterns of development. At stage 3b, the proportion of agreeing forms in the children’s speech is negligible—it is clear that they are not yet using agreement. At the same time, the proportion of tensed forms is sufficiently high to allow us to conclude that tense is already in regular use. At the subsequent stage, 4b, agreement emerges at a significant, though not yet adult-like, level. Notice that at stage 4b, tense suffers a dip

Table 1: Verbs with non-present tense inflection (out of unambiguously tensed verbs)

Child	Stage 3b	Stage 4b	Stage 4c
G	34% (66/194)	21% (44/212)	32% (205/646)
S	37% (19/52)	10% (17/179)	25% (34/135)
P		13% (44/334)	30% (74/246)
Avg	35% (85/246)	15% (105/725)	31% (313/1027)

Table 2: Verbs with non-3sg agreement inflection (out of unambiguously agreeing verbs)

Child	Stage 3b	Stage 4b	Stage 4c
G	3% (5/156)	19% (33/172)	34% (221/650)
S	5% (2/43)	12% (13/109)	38% (51/133)
P		15% (44/303)	40% (98/246)
Avg	4% (7/199)	15% (90/584)	36% (370/1029)

Table 3: Adult usage of non-3sg and non-present tense

Adults from file	non-present	non-3sg
Grégoire 9	28% (184/661)	35% (231/659)
Philippe 11	34% (173/507)	41% (205/506)
Avg	31% (357/1168)	38% (437/1165)

Figure 1. Tense and agreement

in production compared to stage 3b. This interesting correlation between increased use of agreeing forms and decreased use of tensed forms suggests a temporary competition between the two before they both stabilize at the subsequent stage, 4c.

The dissociation between tense and agreement is especially striking in the child production of periphrastic tenses; throughout stage 3b, Grégoire and Stéphane produce numerous instances of the past and future tenses; however, the auxiliary that appears in these utterances is always 3rd person singular: *Papa et Maman est parti* ‘Father and Mother is gone’ (Grégoire 2;0.5).

Turning now to NRFs, we found that children produce steadily fewer of these as their age/PLU stage increases. Our findings are given in Table 4 and graphed in Figure 2.

Comparing Figures 1–2, we can see that the reduction in the use of NRFs over time appears to be inversely correlated with the development of agreement: in a sense, the NRF pattern is the mirror image of the pattern we have found for agreement (Table 2). By contrast, the decrease in NRFs does not appear to correlate with the development of tense; compare Figure 2 to the previous graph of tense (Figure 1). This observation is important in light of existing claims that relate the occurrence of NRFs to the development of Tense. For example, Wexler (1994) has proposed that the underspecification of Tense is responsible for the presence of NRFs (his ‘root infinitives’) in young children’s speech. Our findings suggest at the very least that the development of agreement is also involved; the profile of NRFs is not directly linked to the profile of realization of tense.

### An Optimality-Theoretic Model of Development

Informally, the main idea behind our proposal is the following: At Stage 3b, constraints requiring realization of finiteness compete with constraints on economy of structure,

Table 4: Non-finite root forms (NRFs) out of all verbs

Child	Stage 3b	Stage 4b	Stage 4c
G	28% (83/297)	18% (51/287)	1% (7/711)
S	48% (51/106)	13% (27/205)	2% (3/152)
P		22% (105/476)	6% (14/250)
Avg	33% (134/403)	19% (183/968)	2% (24/1113)

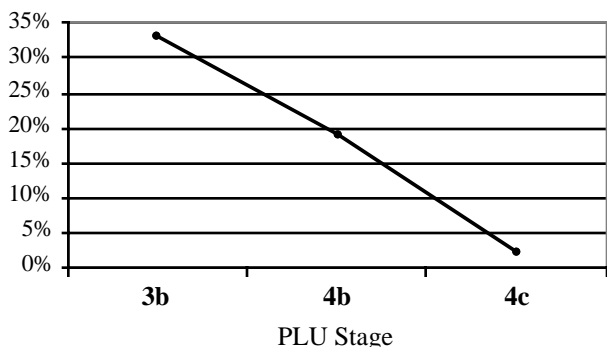

Figure 2. Non-finite root forms out of all verbs

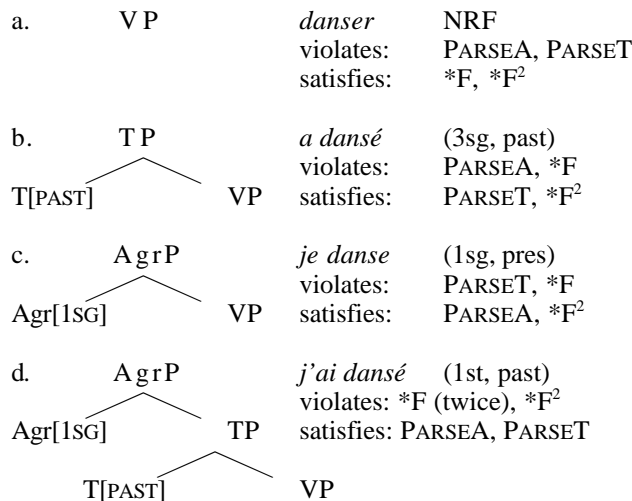

Figure 3. Candidates for input containing past tense and 1st singular agreement features

sometimes resulting in the production of finite verbs and sometimes resulting in the production of NRFs. At Stage 4b, tense and agreement compete for a single structural position; a functional projection which can realize the features either of tense or of agreement (but not both). At Stage 4c, two positions are available, allowing both tense and agreement features to be realized without competition.

Formally, the constraints which require parsing of the functional features (PARSET(ense), PARSEA(reement)) rise in the ranking relative to a fixed hierarchy of constraints penalizing structure. PARSET and PARSEA are Faithfulness constraints ensuring that what is expressed (the output of the grammar) differs minimally from what is intended (the input to the grammar).

Assuming, as is standard in generative syntax since Pollock (1989), that the presence of inflectional categories is indicative of phrase structure above that instantiating lexical categories, the constraints penalizing structure can be stated as \*F (‘No functional heads’) and \*F<sup>2</sup> (‘No pairs of functional heads’) with the invariable ranking \*F<sup>2</sup> >> \*F.<sup>2</sup>

There are four candidate structures relevant to this analysis (we assume that the input to every evaluation has tense and agreement features subject to Faithfulness constraints). They are given in Figure 3 along with examples and the constraints each satisfies and violates.

The key to our proposal is the ability of the Faithfulness constraints to “float” over a certain range in the ranking (unlike the Economy of Structure constraints \*F, \*F<sup>2</sup> discussed above, which remain fixed in their relative ranking) during the course of development. Formally, the model relies on partial constraint ranking (Reynolds, 1994; Anttila 1997, Nagy & Reynolds, 1997) and can predict not only that we see variation in outputs of the developing grammar, but also with what frequency we will see each output. As illustrated in Figure 4, a partial ordering (a) translates into a set of

<sup>2</sup> F<sup>2</sup> >> F invariably because they are part of a Power Hierarchy: F<sup>2</sup> is a local conjunction of two instances of \*F (Legendre, Smolensky & Wilson, 1998; Smolensky, 1995).

Figure 4. Partial ordering and resulting rankings

rankings (b). We see that a different candidate structure wins under each of the rankings in (b); under ranking (bi), a candidate with a nonfinite verb wins, while under ranking (bii) a candidate with a tensed verb (that is, with a functional projection to realize tense features). For any given evaluation, a grammar with the partial ordering in (a) will use one of the rankings, either (bi) or (bii), to determine the optimal candidate. Thus, in any given evaluation, either a tensed verb or an untensed verb will win the competition. We make the further assumption that either of the two rankings has an equal chance of being called upon during an evaluation (for a different assumption see Boersma, 1997). This means that there is a 50% chance that ranking (bi) will be used, yielding an untensed verb as the optimal candidate. To put it another way, we expect to see the untensed candidate 50% of the time (and to see the tensed candidate the other 50% of the time).

This example illustrates well the nature of the conflict underlying the development of finiteness. Functional features can only be parsed (satisfying the Faithfulness constraints PARSET and/or PARSEA) if the Economy of Structure constraints (\*F and possibly \*F<sup>2</sup>) are violated. The conflict is resolved by ranking. If Economy of Structure dominates Faithfulness, then functional features cannot be parsed and the optimal candidate will be a nonfinite form acting as a main verb (an NRF). If Faithfulness dominates Economy of Structure, then functional features will be parsed into a functional head, yielding a finite form as the optimal candidate (recall that *either* tensed *or* agreeing forms count as “finite” under our terminology).

This analysis, set in OT and using partial rankings, also unifies two otherwise incompatible views on the acquisition of syntactic structure. On one side, the Full Competence Hypothesis (or “Strong Continuity”; see, e.g., Poeppel & Wexler 1993) proposes that the full adult-like syntactic structures are available to the child’s grammar essentially from the outset of acquisition. On the other side, the Structure Building Hypothesis (or “Weak Continuity”; see, e.g., Vainikka 1993/4) proposes that a child initially uses syntactic structures much simpler than those of the adult language, over time adding complexity until the adult stage is reached. Our analysis shares with Full Competence the idea that the full range of the adult grammar is available to children; all of the constraints are present (but ranked in a non-adult way), the difference between a child grammar and an adult grammar is of the same type as the difference between two adult grammars (i.e., differing rankings among constraints), and the underlying representations used by children and adults draw from the same set of grammatical features. Simultaneously, our analysis shares with the Structure Build-

Figure 5. Stage 3b

ing Hypothesis the view that children’s representations are simpler than adult structures to begin with and become more complex over time. On our analysis, this is not due to a lack of access to adult grammatical constructs, but rather to a low ranking of Faithfulness constraints relative to constraints prohibiting structure.

The actual course of development of finiteness we propose here is an expanded version of this basic re-ranking schema. We will see that the PARSE constraints advance separately, at one point (Stage 3) with PARSET invariably outranking PARSEA with the result that the observed finite forms will be tensed, but non-agreeing.

**A Stage-By-Stage Analysis of Development**

We begin with stage 3b, where the rankings are as in Figure 5, yielding the 3 rankings given in (a–c).

At stage 3b, PARSET spans a range allowing it to sometimes outrank \*F<sup>2</sup>, and sometimes be outranked by \*F. PARSEA is always outranked by both \*F and \*F<sup>2</sup>.

Of the three rankings, only (c) results in an NRF; under this ranking, it is better not to have a functional projection (satisfying \*F) than to parse tense (which would satisfy PARSET) or agreement (which would satisfy PARSEA). This means that we expect NRFs to comprise one-third of a child’s utterances at Stage 3b.

The other two rankings yield a tensed form, but without agreement. Under these two rankings, PARSET outranks \*F, making it more important to realize tense in a functional projection than to avoid functional projections. Neither ranking yields an agreeing form because this would require two functional projections, and PARSEA is under both rankings outranked by \*F<sup>2</sup>. Thus, we expect tensed forms (without agreement) to comprise the other two-thirds of a child’s utterances at stage 3b.

What we actually observed (Table 4) was 33% NRFs and 67% finite forms, exactly the prediction. Of the finite forms, we counted only non-present forms, and found 35% such forms (Table 1). Recall that when this is compared to the adult production of 31% non-present forms (Table 3), it appears that all finite utterances the children produce at Stage 3 are tensed. Looking at agreement (Table 2), we found very few (4%) non-3sg forms, compared to an adult rate of 38%. So (with a minimal degree of idealization) we find that all finite child utterances at Stage 3 are tensed but non-agreeing, as predicted.

In Stage 4b, PARSEA advances to a position equal to PARSET; both now sometimes outrank \*F<sup>2</sup>, and can sometimes be outranked by \*F. In some rankings PARSET outranks PARSEA, while in others PARSEA outranks PARSET. These ranges yield the 12 rankings given in Figure 6.

Fixed		$*F^2$	>>	$*F$	
Floating:	PARSET				
	PARSEA				
	⇒				
a.	PARSET>>PARSEA>> $*F^2$ >> $*F$	⇒	tensed, agreeing		
b.	PARSEA>>PARSET>> $*F^2$ >> $*F$	⇒	tensed, agreeing		
c.	$*F^2$ >> $*F$ >>PARSET>>PARSEA	⇒	NRF		
d.	$*F^2$ >> $*F$ >>PARSEA>>PARSET	⇒	NRF		
e.	$*F^2$ >>PARSET>>PARSEA>> $*F$	⇒	tensed		
f.	$*F^2$ >>PARSEA>>PARSET>> $*F$	⇒	agreeing		
g.	PARSET>> $*F^2$ >>PARSEA>> $*F$	⇒	tensed		
h.	PARSEA>> $*F^2$ >>PARSET>> $*F$	⇒	agreeing		
i.	PARSET>> $*F^2$ >> $*F$ >>PARSEA	⇒	tensed		
j.	PARSEA>> $*F^2$ >> $*F$ >>PARSET	⇒	agreeing		
k.	$*F^2$ >>PARSET>> $*F$ >>PARSEA	⇒	tensed		
l.	$*F^2$ >>PARSEA>> $*F$ >>PARSET	⇒	agreeing		

Figure 6. Stage 4b

Fixed		$*F^2$	>>	$*F$	
Floating:	PARSET				
	PARSEA				
	⇒				
a.	PARSET>>PARSEA>> $*F^2$ >> $*F$	⇒	tensed, agreeing		
b.	PARSEA>>PARSET>> $*F^2$ >> $*F$	⇒	tensed, agreeing		

Figure 7. Stage 4c

Two of these rankings, (a–b), yield verb forms which are both tensed and agreeing (that is, essentially adult forms), since under those rankings it is more important to realize both tense and agreement than it is to avoid having two functional projections. Another two rankings, (c–d), yield NRFs, since under these rankings it is more important not to have any functional projections than it is to realize either tense or agreement. The rest of the rankings (e–l) yield finite forms which are either tensed (when PARSET outranks PARSEA) or agreeing (when PARSEA outranks PARSET), but not both.<sup>3</sup>

This predicts, then, that only 17% (2 out of 12) of the verb forms uttered at Stage 4b should be NRFs. We observed (Table 4) 19% NRFs, very close to the prediction. Of the remaining verbs, all finite, 17% are predicted to be adult-like (with both tense and agreement), the remaining forms having only one or the other (33% of them with only tense, 33% of them with only agreement). Again, this lines up well with the observations. Further, of the finite verbs we predict 19% non-present forms and observe 15% (Tables 1

<sup>3</sup> Note that a higher degree of constraint overlap yields a larger number of possible rankings for each evaluation, but this does not mean that the child must “exert more effort to choose” where the number of possible rankings is large. If, metaphorically, the child’s task before evaluation is to choose a random position (within its range) for each constraint, the size of this task is affected only by the number of constraints, not by the amount of overlap. Looking in from outside, we can compute which rankings could result and what the individual likelihood is of each, but this has no effect on the actual process of fixing a ranking.

and 3), and predict 23% non-3sg forms and observe 15% (Tables 2 and 3).<sup>4</sup>

Compare stage 4b to stage 3b with respect to the realization of tense. Notice that, while at stage 3b, 100% of the finite utterances were tensed, at stage 4b only 60% (6 out of 10) of the finite forms are tensed. In other words, we predict (and in fact observe) a “dip” in the child’s production of tensed forms. If children were simply “learning tense” (speaking vaguely), we would not have expected them to get worse at any point during the course of development. The proposed analysis provides an explanation for this otherwise puzzling fact. Back in stage 3b, PARSEA was ranked so low as to ensure that tense features were realized in the single functional projection allowed. What has happened at stage 4b is that the tense features and agreement features now compete for realization in the single functional projection available. Since tense sometimes (in fact, half the time) loses to agreement, we predict the observed dip in the proportion of tensed forms, which coincides with an increase in the proportion of agreeing forms.

In the last stage covered in our data, stage 4c (Figure 7 above), PARSET and PARSEA together move to a position high enough in the hierarchy that they invariably outrank  $*F^2$ . This yields 2 rankings, but both produce the same optimal candidate, a finite form which realizes both Tense and Agreement. At this stage, we predict no NRFs, and we observed only 2% NRFs in child speech (Table 4). We also expect the children’s production of non-present forms and non-3sg forms to match the proportion in adult speech, which it does quite well; we observed (Tables 1–3) 31% non-present tense forms compared with 31% for adults, and 36% non-3sg forms compared with 38% for adults.

Figures 8–9 (next page) summarize graphically how the predictions of the model match the observed child data.

### Concluding Remarks

To sum up, our research has uncovered previously overlooked properties of the acquisition of tense and agreement. We found that tense and agreement in French follow distinct courses of acquisition over the three stages studied. While the use of tense starts and ends strong, it suffers a “dip” at the intermediate stage. Meanwhile, agreement develops in a more linear way while the proportion of NRFs drops, also linearly. The distinctive profile naturally leads to an analysis in which, at the intermediary stage, tense and agreement are competing for realization. In particular, an Optimality-Theoretic analysis making use of “floating constraints” (defining partial ranking orders) allow us to predict not only the occurrence of the observed types of utterances, but their frequency as well. This result is novel; previous analyses (e.g.

<sup>4</sup> The predictions here are again scaled by the “expected” proportion of non-present forms and non-3sg forms based on what we found in the observed adult speech (Table 3). 60% of forms are predicted to be tensed by our analysis, and adults produce 31% non-present forms, so we expect to find  $60\% \times 31\% = 19\%$  of (finite) child utterances to be in a non-present form. Similarly, since adults produce 38% non-3sg forms, we expect to find  $60\% \times 38\% = 23\%$  non-3sg forms in the children’s (finite) utterances.

Figure 8. Predicted vs. observed tense and agreement data

Ferdinand, 1996; Pierce, 1992; Wexler 1994, 1998) have provided no clear way even to describe the facts about the changing frequencies of tense and agreement realizations over the course of acquisition. Under our proposal, the frequency predictions are a natural consequence of the re-ranking mechanism. The fundamental principle of OT, that grammars share the same constraints but rank them differently with respect to one another, requires that the acquisition process be one of re-ranking constraints. We have proposed that this re-ranking occurs not in sudden jumps but by spreading constraints across ranges in the rankings, narrowing in on the correct adult ranking. These “floating” or partially ranked constraints allow our model to make frequency predictions that seem to be borne out in child French.

## Abstract

This paper presents Infinite RAAM (IRAAM), a new fusion of recurrent neural networks with fractal geometry, allowing us to understand the behavior of these networks as dynamical systems. Our recent work with IRAAMs has shown that they are capable of generating the context-free (non-regular) language  $a^n b^n$  for arbitrary values of  $n$ . This paper expands upon that work, showing that IRAAMs are capable of generating syntactically ambiguous languages but seem less capable of generating certain context-free constructions that are absent or disfavored in natural languages. Together, these demonstrations support our belief that IRAAMs can provide an explanatorily adequate connectionist model of grammatical competence in natural language.

## Natural Language Issues

In an early and extremely influential paper, Noam Chomsky (1956) showed that natural languages (NL's) cannot be modeled by a finite-state automaton, because of the existence of center-embedded constructions. A second and equally important observation from this work was that a minimally adequate NL grammar must be ambiguous, assigning more than one structure (interpretation) to some sentences, for example, *They are flying planes*.

The first observation led to the development of Chomsky's formal hierarchy of languages, based on the computational resources of the machines needed to recognize them. In this hierarchy, Chomsky's observation about center-embedding is expressed by saying that NL's are non-regular; i.e., they cannot be generated by a grammar having only rules of the form  $A \rightarrow bC$ , where  $A$  and  $C$  are non-terminal symbols and  $b$  is a terminal symbol.

Whether NL's are merely non-regular, belonging in the next, context-free (CF) level of the Chomsky hierarchy, or are more powerful, belonging further up in the hierarchy, became the subject of heated debate (Higginbotham 1984; Postal and Langendoen 1984; Shieber 1985). Non-CF phenomena such as reduplication/copying (Culy 1985) and crossed serial dependencies (Bresnan, Kaplan, Peters, and Zaenen 1982) suggested that a more powerful approach, using syntactic transformations (Chomsky 1957) was called for, but some researchers criticized transformations as having arbitrary power and thus failing to constrain the types of languages that could be expressed (Gazdar 1982). Further criticism of the entire formal approach came from observing that even CF grammars (CFGs) had the power to generate structures, such as a sequence followed by its mirror image, that did not seem to occur in NL (Manaster-Ramer 1986), or which placed an

extraordinary burden on the human parsing mechanism when they did occur (Bach, Brown, and Marslen-Wilson 1986).

## Connectionism and Natural Language

While debates about the complexity of NL were raging, connectionism was beginning to awaken from a fifteen-year sleep. In connectionist models many researchers found a way of embodying flexibility, graceful degradation, and other non-rigid properties that seem to characterize real cognitive systems like NL. This research culminated the publication of a highly controversial paper by Rumelhart and McClelland (1986) which provided a connectionist account of part of the grammar of English using a feed-forward neural network. The paper was soon criticized by more traditional cognitive scientists (Fodor and Pylyshyn 1988; Pinker and Prince 1988), who cited the non-generative nature of such connectionist models as a fundamental shortcoming of the entire field.

Partly in response to these criticisms, many connectionists have spent the past decade investigating network models which support generativity through recurrent (feedback) connections (Lawrence, Giles, and Fong 1998; Rodriguez, Wiles, and Elman 1999; Williams and Zipser 1989). The research we present here is an attempt to contribute to this effort while focusing as strongly as possible on the natural language issues described above. Such an attempt faces a number of challenges.

First, despite analysis of how a network's dynamics contribute to its generativity, it is often uncertain whether the dynamics can support generation of well-formed strings beyond a certain length. That is, it is unknown whether the network has a true "competence" for the language of which it has learned a few exemplars, or is merely capable of generating a finite, and hence regular, subset of the language.<sup>1</sup> Second, it is often easier to model weak, rather than strong generative capacity, by building networks that generate or recognize strings having certain properties, without assigning any syntactic structure to the strings. Third, this lack of syntactic structure inhibits the formulation of an account of syntactic ambiguity in such networks, making them less plausible as models of NL.

---

<sup>1</sup>To be fair, not all connectionists, or cognitive scientists, take seriously the notion that human language has infinite generative capacity. Though we obviously do not have the resources to argue the issue here, we are certain that a model with a provably infinite competence would be more persuasive to the cognitive science community as a whole than would a model without one.

In sum, we are concerned with formulating a recurrent network model that rigorously addresses the set of criteria that emerged from the long debate over the complexity of NL. As an candidate, the remainder of this paper presents a new formulation of RAAM (Pollack 1990), a recurrent network model that addresses the NL issues in a principled way.

### Traditional RAAM

Recursive Auto-Associative Memory or RAAM (Pollack 1990) is a method for storing tree structures in fixed-width vectors by repeated compression. Its architecture consists of two separate networks – an encoder network, which can construct a fixed-dimensional code by compressively combining the nodes of a symbolic tree from the bottom up, and a decoder network, which decompresses a fixed-width code into its two or more components. The decoder is applied recursively until it terminates in symbols, reconstructing the tree. These two networks are simultaneously trained as an auto-associator with time-varying inputs. If the training is successful, the result of bottom up encoding will coincide with top down decoding.

Following the publication of (Pollack 1990), RAAM gained widespread popularity as a model of NL syntax. Some researchers (Blank, Meeden, and Marshall 1991) found it an attractive way of “closing the gap” between the symbolic and sub-symbolic paradigms in cognitive science. Others (Van Gelder 1990) saw in RAAM a direct and simple refutation of the traditional cognitive scientists’ backlash against connectionism, and went as far as to show how traditional syntactic operations like transformations could be performed directly on RAAM representations (Chalmers 1990). As the power of the RAAM model became apparent, variants began to emerge. These included the Sequential RAAMs of (Kwasny and Kalman 1995), which showed how a RAAM could behave like a linked list, and the Labeling RAAMs of (Sperduti 1993), which encoded labeled graphs containing cycles.

In short, RAAM seemed to hold a great deal of promise as a general connectionist solution to encoding not just NL syntax, but all sorts of structured representations.

Still, RAAM was plagued by an apparently diverse set of problems, most notably a failure to scale up to realistically large structures. We believe that these problems can be traced to the original formulation of the RAAM decoder, which works in conjunction with a logical “terminal test”, answering whether or not a given representation requires further decoding. The default terminal test merely asks if all elements in a given code are boolean, e.g. above 0.8 or below 0.2. This analog-to-binary conversion was a standard interface in back-propagation research of the late 1980’s to calculate binary functions from real-valued neurons. However, although it enabled the initial discovery of RAAM training, it led to several basic logical problems which prevented the scaling up of RAAM: 1) The “Infinite Loop” problem is that there are representations which “break” the decoder by never terminating. In other words, some trees appear “infinitely large” simply because their components never pass the terminal test. This behavior breaks computer program implementations or requires depth checking. 2) The “Precision vs. Capacity” problem is that tighter tolerances lead to more decoding er-

rors instead of a greater set of reliable representations. 3) The “Terminating Non-Terminal” problem arises when there is a “fusion” between a non-terminal and a terminal, such that the decoding of an encoded tree terminates abruptly.

In the following section of this paper we present a new formulation of RAAM networks based on an analysis of the iterated dynamics of decoding, that resolves all these problems completely. This formulation leads to a new “natural terminal test”, a natural labeling of terminals, and an inherently higher storage capacity.

### New RAAM Formulation

$$X_L = \frac{1}{1 + e^{-(w_{LX}x + w_{LY}y + w_{LB})}}$$

$$Y_L = \frac{1}{1 + e^{-(w_{LY}x + w_{LY}y + w_{LY})}}$$

$$X_R = \frac{1}{1 + e^{-(w_{RX}x + w_{RY}y + w_{RB})}}$$

$$Y_R = \frac{1}{1 + e^{-(w_{RY}x + w_{RY}y + w_{RY})}}$$

Figure 1: An example RAAM decoder that is a 4 neuron network, parameterized by 12 weights. Each application of the decoder converts an  $(X, Y)$  coordinate into two new coordinates.

Consider the RAAM decoder shown in figure 1. It consists of four neurons that each receive the same  $(X, Y)$  input. The output portion of the network is divided into a right and a left pair of neurons. In the operation of the decoder the output from each pair of neurons is recursively reapplied to the network. Using the RAAM interpretation, each such recursion implies a branching of a node of the binary tree represented by the decoder and initial starting point. However, this same network recurrence can also be evaluated in the context of dynamical systems. This network is a form of *iterated function system* or IFS (Barnsley 1993), consisting of two pseudo-contractive transforms which are iteratively applied to points in a two-dimensional space.

In the past we have examined the applicability of the IFS analogy to other interpretations of neural dynamics (Blair and Pollack 1997; Kolen 1994; Melnik and Pollack 1998; Stucki and Pollack 1992). But in the context of RAAMs the main interesting property of contractive IFSes lies in the trajectories of points in the space. For contractive IFSes the space is divided into two sets of points. The first set consists of points located on the underlying attractor (fractal attractor) of the IFS. The second set is the complement of the first, points

that are not on the attractor. The trajectories of points in this second set are characterized by a gravitation towards the attractor. Finite, multiple iterations of the transforms have the effect of bringing the points in this second set arbitrarily close to the attractor.

As noted before, the Infinite Loop and Terminating Nonterminal problems arise from an insufficient terminal test. Since some trajectories never leave the attractor and all others eventually hit the attractor. The only terminal test that guarantees the termination of all trajectories of the RAAM (IFS) is a test that includes all the points of the attractor itself.

By taking the terminal test of the decoder network to be “on the attractor”, not only are problems of infinite loops and early termination corrected, but it is now possible to have extremely large sets of trees represented in small fixed-dimensional neural codes. The attractor, being a fractal, can be generated at arbitrary resolution. In this interpretation, each possible tree, instead of being described by a single point, is now an *equivalence class* of initial points sharing the same tree-shaped trajectories to the fractal attractor. For this formulation, the set of trees generated and represented by a specific RAAM is a function of the weights, but is also governed by how the initial condition space is sampled, and by the resolution of the attractor construction. Note that the lower-resolution attractors contain all the points of their higher-dimensional counterparts (they cover them); therefore, as a coarser terminal set, they terminate trajectories earlier and so act to “prefix” the trees of the higher-dimensional attractors.

Two last pieces complete the new formulation. First, the encoder network, rather than being trained, is constructed directly as the mathematical inverse of the decoder. The terminal set of each leaf of a tree is run through the inverse left or right transforms, and then the resultant sets are intersected and any terminals subtracted. This process is continued from the bottom up until there is an empty set, or we find the set of initial conditions which encode the desired tree.

Second, using the attractor as a terminal test also allows a natural formulation of assigning labels to terminals. Barnsley (1993) noted that each point on the attractor is associated with an address which is simply the sequence of indices of the transforms used to arrive on that point from other points on the attractor. The address is essentially an infinite sequence of digits. Therefore to achieve a labeling for a specific alphabet we need only consider a sufficient number of significant digits from this address.

### Example of New RAAM Formulation

In this section, we describe how we obtain the attractor and the trees for a RAAM decoder of the sort shown in figure 1. The decoder weights in the present example were obtained by a hill-climbing search for an aesthetically appealing attractor, but the demonstration is valid for any set of decoder weights.

Recall that we are treating the decoder as an IFS that maps each input point  $(X, Y)$  in the range  $[0,1]$  to two other points  $(X_L, Y_L)$  and  $(X_R, Y_R)$  in the same range. To generate the attractor of the IFS, we first apply the two mappings (transforms) to the entire unit square at some fixed resolution. We then re-apply the transforms to the resulting set of points. We repeat this operation until the transforms do not change the

set of points any further at that resolution. Hence, we can visualize the behavior of the decoder in the unit square by examining the set of points obtained through iterated applications of the two transforms.

In figure 2, we have applied the transforms once to all points in the unit square, obtaining two large, overlapping regions, corresponding to the left and right transforms of all the original points. Note that some points are part of both the left and right regions.

Figure 2: The unit square after one application of the transforms. The attractor is shown in gray: dark gray = points reachable from attractor on left transform, light gray = points reachable on right. The small white wedge where the gray areas overlap contains “ambiguous” attractor points reachable on both transforms.

Figure 3: The unit square after two and five applications of the transforms.

Figure 3 shows the unit square after another iteration of the transforms, and after five such iterations. Figure 4 shows the final “Galaxy” attractor obtained when further iterations fail to produce any more contraction. Like any fractal, this attractor exhibits self-similarity, with the two longest arms of the galaxy ending in shapes like that of the whole attractor.

Figure 4 also shows how we derive the tree  $(1(12))$  from a point not on the attractor. Starting at a point not on the attractor (the small circle at the top of the figure), the left transform (dashed line) takes us immediately to the attractor; specifically, to an attractor region labeled 1, indicating that this region is reachable from the other attractor points on the left (first) transform only. Hence our tree so far is  $(1 \dots)$ . The *right* transform of the point at the top takes us to another point

not on the attractor, indicated by the circle in the lower left part of the figure. Like the first point, this point goes to the attractor region labeled 1 on its left transform; however, it also goes to the attractor on its right transform; specifically, to the region labeled 2, which indicates that this region is reachable from the other attractor points on the right (second) transform only. So this second point decodes the tree (1 2), and its parent tree is (1 (1 2)), completing the derivation.

Figure 4: The final attractor, showing derivation of the tree (1 (1 2)) and its daughter tree (1 2). The left transform is shown as a dashed line, and the right transform as a straight line.

By repeating this process for every point not on the attractor, we can map out the set of all trees decoded by the RAAM at a given resolution. As described earlier, each tree in this set corresponds to an equivalence class of points that all decode to that tree. Points in the same class tend to cluster together, giving us an interesting way of laying out the RAAM’s language spatially. Figure 5 shows this phenomenon for a RAAM that we hill-climbed to decode the language  $a^n b^n$  (described in the next section), with grayscale denoting tree equivalence classes rather than attractor points. The dramatic striping pattern of the equivalence classes in this figure is not inherent in the fractal RAAM model, but derives from the comparatively elegant solution that hill-climbing produced for this language.

### Linguistic Advantages of New RAAM

As we described earlier, the new RAAM formulation thoroughly addresses the three shortcomings of the traditional RAAM model. Infinite loops and terminating non-terminals are both eliminated by making the terminal test be a test of whether or not a point is on the fractal attractor of the RAAM decoder.

Furthermore, the new formulation provides a principled account of generativity (grammatical competence). By treating the RAAM as a fractal that can be generated at any arbitrary resolution, we can increase the generative capacity of the RAAM without bound, giving us a model that scales perfectly: hence the name Infinite RAAM (IRAAM). As we have recently shown (?), it is a straightforward matter to hill-climb the weights for an IRAAM that generates all and only the strings in the language  $a^n b^n \cup a^n b^{n+1}, n \leq 5$ .

Figure 5: Tree equivalence classes for the  $a^n b^n$  system. Attractor points cluster at extreme left (colored black, labeled 1 or  $a$ ) and right (colored white, labeled 2 or  $b$ ).

Briefly, the dynamics of the network are such that for any point in the unit square, one of the two transforms of the point is guaranteed to be on the attractor. This behavior corresponds to the terminal component of a recursive grammar in Chomsky Normal Form for the language. In addition, the left transform of any point ends up on the left side of the unit square ( $x = 0$ ) and the right transform ends up on the right side ( $x = 1$ ). Hence, successive application of left/right/left... transforms leads to a zigzag dynamics that balances  $a$ ’s on the left with  $b$ ’s on the right, until a zig or zag lands on the attractor and terminates the oscillation. This behavior corresponds to the recursive component of the grammar. In (?), we provide a constructive proof for obtaining these behaviors at any resolution.

The proof gives us an exact IRAAM “competence” model for this non-regular CF language. Specifically, we show that there exists a set of weights for which a RAAM with an attractor generated at a predetermined resolution contains all and only the trees in the  $a^n b^n$  language. Performance limitations on the sizes of the trees actually produced derive from the resolution at which the non-attractor unit space is sampled, and not from an arbitrary stipulation or a breakdown of the model.

This infinite competence is not the only thing that IRAAM brings to connectionist NL modeling, however. Because IRAAM is a method of encoding and decoding *trees*, not just strings, its strong generative capacity is known. We can therefore use IRAAM as a direct model of hierarchical linguistic structure. An immediate implication of this result is that an IRAAM can be used as a parser and not just a recognizer. To the extent that real NL processing involves the assignment of meaning to strings based on structure, and not merely grammaticality judgments, this ability represents a significant advance in the application of connectionism to NL.

Finally, and perhaps most interesting, is the way in which IRAAM handles syntactic ambiguity. Consider the fractal addressing scheme that we described earlier. Each terminal point (word) on the attractor is associated with an address which is simply the sequence of indices of the transforms taken to arrive on the attractor point from other points on the attractor. Given  $K$  transforms, we would therefore assume

each digit in the sequence would fall in the range  $1, 2, \dots, K$ . For example, a binary-branching IRAAM, with two transforms, would have terminals with address digits 1 and 2. Using a one-digit address, this effectively puts each word into one of  $K$  “part of speech” equivalence classes.

This is not the whole story, though. Because there can be more than one path to a given terminal from some other terminal on the attractor, some terminals will have “ambiguous” addresses, containing digits out of the range  $1..K$ , to express the fact that more than one transform was taken to arrive at that point in the sequence. Continuing the linguistic analogy, this ambiguity corresponds to a given word’s belonging to more than one part of speech, as in Chomsky’s “flying planes” example, where *flying* can be either a verb or an adjective. For the binary-branching IRAAM example, if a given point had both a left and right inverse on the attractor, a one-digit address for that point would have to be a symbol other than 1 or 2. In general, for a  $K$ -ary IRAAM, there are  $2^K - 1$  possible one-digit addresses, consisting of  $K$  unambiguous values and  $2^K - K - 1$  ambiguous values.

This fact has great linguistic importance for IRAAM, for the following reason: typically (but not exclusively), an IRAAM decoder will favor putting the  $k$ th non-ambiguous terminal class in the  $k$ th position in a string of terminals, because the same set of weights is used to generate the attractor and the transients to the attractor. The likeliest non-terminal structure of a binary-branching IRAAM will therefore be (1 2), with structures (1 1), (2 1) and (2 2) being possible but less likely to occur. If, however, this IRAAM contains ambiguous terminals, it will very likely decode the structures (1 3), (3 2) and (3 3) as well.

Returning to the “flying planes” example, let us assign unambiguous verbs like *are* the category 1, unambiguous nouns like *planes*<sup>2</sup> the category 2, and the ambiguous *flying* the category 3. With this assignment, the natural ability of a binary IRAAM to decode the structures (1 (3 2)) and ((1 3) 2) gives us both parses of the expression *are flying planes*. Hence, we have an existence proof of a RAAM that can deal with syntactic ambiguity and non-deterministic grammars.

In short, we believe that IRAAM not only solves the problems of the earlier RAAM model, but also addresses the linguistic inadequacies of recurrent neural net models that we discussed earlier.

## What IRAAM Can’t Do

In the first section of this paper we outlined two linguistic criteria for a plausible NL model: the model should be able to handle “slightly” non-CF phenomena like copying and crossed serial dependencies and should also be incapable of handling CF phenomena absent from or deprecated in NL’s, like mirror-image constructions, or should incur a relatively high cost in producing or parsing those structures.

To investigate the latter point, we tested the ability of the IRAAM model shown in figure 1 to “learn” the context-free languages  $a^n b^n$  and  $ww^R$ ,  $w \in \{a, b\}$ . The training set consisted of the first 14 exemplars of each language (enumerated

<sup>2</sup>Readers troubled by the possibility of *planes* being a singular verb (*The carpenter planes the wood*) can substitute *cars* or some other unambiguous noun here.

in increasing order of length)<sup>3</sup>, with the fractal address 1 representing  $a$  and 2 representing  $b$ . Hill-climbing was used to learn the weights. Both the initial weights and the noise added to each weight came from a Gaussian distribution with zero mean and a standard deviation of 5.0, with the added noise’s standard deviation being scaled by the fraction of the training set missed. The resulting weights were used to generate trees on an IRAAM with a resolution of  $2^{-7}$ . The attractor was generated at that resolution and the initial starting point space was also sampled at that resolution.

Hill-climbing did not produce good results on either of these languages; the average success was six out of 14 strings covered for both languages. It is, however, instructive to look out *how* those successes were achieved. Comparing the best hill-climbed networks from each language (10 strings covered), we found that most of the strings generated by the  $a^n b^n$  network fit the general pattern of the training set: 74% of the strings fit the pattern  $a^n b^n$ . For the best  $ww^R$  network, however, only 14% fit the pattern  $ww^R$ . In other words, the  $a^n b^n$  network was actually producing mostly “grammatical” strings, whereas the  $ww^R$  network was essentially guessing.

We attribute these results to IRAAM’s aforementioned tendency to put symbols of one class ( $a$ ) on the left side of a branch and symbols of another class ( $b$ ) on the right side. In other words, trees of the form  $(a b)$ ,  $(a (a b))$ ,  $((a b) b)$ ,  $(a (a (a b)))$ ,  $((a b) b) b$ , are much more “natural” for an IRAAM than are trees of the form  $(a a)$ ,  $(b b)$ ,  $(b a)$ . But it is precisely the latter types of trees that are used as building blocks for the mirror-image language  $ww^R$ . This bias makes the mirror-image language much harder for an IRAAM to learn than the counting language  $a^n b^n$ , despite the fact that both are expressible by a simple CFG.

Although this result is by no means a proof of any sort, we consider it interesting for two reasons. First, it suggests that the languages generable by an IRAAM share an important formal property with NL, namely, the avoidance of mirror-image constructions. Second, the result illustrates how IRAAM imposes a constraint between the terminal symbol “semantics” and the nonterminal “syntax.” This constraint is absent from the definition of CFG’s (or of any grammar in the Chomsky hierarchy), where any terminal symbol can appear anywhere. To the extent that individual natural languages favor putting a given part of speech in fixed locations in a sentence or phrase (e.g., English generally has subject-verb-object, Japanese subject-object-verb), IRAAM appears to have an advantage over traditional grammars as a model of NL.

## Conclusion and Interpretations

We have demonstrated a new formulation of RAAM, which, by using a fractal attractor as a terminal test, enables the model to show competence and ambiguity, to represent a variety of tree structures, and not to represent deprecated mirror-image structures. We plan to relate this new formula-

<sup>3</sup>The number 14 was chosen because it allowed us to include all the members of  $ww^R$  for  $|w| \leq 3$ . This language has more strings of a given length than the language  $a^n b^n$ , which meant that the exemplars of the latter had to be longer in order to enumerate the first 14 of them. In effect, this makes the  $a^n b^n$  task *harder* than the  $ww^R$  task.

tion to linguistic formalisms like Tree-Adjoining Grammars (Joshi and Schabes 1997) and Categorical Grammars (Steedman 1999) having similar properties. We hypothesize that this relation may be achieved through the use of multiplicative connections to gate lexical varieties into naturally recursive dynamics.

Our work is by no means complete; nor do we mean to imply that NL grammar can be represented in four neurons with 12 weights! On the other hand, the principle of contractive maps and the emergence of fractal attractors in the limit behavior of nonlinear systems are mathematical facts, and have been used successfully in image-compression systems. Recent work by Tabor (1998) provides further evidence for the relevance of such principles to connectionist modeling of natural language. We now have reason to believe that these principles, under the right interpretation and scale, can support a neurally plausible universal grammar.

# The Acquisition of Lexical and Grammatical Aspect in a Self-Organizing Feature-Map Model

Ping Li

Ping@Cogsci.Richmond.Edu

Department of Psychology

University of Richmond

Richmond, VA 23173, USA

## Abstract

This study uses self-organizing feature maps to model the acquisition of lexical and grammatical aspect. Previous research has identified a strong association between lexical aspect and grammatical aspect in child language, on the basis of which some researchers proposed innate semantic categories (Bickerton, 1984) or prelinguistic semantic space (Slobin, 1985). Our simulations indicate that this association can be modeled by self-organization and Hebbian learning principles in a feature-map model, without making particular assumptions about the structure of innate knowledge. In line with results from Li (1999), our study further attests to the utility of self-organizing neural networks in the study of language acquisition.

## Introduction

Most linguistic theories of tense and aspect recognize two kinds of aspect: lexical aspect refers to the inherent temporal meanings of a verb, whereas grammatical aspect refers to a particular viewpoint toward the described situation. For example, whether the verb characterizes a situation as having a temporal boundary or an end result is a matter of lexical aspect, whereas whether the sentence presents a situation as ongoing (progressive/imperfective) or completed (perfective) is a matter of grammatical aspect. In English as well as in many other languages, lexical aspect is typically encoded by verb semantics, whereas grammatical aspect is encoded by morphological markers (e.g., English suffixes *-ing* and *-ed*).

Linguists have developed several systems to capture lexical aspect and grammatical aspect (see Comrie, 1976; Smith, 1997). For lexical aspect, the best-known system is Vendler's (1957) four-way classification of verbs into activities, accomplishments, achievements, and states: (1) activity verbs like *walk* and *run* encode situations as consisting of successive phases over time with no inherent endpoint; (2) accomplishment verbs like *build a house* also characterize situations as having successive phases, but differ from activities in that they encode an inherent endpoint (e.g., house-building has a terminal point and a result); (3) achievement verbs encode situations as punctual and instantaneous, e.g., *recognize a friend* and *cross the border*, and (4) state verbs encode situations as involving homogeneous states with no inherent endpoint, e.g., *know*, *want*, and *possess*. On the basis of whether the verb encodes endpoints, linguists also call activity and state verbs "atelic" (no endpoint), and accomplishment and achievement verbs "telic" (with endpoint). With respect to grammatical aspect, there are two major categories, according to Comrie (1976): imperfective

and perfective. Imperfective aspect presents a situation from an internal point of view, often as ongoing (progressive) or enduring (continuous), whereas perfective aspect presents a situation from an external perspective, often as completed. In English, the imperfective-perfective contrast is realized in the difference between the progressive *-ing* and the past-perfective *-ed*.<sup>1</sup>

Studies of language acquisition have long documented the interaction between lexical aspect and grammatical aspect in child language and in adult second language learning (for a comprehensive review, see Li & Shirai, 2000). In particular, researchers have found that young children initially tend to restrict tense-aspect morphology to specific categories of lexical aspect. This restricted or "undergeneralized" use is found in diverse languages such as Chinese, English, French, Italian, Japanese, and Turkish (see Li & Shirai, 2000 for a review). For example, English-speaking children tend to associate the use of the progressive marker *-ing* only with atelic, activity verbs, whereas they associate the past-perfective marker *-ed* only with telic verbs (accomplishments and achievements).<sup>2</sup> This strong association weakens over time, and eventually children develop adult-like competence in using both the progressive and the perfective suffixes with different lexical aspect categories.

Capitalizing on this strong association in early child language, some researchers hypothesized that children have innate semantic categories that roughly correspond to the lexical aspect distinctions of verbs. In particular, Bickerton (1984) argued that the semantic distinctions between *punctual* (e.g., *jump*) and *nonpunctual* (e.g., *walk*), and between *state* (e.g., *want*) and *process* (e.g., *walk*) are biologically programmed as part of a Language Bioprogram. Bickerton's initial claim for the proposed bioprogram was based on evidence from creole languages, but he also drew on the following evidence from early child language: (1) children treat achievement verbs (punctual) differently from activity verbs (nonpunctual) in their use of grammatical morphology; (2) children treat state verbs differently from activity (process) verbs, in that they use *-ing* only with process verbs and never with state verbs. These patterns prompted Bickerton

---

<sup>1</sup> Note that *-ed* marks both past tense and perfective aspect in English, just as *-s* marks both present tense and habitual aspect. Separate affixes are often used in other languages for tense and aspect.

<sup>2</sup> Some studies also report a third association between the habitual *-s* and state verbs, e.g., Clark (1996).

that children use tense-aspect morphology early on only to mark the bioprogrammed semantic distinctions. In a similar proposal with a somewhat different perspective, Slobin (1985) proposed that children come to the language acquisition task with a pre-structured semantic space in the Basic Child Grammar. This semantic space contains a universal, uniform set of prelinguistic semantic notions, initially independent of the child's linguistic experience, and they act like magnets to strongly attract the mapping of grammatical forms of the input language. Two contrasting categories, *process* and *result*, are in this space, and thus children would tend to map the progressive *-ing* to the process (atelic) verbs and the past-perfective *-ed* to the result (telic) verbs early on.

In this study, we entertain the same empirical results with an alternative proposal that rejects the strong version of the nativist argument on innate semantic categories.<sup>3</sup> In previous empirical studies (Li & Bowerman, 1998; Li & Shirai, 2000), we proposed that the initial lexical-morphological associations could arise as a result of the learner's analyses of the verb-morphology co-occurrence probabilities in the linguistic input, rather than innate biases. In parental speech, there are probabilistic associations between progressive markers and atelic verbs, and between perfective markers and telic verbs (see Li & Shirai 2000 for a review); children's initial undergeneralizations (restricted uses of morphology) might reflect their analyses of these probabilities. This study is a detailed implementation of this idea in a connectionist model. In previous connectionist work (Li, 1999), we explored the use of self-organizing neural networks, in particular, the self-organizing feature maps as a model of language acquisition. Our model was applied to overgeneralization and recovery phenomena in the acquisition of English reversible prefixes (*un-* and *dis-*), in connection with the acquisition of structured semantic representations (the cryptotypes of verbs). In this study, we extend this line of research to examine the undergeneralization of aspectual suffixes (*-ing*, *-s*, and *-ed*), in connection with the acquisition of semantic categories of lexical aspect. More important, we attempt to show (1) how a multiple feature-map model is able to capture the processes of semantic organization that leads to distinct lexical aspect categories that have been claimed to be innate or otherwise prelinguistic, and (2) how the model could derive child-like semantic-morphological associations on the basis of analyzing patterns in parental speech from the CHILDES database (MacWhinney, 1995). Evidence from such a study could shed light on the processes of lexical and morphological development in child language.

Several important properties of self-organizing feature maps make them particularly well suited to the study of lexical and morphological acquisition (see Li, 1999, for a discussion). First, they belong to the class of unsupervised learning networks that require no explicit teacher; learning is achieved entirely by the system's organization in response to the input. These networks provide computationally more

relevant models for language acquisition: one could argue that child language acquisition in the natural setting (especially the organization and reorganization of the lexicon) is largely a self-organizing process that proceeds without explicit teaching (MacWhinney, 1998). Second, self-organization in these networks allow for the gradual formation of structures as activity bubbles on 2-D maps, as a result of extracting an efficient representation of the complex statistical regularities from the high-dimension input space (Kohonen, 1989). This property allows us to model the emergence of semantic categories as a gradual process of lexical development. Self-organizing feature maps are also biologically plausible models: one could conceive of the human cerebral cortex as essentially a self-organizing map (or multiple maps) that compresses information on a 2-D space (Spitzer, 1999). Third, several self-organizing maps can be connected via *Hebbian learning*, a co-occurrence learning mechanism, according to which the associative strength between two neurons is increased if the neurons are both active at the same time (Hebb, 1949). In a multiple feature-map model (Miikkulainen, 1997), initially, all units on one map could be associated with all units on the other map; as self-organization takes place, the associations become more focused, so that eventually only the maximally active units on the two (or more) maps are associated. This procedure allows us to model one-to-many or many-to-many associations between forms and meanings on the basis of how often they co-occur and how strongly they co-activate in the representation. In short, self-organization and Hebbian learning are two important computational principles that aid us in the understanding of lexical representation and morphological generalization in language acquisition.

## Method

### Network Architecture

DISLEX is a multiple feature-map model of the lexicon that relies on self-organization and Hebbian learning principles (Miikkulainen, 1997). In this study, we use the basic architecture of DISLEX to model the acquisition of lexical and grammatical aspect. In this model, different feature maps dedicated to different types of linguistic information (orthography, phonology, or semantics) are connected through associative links via Hebbian learning. During learning, an input pattern activates a unit or a group of units on one of the input maps, and the resulting bubble of activity propagates through the associative links and causes an activity bubble to form in the other map. If the direction of the associative propagation is from phonology or orthography to semantics, *comprehension* is modeled; *production* is modeled if it goes from semantics to phonology or orthography. The activation of co-occurring lexical and semantic representations leads to continuous organization in these maps, and to adaptive formations of associative connections between the maps. Figure 1 presents a schematic diagram of the architecture of the model.

---

<sup>3</sup> Note that it is fundamental to the Language Bioprogram hypothesis that the semantic categories are biologically hard-wired, whereas this is left more open in the Basic Child Grammar hypothesis.

Figure 1: A multiple feature-map model of the lexicon (Miikkulainen, 1997)

In this study, we used no orthographic maps since we were modeling lexical and morphological acquisition in young children who are preliterate. We constructed two self-organizing maps, each of the size of 50 x 50 units, one for the organization of phonological input (henceforth the phonological map), and the other for the organization of semantic input (the semantic map). All simulations were run on a SUN Ultra workstation, using the DISLEX codes configured by Miikkulainen (1999).

### Input Representations

In order to model the role of linguistic input in children's acquisition of lexical and grammatical aspect, we selected as our input data the parental or caregivers' speech in the CHILDES database (MacWhinney, 1995). We extracted all the utterances of the parents, caregivers, and experimenters from the CHILDES database in over half of the English corpus (from Bates to Korman). Although not all of these utterances are child-directed, they form a representative sample of the speech that children are exposed to (e.g., dinner table talks, activities of free plays, and storytelling). A verb from this corpus was chosen as an input to the network if it occurred in the parental or caregivers' speech for five or more times in a given age period (see below). With this criterion we selected a total of 562 words (types) as input to our network. They were inputted to the network in four stages, according to the age groups at which they occurred (see below).

Previous connectionist models of language acquisition have often relied on the use of artificial input/output representations (e.g., randomly generated patterns of phonological or semantic representations) or representations that are constructed ad hoc by the modeler. Representations of linguistic information in this way are often subject to the criticism that the network works precisely because of the use of certain linguistic features. To overcome potential limitations associated with this approach, we used more realistic input data to simulate the acquisition of aspect. We represented our inputs as follows.

**Phonological representations** to our network were based on a syllabic template coding developed by MacWhinney and Leinbach (1991). Instead of a simple phonemic rep-

resentation, this representation reflects current autosegmental approaches to phonology, according to which the phonology of a word is made up by combinations of syllables in a metrical grid, and the slots in each grid made up by bundles of features that correspond to phonemes, *C*'s (consonants) and *V*'s (vowel). The MacWhinney-Leinbach model used 12 *C*-slots and 6 *V*-slots that allowed for representation of words up to three syllables. For example, the 18-slot template *CCC VV CCC VV CCC* represents a full trisyllabic structure in which each *CCCVV* is a syllable (the last *CCC* represents the consonant endings). Each *C* is represented by a set of 10 feature units, and each *V* by a set of 8 feature units.

**Semantic representations** to our network were based on the lexical co-occurrence analyses in the Hyperspace Analogue to Language (HAL) model of Burgess and Lund (1997). HAL represents word meanings through multiple lexical co-occurrence constraints in large text corpora. In this representation, the meaning of a word is determined by the word's global lexical co-occurrences in a high-dimensional space: a word is anchored with reference not only to other words immediately preceding or following it, but also to words that are further away from it in a variable co-occurrence window, with each slot (occurrence of a word) in the window acting as a constraint dimension to define the meaning of the target word. Thus, a word is represented as a vector that encodes the entire contextual history of that word in a high-dimensional space of language use. We used 100 dimensions for the encoding of each vector.

### Task and Procedure

Upon training of the network, a phonological input representation of the verb was inputted to the network, and simultaneously, the semantic representation of the same input was also presented to the network. By way of self-organization, the network formed an activity on the phonological map in response to the phonological input, and an activity on the semantic map in response to the semantic input. The phonological representations of the corresponding aspectual suffixes were also co-activated with the phonological and semantic representations of the verb, depending on whether the verb co-occurs with *-ing* *-ed*, or *-s* in the parental speech in the CHILDES database. As the network received input and continued to self-organize, it simultaneously formed associations through Hebbian learning between the two maps for all the active units that responded to the input. The network's task was to create new representations in the corresponding maps for all input words and to be able to map the semantic properties of a verb to its phonological shape and its morphological pattern.

To observe effects of the interaction between lexical and grammatical aspect in the parental input on the network's learning and representation, we designed four stages to train the network, according to the different age groups of our input data. (1) *Input Age 1;6* (13-18 months). Although parental/caregivers data in the CHILDES database are available from an age when the child is 6 months old, there are relatively few morphological markings prior to the period when the child is 12 months old. A total of 186 verbs fit

our selection criteria for the period when the child is between 13-18 months old, out of which 34 (18%) occurred with *-ing*, 9 (5%) with *-ed*, and 9 (5%) with *-s*. (2) *Input Age 2;0* (19-24 months). 324 verbs were selected, which include the new verbs as well as verbs from the previous stage, among which 76 (23%) occurred with *-ing*, 23 (7%) with *-ed*, and 24 (7%) with *-s*. (3) *Input Age 2;6* (25-30 months). 419 verbs were selected, among which 82 (20%) occurred with *-ing*, 35 (8%) with *-ed*, and 31 (7%) with *-s*. (4) *Input Age 3* (31-36 months). 562 verbs were selected, among which 123 (22%) occurred with *-ing*, 70 (12%) with *-ed*, and 61 (11%) with *-s*. These stages ensure an incremental growth of vocabulary and a coarse frequency coding: a verb or a suffix was presented to the network for the number of times it occurred across the four stages.

## Results and Discussion

We focus here on three levels of analysis of our modeling results: the role of input, the emergence of lexical aspect categories, and the formation and relaxation of strong associations between lexical and grammatical aspect.

### The Role of Input

One important rationale behind the current modeling effort is the understanding of the role of the linguistic input in guiding children’s acquisition of lexical and grammatical aspect. Earlier we emphasized the relationship between patterns observed in children’s speech and those in adult speech with respect to the interaction between lexical and grammatical aspect. But a simple correlation between children’s and adults’ patterns tells us only that the child is sensitive to the linguistic environment and is able to incorporate information from that environment into his or her own speech. It does not tell us how the child actually does this, or what mechanisms allow the child to do this. Thus, we wanted to test if a connectionist network, endowed with self-organization and Hebbian learning principles, is able to display learning patterns as the child does. If so, we can conclude that self-organization and Hebbian learning could provide the necessary kinds of mechanisms that drive the formation of patterns in children’s acquisition. In this way, our modeling enterprise provides insights into the mechanisms that underlie the learning process.

Table 1 presents a summary of the major patterns of the network’s learning according to the tense-aspect suffixes it produced at the different learning stages. It shows the results of the network’s production of three suffixes, *-ing*, *-ed*, and *-s* with three types of verbs, atelic, telic, and stative.<sup>4</sup> The results are based on the analyses of the activation of units on the phonological map that each verb in the semantic map activated, after the network had been trained for 200 epochs at each stage. The table does not include instances in which the network produced multiple suffixes with a given verb (see Table 3 for these instances).

The results as shown in Table 1 are highly consistent with empirical patterns observed in early child language: the use of the progressive aspect is closely associated with atelic

verbs that indicate ongoing processes, while that of perfective aspect is closely associated with telic verbs that indicate actions with endpoints or end results. In particular, in early child English, *-ing* is restricted to activity verbs, the perfective/past marker *-ed* restricted to telic verbs, and habitual *-s* restricted to stative verbs (see Introduction). Our network, having taken in input patterns based on realistic adult speech, behaved in the same way as children do. For example, at Input Age 1;6, the network produced *-ing* predominantly with atelic verbs (75%), *-ed* overwhelmingly with telic verbs (82%), and *-s* exclusively with stative verbs (100%). Such associations remained strong at Age 2, but gradually became weaker at later stages (the association between *-s* and stative verbs remained strong throughout).

Table 1: Network’s production of grammatical suffixes with lexical aspect categories\*

VERB	TENSE-ASPECT SUFFIXES					
	Age 1;6			Age 2;0		
	<i>-ing</i>	<i>-ed</i>	<i>-s</i>	<i>-ing</i>	<i>-ed</i>	<i>-s</i>
Atelic	75	18	0	66	16	0
Telic	25	82	0	28	84	0
Stative	0	0	100	0	0	100
VERB	Age 2;6			Age 3;0		
	<i>-ing</i>	<i>-ed</i>	<i>-s</i>	<i>-ing</i>	<i>-ed</i>	<i>-s</i>
	Atelic	64	26	0	52	9
Telic	31	74	0	44	77	10
Stative	0	0	100	4	14	80

\* Values represent percentages of verbs that occurred with the given suffix. Note that the percentages within a given column does not always add to 100%, reflecting the fact that some verbs could not be easily classified into one or the other category. This is also true for other tables.

Interestingly, when we analyzed the actual input to our network, we found similar patterns. Recall that the input to our network was based on the adult speech from the CHILDES database. Table 2 presents the percentages of use of suffixes with different verb types in the input data.

Table 2: Percentage of use of grammatical suffixes with lexical aspect categories in the input data

VERB	TENSE-ASPECT SUFFIXES					
	Age 1;6			Age 2;0		
	<i>-ing</i>	<i>-ed</i>	<i>-s</i>	<i>-ing</i>	<i>-ed</i>	<i>-s</i>
Atelic	69	22	0	74	15	17
Telic	28	77	33	24	77	0
Stative	3	0	67	2	8	83
VERB	Age 2;6			Age 3;0		
	<i>-ing</i>	<i>-ed</i>	<i>-s</i>	<i>-ing</i>	<i>-ed</i>	<i>-s</i>
	Atelic	67	23	20	67	23
Telic	25	69	20	31	65	8
Stative	8	8	60	2	12	69

This high degree of correlation between the network production and the input shows that our network was able to

<sup>4</sup> Atelic verbs correspond to Vendler’s activities, telic to accomplishments and achievements, and stative to state.

learn on the basis of the information of the co-occurrences between lexical aspect (verb types) and grammatical aspect (use of suffixes). This learning ability was due to the network's use of Hebbian learning in computing and registering (a) when the semantic, phonological, and morphological properties of a verb co-occur and (b) how often they do so.

Note that the patterns of the two tables are consistent and similar, but not identical. This is important because if the learner, child and network alike, simply mimicked what's in the input by recording each individual word and suffix and their co-occurrence, the learner would have no productive control of the relevant linguistic device and would simply produce the patterns verbatim. Our results suggest that the associations between verb types and suffixes are stronger in the network's production than in the input to the network. Our network, like the child, behaved more restrictively than what is in the input with respect to the use of tense-aspect suffixes (see Li & Shirai, 2000, for details on this point).

### The Emergence of Lexical Aspect Categories

As discussed earlier, a distinct property of feature maps is that the structures in the network's representation can be clearly visualized as activity bubbles or patterns of activity on a 2-D map. Figure 2 presents a snapshot of the network's self-organization of the semantic representations of 186 verbs at the end of the Input Age 1;6.

Figure 2: Network representations of verbs in the semantic map. Only the left portion of the complete map is shown due to space limit. Words longer than four letters are truncated.

An examination of this map shows that the network has clearly developed structured semantic representations that correspond to categories of lexical aspect such as telic verbs, atelic verbs, and stative verbs. Our network formed clear clusters of verbs by mapping similar verbs onto nearby regions of the map. For example, towards the lower right-hand corner, stative verbs like *feel*, *know*, *think*, *remember*, *wonder*, *love*, and *like* are mapped to the same region of the map. A second cluster of verbs occurs towards the lower left-hand corner, including verbs like *see*, *read*, *hear*, *say*, *ask*, and *tell*, all being verbs of visual or auditory activities. Still a third chain of verbs can be found in the middle-to-left portion of the map, including verbs like *catch*, *fix*, *break*, *knock*, *grab*, and *throw*, all of which are telic verbs indicat-

ing actions that lead to clear end results. Finally, a cluster of verbs can be found spanning the upper end of the map, including (from left to right) *rub*, *scrub*, *sleep*, *shout*, *laugh*, *drink*, *walk*, *kiss*, *cry*, *swim*, and *dance*, all of which are atelic activity verbs, and many of them co-occur with *-ing* early on. In contrast to this layer of verbs, the left-most columns feature primarily telic verbs, such as *finish*, *hide*, *build*, *reach*, *make*, *go*, *give*, *get*, and *find*. Of course, the network's representation at this point is still incomplete, as self-organization is still moving continuously from diffuse to more focused patterns of activity.

Crucially, on the one hand, these clusters form concentrated patterns of activity, providing the basis for semantic categories, and on the other hand, they also form focused associative pathways to the phonological and morphological representations of verbs on the other feature maps. When concentrated activities occur both horizontally (within a 2-D map) and vertically (across the maps), the semantic categories of lexical aspect will behave like magnets for the mapping of grammatical morphemes. Thus, when new verbs share enough similarities with verbs of a lexical aspect and fall within these clusters, their mapping to corresponding grammatical aspect will be readily assimilated through the existing associative pathways going from verb semantics to suffixes. This explanation provides an alternative account of the Basic Child Grammar, according to which the initial semantic categories that strongly attract grammatical mappings are privileged and pre-linguistic.

The results from our modeling offer a new way of thinking about the acquisition of categories of lexical aspect. Verbs in a lexical aspect category form complex relationships, in that they vary in (a) how many semantic features are relevant to the category, (b) how strongly each feature is activated in the representation of that category, and (c) how features overlap with each other across category members. Traditional analytical methods are much less effective, if not impossible, in dealing with these complex semantic relationships. By contrast, connectionist models that rely on distributed feature representations and nonlinear learning are ideally suited to accounting for the properties of featural overlapping and weighted featural composition (see Li & MacWhinney, 1996 for a discussion).

### From Strong Associations to Diverse Mappings

The above results suggest that the learning of grammatical suffixes is not simply the learning of a rule such as adding *-ing* or *-ed* to a verb to mark the progressive aspect or the perfective aspect, but the accumulation of associative strengths that hold between a particular suffix and a complex set of semantic features distributed across verb forms. This learning process can be best described as a statistical, probabilistic process in which the learner implicitly tallies and registers the frequency of co-occurrences (strengthening what goes with what) and co-occurrence constraints (inhibiting what does not go with what) among the semantic features, lexical forms, and tense-aspect suffixes.

This co-occurrence-and-constraint process is modeled in our network by Hebbian learning of the associative connections between forms and meanings. Hebbian learning can account for the relaxation of the associations as well as the

strong associations. Table 3 presents the same simulation results as Table 1, except here we added the multiple suffixation patterns -- a given verb was counted for multiple number of times in the table depending on the number of suffixes with which it co-occurred.

Table 3: Network's production of grammatical suffixes with lexical aspect categories (multiple suffixations)

VERB	TENSE-ASPECT SUFFIXES					
	Age 1;6			Age 2;0		
	<i>-ing</i>	<i>-ed</i>	<i>-s</i>	<i>-ing</i>	<i>-ed</i>	<i>-s</i>
Atelic	75	16	0	62	29	6
Telic	28	75	0	32	66	31
Stative	0	8	100	0	4	63
VERB	Age 2;6			Age 3;0		
	<i>-ing</i>	<i>-ed</i>	<i>-s</i>	<i>-ing</i>	<i>-ed</i>	<i>-s</i>
	Atelic	64	40	44	52	38
Telic	32	60	12	43	53	26
Stative	0	0	44	5	9	44

A comparison of this table with Table 1 reveals that for the early stages (1;6 and 2;0) the two tables are very similar; for the later stages, however, they become different, mainly with respect to the uses of *-ed* and *-s*. Detailed analyses show that over 50% of all suffixed verbs had more than one suffixes at Input Age 3;0, compared to only 5% at Input Age 1;6. These results suggest that multiple suffixation might be a driving force for the learner to break from the strong associations to more diverse associations between lexical and grammatical aspect. There was relatively little change with the *-ing* verbs, because the majority of the verbs early on were atelic verbs that took *-ing*. These same patterns were also found to be true of the parental input in the CHILDES database (see Li & Shirai, 2000, for detailed discussion).

## Conclusion

In this paper I showed that self-organizing neural networks can be used successfully to model language acquisition, following up on Li (1999). Self-organization and Hebbian learning in such networks are two important computational principles that can account for the psycholinguistic processes in the acquisition of lexical and grammatical aspect. Focused associative pathways between forms and meanings lead to particularly strong associations between lexical aspect and grammatical aspect, thereby to undergeneralized patterns of grammatical morphology as observed in early child language. Increasing associative links along with incremental vocabulary growth lead to diverse mappings. Finally, self-organization of the semantic structure of verbs leads to the formation of lexical aspect categories, on the basis of the network's analysis of the complex relationships in a high-dimensional space of language use. Our results lend insights into the mechanisms and processes of lexical-morphological acquisition, and may also generate interests in further empirical studies against which we can compare detailed patterns of modeling results.

## Acknowledgments

This research was supported by a grant from the National Science Foundation (#BCS-9975249). I am grateful to Brian MacWhinney and Risto Miikkulainen for their help, comments, and discussions at various stages of the project, and to Curt Burgess and Kevin Lund for making available their semantic vectors to our modeling.

## Abstract

Both dual mechanism and connectionist single mechanism accounts predict that phonologically similar irregulars can interfere with regular past tense production. In dual mechanism accounts, such interference depends on irregular frequency but not on the frequency of regulars with the possible exception of high frequency regulars. Such models predict that high and low frequency regulars are equally susceptible to interference from irregulars, or that high frequency regulars would be more affected than low frequency ones. Connectionist single mechanism models, on the other hand, claim that low frequency regulars are more susceptible to interference from irregulars than high frequency regulars. We present results from two experiments that investigate interference from irregulars on the past tense production of high and low frequency regular verbs. In these experiments, high frequency regulars were less affected by interference from phonologically similar irregulars than low frequency regulars. These results support connectionist single mechanism models of past tense verb production.

The dichotomy between regular and irregular patterns permeates many levels of language. In many areas, accounting for differences between regular and irregular patterns has become the battlefield on which competing theories of language processing win or lose. One such case, which has received much attention in recent years, is the production of the past tense form of English verbs. This case has become the focus of an ongoing debate between dual mechanism and connectionist single mechanism models of word processing (MacWhinney B. & Leinbach, J., 1991; Marchman et al., 1999; Marcus, 1995a, 1995b, 1996; Pinker 1991, 1999; Pinker & Prince, 1991, Plunket & Marchman, 1993, 1996; Rumlehart & McClelland, 1986; Seidenberg 1997).

**Dual Mechanism Accounts.** In dual mechanism accounts (Marcus, 1995a, 1995b, 1996; Pinker 1991, 1999; Pinker & Prince, 1991), regular past tense is produced via a rule (add *-ed*) that applies to the root stem of the verb, which is stored in the mental lexicon. Irregulars, on the other hand, are

formed via associations between present and past tense forms, each of which is stored as a separate lexical entry. The add *-ed* rule applies as a default to verbs without a separate lexical past tense entry (regulars and non-words). The existence of a separate past tense entry, as in the case of irregulars, blocks the application of the add *-ed* rule. However, if the representation of a past tense entry is weak (due to low frequency), the add *-ed* rule could be applied erroneously, causing an over-regularization error (buy > \*bued). Such errors are well documented both under natural and experimental conditions (Berko, 1958; Bybee & Slobin, 1982; Marcus et al., 1992). In addition to irregulars being regularized, regulars can also be incorrectly produced as if they were irregulars (e.g., vie > \*vought). This phenomenon of "irregularization" has also been documented both in and out of the laboratory (Bybee and Moder, 1983; Xu & Pinker, 1995).

Pinker (1999), in his most recent version of a dual mechanism model, provides an account of irregularization. In his model, the word association mechanism responsible for irregular past tense production is a connectionist type neural network that contains both *irregular* and *high frequency regular* items. In the course of past tense production, the network attempts to compose a past tense form on the basis of the present tense. Phonological overlap between regular and irregular items can cause two types of interference during this computation. First, an incorrect form may gain enough activation to actually block the add *-ed* rule resulting in an irregularization error. Alternatively, regular past tense production could be successful, but the spurious activation caused by interference may slow down production.

By this account, interference (and past tense production) is generally insensitive to the frequency of regular verbs. One exception may result from the encoding of regular past tense forms of high frequency regular verbs in the associative network. The encoding of these past tense forms in the network can sometimes cause high frequency regulars to be more affected by interference from irregulars than low frequency regulars:

"As mentioned in note 11, sometimes high-frequency regular verbs are, paradoxically, *slower* to produce than low-frequency verbs. One explanation is that stored forms always inhibit the rule, even if they are identical to the form the rule is trying to create. Just as *broke* blocks the creation of *breaked* an entry for *walked* that is stored in memory may block the creation of *walked* by rule, slowing down the rule production (compared to, say, *stalked*, whose memory entry is too weak to slow down the rule)."

(Pinker, 1999, page 303, fn 22)

**Connectionist single mechanism Accounts.** Connectionist single mechanism models rely on a single mechanism to account for both regular and irregular past tense production (MacWhinney, B. & Leinbach, J., 1991; Marchman, Wulfeck, & Weismer, 1999; Plunket & Marchman, 1993, 1996; Rumlehart & McClelland, 1986; Seidenberg 1997). The claim is that both regulars and irregulars are represented in a single neural network. The network encodes mappings between present and past tenses as weighted links between forms. More exposure to a particular mapping strengthens the corresponding link. In this way, the strength of mappings for both regular and irregular items is determined by item frequency and the consistency of the present to past tense mapping within the neighborhood of phonologically similar verbs.

In this model, interference on regular and irregular past production is the result of a single mechanism. As activation spreads and a past tense form (regular or irregular) is being selected, interference from overlapping mappings (regular or irregular) can cause interference. In past tense production, a target form must reach a critical activation level before it is selected. In order for this to happen, activation of competing forms must be suppressed. If a competing form is not suppressed and its activation exceeds that of the correct form and reaches a critical threshold, an irregularization error occurs. However, even if correct selection is eventually successful, the activation of competing forms may cause the system to take longer to settle on the correct form and may thus result in slowed production. In this account, due to the greater strength of their mappings, high frequency regular and irregular verbs are less susceptible to interference from other items than low frequency verbs. Thus, the connectionist single mechanism account and the dual mechanism account both predict the same two types of possible interference: (1) irregularization errors, and (2) slowing of correct production. However, the two accounts differ in their prediction of how interference will affect high and low frequency regulars. The dual mechanism account predicts that interference should result in more errors and slower production for high frequency regular verbs than for low frequency regular verbs. The connectionist single mechanism account, on the other hand, predicts more errors and slowed production for the low frequency regulars than for the high frequency regulars. The following experiments tested these contrasting predictions.

## Experiment 1

This experiment investigated the effects of interference from irregulars on regular past tense production. More specifically, we tested the degree to which high and low frequency regulars are differentially affected by such interference.

One potential problem facing an investigation of this type is the subtle nature of interference effects from irregulars. In order to get around this problem, we designed the experiment so as to enhance the interfering effects of irregulars. According to both models, phonological overlap can yield irregularization errors and slowed production. We reasoned that one possible way to enhance the effect of phonological similarity is to make this similarity more salient by having participants produce the past tense form of an irregular verb (e.g., *buy*) immediately prior to producing the past tense form of a phonologically similar regular verb (e.g., *die*). This was done for both high and low frequency regulars creating the two interference conditions shown in Table 1. We decided on an all auditory presentation of stimuli and responses so as to further enhance the (possibly interfering) effect of phonological similarity. We also had a control condition in which the same regular verbs were preceded by non-similar irregulars, creating the two control conditions shown in Table 1. Thus, the complete design was 2 X 2 with factors Frequency (high vs. low) and Context (interference vs. control).

**Table 1:** Experiment 1 Conditions. Shown is the regular target (**in bold**) with the irregular from the preceding trial.

Frequency	Context	
	Interference	Control
High	Buy	Hear
	<b>Die</b>	<b>Die</b>
Low	Buy	Hear
	<b>Vie</b>	<b>Vie</b>

Both models predict that the interference condition will be slower and more error prone than the control for both high and low frequency regulars. However, the two models differ in their predictions for the interaction between context and frequency. The dual mechanism model claims that the difference between the interference and control conditions will either be equal for both high and low frequency regulars, or perhaps be greater for high than low frequency regulars. According to Pinker (1999), high frequency regulars should be more susceptible to interference when the experimental list includes a high proportion of irregular verbs, as in the present experiment (50%):

"... the harmful effects of high frequency tend to occur when the word list has a high percentage of irregular forms, encouraging subjects to go to their mental lexicons on every trial..."

(Pinker, 1999, pp. 303, f. 22)

The connectionist single mechanism account, on the other hand, predicts that the difference between the interference and control conditions will be greater for the low frequency regulars than for the high frequency regulars.

## Method

**Participants.** 61 undergraduate students from the Department of Psychology at the University of Southern California received extra credit to participate in the experiment. All were native speakers of English.

**Materials.** 20 Monosyllabic English irregular present tense verbs were matched with 20 phonologically similar monosyllabic high frequency (Mean frequency 185) and 20 phonologically similar monosyllabic low frequency (Mean frequency 3) present tense regular verbs creating 20 *high interference pairs* and 20 *low interference pairs*. The same set of items was then regrouped such that each irregular verb was matched with a non-similar sounding high and low frequency regular verb creating 20 *high control pairs* and 20 *low control pairs*. Verb frequencies were taken from the Francis & Kucera (1982) corpus.

To ensure that each participant responded to each regular item only once, the prime and control pairs were divided into four lists (1A/1B, 2A/2B) each containing one-quarter of the experimental pairs with the number, type, and frequency of pairs balanced across lists. 23 regular and 44 irregular monosyllabic present tense verbs were selected as fillers to balance the appearance of regular and irregular items on the four lists. The lists were ordered in a pseudo-random fashion. Presentation of lists was balanced across participants.

A practice list was also created consisting of 10 regular and 10 irregular present tense verbs that were not included in the experimental lists.

All items were read by a male native speaker of English and digitally recorded in 16 bit 20 MHZ format. Individual words were later excised using a digital sound manipulation program.

**Procedure.** Stimuli were presented to participants through headphones at 2000 ms intervals using the PsyScope program (Cohen, J., MacWhinney, B., Flatt, M., & Provost, J., 1993). Participants were instructed to say the past tense form of the verb they heard. In order to encourage rapid responses and reduce possible strategy effects, participants were instructed to say the past tense as quickly as possible. If participants didn't answer within a 1500ms interval, they were signaled with a beep. Responses were coded as either 'correct', 'incorrect' or 'equipment error'. All participants received the same 20-item practice list before being tested on one of the two A/B list sets. Order of presentation of the lists was alternated giving a total of four potential presentation patterns (1a>1b, 1b>1a, 2a>2b, 2b>2a) that were counterbalanced across participants. There was a short break between the lists. The total testing time was approximately 30 min. Participant responses were recorded.

Recordings were used to verify initial coding of responses and to transcribe and code responses for the error analysis.

## Results

Data were included only for responses to regular targets that followed the correct production of the preceding irregular item. Responses to regulars that followed an incorrect irregular were not included because in such cases it is not clear whether participants had processed the preceding irregular. Six participants (4% of data) and three items (2% of data) had to be removed from the analyses due to insufficient data contribution. Initial analyses of list order effects indicated that there was no interaction between list presentation order and any of the conditions of the experiment. Thus, the data from initial and second presentations were collapsed.

**Error analysis.** Responses were classified as follows:

- (1) *Correct*: the regular past tense form was correctly produced.
- (2) *Irregularization Error*: the regular past tense form was incorrect and the form of the error had a direct relationship to an existing past tense irregular form. (e.g., the past tense of 'vie' produced as 'vought').
- (3) *Miscellaneous Error*: the regular past tense form was incorrect and the form of the error did not relate to an existing irregular past tense form (e.g., vie > died).

Table 3 shows the distribution (raw numbers and percentages) of response types in the different conditions.

**Table 3:** Response types in Experiment 1

Response Type	Context	
	Interference	Control
	High	
Correct	344 (95%)	349 (96%)
Irregularization Error	7 (2%)	3 (1%)
Misc. Error	13 (4%)	10 (3%)
	Low	
Correct	256 (88%)	273 (91%)
Irregularization Error	13 (4%)	4 (1%)
Misc. Error	20 (7%)	22 (7%)
	Total	
Correct	600 (92%)	622 (94%)
Irregularization Error	20 (3%)	7 (1%)
Misc. Error	33 (5%)	32 (5%)

To assess the effect of frequency and context on response type we conducted a log-linear analysis on these responses starting with the maximal model – Context (interference vs. control) x Frequency (high vs. low) x Response Type (correct vs. irregularization error vs. miscellaneous error). The only terms that are of potential interest here are the interaction terms that included the response type and that were crucial for the model's fit. The

terms that met these criteria in this experiment were the term expressing the interaction between context and response type (LR  $\chi^2(2)=7.03$ ,  $p<.0297$ ) and the term expressing the interaction between frequency and response type (LR  $\chi^2(2)=15.17$ ,  $p<.0005$ ). The three-way interaction between context, frequency and response type was not significant (LR  $\chi^2(2)=.7698$ ). Thus, while both context and frequency had an effect on response type, these effects were independent of each other. Participants made more errors with the low frequency verbs than with the high frequency verbs but this frequency effect was comparable in the interference and control conditions. To better examine the distribution of the different response types in the interference and control conditions, we combined the responses from the high and low frequency conditions (as in the bottom part of Table 3). While in both prime and control conditions there is an equal percentage of miscellaneous errors (5%), the prime condition has more irregularization errors (5%) than the control condition (3%). This difference proved to be significant according to a chi-square test including correct responses in the analysis ( $\chi^2(1)=6.47$ ,  $p<.0394$ ), as well as an analysis of the error data alone ( $\chi^2(1)=6.62$ ,  $p<.0364$ ).

**Latencies.** Figure 1 shows RTs for correct responses in all four conditions. While low frequency regulars were produced slower in the interference than in the control condition, high frequency regulars were actually produced faster in the interference condition. An ANOVA with factors Frequency (high vs. low) and Context (interference vs. control) revealed a main effect of frequency whereby participants took significantly longer to produce the past tense form of low frequency regular verbs compared to high frequency ones (1322 ms vs.1214 ms),  $F_1(1, 54)=111$ ,  $p<.001$ ,  $F_2(1, 35)=7.244$ ,  $p<.01$ . Context had no main effect,  $F_1, F_2<1$ . The interaction between context and frequency was significant by participants,  $F_1(1, 54)=4.095$ ,  $p<.048$ , although not by items,  $F_2<1$ .

Figure 1: RT Experiment 1

## Discussion

Consistent with the predictions of both the dual mechanism and the connectionist single mechanism accounts, interference from a similar sounding irregular was found to

increase the likelihood of making an irregularization error in producing the past tense form of regular verbs. However, the error data show that, in contrast to the claims of Pinker's (1999) dual mechanism account, the production of low frequency regulars is overall more prone to errors than the production of high frequency regulars. Nevertheless, the error data did not provide strong support for the connectionist single mechanism account because high and low frequency regulars were affected equally in both the control and interference condition. This failure to detect a significant effect may be a reflection of a true lack of interaction, as the dual mechanism model may predict, or it may simply be a result of a lack of power due to the subtlety of the effect and low cell count (participants produced very few errors overall.) A more informative measure of performance that is not prone to the small cell size problem and its associated low power was provided by response latencies in correct regular past tense production.

The analysis of response latencies revealed, as in the error data analysis, a general advantage for high frequency regulars such that they were faster than low frequency regulars. Importantly, this finding precludes a speed accuracy trade-off explanation of the error data. There are two aspects of these results, however, that need to be dealt with before any further interpretation of the latency data can be made. First, the past tense form of high frequency verbs was produced faster in the interference condition than in the control condition, in contrast to the predictions of both models. Second, the fact that the interaction between frequency and context was significant only in the by-participants analysis but not in the by-items analysis suggests that items varied in some important aspect that we may have overlooked. One such aspect may be related to priming effects between the present tense forms, independent of the production of the past tense. To perform the task, participants had to, first, process the present tense form of each verb, and, second, generate the past tense form. Thus, response times in this task indicate not only the time it took participants to generate past tense forms but also the time it took them to process the present tense forms. It may be that phonological similarity, which caused interference in the production of the past tense form, facilitated the processing of the present tense form. The high frequency regulars may have thus elicited faster responses in the interference condition because, for these verbs, phonological similarity benefited the processing of the present tense forms more than it interfered with the production of the past tense forms. For the low frequency regulars, on the other hand, phonological similarity may have interfered with the production of the past tense forms more than it benefited the processing of the present tense forms. Differences between items in the relative strengths of the benefit and the interference associated with phonological similarity may also help explain the differences between the by-participants and by-items analyses. It is important to note here that this interpretation only applies for the specific irregular/regular pairs as used in

this experimental manipulation and not for regular verbs in general. In order to test this interpretation, it is necessary to confirm the facilitatory effects of phonological similarity on the processing of the present tense in the interference condition and then reanalyze the data taking these effects into account. Experiment 2 was undertaken to directly measure the effect of phonological similarity on the processing of the present forms.

## Experiment 2

This experiment was identical to Experiment 1 in materials and procedure but employed a repetition task instead of past tense generation. Thus, in Experiment 2, the interference condition of Experiment 1 became a priming condition in which the preceding phonologically similar irregular could prime the recognition of the regular target item.

### Method

**Participants.** 25 undergraduate students (different from Experiment 1) from the Department of Psychology at the University of Southern California received extra credit to participate in the experiment. All were native speakers of English

**Materials.** Same as in Experiment 1.

**Procedure.** Same as in Experiment 1 except that participants were instructed to repeat the verb that they heard rather than produce the past tense. The presentation interval was reduced to 650 ms and the time-out interval to 600 ms.

### Results

As with Experiment 1, only responses to regular verbs that followed the correct repetition of the preceding irregular verb were included. 3 subjects (5% of data) and 4 items (7% of data) were excluded from the analysis due to insufficient data contributions. Mean RTs are shown in Figure 2. An ANOVA with factors Frequency (high vs. low) and Context (prime vs. control) revealed a main effect

of frequency whereby high frequency verbs were repeated faster than low frequency verbs (558 ms vs. 591 ms),  $F_1(1, 21)=39.59$ ,  $p<.0001$ ,  $F_2(1, 34)=3.923$ ,  $p<0.056$ . There was also a main effect of context whereby participants were faster at repeating target items in the prime condition than in the control condition, (564 ms vs. 592 ms),  $F_1(1, 21)=7.062$ ,  $p<.015$ ,  $F_2(1, 34)=6.062$ ,  $p<0.019$ . There was no interaction between context and frequency,  $F_1, F_2<1$ .

### Discussion

The fact that both high and low frequency regulars were repeated faster in the prime condition confirms the claim that the interference condition of Experiment 1 also involved facilitation of the initial processing of the present tense. Furthermore, the lack of context by frequency interaction in Experiment 2 suggests that the context by frequency interaction observed in Experiment 1 was not related to the processing of the present tenses but was only related to the generation of the past tense. Most importantly, however, the results of Experiment 2 can be used to reanalyze the results of Experiment 1 while factoring out the priming effects related to the processing of the present forms.

**Combined Experiment 1 and 2 Analyses.** One possible way to factor out the effects of present tense priming is by repeating the by-items analysis of Experiment 1 with Experiment 2 response times as covariates. Due to differences in the magnitude and variability of response times in the two experiments, response times were log transformed (Emerson, 1991). An ANCOVA of the log transformed RTs in Experiment 1, with factors Frequency (high vs. low), Context (interference vs. control), and covariates Prime and Control Log RTs from Experiment 2, found no main effect for context,  $F<1$ , a marginally significant main effect of frequency,  $F(1,32)=3.391$ ,  $p<.075$ , and finally, a significant interaction between context and frequency,  $F(1, 32)=4.176$ ,  $p<.049$ . Thus, a by-items analysis in which the processing of present tenses was controlled for, found, as did the original by-participants analysis, a significant interaction between context and frequency.

To further explore the nature of this interaction we calculated the partial correlation between the interference on each item in Experiment 1 (RT in interference condition minus RT in control condition) and their frequency (log transformed) while controlling for the item's priming in Experiment 2 (RT in prime condition minus RT in control condition). This analysis found that item frequency and the extent of interference for that item were negatively correlated ( $r= -0.35$ ,  $p<.037$ ) such that the higher the item frequency, the less was the effect of interference.

### Discussion of Combined Analyses

The reanalysis of Experiment 1 showed that once the effects of processing the present tense were factored out, the item analysis corroborated the participant analysis in showing a

significant interaction between interference and frequency. Importantly, this analysis revealed that low frequency regulars were affected by interference more than high frequency regulars. This finding is squarely incompatible with Pinker's (1999) dual mechanism account.

### General Discussion and Conclusions

Two production experiments tested the extent to which irregular verbs could interfere with the past tense production of regular verbs. Irregularization errors were more likely when regular verbs were preceded by phonologically similar irregulars than when they were preceded by phonologically dissimilar irregulars. Furthermore, overall production errors were more likely for low frequency regular verbs than for high frequency regular verbs. Finally, an analysis of latencies of correct responses showed that, once the effects of processing the present tenses are controlled for, high frequency regulars are more immune than low frequency regulars to interference from phonologically similar irregulars.

These findings are incompatible with the prediction of Pinker's *Words and Rules* dual mechanism model (Pinker, 1999) that high frequency regulars should be affected by interference more than low frequency regulars. One obvious way in which Pinker's model could be modified to account for our findings is by simply changing it to say that regular past tense production could benefit (rather than be hindered) by the existence of a form in the associative network. While such modification may help account for the current findings, it is not clear what its other consequences may be.

Clearly, frequency effects are not the only relevant evidence for understanding the mechanisms underlying past tense production. Thus, the present findings should not be viewed as the ultimate proof that the connectionist approach is right and that the dual mechanism account is wrong. Rather, the present findings should be viewed as adding one piece to a growing body of evidence that suggests that the separation of language processing into two mechanisms is buying less and less in terms of explanatory power but costing more and more in terms of unnecessary theoretical baggage.

## Abstract

Why are some pairs of objects (or events) perceived to be more similar to each other than other pairs? A computational level theory of perceived similarity is presented that extends previous geometric and set-theoretic formulations. Like previous approaches, the current account posits that the similarity of two objects is a function of the common and distinctive features of the two objects. Unlike previous approaches, similarity is also a function of higher-order compatibility relations among features (as it is in models of analogy). Objects (or concepts) are represented as directed feature graphs as opposed to feature vectors or sets. Like current accounts of human analogical processing, the approach presented here holds that representational elements are put into correspondence during the comparison processes. Correspondences are chosen in order to maximize an objective function. The function contains four terms that are motivated by theories of human comparison. The maximum of the function is monotonically related to perceived similarity. Thus, similarity is characterized as the byproduct of comparison and structural alignment. The objective function serves as a quantitative computational level theory of human comparison.

## Introduction

Since William James (1890/1950), psychologists have held that detecting the “sameness” or similarity of objects is at the backbone of cognition. Clearly, detecting similarities between novel events and previous experiences is crucial in reasoning, analogy, and object recognition. Many theories of category learning hold that similarity is the basis for categorization (see [7]). A fundamental question then is what makes two objects similar?

Almost all accounts of perceived similarity hold that similarity increases as the number of feature matches increases and decreases as the number of feature mismatches increases. In geometric models of similarity, such as multidimensional scaling (MDS) models of similarity, concepts or objects are represented as points in a multidimensional space and similarity is inversely related to the distance between points in the space [20]. Objects that match on many features will be closer together in the space than objects that mismatch on a number of features. Unfortunately, the axioms of metric spaces (e.g., minimality, symmetry, and the triangle inequality) appear to be violated by human similarity judgments (see [22]). More recently, Medin, Goldstone, and Gentner (1993) have demonstrated that an object can be rated as both more similar and more dissimilar to the same object in an object pair, which seems problematic for distance models.

Tversky’s (1977) contrast model is a non-metric set-theoretic account of perceived similarity that aims to address some of the shortcomings of the distance models. Tversky’s model is based on evaluating sets of matching and mismatching features:

$$\mathbf{sim}(x, y) = \gamma_1 \mathbf{F}(X \cap Y) - \gamma_2 \mathbf{F}(X - Y) - \gamma_3 \mathbf{F}(Y - X) \quad (1)$$

where  $\gamma_1, \gamma_2, \gamma_3 \geq 0$

where  $\mathbf{sim}(x, y)$  reads “the similarity of  $x$  to  $y$ ,”  $X$  is the set of features that represents  $x$ ,  $Y$  is the set of features that represents  $y$ ,  $X \cap Y$  is the set of features common to  $x$  and  $y$ ,  $X - Y$  is the set of features uniquely possessed by  $x$ ,  $Y - X$  is the set of features uniquely possessed by  $y$ ,  $\gamma_1$ ,  $\gamma_2$ , and  $\gamma_3$  are free parameters, and  $\mathbf{F}$  is a function over sets of features related to the features’ saliency. For simplicity and without loss of generalization, we assume here that all features are equally salient:

$$\mathbf{F}(X) = |X| \quad (2)$$

where  $|X|$  denotes the cardinality of the set  $X$ . Of course, in many situations certain features will weigh more heavily on the evaluation of similarity than other features.

Tversky’s contrast model can account for asymmetries that occur in similarity judgments. For example, “North Korea” is rated as being more similar to “China” than vice versa. The contrast model can explain such asymmetries by setting  $\gamma_2 > \gamma_3$ . Ostensibly, when comparing  $x$  and  $y$ , the focus is on first term  $x$ , which I will refer to as the *target*, and not on the second term, which I will refer to as the *base*. Both  $x$  and  $y$  will be referred to as *analogs*. In the example above, most people know more about China than North Korea. Accordingly, when evaluating how similar China is to North Korea  $|X - Y|$  will be larger than  $|Y - X|$ . Another comparison related explanation for asymmetries is that subjects prefer the base to be the object out of an object pair that allows for more analogical inferences to be projected [1]. Such asymmetries may be attributable to the similarity predicate in particular. Another alternative is that asymmetries arise from general principles related to sentence interpretation such as the figure/ground relationship between the target and base [21] or from general syntactic properties [6].

Although the contrast model can address a wide range of data, it cannot account for judgments of similarity that are relational or analogical in nature. Two analogs can be similar

even when the analogs do not have many features in common. To use Gentner’s example, one reason people judge the solar system and an atom as being similar is that our representations of these two systems share a number of higher-order relational matches (as opposed to simple feature matches). For example, electrons revolving around a larger nucleus can be put in correspondence with planets revolving around a larger sun. Although the elements of the two systems are not inherently similar (e.g., a nucleus and the sun differ in size and composition), the two analogs are judged to be similar because a mapping between the two systems exists that preserves higher-order commonalities (e.g., the sun maps to the nucleus and the planets map to the electrons). Of course, there are simpler cases of different dimensions being put in correspondence. For example, people equate high-pitched sounds with bright lights and when asked, “Which is brighter, a sneeze or a cough?” people readily answer that a sneeze is brighter [16]. The contrast model assumes that only identical features can match and does not envisage a matching process that attempts to preserve higher-order compatibilities.

More current models of comparison and analogy (e.g., [2, 13, 11]) do establish relational correspondences when comparing objects. These models tend to prefer mappings between analogs when 1) identical features can be mapped to one another, 2) there are higher-order compatibilities and structures replicate in both analogs, 3) the mapping between the two analogs is or almost is one-to-one. Although these constraints are common to all successful models of human comparison, it is not always clear how these constraints are weighted and manifested in models. In other words, different models may adopt widely different matching algorithms (e.g., [2, 11]), but can be quite similar at the computational level of analysis (in the sense of Marr, 1982). It is important to know what the commonalities and differences of competing models are in order to identify the critical issues that deserve empirical investigation.

The goal of this paper is to specify a computational level theory of comparison and similarity that is quantitative, easily understood, and falsifiable. The computational level theory takes the form of a similarity equation consisting of four terms that combine linearly (weighted by parameters). Unlike algorithmic level models where principles are often obscured within the details of the processing mechanisms, principles in the similarity equation appear as separate terms and it is clear how different principles are weighted. Best fitting parameters for a data set are interpretable and clear predictions can be made about how the best fitting parameters should change as task demands change.

Such a theory might make the common ground between models more obvious to the extent that process models conform to the same underlying computational level theory. A successful computational level theory would also make each algorithmic model’s contribution to the field clearer. For instance, a model that simply conformed to the computational level theory and made no new predictions would have no

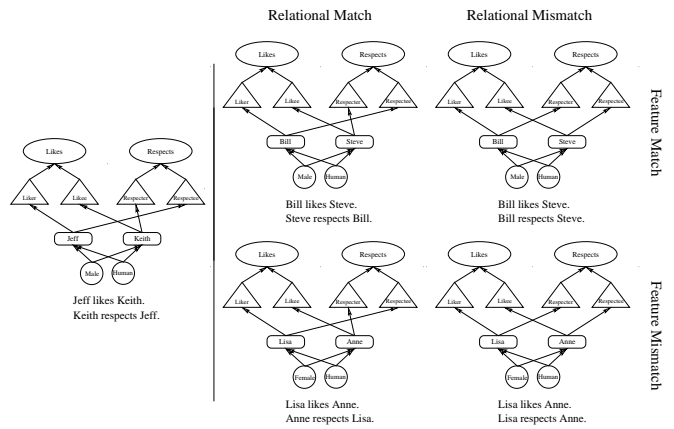

Figure 1: The target analog and its corresponding representation  $S^x$  are shown to the left of the dividing line (subjects were not shown  $S^x$ , just the text). To the right of the dividing line, an example base analog is shown for each of the four conditions (along with its  $S^y$ ).

“added value.” Many current models do have “added value.” For example LISA [11] makes predictions about how working memory limitations and discourse setting affects comparison, MAC/MAC [3] explicitly models retrieval processes in comparison, and IAM [13] focuses on the incremental nature of analogical mapping.

Although theories of comparison hold that similarity and analogical processing are deeply related [5], the linkage between similarity and comparison is even more direct in the similarity equation. In the similarity equation, the correspondences (i.e., mappings) between the two analogs are chosen so as to maximize the similarity equation, much like how an energy function is minimized in a Hopfield network when performing a computation [10]. The maximal value of the similarity equation is monotonically related to the perceived similarity of the two analogs. Thus, similarity both drives the comparison process and is an outcome of it. In the remainder of the paper, the details of the similarity equation are presented as well as some data fits.

### Mathematical Formulation

Analogs  $x$  and  $y$  are represented as directed graphs. Analog  $x$  has  $m$  different representational elements or nodes, while analog  $y$  has  $n$ .  $S^x$  is an  $m$  by  $m$  matrix that capture the connectivity of analog  $x$ . Each entry in  $S^x$  is either 0 or 1.  $S^x_{24}$  set to 1 signifies that node 2 binds to node 4. Notice that this relationship is not symmetrical — part 4 is a parent of part 2, but part 2 is not necessarily a parent of part 4. Analog  $y$  is represented in an identical fashion by  $S^y$ . Figure 1 illustrates some examples of analogs and the graphs that represent them.

In evaluating the similarity of  $x$  to  $y$ , correspondences are established between the representational elements of  $x$  and  $y$  (i.e., the nodes in  $S^x$  and  $S^y$ ). These correspondences or mappings are recorded in the  $m$  by  $n$  matrix  $A$ . Each entry in  $A$  is either 0 or 1.  $A_{ij}$  equal to 1 indicates that element  $x_i$

(of  $x$ ) maps to element  $y_j$  (of  $y$ ). The mappings are selected so as to maximize the value of the similarity equation. The idea is that perceived similarity arises out of a comparison process that establishes mappings between the two analogs. Such mappings would prove useful in analogical reasoning and inference.

For real world problems, it is impractical to try all  $(\frac{mn}{2})^2$  combinations in search of the best mapping. The theory presented here is a computational level theory of comparison and similarity and does not address this issue. The solutions to difficult real world problems can be approximated using combinatoric optimization procedures such as simulated annealing [14]. In essence, every algorithmic model of analogy solves this combinatoric optimization problem by heuristically combining mapping constraints.

The similarity equation consists of four terms that combine linearly:

$$\mathbf{E}(x, y) = \alpha_1 \Theta(x, y) + \alpha_2 \Upsilon(x, y) + \alpha_3 \Omega(x, y) + \alpha_4 \Phi(x, y) \quad \text{where } \alpha_1, \alpha_2, \alpha_3, \alpha_4 \geq 0.$$

The four terms are defined below. The terms are organized from most semantic in nature to most structurally focused.

The  $\Theta$  term is analogous to Tversky's (1977) contrast model and captures raw semantic similarity:

$$\begin{aligned} \Theta(x, y) &= \varphi_1 \mathbf{f}(X \cap Y) - \quad (4) \\ (1 - \varphi_1) &\left( \delta_1 \mathbf{f}(X - Y) + (1 - \delta_1) \mathbf{f}(Y - X) \right) \\ &\text{where } 1 \geq \varphi_1 \geq 0, \text{ and } 1 \geq \delta_1 \geq 0 \end{aligned}$$

where  $\varphi_1$  determines the relative importance of commonalities and differences in determining the similarity of two analogs. The parameter  $\delta_1$  determines how asymmetric the similarity judgment is. Given that the focus of a comparison is usually on the target,  $\delta_1$  should be greater than .5.

The second term captures semantic similarity arising from correspondences:

$$\Upsilon(x, y) = \sum_{i=1}^m \sum_{j=1}^n A_{ij} \mathbf{C}(x_i, y_j) \quad (5)$$

where  $\mathbf{C}(x_i, y_j)$  is:

$$\mathbf{C}(x_i, y_j) = \begin{cases} \varphi_1 \mathbf{F}(x_i) & \text{if } x_i \text{ is identical to } y_j, \\ \text{else } (\varphi_1 - 1) \mathbf{F}(x_i). \end{cases} \quad (6)$$

The  $\Theta$  term and Tversky's contrast model do not distinguish between commonalities and differences that arise from relational elements that are in correspondence and those that are not in correspondence. The  $\Upsilon$  term specifically addresses commonalities and differences that are in correspondence (i.e., elements linked in  $A$ ). Commonalities arising from correspondences are processed differently (i.e., have different time courses and differentially affect perceived similarity)

than commonalities (or matches) that are not in correspondence [8]. Likewise, differences that can be put into correspondence are psychologically distinct from differences that cannot be put into correspondence [15].

Humans are also sensitive to higher-level matches (i.e., compatibility relations), as in the solar system/atom example. Analogs are perceived as similar when they have a common relational structure. The  $\Omega$  term captures this type of similarity and it is high when elements from one analog map to elements in the other analog and their parents are also in correspondence.

$$\Omega(x, y) = \quad (7)$$

$$\sum_{i=1}^m \sum_{j=1}^m \sum_{k=1}^n \sum_{l=1}^n S_{ij}^x S_{kl}^y A_{ik} A_{jl} \mathbf{F}(x_i) \mathbf{F}(x_j) \mathbf{F}(y_k) \mathbf{F}(y_l).$$

The  $\Phi$  term is purely structural and ranges from 0 to 1. The  $\Phi$  term is 1 when the mapping between  $x$  and  $y$  is a bijection (one-to-one and onto). In general people prefer analogies or mappings that are one-to-one [4]. Here, we assume that complete mappings are also preferred. The  $\Phi$  term is defined as:

$$\begin{aligned} \Phi(x, y) &= \delta_1 \left( \frac{1}{1 + \sum_{i=1}^m \mathbf{F}(x_i) \left(1 - \sum_{j=1}^n A_{ij}\right)^2} \right) + \quad (8) \\ (1 - \delta_1) &\left( \frac{1}{1 + \sum_{i=1}^n \mathbf{F}(y_i) \left(1 - \sum_{j=1}^m A_{ij}\right)^2} \right) \end{aligned}$$

The data sets considered in the next section are all from controlled experiments and mappings exist that lead to maximal values of  $\Phi$ . Under these conditions, only these solutions are considered by subjects (i.e., the parameter  $\alpha_4$ , weighting  $\Phi$ , is set to a value large enough to prohibit consideration of incomplete or conflicting mappings).

## The Similarity Equation and Human Data

In this section, data from Goldstone (1994) and data from two new experiments is fit by the similarity equation. The fits are intended to illustrate how the similarity equation can be applied to human data and should not be taken as a definitive test of the equation's form. The equation's form will certainly be refined as it is applied to more data sets.

### Goldstone (1994) Experiment 2

The similarity equation was applied to data from Goldstone's (1994) Experiment 2. Subjects rated the similarity of two displays. Each display consisted of a pair of schematic butterflies. Each butterfly could be represented by four features (type of tail, type of body, type of wings, type of head). The number of matches in place (correspondences as in Equation 5) and the number of matches that were not in correspondence was manipulated, yielding fifteen conditions. Table 1 illustrates the fifteen within subject conditions. Only the  $\Theta$  and the  $\Upsilon$  terms from the similarity equation are relevant

Table 1: Various feature transformation from Goldstone’s (1994) Experiment 2. In the Target column, each of the four positions in each letter string represents a part of the target stimulus (i.e., the second position in each string could denote the head). Each letter (A, B, C, D, W, X, Y, or Z) represents a particular feature value. The base stimulus is always represented as ABCD. The next two columns list the number of  $\Theta$  and  $\Upsilon$  matches. The Rated Similarity column denotes human subjects’ rated similarity of the base and target stimuli.

Target	$\Theta$ Matches	$\Upsilon$ Matches	Rated Similarity
WXYZ	0	0	1.91
XYDZ	1	0	1.48
YZDD	1	1	3.09
XYCZ	1	1	3.12
BAYZ	2	0	3.11
YZCD	2	2	4.65
BADZ	3	0	3.60
BACZ	3	1	4.52
BADD	3	1	4.57
ABDZ	3	2	4.96
ABDD	3	3	6.56
ABCZ	3	3	6.78
BADC	4	0	4.82
BACD	4	2	6.38
ABCD	4	4	8.79

for fitting this dataset, along with the  $\alpha_1$  and  $\alpha_2$  parameters, because 1) asymmetries were not a concern ( $|X|$  is equal to  $|Y|$ ), 2) differences and commonalities in Equations 4 and 5 are perfectly correlated allowing all difference terms to be dropped (i.e.,  $\varphi_1$  is set to 1), 3) the value of  $\Omega$  and  $\Phi$  do not vary across conditions.

For simplicity, a linear relationship was assumed between the maximal value generated by the similarity equation and subjects’ similarity ratings. Of course, similarity is probably a more complex function of  $E(x, y)$  for a number of reasons, including the presence of scale effects [19]. Nevertheless, with this simplifying assumption, the similarity equation accounted for 97.0 % of the variance in the data. The similarity equation states that different sources of similarity combine additively. A modified version of the equation was fit to the data that contained a term capturing the interaction between  $\Theta$  and  $\Upsilon$ . This augmented equation did not capture significantly more variance (97.3%), supporting the stance that the terms combine additively. The fit for SIAM, a special purpose interactive connectionist model developed by Goldstone (1994), was equivalent (it accounted for 97.7 % of the variance). The similarity equation offers a simpler account of the data — perceived similarity arises from a linear weighting of the  $\Theta$  and  $\Upsilon$  terms. To SIAM’s credit, it can account for aspects of the time course data, like that subjects tend to weight matches in correspondence (i.e.,  $\Upsilon$  matches) more later in processing than  $\Theta$  matches (this is SIAM’s added value). Such data is outside the province of a computational

level theory.

## Experiment 1

In Goldstone’s (1994) Experiment 2, the  $\Omega$  term was not relevant to the data fit. To further test the predictions of the similarity equation, I collected data from subjects in a task in which higher-order relations could impact the similarity equation’s predictions (i.e., the  $\Omega$  term’s value varies across conditions). In Experiment 1, subjects rated the similarity of two situations. The number of higher-order relations shared by the two situations was manipulated (as well as the number of  $\Theta$  and/or  $\Upsilon$  matches). The main prediction the similarity equation makes in Experiment 1 is that feature and relation matches will affect rated similarity additively.

**Subjects** Twenty-one Northwestern University undergraduate students participated in the experiment for course credit.

**Design and Overview of the Experiment** The two variables (Feature Match/Mismatch and Relation Match/Mismatch) were crossed for a 2 X 2 within subjects factorial design. The design is illustrated in Figure 1. The value of each term in the similarity equation for each condition is shown in Table 2. On each trial, subjects rated the similarity of two situations. Subjects completed 20 trials in each condition for a total of 80 trials. The order of trials was randomized for each subject.

**Stimuli and Counterbalancing** Each stimulus contained the descriptions of two situations. Each situation description consisted of two sentences (see Figure 1). One situation description was displayed on the left side of the screen. The other situation description was displayed on the right side of the screen. Above the description on the left side of the screen was the label “Situation A.” Above the description on the right side of the screen was the label “Situation B.” Underneath the descriptions was a rating scale (1 indicated low similarity and 9 indicated high similarity).

Each situation contained two characters that were either both male or both female. Character names were randomly chosen (subject to constraints imposed by the trial’s condition) without replacement from the following list of names: Anne, Jennifer, Linda, Susan, Wendy, Bill, Jeff, John, Keith, and Steve. On Feature Match trials, the gender of the characters in both situations matched (i.e., all characters were male or female). Whether the common gender was male or female was randomly determined for each Feature Match trial. On Feature Mismatch trials, the genders of the characters in the two situations were different such that the two characters from one situation were both male and the two characters from the other situation were both female. On each Feature Mismatch trial, it was randomly determined whether situation A contained the male or female characters.

Both characters from a situation appeared in both sentences. Each sentence contained a predicate that linked the two characters. The same predicates appear in both situations. Two predicates were randomly chosen without

Table 2: The values of the four terms for the four conditions in Experiments 1 and 2. Notice that  $\Theta$  and  $\Upsilon$  are perfectly correlated.

	$\Theta$	$\Upsilon$	$\Omega$	$\Phi$
Feature Match/Relational Match	8	8	12	1
Feature Mismatch/Relational Match	7	7	12	1
Feature Match/Relational Mismatch	8	8	10	1
Feature Mismatch/Relational Mismatch	7	7	10	1

replacement for each trial from the following list: is taller than, respects, and likes. Which predicate appeared in the first or second sentence within a situation was random. It was also random whether or not the same character appeared first in both sentences in situation A (the character order is fixed for situation B given the character order in situation A and the trial’s condition). Again, Figure 1 illustrates an example situation pair for each condition.

**Procedure** Text was displayed in black on a white background. Trials began with a message displayed in the upper left corner of the screen alerting the subject to prepare for the next trial. After 1000 ms, this message was removed and the stimulus was displayed (i.e., the two situations along with the rating scale). Subjects then pressed a key (1 through 9) to indicate how similar the two situations were (1 indicated low similarity and 9 indicated high similarity). After subjects responded, there was a 1500 ms pause and then the next trial began.

**Results** Table 2 shows the values of the four terms for each condition. As in the previous fit, the number of relevant parameters required can be reduced to 2 (the  $\alpha_1$  parameter for the  $\Theta$  term and the  $\alpha_3$  parameter for the  $\Omega$  term). The mean similarity ratings (averaged across subjects) for each condition are shown in Table 3. The similarity equation fit 99.9% of the variance in the data. To provide a stronger test, individual subjects’ data was fit. Of course, the fit for this data will not be as good because the data for individual subjects is not as stable and each subject uses a slightly different rating scale (i.e., high similarity for one subject may result in a rating of 8, while another subject may give a rating of 7). Nevertheless, the equation fit 71.9% of the variance ( $df=81$ ). A modified version of the equation was fit to the data that contained a term capturing the interaction between  $\Theta$  and  $\Omega$ . This augmented equation did not capture significantly more variance (72.1%,  $df=80$ ), supporting the stance that the terms combine additively.

## Experiment 2

A second experiment explored how task demands affect comparison. The materials and procedure were identical to the previous experiment except that after making a similarity judgment subjects were asked to state how the people in the

Table 3: Similarity ratings for each condition (averaged over subjects) in Experiment 1.

	Relational Match	Relational Mismatch
Feature Match	8.23	4.50
Feature Mismatch	7.51	3.39

target and base analogs corresponded to one another. This judgment should force subjects to focus more on high-order relational matches and should lead to a higher weighting of the  $\Omega$  term relative to the  $\Theta$  term in the similarity equation.

**Subjects** Seventy-one Northwestern University undergraduate students participated in the experiment for course credit. The subjects were from the same population as the subjects in Experiment 1. Experiments 1 and 2 were run concurrently (though no subjects participated in both experiments).

**Design and Overview of the Experiment** The design was very close to that of Experiment 1. The main difference was that subjects made a correspondence judgment after making a similarity judgment. Another difference was that subjects performed sixty trials (fifteen in each condition) as opposed to the eighty trials performed in Experiment 1.

**Stimuli and Counterbalancing** The stimuli and counterbalancing were identical to Experiment 1 with the following addition — after making a similarity judgment, one character was randomly chosen from situation A and another character was randomly chosen from situation B and subjects were asked if they corresponded to one another.

**Procedure** The procedure was identical to Experiment 1 except that subjects made a correspondence judgment immediately after making a similarity judgment. After making the similarity judgment, a text message appeared below the rating scale. The message asked if a particular character from situation A corresponded to a particular character from situation B. Subjects were instructed to press the ‘Y’ key if they thought the two characters corresponded and to press the ‘N’ key if they thought the two characters did not correspond. The Yes/No question was displayed along with both situation descriptions and the rating scale. After making the correspondence judgment, there was a 1500 ms pause and then the next trial began.

**Results** The main predictions held. Table 4 shows the mean ratings for each condition. Feature matches had a small effect on rated similarity while relational matches had a large effect on rated similarity. The ratio  $\alpha_3/\alpha_1$  was three times larger in Experiment 2 than it was in Experiment 1. Subjects also made the correspondence judgments in the manner predicted by the similarity equation’s mapping matrix  $A$ . In terms of fit, 99.9% of the variance in the averaged data was accounted for. For individual subject fits, 66.1% ( $df=281$ ) of the variance was accounted for and adding an interaction term did not improve the fit (66.1%,  $df=280$ ).

Table 4: Similarity ratings for each condition (averaged over subjects) in Experiment 2

	Relational Match	Relational Mismatch
Feature Match	8.32	4.47
Feature Mismatch	8.02	4.08

While the fits from Experiments 1 and 2 (as well as from Goldstone’s Experiment 2) suggest different sources of similarity combine additively, I predict that after consideration of more diverse data sets (e.g., [9]) the similarity equation will be revised to make allowances for interactions between terms under certain conditions. The equation and data presented here are simply intended to motivate a new framework for approaching comparison and similarity.

## Discussion

The similarity equation presented here is a computational level theory of human comparison and perceived similarity that can account for basic findings in the similarity and analogy literatures. The equation provides clarity to the discussion of similarity because it distinguishes between a number of different factors that can affect perceived similarity. An accurate characterization of similarity is critical given its central role in theories of categorization, decision making, analogy, problem solving, and object recognition.

Twenty years after Tversky’s (1977) classic paper, many of the same questions remain. How are the representations of analogs determined, how do they change as an outcome of comparison, and how is feature saliency modulated? One possibility is that instead of static representations being compared, retrieval and comparison are interleaved such that the current mappings between the analogs direct which other information is retrieved and represented in the base and target. Analogical inference may also direct the construction of the target analog’s representation. In other words, properties or features can emerge as a result of the comparison process [18]. Hopefully this work will demarcate what is known and what is common to competing models so that researchers can wisely focus their efforts.

## Acknowledgments

I would like to thank John Hummel and Keith Holyoak for illuminating discussions. I would like to thank Dedre Gentner and Arthur Markman for their helpful comments on a previous draft. Finally, I would like to thank Rob Goldstone for providing me with his data.

## Abstract

With certain masks used in Japanese Noh drama the apparent facial expression is a function of the vertical viewing angle. Rotation in depth produces changes in the retinal image of the face which viewers may confound with the distortion of features due to muscular action. In particular, as the mask is tilted forward it appears to smile, and as it is tilted backwards it appears sad. We explored this effect in two experiments with a Noh mask and one with a 3-D model of a laser-scanned human face. Separate British and Japanese subject pools were used to investigate cross-cultural effects. The results confirmed a systematic relationship between vertical angle of view and judged affect. For the Noh mask the effect was culturally moderated, whereas for the human face there was no significant effect of culture. These results are discussed and interpreted in terms of perceptual strategies for processing familiar and unfamiliar faces.

## Introduction

A variety of visual cues inform the viewer of affect. Muscular action of the face (Ekman & Friesen, 1978), causing feature displacement and consequent wrinkling of the skin, conveys the most salient information. Visible changes in skin hue caused by modulation of blood flow are also telling signs to internal state. A further source of information about affect is delivered by body posture: positive affect is accompanied by an upright posture with the head held high and negative states may be signaled by a bowed head and crouched posture (Darwin, 1872).

Visual processing of the feature displacement and textural cues to face muscular action requires a representation sensitive to the fine metric properties of the spatial patterns on the surface on the face (Lyons *et al.*, 1999, 2000). Rotation and translation of the head in 3-D space accompanying vertical movements of the head or changes in viewpoint, distort configural relations on the face as they appear in the 2-D projection of the face on the retina. Indeed the signals from facial muscle action and head posture conflict. Affect should be judged relatively positively in a head held up and back. Under frontal viewing conditions, tilting the head backwards reduces upward curvature of the mouth in the 2-D projection of

Figure 1: Magojiro mask used in the Japanese Noh drama.

the face, giving the impression of a sadder or negative expression. Tilting the head forward, a negative head posture signal, increases upward curvature of mouth - which usually accompanies the muscular action signaling a smile. It is therefore interesting to ask whether the changes due to rigid displacement of the head interferes with the interpretation of featural and textural cues due to muscular action of the face. Our interest in this question was stimulated when we learned of an illusion of facial expression perception involving masks (figure 1) used in Japanese traditional Noh drama (Komparu, 1983). It has been known for centuries in the Noh theater that certain masks, particularly those used to portray young female roles, appear to change expression as the vertical inclination of the mask changes (figure 2). Tilt the mask for-

ward and it appears to smile; tilt it backwards and it appears sad.

Is this phenomenon evidence for a lack of invariance of the facial expression recognition system under rigid transformations? Or are special techniques employed by the mask carver and Noh actor to trick the visual system into mistaking a rigid rotation of the mask for a non-rigid distortion of its internal features? We conducted three experiments to investigate the following questions (1) Do changes in vertical inclination in fact generate different perceptions of affect? (2) Is the effect culturally moderated or does it depend on familiarity with the mask? (3) Is the effect particular to the Noh mask or does it generalize to the human face?

## Materials and Methods

### Stimuli

Stimuli for **Experiment 1** consisted of photographs of a Noh mask (figure 2) at 13 inclinations, from  $-30^\circ$  to  $+30^\circ$  in equal  $5^\circ$  increments. An antique Magojiro mask, used for young female roles, dating to the Edo period (1600-1868) was photographed on a Noh stage under lighting conditions similar to what would be used during a performance. The mask was photographed from a frontal viewpoint using a digital camera (Kodak Professional DCS 460) from a distance of 7.7m with a 200 mm lens. The 3060x2036 pixel 24-bit color images were cropped and re-sampled to 300x400 pixel tiff images. Stimuli for **Experiment 2** (figure 3) comprised the same images, but cropped so as to emphasize the internal features of the face. Stimuli for **Experiment 3** (figure 4) were derived from the head and face of a 30 year old Japanese female model posing a neutral expression similar to that of the Noh mask. A Cyberware 3030 Color 3-D scanner was used to acquire shape and color information of the model's head. The 24-bit RGB color map was acquired under room light from an overhead fluorescent lamp. Screen captures were taken at 13 (virtual) head inclinations from a reconstructed 3-D model of the head, the face oriented frontally and saved as 24-bit 300x400 pixel tiff images. The vertical viewing angles varied from  $-30^\circ$  to  $+30^\circ$  in equal  $5^\circ$  increments. Inter-ocular distance and eye position were normalized for each stimulus set and matched across sets.

### Experimental Procedure

Experiments were run in separate laboratories in London and Kyoto. In each case the stimuli were displayed on a 17 inch 24-bit color computer monitor in a slightly darkened room. Viewing distance was approximately 60 cm. Following a practice trial, four epochs of all 13 stimuli were presented in succession, with presentation order randomized within each epoch. Presentation order was as follows: fixation point (500 ms) - blank (400 ms) - stimulus (300 ms). Subjects were instructed to respond whether the stimulus face appeared happy or sad by pressing the left or right shift key. Japanese subjects were instructed in Japanese using the terms “*yorokobi*” and “*kanashimi*”. Left/right assignment of response keys

was counterbalanced across subjects. The words “happy” and “sad” (in English for both subject groups) appeared on the response-appropriate side of the screen for each subject to maintain correct response orientation. All Japanese subjects were familiar with the English terms. Reaction times and decision type were recorded automatically for each subject for each trial.

### Subject Pool

Different subjects were run for each of the three experiments. There were 5 females and 5 males from each cultural group for each experiment, making 60 subjects in total. Subjects were undergraduates, graduates and staff from Doshisha University, Kyoto and University College London. Ages ranged from 18 to 50 years. All had normal or corrected-to-normal vision. All were either native to the country of testing or had first-school education in that country. The Japanese subjects were familiar with Noh masks as images or, occasionally, objects. None of the UK subjects had familiarity with Noh or had visited Japan.

## Results

All three experiments had the same mixed, 3-factor repeated measures design. There were 13 levels of the first factor (inclination), which varied within subjects, and one level of the first between-subjects factor (culture) and the second between-subjects factor (gender). Both RTs and response (as the proportion of “happy” responses over 4 trials) were examined. Following initial analysis, in which the full range of scores were examined, only the seven mid-range scores ( $-15^\circ$  to  $+15^\circ$ ) in the following treatment. Preliminary data analysis confirmed parametric, normal distributions of the scores reported here. There were no significant differences in the pattern of results when the full range was included. However, the full-range analyses may be less reliable due to non-Gaussian distribution of scores at some of the endpoints. RT (medians) showed no systematic relationship to the other variables, and are not reported here. Gender had no effect on any of the analyses and effects of gender were not considered further. Table 1 outlines the significant finding for each experiment. The relevant graphs are shown in figure 5. These analyses show a significant linear relationship between angle of inclination and rated happiness for all three experiments. The Noh mask, but not the scanned face, is classified differently by Japanese and British viewers. Further analyses and their justification in terms of individual experimental hypotheses are reported below.

### Experiment 1 - Full Mask

The experimental hypothesis was that the Noh mask would generate changes in perceived affect as a function of vertical angle. The perception of facial expressions is thought to be similar for our two cultural groups (Matsumoto, 1992), hence similar results were expected for the two subject groups.

The results confirmed the predictions in general terms, but with some important deviations. The groups differed in

Figure 2: Stimuli for Experiment 1. Edo-period Magojiro mask at 13 different vertical inclinations.

Figure 3: Sample stimuli for Experiment 2. Same images as in figure 2 but with the edges of the mask cropped to highlight internal features. Images from left to right show the mask at inclinations of  $-15^\circ$ ,  $0^\circ$ , and  $15^\circ$ .

Figure 4: Sample stimuli for experiment 3. Images captured from rendered 3-D model of a Japanese female face obtained using a Cyberware laser scanner. Images from left to right show the face at inclinations of  $-15^\circ$ ,  $0^\circ$ , and  $15^\circ$ .

the inclination at which a “neutral” expression is perceived. Japanese viewers rated the back-tilted mask more positively than British viewers. This may reflect different boundaries in terms of perceived facial expression on the categories of “happy” and “sad” and their cognates in Japanese or lower rates of sadness recognition for Japanese viewers. We address this further in Experiment 3. A second unexpected finding is that the groups differed in the linearity of the relationship with inclination angle (interaction of group and inclination was highly significant). While the relationship was linear over this range for the British subjects, for the Japanese subjects, the proportion of “happy” responses peaked at  $5^\circ$ , and then dipped. At  $15^\circ$ , mean “happy” response was no greater than at  $-10^\circ$ . Why should this change in perceived expression occur? One possibility is that the Japanese viewers were more sensitive to postural cues in the images of the head. A head bowed forwards may be seen as “sadder”. Perhaps the two subjects groups weight the posture and internal features cues differently. For the Noh mask images used, pose cues are most visible in the disposition of the top of the head and the chin with change in inclination of the head.

### Experiment 2 - Cropped Mask

In this experiment, the face images were cropped to diminish cues to head pose and emphasize internal features of the face (figure 3). The experimental prediction was that this may eliminate the non-linearity in the relationship between perceived expression and vertical inclination in the Japanese viewers. The results supported this. In this study, the “dip” at greater positive inclinations was greatly reduced. Thus it appears that Japanese viewers take account of cues to head pose in ascribing expression to the image of the vertically inclined mask.

Otherwise, experiment 2 replicates the main findings of experiment 1: a linear relationship between angle of inclination and judged expression; as well as a group difference

emerged between Japanese and British viewers. The group difference may indicate that the terms “happiness” and “sadness” in English and Japanese do not share similar extensions. This would suggest that Japanese may be more willing than British viewers to ascribe “happiness” (a socially acceptable facial signal) to a relatively “unhappy” face, despite the apparent reversal of this pattern for masks at high forward tilt. If this were so, we would expect a similar disparity between groups to emerge when images of natural faces are perceived. Experiment 3 explores this possibility.

### Experiment 3 - Human Face

This experiment used stimuli generated from a 3-D laser scan of a human face (figure 4) to explore the question: do group differences in ascribing expression to a cultural artifact, the Noh mask, extend to natural face images? If they do, we may infer that cultural and linguistic interpretations of facial expression may differ between these groups. If they do not, then the Noh mask may have special perceptual status for Japanese viewers. The findings strongly support the latter conclusion. The relationship between inclination angle and happy-sad judgments was to all purposes identical in both groups. Mann-Whitney non-parametric t-tests explored group differences at each orientation point. None approached significance. We can conclude that the Noh mask effects reported in Experiments 1 and 2, including both the dip in the function at high angles of forward tilt and the “happier” classification at most other angles, reflected a cultural phenomenon - but one related to *perceptual* processing differences between the groups. Though the laser-scanned face did not replicate the lighting conditions of the naturally photographed images used in Experiments 1 and 2, the relationship between inclination and judged expression still held, suggesting that the difference in lighting differences did not contribute notably to the illusion for this set of conditions.

Table 1: Summary of F values, separate ANOVAs for each experiment (SPSS GLM).

	F(6,216) Main effect of inclination	F(1,36) Main effect of group	F(6,216) Group inclination interaction	F(1,36) Main effect of inclination Linear trend	F(1,36) Group inclination Quadratic fit
Experiment 1 Full Mask	10.5 p < 0.001	NS	4.67 p < 0.001	15.33 p < 0.01	7.56 p < 0.01
Experiment 2 Cropped Mask	23.9 p < 0.001	5.27 p < 0.05	3.47 p < 0.01	55.77 p < 0.001	3.47 p < 0.01
Experiment 3 Scanned Face	14.96 p < 0.001	NS	NS	36.88 p < 0.001	NS

## Discussion

The three experiments confirmed that the angle of vertical inclination of a face profoundly influences a simple expression discrimination task: faces tilted down have a happier cast than those tilted back. This may be understood in terms of the projection of the three-dimensional facial surface onto the image. An earlier study (Cavanagh *et al.*, 1988) noted the effect as an example of the failure of shape constancy under rotation in depth. Another study (Kappas *et al.*, 1994) looked at viewpoint dependence of facial expression recognition using video clips of posed dynamic expressions as well as a schematic wire-frame model of the face, both quite different from the Noh mask stimuli and scanned face used here. However, that work did not attempt to look at facial expression cues separately from pose cues, as in experiment 2, or study different cultural groups.

A surprising but consistent (40 subjects altogether) finding was that the Noh mask elicited different responses in the two cultural groups. The skilled processing of faces has typically been described as configural (Diamond & Carey, 1986; Young *et al.*, 1987). That is, skilled viewers take account of the various face features and their disposition in coming to a unified account of the identity or reading of the face. Their reading of the face cannot be predicted on the basis of local featural detail. One possibility is that familiarity may have delivered a greater degree of configural processing for the mask in Japanese than British viewers, for the Noh mask occasionally appears in the Japanese media, though an understanding of Noh, or interest in Noh as a tradition is no longer widespread in the Japanese population. One local feature that reliably signals “happy-sad” is the curvature of the mouth. It is possible that British viewers of the Noh mask took account of this feature alone. For Japanese viewers, other aspects of the face may have moderated the effect. Only further experiments will indicate what facial aspects these may be.

At the outset of these studies, we speculated that the three-dimensional structure of the Noh mask and the disposition of the painted features, may be intentionally designed to elicit changes of perceived expression with small changes in pose. Examination of the 3-D structure of the mask showed, for example, that the depth of the mouth region is exaggerated

Figure 5: Mean response versus vertical inclination for the 3 experiments.

relative to the human face. Our psychological studies confirmed that small changes in pose of the mask lead to significant changes in perceived affect. A forward tilted mask appeared relatively happy and one tilted backwards, relatively sad. Paradoxically, however, in the stylized use of mask pose in Noh drama, the convention is the opposite to our findings. In one gesture known as *terasu* (shining), signifying a happy state, the mask is turned upwards. In another known as *kumorasu* (clouding), signifying a sad state, the mask is turned downwards (Komparu, 1983).

In this connection, it is notable that Zeami (1363-1443), the most influential early Noh dramatist, ranked *yugen*, or subtle profundity, as the highest aesthetic principle of Noh (Zeami, 1968). In the framework of the Noh world, a joyful pose tempered with a slightly sad mouth may be appreciated as more beautiful than a direct expression of joy. Likewise, sadness or pain masked with a smiling mouth suggests more emotional complexity than an display of pure sadness. A further interpretation is possible, not necessarily in conflict with the above. The psychometric curves (figure 5) show that small changes in inclination angle significantly affect perceived facial expression. Minor movements of the actor's head may trick viewers into thinking that the internal features of the mask are moving non-rigidly as if it were an animated living face. One of the authors (MJL) has observed this effect while watching a Noh play. In a related perceptual effect, a rigid 3-D stick man figure rocked longitudinally back and forth can appear to walk with non-rigid limb movement in 2-D projection (Sinha & Poggio, 1996).

### Acknowledgements

We are grateful to Hotaka Komparu for loan of the Magojiro mask and a helpful discussion about Noh drama; the management at Nara Shin Kokai Do for access to the Noh stage; Akiko Tohma and Katsunori Isono for their generous help; Larry Maloney and Patrick Cavanagh for stimulating discussions; and Vicki Bruce for encouraging us to pursue this study.

## Abstract

We investigate the effects of word frequency and lexical neighbourhood density on word recall and recognition. We found a three-way interaction between memory task, the size of lexical neighbourhood of a target word, and target word frequency. In particular, performance on low frequency words with many lexical neighbours was surprisingly good in the recognition condition. The results show that the number of lexical neighbours of the target moderates the word frequency effect in recognition. Large neighbourhood size always has a facilitatory effect upon performance. The findings are contrasted with those observed in lexical access in speech production.

## Introduction

To what extent is retrieving a word when speaking like accessing a fact from long-term memory? In particular, how do the language processes involved in lexical access for spontaneous speech production relate to the memory processes involved in the retrieval of word lists from long term memory? On the one hand, our intuition is that lexical retrieval is like recall. Indeed, we even talk in these terms in every day use, using constructions such as “I cannot recall that word”. On the other hand, some models of lexical access in speech production involve search through a list of phonological forms (Butterworth, 1980, 1989; Fay & Cutler, 1977). Such a search might well involve an element of recognition when the appropriate form is reached. This paper looks at two psycholinguistic variables that are well known to influence lexical access (word frequency and lexical neighbourhood size), and investigates their effect on free recall and recognition performance. We compare their effects on a memory task with their effects on a language production task.

Word frequency is an important variable in all language tasks, including speech production (Harley, 1995). Frequency always has a facilitatory effect in speech production. For example, we are faster to name high frequency words and objects with high frequency names (see Jescheniak & Levelt, 1994; Oldfield & Wingfield, 1965). Harley and Bown (1998), using a laboratory-based “tip-of-the-tongue” (TOT) induction task (Brown &

McNeill, 1965), showed that we are more likely to experience a TOT state on less common words.

The second variable employed in this study is lexical neighbourhood size. Some words (e.g. “corpse”) are phonologically unique in that there are no other words that sound like them. Other words (e.g. “cage”) have a large number of phonological neighbours (“page”, “rage”, “sage”, and “cave”, among others). Obviously we need a suitable measure of lexical similarity; we discuss this below. It is well established that a word’s lexical neighbours play in an important role in word recognition (e.g. Glushko, 1979; Grainger, 1990). It is now also becoming apparent that they play some role in word production. Harley and Bown (1998) showed that the number of phonological neighbours a word has affects lexical retrieval in the tip-of-the-tongue state. In particular, they showed that when word length and frequency are controlled for, people are more likely to have difficulty with words that have few phonological neighbours. This result showed that a large set of potential responses can in fact increase the chances of successful retrieval of the target. Harley and Bown hypothesised that structurally similar items provide supporting activation for each other. This finding also supports the “insufficient activation” hypothesis for the origin of TOTs (Burke, MacKay, Worthley, & Wade, 1991).

Although research on the effects of neighbourhood density on lexical access in speech production is at an early stage, the pattern observed is that it is easier to produce frequent words that have many neighbours. Will this pattern be observed in memory tasks? Of course, the pattern observed might well differ depending upon the exact task used. In particular, we might observe different outcomes depending on whether we use a recognition or recall memory task.

The effect of word frequency on recognition is well known, if poorly understood. The “word frequency effect” is the finding that recognition memory is better for low frequency words than high frequency words (Baddeley, 1990; Gregg, 1976; see Guttentag & Carroll, 1998, for a recent review). In recognition, we make a judgement about whether or not we have recently seen a particular item. Is

the stimulus activated because of recent exposure, or is it activated just because of an intrinsic property, such as its high frequency? There is no such conflict in the case of low frequency words, where high activation of the stimulus representation is much more likely to have come from recent exposure in the study list. Put more colloquially, frequent words are less distinctive. This line of reasoning is commonly known as the *memorability hypothesis* (e.g. Brown, Lewis, & Monk, 1977).

Less is known about how word frequency affects performance in a recall task. If frequency operates by raising the activation levels of frequently used items (e.g. Morton, 1979), then the free recall of a high frequency word should be relatively easy and that of a less frequent word relatively difficult. In summary, frequency should facilitate recall but might hinder recognition. In the light of these hypotheses, the finding that in speech production high target word frequency always has a facilitatory effect suggests that lexical access is more like recall than recognition.

The effect of a large lexical neighbourhood is to increase the number of potential responses. The existence of plausible alternative responses may have different effects on recall and recognition. Recognition is more difficult when selecting from a large set of plausible responses than a smaller set (e.g. in the long-term memory version of Sternberg, 1966). Crucially, the similarity between targets and distractors affects recognition (Dale & Baddeley, 1962). Hence large lexical neighbourhoods should hinder recognition.

It is less clear how neighbourhood size will affect recall. If free recall acts like speech production, we would expect that words with many neighbours should be relatively easy to recall. One way of conceptualising this is that a word's neighbours should act as possible retrieval cues. On the other hand, in the two-process, generation-recognition account of free recall (Anderson & Bower, 1974; Kintsch, 1970), recall contains within it an element of recognition. In this case, the recall of words with many neighbours will be either hindered, or the effects of the two processes may cancel out so that no difference is observed. We attempt to explore these issues by examining the effect of the target word's phonological neighbourhood.

It is unclear how word frequency and lexical neighbourhood size will interact. If either recognition or recall resembles speech production while the other does not, we will obtain a three-way interaction with particularly poor performance on low frequency words with few neighbours. The simplest prediction is that speech production resembles recall, and that the pattern observed in speech production should therefore also be observed in the free recall task. It is less clear what should happen in the recognition task. One possibility is that the word frequency effect should overwhelm any effects of neighbourhood size, but any prediction here is prematurely speculative.

In summary, the aim of this paper is to examine the effects of word frequency and lexical neighbourhood size on measures of memory.

## Method

### Participants

We tested 30 volunteers, who had a mean age of 34 years. They were all psychology undergraduates of the University of Dundee, Scotland. Ten females and five males took part in each of the two experimental conditions.

### Materials

All of the words used in the experiment were nouns of one or two syllables in length. The experiment required a printed list of target words used in the learning phase of the study, and a printed list of these words plus distractor words in the recognition condition.

The target items were the same as those of Experiment 2 of Harley and Bown (1998). There were 60 words in the target list, of which 30 were of high frequency (at least 100 instances per million words, with a mean of 163.7, as sampled in Francis & Kucera, 1982), and 30 of low frequency (under 9 instances per million, with a mean of 3.7). Within each list of 30, 15 of the target words had a dense lexical neighbourhood as evidenced by a mean N value of 15.1 (see Coltheart, Davelaar & Besner, 1977; our figures were taken from the MRC Database of Coltheart, 1981). The remaining 15 words had no close orthographic neighbours as evidenced by a mean N value of 0. The N value is a measure of a word's orthographic neighbourhood size: it is the number of other words that can be made from a particular word by changing one letter. Obviously the higher the N score, the larger the orthographic neighbourhood. Orthographic and phonological neighbourhood sizes are highly correlated. This issue is discussed in depth in Harley and Bown (1998), who found the same results whether orthographic or phonological neighbourhood size was used. The properties of the materials are summarised in table 1.

Table 1: Properties of materials

Condition	Frequency	N Value
High F, high N	246.7	15.1
High F, low N	225.5	0
Low F, high N	7.2	15.1
Low F, low N	5.6	0

This process yielded four sets of fifteen target words, balanced for frequency and orthographic neighbourhood size, comprising words of high frequency and high N value, high frequency and low N value, low frequency and high N value, and low frequency and low N value. The words were combined in random order to form one list.

The target words were printed in black ink, one beneath the other, in two columns on A4 paper in random order for use in the presentation phase of the experiment. Examples include “ball” and “date” (high frequency, high N), “cage” and “dove” (low frequency, high N), “growth” and “view” (high frequency, low N) and “corpse” and “tinsel” (low frequency, low N).

The recognition condition of the experiment consisted of the targets and 60 distractor items. In this particular experiment, the distractors were related in meaning to items from the target word set. Although it is clearly of interest to study other types of distractor, we wanted to make this task similar to speech production. Therefore the potential competing words were maximally plausible alternatives that were semantically similar to the targets. The target words were paired with close semantic associates. The items for the recognition task were also hand-printed in black ink, one beneath the other, in random order, on a single sheet of A4 paper.

## Procedure

All participants were given 5 minutes in which they were told to read the presentation list of 60 words and to try to remember them. This was followed by an interval of 5 minutes during which participants engaged in conversation and listened to music. Participants in the recall condition were then given 5 minutes to write down as many words as they could recall from the presentation list. Participants in the recognition condition were told they had 5 minutes to read the recognition list of 120 words and underline in pencil any words that they thought they had previously seen.

## Results

The experimental design comprised three factors. There was a between-subjects factor of memory task (with the two levels of free recall and recognition). There were two within-subjects factors, one of word frequency (with the two levels of high and low frequency) and one of lexical neighbourhood size (with the two levels of high N score and low N score).

A 2x2x2 ANOVA on the correct memory scores of the participants showed main effects of memory task ( $F(1, 28) = 14.72, p < 0.001; MSE = 143.0$ ), word frequency ( $F(1, 28) = 7.71, p < 0.025; MSE = 27.1$ ), and neighbourhood size ( $F(1, 28) = 27.9, p < 0.001; MSE = 130.2$ ).

Importantly, there was a significant three-way interaction between memory task, word frequency, and lexical neighbourhood size ( $F(1, 28) = 10.80, p < 0.01; MSE = 27.1$ ). There was also a significant two-way interaction between memory task and word frequency ( $F(1, 28) = 12.96, p < 0.005; MSE = 49.4$ ). The interaction between memory task and neighbourhood size approached significance ( $F(1, 28) = 3.95, p = 0.06, MSE = 18.4$ ), but there was no hint of any interaction between frequency and

neighbourhood size ( $F(1, 28) = 1.2$ ). Figure 1 summarises these results.

As was expected, the level of recognition performance was better than that of free recall. Performance on words with dense lexical neighbourhoods was better than that on words with sparse neighbourhoods across both the recall and recognition conditions. Performance on high frequency words was generally better than on low frequency ones. The likely source of the three-way interaction, however, is that low frequency, dense-neighbourhood words perform unusually well in the recognition task (or unusually poorly in the recall condition). Words with many neighbours are significantly easier to recognise than those with few neighbours ( $t[28] = 4.01, p < 0.001$ ). There is no difference between the corresponding conditions in the recall task ( $t[28] = 1.10$ ). Indeed, recognition performance for the less frequent words with many neighbours was the best of all conditions. A consequence of this interaction is that there is no word frequency effect for words with few neighbours in the recognition task; performance on low frequency words is in fact worse than that on high frequency words, although not significantly so ( $t[28] = 0.95$ ).

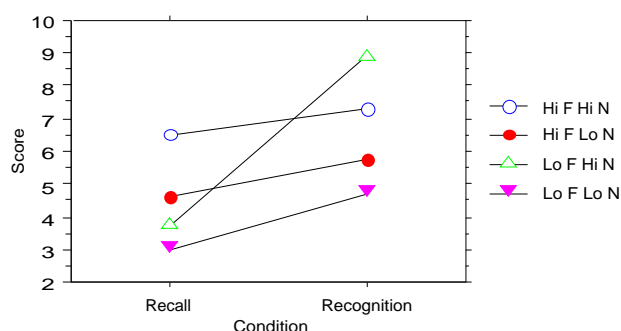

Figure 1: The effects of word frequency and lexical neighbourhood size on recall and recognition.

## Discussion

In summary, we obtained a three-way interaction between memory task, word frequency, and phonological neighbourhood size, demonstrating that these two variables have significant differential effects upon recall and recognition. Large neighbourhood size always has a facilitatory effect on both recall and recognition performance, suggesting that the neighbours of target items act as a source of support rather than interference. In the recognition task, performance on words with few neighbours was better on high frequency words than low frequency words, reversing the usual frequency effect.

In the recall task, performance on high frequency words was uniformly better than on low frequency words, confirming our predictions based on the consideration of lexical activation levels. The amount of facilitation provided by dense lexical neighbourhoods is not large, but

words with many neighbours are easier to recall than words with few.

The findings in the recognition task are more complex. The word frequency effect in recognition, whereby less frequent items are easier to recognise than high frequency words, was replicated only for words with many lexical neighbours. There was no advantage (indeed, a slight disadvantage) for low frequency words with few neighbours. This suggests that any account of the word frequency effect must take into account the role of lexical neighbourhood size. The other conditions in the recognition task are in line with those of the recall task, bearing in mind the expected generally better performance in the recognition task.

Why should low frequency words with no or few neighbours be particularly difficult to recognise? The result appears contrary to the memorability hypothesis. A word which is orthographically and phonologically unique as well as uncommon should be more noticeable and therefore memorable than one with many neighbours.

There are at least two possible explanations. The first is that during the study phase, a target word primes the words in its neighbourhood. During the test phase of the experiment, the primed items then cue the target. The more neighbours there are to act as primes in the test phase, the more likely is a correct response. Words with few neighbours do not have this advantage.

Consideration of the attention-likelihood model of Glanzer and Adams (1990) suggests another explanation. They suggested that in the study phase of a recognition experiment, people pay more attention to some items than others. In general people might redistribute effort at encoding or in rehearsal towards troublesome items (see also Fritzen, 1975; Hastie, 1975; Murnane & Shiffrin, 1975). Low-frequency words with many neighbours may strike participants as odd. They therefore pay a disproportionate amount of attention to them, in particular ensuring that the low-frequency target is not in fact one of its own neighbours. On the other hand, it is possible that participants consider low-frequency words with few neighbours to be "obvious", and therefore pay little attention to them. In the recognition phase, performance will be poor on those items that had less attention allocated to them in the study phase (the low-frequency few-neighbours words). We cannot distinguish between these two possible explanations on the basis of our current data, and of course, they may not be incompatible.

Attention-likelihood theory is one explanation of the "mirror effect". Consider an experiment with two conditions (e.g. high and low frequency items) where the items in one are better recognized than items in the other. Then the superior condition will give better recognition of previously-seen items (i.e. targets) as being old but also better recognition of new items (i.e. distractors) as being new. (See Glanzer, Adams, Iverson, & Kim, 1993; Glanzer, Kim, & Adams, 1998; Stretch & Wixted, 1998; but see also Murdock, 1998.) Consideration of lexical

neighbourhood size may be helpful in giving an account of the mirror effect.

Another surprising finding is that, counter to our intuitions and prediction, the pattern of performance observed by Harley and Bown (1998) in the TOT task is here mirrored in the recognition task, and not in the recall task. In particular, Harley and Bown found a large difference between low frequency words with dense and sparse neighbourhoods. Here we only observed this difference in the recognition task. This suggests that lexical access in speech production contains an important recognition component. Of course, some caution is necessary in making this claim; it is necessary to reproduce our findings on a task more directly oriented to speech. There are at least two possible loci for a recognition component in lexicalization. First, lexical search models such as those of Butterworth (1980) and Fay and Cutler (1977) involve search through ordered lists of lexical entries. Selecting the correct entry might involve recognition. Second, speech production might contain an element of monitoring and editing. These processes might involve recognition. There is independent evidence for the existence of monitoring processes from self-repair of speech (see Levelt, 1989) while others (e.g. Baars, Motley, & MacKay, 1975; Butterworth, 1982) postulate that it is necessary to account for characteristics of speech errors.

An important caveat to any conclusion regarding the resemblance of speech production to other memory tasks concerns what happens in the tip-of-the-tongue state. The presumption in the literature is that a TOT state is an extended form of a hesitation in normal speech (see Harley, 1995, for a review; see also Levelt, 1989). Harley and Bown (1998) suggested that strategic factors might sometimes be operative in laboratory-induced TOT states. In particular, we suggested that there might be an editor responsible for monitoring the output of the interlopers, the words that often spontaneously come to mind when in a TOT state. Others have also proposed that our potential speech output can be edited by a late-acting monitor (e.g. Levelt, 1989). This editor might sometimes discard grossly implausible candidates. The editor must be far from perfect, however, as many implausible candidates are often output; and about a quarter of the time these interlopers bear no obvious relationship to the target. If and when it operates, this post-access monitor might plausibly contain an element of a recognition process. There is no reason to suppose that this applies to either spontaneous production or the strivings to retrieve the target word itself.

If this is the case, the recognition component observed in TOT states comes from the action of post-access strategic processes, rather than the processes of lexical retrieval themselves.

In summary, we have shown that lexical access in the tip-of-the-tongue state surprisingly resembles performance on a recognition task rather than on a free recall task. We have also shown that the word frequency effect in recognition is moderated by the size of the lexical neighbourhoods of the target items. The exact way in

which neighbours exert their effects in these tasks remains to be explored.

# A Generative Connectionist Model of the Development of Rule Use in Children

Stuart Marcovitch (stuartm@psych.utoronto.ca)

Philip David Zelazo (zelazo@psych.utoronto.ca)

Department of Psychology, University of Toronto  
Toronto, ON, M5S 3G3, Canada

## Abstract

The cascade correlation algorithm (CASCOR), a generative connectionist model, was used to simulate age-related changes on the dimensional change card sort (DCCS), which has traditionally been used to evaluate the complexity of children's rule-use abilities. Like 2.5-year-olds, inexperienced networks behave as if following one rule; slightly more experienced networks (akin to 3-year-old children) behave as if following a pair of rules; and the most experienced networks (akin to 5-year-olds) behave as if following two pairs of rules. Analysis of the networks' activation levels revealed that mastery of simple rules is a necessary precondition for using higher order rules. The model also generated four novel predictions that can be tested in future research with children.

## Introduction

Since its inception, artificial intelligence has made a large impact on the field of psychology. The infusion of computer generated models into psychological research has become increasingly common. In the past decade, connectionist models have become particularly influential as a research tool in psychology. Connectionist models benefit psychology in three ways: (a) successful simulation requires formalization of the assumptions of the model, (b) analyzing the solution of a connectionist network may provide insight into the psychological mechanisms used, and (c) the model may generate novel (and often counter-intuitive) predictions. In particular, connectionist modeling used in conjunction with empirical research has the potential to shed light on patterns of development across a wide range of cognitive domains. Researchers in developmental psychology have already employed connectionist models to simulate developmental phenomenon in a variety of cognitive tasks (e.g., McClelland & Jenkins, 1991; Schultz, Schmidt, Buckingham, & Mareschal, 1995; see Elman et al., 1996, for a comprehensive review). Often, the results of these simulations call into question contemporary explanations of cognitive development.

According to Cognitive Complexity and Control theory (CCC; Frye, Zelazo, & Palfai, 1995; Zelazo & Frye, 1997), developmental improvements on tasks assessing deliberate reasoning and intentional action can be attributed to the acquisition of increasingly complex rule systems. Specifically, CCC postulates that young children (2.5 years) can use one rule, slightly older children (3 years) can use a pair of rules, while the oldest preschoolers (5 years) can use two incompatible pairs of rules. Rule-based card sorting paradigms have been employed to illustrate the number of

Figure 1: Stimuli for DCCS

rules that children can use. In these tasks, children are given cards that can be placed in one of two boxes based on a rule. For example, Zelazo, Reznick, & Piñon (1995) instructed 2.5-year-olds to sort pictures into categories such as things found inside the house versus things found outside. Typically, these children were able to sort the first card correctly, but then perseverated and sorted all subsequent cards in the same box. Thus, these results demonstrated that 2.5-year-old children could sort by one rule (e.g., if picture of things found inside the house then put card there), but not by a pair of rules (e.g., if picture of things found inside the house then put card here, but if picture of things found outside, then put card there).

The Dimensional Change Card Sort (DCCS; Frye et al., 1995; Zelazo, Frye, & Rapus, 1996) has also been used to reveal age-related changes in the number of rules children can use simultaneously. In the standard task, children are shown two *target cards* that differ on two dimensions, say color and shape (e.g., red car and blue flower). Children are presented with *test cards* that share one dimension with one target and the other dimension with the other target (e.g., red flower and blue car, see Figure 1). In the pre-switch phase, children are instructed to sort the test cards (i.e., match the test card to the appropriate target card) according to one rule (color or shape). After a predetermined number of pre-switch trials (e.g., 5, see Zelazo et al., 1996), children are asked to sort the same test cards by the other rule. So, the same test card will be sorted differently in the pre-switch and post-switch phases. On this task, 3-year-old children tend to pass the pre-switch phase, but fail the post-switch phase. This indicates that these children can sort by one pair of rules (e.g., in the color game, if it's red it goes here, but if it's blue it goes here), but not by two incompatible pairs of rules (e.g., if it's the color game, then if it's red it goes here, and if it's blue it goes here *but* if it's the shape game, then if it's a flower it goes here and if it's a car it goes here.) Five-year-old children tend to pass both the pre-switch and post-

switch phase, which illustrates that they can sort by two incompatible pairs of rules in the same context, and arguably requires the use of a higher order rule for selecting between pairs of rules.

The goal of the present study was to simulate the development of rule use in children using a generative connectionist model. Our study had three objectives: (a) to capture the age-related changes that are observed in children's sorting between the ages of 2.5 and 5 years, (b) to generate novel predictions, and (c) to explore what the internal structure of the connectionist networks reveals about the structuring of dimensions and features within the dimensions *vis à vis* success on the task.

In the present study, we used the cascade correlation learning algorithm (CASCOR; Fahlman & LeBiere, 1990) to simulate children's performance on the DCCS. Some researchers (e.g., Shultz, 1991) have suggested that CASCOR is appropriate in simulations of cognitive development because it embodies Piaget's principles of assimilation and accommodation. CASCOR is a generative algorithm that begins with connections between all the inputs and the output, but no hidden units. The model attempts to learn the training set in the constraints of this architecture, a phase akin to the Piagetian concept of assimilation. However, if the training set cannot be learned within a specific network architecture, hidden units are recruited as needed to increase computational power. Each hidden unit receives connections from all input units and all previously recruited hidden units. The restructuring of the network to create a more adaptive architecture is akin to the Piagetian concept of accommodation. One advantage of CASCOR is that the hidden unit chosen for recruitment is the one that will produce the lowest overall error. Consequently, the modified network is poised to solve the task at hand, and will do so more efficiently (using fewer hidden units) than networks with fixed architectures.

### Training Phase

Age-related changes in the DCCS were simulated using CASCOR. The networks had 15 inputs. The first input determined the game that was to be played (color or shape). The next 12 input units determined the color and shape of the stimulus cards. Each card was coded across 4 attribute units (red, blue, car, flower). A value of 1.0 indicated the presence of an attribute while a value of 0.0 indicated the absence of the attribute. For example, the values {1.0, 0.0, 0.0, 1.0} indicated a red flower. The test card and the two target cards were each represented by specific configurations across the 12 units. The 14<sup>th</sup> and 15<sup>th</sup> units were context units, which determined if the network was learning in the *training* context {1.0, 0.0} or the *test* context {0.0, 1.0}. These context units were necessary to distinguish learning that occurred in the natural environment (training) from the laboratory environment (test). There was one output unit that returned a value ranging from -0.5 to 0.5. Matching to the first target card was assigned an output value of -0.5, whereas matching to the second target card was assigned an output value of 0.5. The target value that

was closest to the actual output value was considered the matching target.

In the training set, the network received a set of simple rules. The network was presented with the relevant game (e.g., color), a bidimensional test card (e.g., red flower), and two bidimensional target cards (e.g., a red car and a blue flower). For all the examples in the training set, the context units were set to the training context (i.e., 1.0, 0.0).

The network updated its weights based on a supervised learning algorithm. The network's output was compared to the expected output (i.e., in the color game, a red flower should be matched to the red car), and the weights were updated using the quickprop algorithm (Fahlman, 1988) and batch learning (i.e., the weights were updated after each epoch, as opposed to each example). Quickprop is a weight adjustment algorithm that is much quicker than backprop because it uses second-order (curvature) information as well as first-order (slope) information when adjusting weights, whereas backprop is restricted to slope information. Slope information indicates the direction of change; curvature information provides an index of the change in slope, which is used to determine the magnitude of weight change (Mareschal & Shultz, 1996; also see Fahlman, 1988, for more details).

In the training phase of the simulation, all possible training combinations were used. That is, 2 games (color or shape) X 4 test cards (red flower, blue flower, red car, blue car) X 4 target combinations (red flower, blue flower, red car, blue car for target 'A'; target 'B' differed from target 'A' on both dimensions), which yielded 32 training examples. Because the preliminary goal was to simulate data that were averaged over groups of children, a cross-sectional design was implemented as per previous studies of the DCCS with children (e.g., Zelazo et al., 1996). Twenty networks were trained in each of 5 conditions that differed on the number of epochs of training that the network experienced. The conditions were 50, 75, 100, 150, and 225 epochs.

### Test Phase

After various amounts of exposure to the training set, training was halted so that the network could be tested. Testing consisted of changing the training set to five examples (pre-switch trials) that correspond to the five trials of the pre-switch phase of the DCCS. In all five trials, the network was presented with the same game (i.e., shape), the same two target cards (i.e., target 'A' was a red flower, target 'B' was a blue car), and the context nodes were set to the test context (i.e., 0.0, 1.0). The two possible test cards were presented (i.e., red car and blue flower) on alternate trials with one test card presented three times and the other test card presented twice. The network updated its connection weights after each pre-switch trial. After the fifth pre-switch trial, the network was tested on two post-switch trials. These were equivalent to the pre-switch trials, except now the network was asked to sort by the other dimension (e.g., color). The output revealed how the network sorted each of the two test cards. Because weights were *not*

updated in the post-switch phase, two post-switch trials were sufficient for the appropriate categorization of the network.

The network outputs were categorized into one of four categories based on criteria used with children (e.g., Zelazo et al., 1996):

- (1) Fail Pre-Switch - The network incorrectly sorted on two or more pre-switch trials.
- (2) Fail Post-Switch (same box) – The network passed the pre-switch phase, but incorrectly sorted on one of the two test trials in the post-switch phase (i.e., the network put all of the cards in the same box).
- (3) Fail Post-Switch (perseveratively) – The network passed the pre-switch but incorrectly sorted both test cards in the post-switch phase (i.e., the network perseverated on the two original rules).
- (4) Pass Post-Switch – The network correctly sorted both test cards in the post-switch phase.

## Results

The CASCOR network began with the 15 input units and the one output unit. Although the network did not initially contain hidden units, these were recruited as needed through the progression of the simulation. The number of hidden units recruited was noted. The number of networks in each of the four classifications is displayed in Table 1.

Table 1: Performance of CASCOR networks on DCCS

No. of Epochs	Categorization of Network			
	FPre	FPost Box	Fpost Pers	Pass
50	12 (1*)	2 (1*)	0	6 (1*)
75	5 (5*)	7 (7*)	5 (5*)	3 (2*)
100	10 (10*)	2 (2*)	5 (5*)	3 (3*)
150	2 (2**)	1 (1*)	4 (2*, 2**)	13 (3*, 10**)
225	1 (1**)	0	0	19 (19**)

*Note.* FPre = Fail Pre-Switch; Fpost Box = Fail Post-Switch (same box); FPost Pers = Fail Post-Switch (perseveratively); Pass = Pass Post-Switch. The number of hidden units recruited by the networks is represented by asterisks (\*). For example, 3\* means three networks recruited one hidden unit, while 10\*\* means 10 networks recruited 2 hidden units.

In the 50-epoch condition, 12 out of 20 (60%) of the networks failed the pre-switch phase. For the slightly more experienced network in the 75-epoch condition, 15 out of 20 (75%) of the networks passed the pre-switch phase. Furthermore, 12 out of 15 (80%) of those networks went on to fail the post-switch phase. In the 225-epoch condition, 19 out of 20 (95%) of the networks passed the pre-switch phase. All of those networks (100%) went on to pass the

post-switch phase. Overall, this pattern of results mirrored the pattern found in the empirical literature. Namely, the youngest children tend to fail the pre-switch phase, indicating failure to use a single pair of rules systematically. The slightly older children pass the pre-switch phase but fail the post-switch phase. Finally, the oldest children tend to pass both the pre-switch and post-switch phases, arguably indicating that they were capable of using a higher order rule for selecting between two incompatible pairs of rules.

Table 2: Number (and row percentages) of networks in each classification based on the number of hidden units.

No. of Hidden Units	Categorization of Network			
	FPre	FPost Box	Fpost Pers	Pass
0	11 (61%)	1 (6%)	0	6 (33%)
1	16 (33%)	11 (23%)	12 (25%)	9 (19%)
2	3 (9%)	0	2 (6%)	29 (85%)

*Note.* FPre = Fail Pre-Switch; Fpost Box = Fail Post-Switch (same box); FPost Pers = Fail Post-Switch (perseveratively); Pass = Pass Post-Switch.

The number of hidden units the network recruited seems to be related, albeit imperfectly, to performance on the DCCS. Table 2 displays the classification of networks across all five conditions based on the number of hidden units. A chi-squared analysis revealed a relation between the number of hidden units and the DCCS classification,  $\chi^2(6, N = 100) = 49.40, p < .01$ . The majority of networks with no hidden units fail the pre-switch phase, while the majority of networks with two hidden units pass both the pre-switch and post-switch phases. Networks with one hidden unit tend to be transitional and distributed across all four conditions. Thus, it can be argued that by acquiring more sophisticated internal representation (measured by the number of hidden units), more complex rules can be solved.

The current findings are congruent with Siegler's (1996) notion that cognitive development is driven by changes in strategy selection. According to this notion, children typically have a number of strategies available to them to solve any task. With age, the likelihood of selecting more appropriate strategies increases. However, even at older ages, children sometimes select inappropriate strategies. In the current simulations, increases in the number of hidden units may correspond to increases in the likelihood of selecting a more appropriate strategy. For example, networks with two hidden units usually adopt the most appropriate strategy (85% of the time), but occasionally adopt a less-appropriate strategy.

In addition to capturing the general pattern of age-related changes on the task, the simulations offer several predictions that raise interesting questions for future empirical work:

- (1) In networks that passed the pre-switch phase but failed the post-switch phase, there was a developmental increase in the proportion that failed perseveratively (as opposed to sorting cards in the same box). In the four network conditions where these types of errors occur, the proportions that failed perseveratively were 0%, 42%, 71%, and 80%, for 50, 75, 100, and 150 epochs respectively. We expect a similar increase with children.
- (2) The proportion of networks that passed the pre-switch phase followed a U-shaped developmental trajectory. The proportions in the network conditions were 40% at 50 epochs, 75% at 75 epochs, **50%** at 100 epochs, 90% at 150 epochs, and 95% at 225 epochs respectively. It is predicted that children will follow a similar U-shaped trajectory.
- (3) The unexpected decrease in the proportion of networks that pass the pre-switch phase occurred in the same condition (100 epochs) as when the networks began to fail the post-switch phase perseveratively as opposed to putting the cards in the same box. Arguably, this occurred because the networks are beginning to categorize both dimensions simultaneously. This will lead to a decrease in performance in the pre-switch phase (sorting is more likely to be based on the wrong dimension), and an increase in perseverative errors in the post-switch phase (more likely to sort the cards according to the dimension that was previously correct). It is predicted that careful analyses of children's performance will reveal similar trends.
- (4) Although 60% of the networks at 50 epochs failed the pre-switch phase, those that passed tended to pass the post-switch phase (6 out of 8, 75%). It is predicted that the youngest children (2.5-year-olds) who are able to pass the pre-switch phase will succeed in the post-switch phase. Perhaps these children have learned to sort a pair of rules, but fail to link the rules in the pre-switch to the rules in the post-switch. As a result, the post-switch phase is treated independently of the pre-switch phase, with a consequent absence of proactive interference.

### Analysis of Network Activations

A primary benefit of connectionist simulations to cognitive psychology is the ability to analyze the internal representations of the networks. To that end, cluster analyses were carried out on the activations of the hidden units and the output node in the networks for each of the training examples. Figure 2 displays graphically the results from the analysis of one randomly selected network in the 225-epoch condition<sup>1</sup> (i.e., after the network had learned to

sort successfully on both pre-switch and post-switch trials). Each training example is represented by a string of seven letters. The first letter denotes which game the network is required to play. The next six letters denote the test card, the first target and the second target respectively. Training examples that are clustered together elicit similar activation levels from the hidden units and the output. Because the features of the first target card necessarily determine the features of the second target card (e.g., red flower is always paired with blue car), only the first target card is discussed in the analysis.

As can be seen from Figure 2, group A contains all of the examples that have flowers both in the test card and in the target card. In contrast, all training examples that have cars in the test card and in the target card are in group B. Thus, the network appears first to discriminate, at least partially, on the basis of the shape dimension.

Group A (the flower group) can further be separated into 2 subgroups, C and D. Of all the test cards in group A, subgroup C contains all of the blue test cards, whereas subgroup D contains most of the red test cards (75%). Similarly, group B (the car group) can be further separated into subgroups E and F. Of all the test cards in group B, most of the blue test cards (80%) are in subgroup E, whereas most of the red test cards (75%) are in subgroup F. Therefore, once the shape dimension is established, the network appears to discriminate on the basis of color.

Correct performance on the DCCS requires more than successful categorization of the stimuli by the appropriate dimension. It is also necessary to categorize the stimuli by the type of game that is to be played. In Figure 2, all branches labeled G indicate the six places where this occurs. Based on the network's activation levels, we can speculate that success on the DCCS may first involve categorizing the stimuli by one dimension. Once this categorization has been established, the stimuli are then categorized by the other dimension. Only when both dimensions are appropriately categorized can a higher order rule that discriminates between the two dimensions, such as the type of game, be considered. This interpretation is consistent with CCC theory (Frye et al., 1995; Zelazo & Frye, 1997). For example, Zelazo (1999) suggested that success on the pre-switch phase of the DCCS requires the conjunction of two simple rules into a contrastive pair of rules. Each pair of rules must then be mastered before a higher order rule controlling their selection can be evoked. Without this higher order rule, children will select the rule that is most strongly associated with the given context (i.e., fail perseveratively on the post-switch phase).

### Conclusions

In conclusion, the CASCOR simulations were successful in its three goals. First, the age-related changes on the DCCS task were simulated. Namely, inexperienced networks failed the pre-switch phase, slightly more experienced networks

---

<sup>1</sup> Cluster analyses on less experienced nets revealed similar patterns as the 225-epoch condition. However, the results were

---

more variable. It appears that experience stabilizes the clustering structure.

Figure 2: Cluster analysis on hidden and output unit activations of a randomly selected network in the 225-epoch condition.

passed the pre-switch phase but failed the post-switch phase and the most experienced networks passed both the pre-switch and post-switch phases. Second, novel predictions were generated and will be tested in future research. These include (1) an age-related increase in the number of children who fail the post-switch phase perseveratively (as opposed to sorting all the test cards in the same box), (2) a U-shaped developmental curve depicting performance on pre-switch trials, and (3) those very young children who pass the pre-switch phase will also pass the post-switch phase due to a relative lack of proactive interference. Third, cluster analyses on the hidden and output unit activations suggest that the formation of a higher order rule requires that the stimuli can be appropriately categorized by the appropriate dimensions. Further empirical research, coupled with modifications to modeling, hopefully will lead to an increased understanding of the mechanisms involved in the development of children's flexible rule use.

### Abstract

There has been a revival of interest in the question of the optimal training schedule for a difficult discrimination. McClelland (personal communication) argues that the optimal schedule is one which starts with a much easier discrimination on the same dimension as the difficult one, arranged so that the easy problem can be made to gradually converge on the more difficult one. He further argues, in agreement with Saksida (1999), that the reason for this is that representations are more easily formed during acquisition of the easy problem, which can then be put to use in solving the difficult discrimination. As associative learning theorists we are more familiar with another account - that initiated by Lawrence (1952) - which agrees that the optimal schedule is one which employs a strategy of transfer along a continuum. Where the accounts differ is in the mechanism for transfer; rather than appealing to representation formation, this account explains the benefits of training on the easier problem in terms of the dimensional features / elements that acquire associative strength and their ability to generalize appropriately to the hard problem. In this paper we report experiments that attempt to distinguish between these two accounts by manipulating / deconfounding stimulus exposure and training. We demonstrate the basic effect, and show that pre-exposure to the stimuli that comprise the easy problem is less effective than pre-exposure to the stimuli that make up the more difficult discrimination. Our conclusion is that this latter result is not what one would predict from the non-associative account given above, but that it fits well with McLaren, Kaye, and Mackintosh's model of perceptual and associative learning.

### Introduction

Lawrence (1952) demonstrated that it was possible for training on an easy perceptual discrimination to transfer to a more difficult problem on the same dimension. An example of the type of problem that he studied would be a brightness discrimination between two rectangles in similar shades of gray (hard version) or black and white rectangles (easy version). Groups of pigeons trained on these problems for the same number of trials can reach a point where the group trained on the easy problem have solved it, i.e. they have learned to peck at one rectangle for grain and to ignore the other, whereas the group trained on the hard problem have made little progress. If both groups are now trained on the hard problem for a further number

of trials, i.e. the group previously trained on the easy version of the problem are now switched to the harder version, then the result of interest is that the group switched from easy to hard acquires the hard problem much more rapidly than the group trained on the hard problem from the outset. This result holds despite the fact that the total amount of training is the same for both groups, and that the group that acquires the problem more slowly is the one that has received more training on that specific problem. This is the phenomenon of transfer along a continuum (TAC), and is the subject of the research reported in this paper.

The standard associative account of this phenomenon appeals to the notion of generalization. The stimuli for the easy problem become associated with reward and non-reward respectively, and then generalize to the stimuli for the hard problem (e.g. see Mackintosh, 1983). This is more effective than training on the hard problem itself because it is so difficult to learn, which is taken to be because the stimuli are so similar to one another. Figure 1 can be used to illustrate one possible instantiation of this explanation. On this approach, a stimulus is represented by a set of activated elements or units, a distributed representation. Variation along a stimulus dimension such as brightness will, for the most part, be represented by different elements corresponding to different values on the dimension, rather than the activation level of an individual element being the primary indicator of value on the dimension (c.f. chapter by Thompson in Mostofsky, 1965). Each element has a 'tuning curve' such that it responds most strongly to a certain value on the dimension and this response drops off fairly rapidly with 'distance' from this optimal value. Note that many elements will be active when any stimulus with value on that dimension is present, the coding is via a pattern of activation. Learning will proceed via association between the elements activated by a stimulus and other units representing reward. We are now in a position to explain Lawrence's results. In the case of the easy problem (shown top in the figure) the stimuli are well separated on the dimension and there is relatively little overlap between the patterns of activation that represent them. Learning proceeds rapidly, favoring those elements which are most active on a trial, and there is little generalization between stimuli to slow acquisition of the problem. In the case of the hard problem (shown bottom in the figure)

Figure 1: Stimulus representation on a dimension for easy (top) and hard (bottom) discriminations.

the situation is somewhat different, in that the large degree of overlap between the stimulus representations results in considerable generalization between the stimuli, and this is what makes the discrimination difficult. The elements that are most active, and so dominate learning, are not those that best discriminate between the stimuli. As a result acquisition is slow. Now consider the case where the easy problem is first acquired, and then the subjects are switched on to the hard problem. The training on the easy problem will result in exactly the elements that are the most predictive of reward or non-reward in the hard problem gaining considerable associative strength because they are highly activated by the easy stimuli. Thus the learning will transfer well to the hard problem, and will be more than an equivalent amount of training on the hard problem would have provided (because of the relatively large activations of the elements concerned).

There is another tradition in psychology, however, that appeals to quite different, non-associative processes to explain the phenomenon of transfer along a continuum. It can be traced back at least as far as the work of Eleanor Gibson (1969), who conjectured that a process of differentiation, contingent on exposure to the stimuli in question, resulted in representations of the stimuli that better enabled discrimination between them. Gibson's thesis is perhaps most naturally captured in terms of competitive learning coding schemes that require no explicit instruction to develop representations that capture the structure of a stimulus set that they are exposed to. Our example of such a system is that due to Saksida (1999), which is explicitly designed to deal with phenomena of the kind under consideration here. Figure 2 allows us to contrast Saksida's model with the standard associative account. Instead of stimulus elements being directly associated with reward representations (shown top), there is a non-associative pre-processor prior to association to reward representations (shown bottom in the

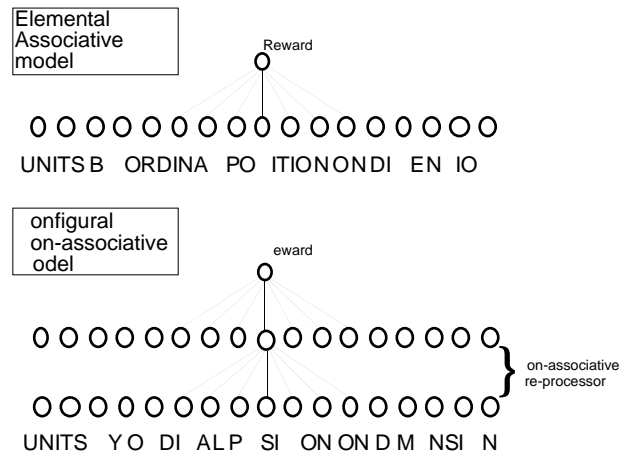

Figure 2: Architecture for associative and non-associative models of TAC.

figure). The model develops a representation of the input at this intermediate, competitive layer, and, in Saksida's model, it does so in a way that drives initially overlapping representations for two stimuli apart so that they become more discriminable (i.e. differentiation). The interesting possibility raised by such a model is that the explanation for TAC might be quite different to that generated by the associative account given earlier. Instead of appealing to generalization of associative strength from the easy problem to the hard version, it could be that training on the relatively easy problem could develop a coding at the competitive layer that meant that the hard problem was no longer as difficult as would have been the case. Whereas before the hard problem would have (initially at least) given rise to highly overlapping patterns of activation at the competitive layer, now the patterns of activation are better separated because of the coding scheme developed for the dimension whilst solving the easier problem. In a sense what happens is that the process of developing discriminable representations for the easier problem drags apart the representations for the harder problem as well. Saksida herself is quite definite on this..."One clear prediction of the current model is that exposure to a pair of similar stimuli will facilitate discrimination of stimuli that are even more similar along the same dimension." and..."pre-exposure to two stimuli will facilitate discrimination of other stimuli whose representations fall between them on the competitive layer" Saksida (1999). The only provisos being that the easier discrimination should itself employ relatively similar stimuli, and should be studied long enough for the stimuli to become discriminable (i.e. for the competitive layer to develop the necessary representations).

The strategy adopted in this paper is to contrast these two accounts with specific reference to the issue of whether or not TAC is best characterized as due to elementally-based generalization or rather to perceptual

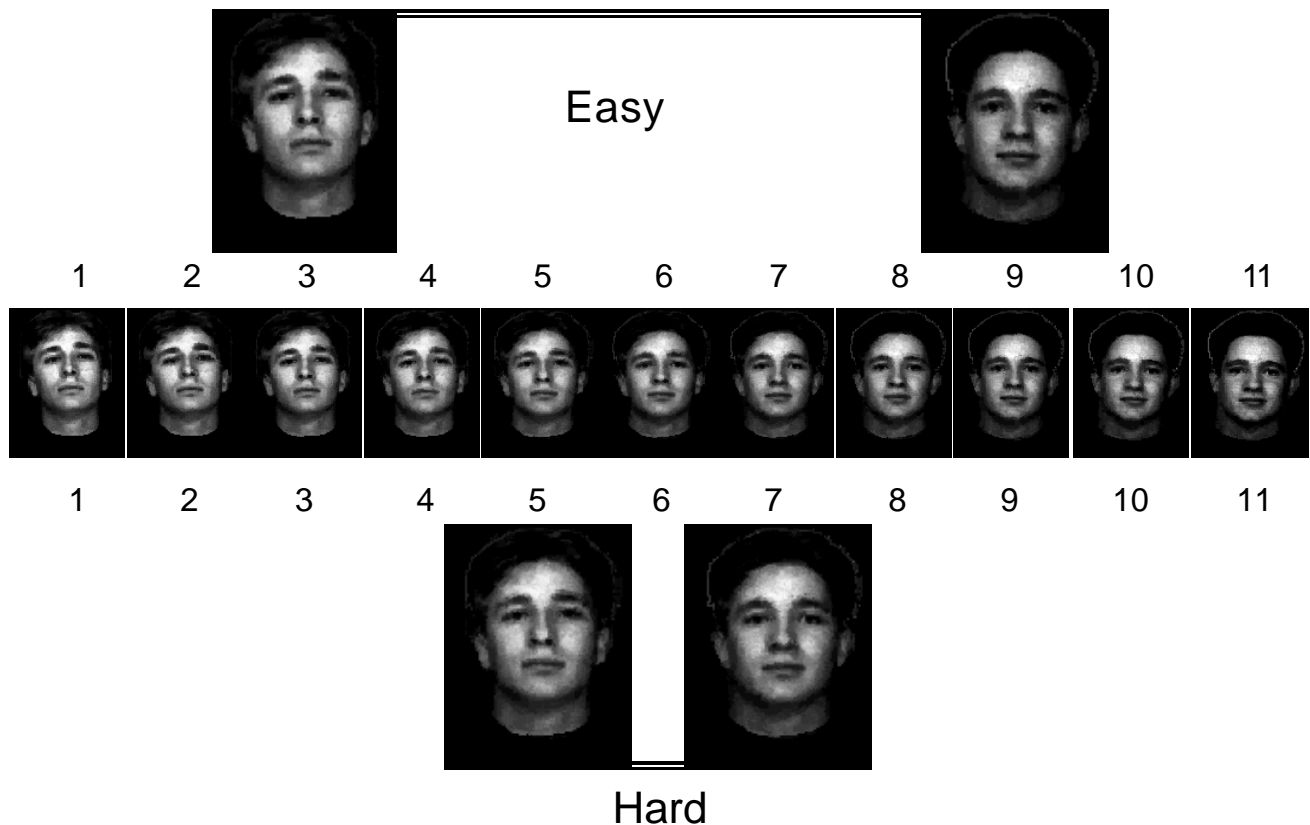

Figure 3: One of the four morphed face dimensions used in these experiments.

differentiation as a result of representation formation. Experiment 1 demonstrates TAC using stimuli that meet Saksida's criteria for her models application. Experiment 2 then assesses whether the effect can be explained predominantly in terms of representation development by looking at the effects of pre-exposure to the stimuli used in the easy and hard problems. The logic here is that if TAC is mainly due to representation development, then the training phase is effectively equivalent to a pre-exposure phase, and so explicit pre-exposure should generate the same pattern of results.

### Experiment 1

#### Stimuli and Apparatus

In all phases of the experiment, pictures of faces were shown in the form of gray-scale images. These had been created from standard passport photographs of university undergraduates, which had been scanned into the computer. These stimuli were presented on an Apple Macintosh computer running Microsoft Basic. They were 3.5 cm by 4.5 cm and subjects sat approximately 50 cm from the screen. The face stimuli for this experiment were constructed by taking pairs of faces and morphing from one to the other in 10 equal steps, giving a dimension with 11 values in all. The faces in a given pair are chosen to be similar (which aids the morphing process in keeping the transitions smooth) so that neighboring stimuli on the dimension are very similar indeed. Figure 3 illustrates the morphed face dimension for one pair of faces, there were

four pairs of faces in total and the faces at 3 and 9 on the dimension always constituted the easy problem and those at 5 and 7 the hard version. All four dimensions were used concurrently for every subject, with the assignment of the face dimensions to the conditions of the experiment counterbalanced appropriately. Pilot testing revealed that the discriminations were difficult (even for the 3 vs. 9 case) but possible under the conditions of this experiment, and subjects reported that their performance was hard to characterize in terms of rules based on features (desirable if performance is to be associatively driven).

#### Subjects and Design

Subjects were 40 Cambridge undergraduates and graduates with an age range of 18 - 30. They were randomly assigned to two equal groups, one of which (Group Easy) was pre-trained on the easy problem for all four dimensions concurrently for a fixed number of trials (40 trials in total, five for each face), the other (Group Hard) was pre-trained on the hard version for all four dimensions for an equal number of trials. After the pre-training phase both groups were then trained on the hard problem for all four dimensions concurrently (again 40 trials in total, five for each individual face). This was followed by a final test phase in which performance on the hard problem for each dimension was assessed without giving the feedback used in pre-training and training. In this phase each face is also shown 5 times. The data of interest are the responses to the stimuli in this final test phase. If the discrimination between 5 and 7 is better

learnt after pre-training on 3 and 9 then this would be evidence of TAC.

## Procedure

In both the pre-training and training phases of the experiment, subjects were told that once they pressed the space bar, a constant stream of stimuli in the form of faces would appear on the screen, and that their task was to sort these stimuli into two categories. They were to do this by pressing one of two keys ('x' on the left or '.' on the right) and would receive immediate feedback as to the correctness of the response. If they did not respond within a few seconds (4.25 sec) they would be timed out. The subjects were told that the faces were randomly and equally allocated to either left or right key and that their task was to simply find out and remember which ones were 'right' and which ones were 'left'. Once the subject initiated the experiment, trials were continuous. Stimuli were presented singly, and each trial started with a '+' for 0.7 sec which was then replaced by a rectangular frame for 0.2 sec. Each face appeared and stayed in the screen for a maximum of 4.25 sec and disappeared once a response or time-out was made. Feedback was then given for 1 sec, either 'correct' displayed in the center of the screen or 'error' and a beep if the wrong key was chosen.

After they had completed the pre-training and training phases, subjects progressed to the test phase of the experiment. Subjects were told to categorize the stimuli into the two categories based on the judgments they had made in the training phase. So, if a face had been 'a left key stimulus' in the training phase, it was to be allocated again to the 'left key' category in the testing phase. This time no feedback was given. The procedure of stimulus presentation was as before with the exception that feedback was replaced in this phase by a 1 sec pause between the subject's response and the proceeding stimulus.

## Results

The results of Experiment 1 are shown in Figure 4. One key, e.g. the left key, is designated the negative category (a press scores -0.5 for that stimulus) and the other right key the positive category (scores +0.5) during test.

Figure 4: Results for Experiment 1.

Key assignments were counterbalanced across subjects so that the positive category has equal numbers of left and right key responses (at least by design). The test score indicates the average of the key presses across subjects, and would be zero if subjects were indifferent to which stimulus went with a given key, and ranges from +0.5 to -0.5. The group pre-trained on the easy problem (3,9) shows much better performance on the hard discrimination than the group pre-trained on that discrimination (5,7) itself. That is, the 3,9 group has more positive scores for its positive stimulus on test, and more negative scores for its negative stimulus.

These impressions are borne out by statistical analysis, in which all probabilities are two-tail unless otherwise specified. ANOVA on the results with a between subjects factor of type of pre-training (3,9, vs. 5,7) and a within subjects factor of type of stimulus (- vs. +) gave an  $F(1,38) = 27.75$ ,  $p < .001$  for the main effect of type of stimulus and  $F(1,38) = 4.39$ ,  $p < .05$  for the interaction between the two factors. The first effect refers to the fact that the positive stimulus is, overall, given a more positive score than its negative counterpart, the interaction reveals that the difference in score between positive and negative stimuli was significantly greater for the 3,9 group who were pre-trained on the easy problem. This demonstrates transfer along a continuum with these stimuli. Planned comparisons on the positive and negative stimuli for each group separately reveal that both groups are significantly better than chance on the test discrimination,  $F(1,19) = 24.9$  and  $5.52$ , both  $p < .05$ . Thus both groups can be said to have learned the discrimination.

## Discussion

Experiment 1 provides a convincing demonstration of transfer along a continuum in human subjects using an artificial dimension constructed by morphing between similar faces. Performance on the hard problem after pre-training on the easy problem is much better than if pre-training had been on the hard problem used during training and test. Nevertheless, both groups were able to acquire the discrimination under the conditions of the experiment.

We are now in a position to ask if this TAC effect is simply due to exposure to the stimuli used in the easy problem, or if instead it requires that subjects be trained on the easy problem for the effect to occur. Experiment 2 seeks to answer this question by pre-exposing subjects to the stimuli of either the easy or hard problem instead of pre-training them.

## Experiment 2

In this experiment the stimuli are the same as in Experiment 1, and two new groups of 20 subjects from the same population are assigned to two different pre-exposure conditions. These are equivalent to the pre-training conditions of Experiment 1 except that a) no response is required as it is pre-exposure and b) each stimulus is shown for a fixed duration of 2 sec. This

duration was chosen to ensure that subjects in this experiment received the same or greater total time of exposure to the stimuli compared to all the subjects in Experiment 1. Thus subjects were pre-exposed to the stimuli that constituted either the easy or the hard problem, then trained on the hard problem exactly as in Experiment 1, then tested exactly as in Experiment 1. If the results of Experiment 1 were predominantly due to exposure to the stimuli of a given problem, then the results of this experiment should resemble those of the previous experiment. If, on the other hand, they were strongly dependent on the training element during pre-training then we might expect the results to differ in that evidence for any TAC effect should disappear.

## Results

The results of Experiment 2 are shown in Figure 5.

Figure 5: The results of Experiment 2.

Once again an ANOVA with one between factor of type of pre-exposure (3,9, vs. 5,7) and one within factor of stimulus type (5 vs. 7) was conducted which gave an overall main effect of stimulus type,  $F(1,38) = 9.84$ ,  $p < .005$ , but no significant interaction between the two factors ( $F < 1$ ). Thus there is good evidence for acquisition of the discrimination, but no significant evidence that pre-exposure to either the easy or hard problem stimuli had any differential effect. Contrary to expectations on a differentiation account of TAC, the group pre-exposed to the hard problem stimuli was actually numerically better on test. Planned comparisons on the two groups revealed that the group pre-exposed to the hard problem was significantly better than chance on test,  $F(1,19) = 7.26$ ,  $p < .05$ , whilst the other group was only marginal,  $F(1,19) = 2.89$ ,  $p(1\text{-tail}) = .052$ .

As the two experiments are highly comparable in their stimuli, apparatus, procedures and subject populations we can compare them in a single analysis. When this is done there is a three way interaction ((pre-trained vs. pre-exposed) x (problem, 3,9 vs. 5,7) x (stimulus on test, 5 vs. 7) that indicates that the effect of pre-exposure in Experiment 2 is significantly different to the effect of pre-

training in Experiment 1. Finally, pre-exposure to the easy problem in Experiment 2 was significantly less effective than pre-training on the easy problem in Experiment 1  $F(1,38) = 4.83$ ,  $p < .05$ . This is despite the fact that pre-exposure in Experiment 2 was at the maximum level observed in Experiment 1 (where the fluctuations were due to different speeds of response during pre-training).

## Discussion

The results of Experiment 2, taken in conjunction with those of Experiment 1, do not support a differentiation account of transfer along a continuum. The effect of pre-exposure to the problem stimuli is seen to produce the converse pattern of results to pre-training, that is, with regard to learning the hard problem during the training phase, pre-exposure to the easy problem is less effective than pre-exposure to the hard problem, whereas pre-training on the easy problem is much more effective than pre-training on the hard problem. This pattern of results strongly suggests that the advantage that accrues as a result of pre-training on the easy problem is due to generalization of the associations acquired during that pre-training.

One loose end in this experiment concerns the extent to which pre-exposure can be said to have an effect at all, given that the two groups do not differ significantly. Some light can be cast on this issue by considering the data from a previous series of experiments (McLaren, 1997) which used the same procedures and stimuli, but merely trained the face discrimination (as here) but without any pre-training or pre-exposure. Under these circumstances the hard problem was not solved (mean difference between the positive and negative stimuli was only .037,  $F < 1$ ), and a comparison between these results and those of Experiment 2 reveals that the group pre-exposed to the hard problem is better than the group simply trained on the hard problem,  $F(1,43) = 2.64$ ,  $p(\text{one-tail}) = 0.055$ . This means that pre-exposure to the hard problem has had a near significant beneficial effect (i.e. we have some evidence for perceptual learning), though this is not true of pre-exposure to the easy problem ( $F < 1$ ).

## General Discussion

In this paper we have contrasted two classes of model of TAC, associative and non-associative versions. We should make it clear that while we have found no evidence that supports the non-associative account relative to the associative version, nor do our results falsify the non-associative position adopted by Saksida and others. What is needed to rescue this account is a parametrisation of the non-associative model that allows the generalization from pre-training to dominate any effects of representation formation and differentiation. In these circumstances the two types of models would in some sense be different instantiations of the same psychological theory.

Taking Saksida's account first: the perceptual learning effect seen in Experiment 2 would be due to representation

formation and differentiation, as the initially overlapping patterns of activation for the two to-be-discriminated stimuli were pushed apart by competitive learning, and the TAC effect would be due to generalization associations to reward and non-reward formed during pre-training to training and testing. The model would be constrained so that the latter effect would be stronger than the former, which is not a typical feature of this class of model. The more natural account would attribute the difficulty of the hard problem to the need to establish well differentiated representations of the stimuli, a process that was aided by training on the easy problem. It may well be that the need both to model TAC and perceptual learning within this class of model may impose unsustainable constraints on its ability to function effectively, but this is a question for future research.

The associative account offered here follows McLaren *et al's* (1989) theory of association and representation. The explanation of TAC is the standard associative account given earlier in this paper, but the explanation of the perceptual learning effect seen in Experiment 2 may bear further exposition. On this theory, exposure to two similar stimuli that will be represented as overlapping patterns of activation results in a decrease in the salience (in this case this can be understood as the degree of activation) of the elements representing those stimuli. This occurs to the extent that they become predicted by associations from other elements. The reduction in salience will be greatest for the elements shared by the two stimuli (the overlap) because they are encountered, and hence engage in learning, twice as often as the elements unique to either stimulus. The effect is that the elements that make the discrimination difficult (because they are shared by the stimuli and lead to generalization between them) become relatively less salient than those that enable discrimination between the stimuli. This consequence of pre-exposure leads to the discrimination between the stimuli becoming easier, as the distinctive features (represented by the unique elements) of each stimulus are now able to preferentially engage in learning. The result is perceptual learning, in that the discrimination is learned faster after pre-exposure. The effect is predicted to be greater for more similar stimuli, which fits well with the greater pre-exposure benefit for the harder problem. This is because the more similar stimuli are taken to have a higher proportion of shared elements, and so the effect of reducing these elements' salience relative to the unique, distinctive elements of the stimuli is proportionately greater.

## Conclusion

Associative theories of representation development and learning are adequate to model the transfer along a continuum effect reported here. Non-associative theories that appeal to competitive learning or some other mechanism for representation formation are probably able to instantiate the same psychological theory, but offer nothing new in modelling these data. The challenge is to find data that require this type of theory rather than an associative account.

## Abstract

Can regular and irregular verb forms be accommodated by a single representational mechanism or is a dual mechanism account required? In a first experiment, we used a cross-modal repetition priming paradigm to investigate the mental representation of regular and irregular verb forms in French. Subjects heard a spoken prime (such as aimons) immediately followed by lexical decision to a visual probe (such as aimer). We contrasted four types of French verbs, varying in the phonological and morphological regularity of their verb form inflection. These were (i) regular verbs (aimons/aimer) (ii) verbs that undergo predictable phonological changes (sèment/semmer) (iii) verbs to which sub-rules apply (teignent/teindre) and (iv) irregular verbs with idiosyncratic alternations (vont/aller). The infinitive forms of these verbs were presented as target in three prime conditions: preceded either by a regular form, an irregular/modified form (except for the regular verbs), or a control unrelated prime. Morphologically related primes, whether regular or irregular, significantly facilitated lexical decision responses for all four verb classes. The same pattern of results was observed in a second experiment using a masked priming paradigm. These results contrasted with English, where regularly inflected verbs prime their stems but irregular verbs do not. We argue that the pattern observed in French reflects the decomposability of French irregular forms.

## Introduction

Psycholinguistic models have proposed a distinction between information that can be obtained through rules and information that must be recalled from a list. On the one hand, distributed approaches argue for a single mechanism underlying the representation and processing of both regular and irregular items (Plunkett & Marchman, 1993) and, on the other hand, symbolic approaches argue for a dual mechanism account, where regular forms are generated by rule but irregular forms are stored as rote-learned whole forms (e.g. Pinker, 1991). Many studies tackle this issue by trying to determine whether the co-occurrence of regular and irregular verb forms in a given language can be accommodated by a single representational mechanism or whether a dual mechanism account is required.

In English, verbs have only three types of morphological processing contexts: 3rd person singular, past tense and progressive forms (jumps, jumping, jumped). This inflec-

tional system offers a sharp contrast between a single, dominant, regular process of past-tense formation (adding the regular affix -ed to an unchanged stem) and a small, heterogeneous group of irregular past-tense forms (mostly of an idiosyncratic nature).

Several sources of evidence suggest that the linguistic differences between regular and irregular forms lead to differences in the way these forms are represented in the English mental lexicon. A major source of evidence is research using repetition priming tasks, where a test word is preceded by a related prime word. The target word walk, for example, is preceded either by a morphologically related word (e.g. walked), or an unrelated word (e.g. goal). Previous research done in English shows diminished or absent priming between irregular tense and the stem (drove/drive) versus a strong priming effect between regular pairs such as walked/walk (Kempey & Morton, 1982; Napps, 1989; Stanners, Neiser, Herson & Hall, 1979). Pinker (1991) claimed that these results support the dual mechanism dichotomy. Convergent results have been observed using the cross-modal paradigm, where the prime is presented auditorily (Marslen-Wilson, Hare & Older, 1995). Again significant priming is only observed for regular inflected forms (such as walked/walk) and not for irregular ones (such as dug/dig).

In this framework, priming is explained as reflecting the fact that regular forms share a representation with their stem, and both inflected and non-inflected forms of a given verb map directly onto the representation of the stem at the level of the lexical entry. The morphological priming effect results from the repeated activation of the same morpheme by prime and target. On the contrary, an irregular form will have a separate form representation from the stem to which it is related and this may lead to a reduction of priming between the two items, under specific testing conditions. This may be due either to competition between the two representations (stem and irregular form) or as a consequence of the blocking function assigned to the listed irregular form (the presence of a lexical entry for the irregular form will prevent the application of the default suffix).

One problem with English, however, as a basis for generalisations about regularity and irregularity, is that the English past-tense forms do not differ simply in regularity, but also along a number of dimensions, including contrasts in

basic morphological procedure (suffixation versus stem change), the absence versus presence of phonological constraints on morphological processes, and high versus low type frequency of classes of past forms. In order to disentangle potential evidence about the general properties of morphological systems from the possible idiosyncrasies of English past tense formation, it is necessary to conduct parallel experiments in other languages which exhibit comparable but cleaner contrasts between regular and irregular procedures.

One language that we have looked at already in this light is Italian. This is a much richer inflected language (with many different types of tense and person suffixes) where there are a number of irregular past-tense forms that obey similar criteria for irregularity as the English irregulars, but where they occur in a morphologically more structured and phonologically more predictable linguistic environment. Using a cross-modal priming paradigm, Orsolini and Marslen-Wilson (1997) observed the same amount of priming when the prime was regular and when it was irregular. They suggest a possible account that attempts to capture the sub-regularities of the verb forms through an explicit system of rules rather than relying on an analogical network to represent them implicitly.

Here we report an extension of this research to French, which, like Italian, has a richer inflectional system than English, and which allows us to explore a wider range of types of irregularity. In French, verbs are organised into three basic morphological classes, called conjugations. These distinctions use as first criteria the infinitive form and as second the imperfect form. The major class is conjugation 1, containing verbs with infinitives ending in *-er* (such as aimer, voler...). This is the most productive class and fully regular. Conjugation 2 is formed by verbs that have an infinitive in *-ir* and imperfect in *-iss-* (such as finir, salir...). It is a smaller class than conjugation 1 and it is no longer productive, but it is fully regular. Conjugation 3 contains verbs with infinitives ending in *-ir* (and that do not have an imperfect in *-iss-*), *-oir*, *-re* (such as dormir, boire, peindre...) and the verb aller. Verbs contained in this group are highly irregular.

In our experiment we used four types of verbs. The first condition was wholly regular verbs from the first conjugation such as aimer; the second condition was regular verbs from the first conjugation but that in a few forms have a phonologically triggered surface change, such as amener-amène. These types of phonological changes (reflecting a high/low alternation) are also observed in the case of gender marking (fermier-fermière). We will call this condition the morphophonological constraint group. The third group consisted of irregular verbs from conjugation 3 but where the irregularities were common to at least 10 verbs such as teindre-teignent, peindre-peignent. Verbs in this group are closest to the ones used in the Italian experiment; we will refer to it as the sub-regularity group. The fourth group, more similar to the type of irregularity found in English was made up of highly idiosyncratic suppletive alternations such as aller-vont.

If the patterns of results observed in English and in Italian are not language specific but are due to the type of irregu-

larities then in French we should observe the same amount of priming when the prime is regular and in the morphophonological and sub-regularity irregular conditions. On the contrary, when the prime is an idiosyncratic form, we may, as in English, observe no or less priming than with a regular form. Priming effects in this experiment are evaluated by comparing reaction times when the prime is related versus unrelated to the target, and also by comparing response latencies when the related prime is regular and when it is irregular.

## Experiment 1

### Method

**Material and Design** We used a cross-modal paradigm. The prime was auditorily presented and immediately followed by a visual presentation of the target-item. Subjects made a lexical decision response to the visual target, which was preceded by a regular or irregular related or unrelated prime.

Ninety-six verbs falling in four categories were selected, as described earlier, and examples are listed in Table 1 below. We used as the target the infinitive form of the verb. We chose for each verb of each category, three types of prime (verb forms): A regular form, an irregular form and a control (or baseline) word matched on the regular form. To keep the design balanced, regular verb targets were preceded by two different regular targets. Targets were between 4 and 11 letter long.

Table 1: Examples of stimuli.

Verb Type	Infinitive Target	Forms Regular	Irregular
Regular	<i>aimer</i>	<i>aimerons</i> <i>aimons</i>	<i>n/a</i>
Morpho-phonologic constraints	<i>semer</i>	<i>semons</i>	<i>sème</i>
Sub regularity	<i>teindre</i>	<i>teindra</i>	<i>teignent</i>
Idiosyncratic	<i>aller</i>	<i>allons</i>	<i>iront</i>

For each of the 96 regular primes, we selected a control word that was matched to the regular experimental prime for surface frequency, number of syllables and tense and person of the verb form. None of the neutral condition words were morphologically, semantically or phonologically related to the target. We also constructed filler pairs in order to reduce the proportion of related pairs within the list. We added 64 pairs in which the target was a word (such as calculons/partir), and 160 pairs in which the target was a non-word (such as marchera/enteler). Each prime list was composed of 96 experimental words (of which 64 were related to the target and 32 were not), 64 words with an unrelated target word, 160 words with a nonword target (64

pairs in which prime and target shared formal features and 96 primes followed by a nonword target which was unrelated). To sum up, we had 160 word-word pairs and 160 word-nonword pairs.

In order to avoid the repetition of a given target for a subject, we constructed 3 experimental lists of 320 items each. A given target appeared only once in each list: with a regular related prime in one list, an irregular related prime in the second list and a control prime in the third one. In each list, 2/3 of the experimental prime-target pairs were morphologically related (64 pairs). The number of pairs of each experimental condition was equal (8) in each list. Each subject heard only one list so that each saw a third of the items with a regular related prime, a third with an irregular related prime and a third with a control prime. The list of targets was the same for all subjects, only prime lists varied. To give a break to the subjects we split up each list. Experimental pairs of each condition were equally distributed in each segment of the list. Each part of the list started with 10 items that were not experimental ones. Before starting to hear the list itself, the subject had training with 20 prime-target pairs. The experimental session lasted 25 minutes.

**Procedure** A French female native speaker recorded primes on a DAT. Each prime was then digitized at a rate of 22kHz and stored on computer hard disk. Each word was isolated in a single independent file. This allowed us to control the time between the end of the prime and the presentation of the target. The prime was binaurally presented to the subject and was immediately followed (ISI 0ms) by the presentation of the target. This latter was written on a CRT screen in front of the subject. The target stayed on the screen until the subject made a response. The task of the subject was to push one of the two buttons on a response box (one for word, the other for non-word), as fast as he or she could. Subjects were alone in the testing room.

**Participants** Thirty-six students of Psychology at the University Paris V - René Descartes took part to the experiment. All were native French speakers and they were between 18 and 30 years old.

## Results

Reaction times higher than 1500 ms were eliminated from the statistical analyses; less than 1% of reaction times were suppressed with this criterion. There were 2% of errors on experimental words. Analyses of variance were conducted on the inverse reaction time data. This allowed outliers to be included without unduly affecting the estimates of condition mean (Ratcliff, 1993; Ulrich & Miller, 1994). Two analyses have been run: one across subject (F1) and the other across item (F2). Reaction times per conditions are presented in Figure 2. This also gives the priming effects and their associated significance values.

First, comparing regular conditions and control conditions, we observed an effect of morphological priming ( $F(1,35)=103.17$ ,  $p<.000$ ;  $F(1,92)=119.45$ ,  $p<.000$ ) and an effect of type of verbs per subjects ( $F(3,105)=9.19$ ,

$p<.000$ ;  $F(1,92)=2.05$ , n.s.) but no interaction between these two factors ( $F(1,35)<1$ ;  $F(1,92)<1$ ). Comparing irregular conditions with control conditions, we observed an effect of morphological priming ( $F(1,35)=80.43$ ,  $p<.000$ ;  $F(1,92)=142.33$ ,  $p<.000$ ) and an effect of type of verb ( $F(3,105)=7.04$ ,  $p<.000$ ;  $F(1,92)=2.26$ ,  $p=.09$ ) but no interaction between the two ( $F(3,105)=1.31$ , n.s.;  $F(3,92)=1.83$ , n.s.). Comparing regular and irregular conditions, we observed no effect of type of priming ( $F(1,35)=2.98$ , n.s.;  $F(1,92)=1.01$ , n.s.), an effect of verb types per subject ( $F(3,105)=4.31$ ,  $p<.007$ ;  $F(1,92)=1.13$ , n.s.) but again no interaction ( $F(1,35)<1$ ;  $F(1,92)<1$ ).

These results show that irregular and regular verb forms prime their infinitive form equally, and that these priming effects do not vary with the type of verb (irregular vs. regular).

Table 2: Results of Experiment 1

Type of verbs	Primes	Targets	RT(ms)	Priming effect
Regular	<i>aimerons</i>	<i>aimer</i>	523	44**
	<i>aimons</i>		530	37**
	<i>porterons</i>		567	
Morpho-phonologic constraints	<i>semons</i>	<i>semer</i>	539	57**
	<i>sème</i>		545	51**
	<i>votons</i>		596	
Sub regularity	<i>teindra</i>	<i>teindre</i>	553	60**
	<i>teignent</i>		551	62**
	<i>nichera</i>		613	
Idiosyncratic	<i>allons</i>	<i>aller</i>	544	49**
	<i>irons</i>		545	48**
	<i>tenons</i>		593

## Discussion

This cross-modal priming experiment presented a pattern of results which was very clear cut: a massive morphological priming effect and no interaction between this effect and the type of primes (regular vs. irregular) or the type of verbs. These results show that in French there is no difference in the amount of priming produced by a regular verb form and the one produced by an irregular verb form on the identification of their infinitive.

A major concern in cross modal experiments is to determine if the priming effects observed for morphologically related pairs are due to shared morphemes in a morphologically structured mental lexicon, or if they are due to the semantic relationships between the morphologically related pairs. Given the across-the-board priming effects in Experiment 1, and given that all the primes and targets were highly semantically as well as morphologically related, we decided to run the same materials in a second experiment using a masked priming technique developed by Forster and Davis (1984). The masked priming technique has been shown to be highly sensitive to overlap at the level of form (Forster, Davis, Schoknecht, & Carter, 1987; Forster and Taft, 1994), but not of meaning. Although masked priming

effects for associatively related pairs have been observed (Sereno, 1991), no pure semantic effect had been reported. In masked priming a forward pattern mask is presented immediately before the prime and the prime is then covered by the target item: this latter is used as a backward mask. The temporal interval between the onset of the priming stimulus and the subsequent target stimulus is very brief (47 ms in our experiment). At these short prime durations, the combination of forward and the backward masking prevents the subject from consciously seeing the prime. The consequence of this is that the participant's responses are not influenced by a conscious appreciation of the relationship between the prime and the target. This reduces the possibility that any priming effect is due to the fact that the participant realises that the prime and the target often share a common morpheme.

## Experiment 2

### Method

**Material and Design** Our second experiment used a masked-priming paradigm with the same stimuli as the previous experiment. We added two additional controls: a semantic condition, where the prime and the target were semantically related, to check that the masked priming paradigm was not picking up semantic effects; and an orthographic condition where the prime and the target orthographically overlapped to the same degree as the related pairs but had no semantic or morphologic relationship. We selected 24 target-words. For each target word in this condition (such as *mâcher*), one prime was semantically related to the target (*broyait*), one prime was phonologically related to the target (*machine*) and the third type of prime was an unrelated control (*progrès*). As a consequence of these changes we removed 24 word/word filler pairs to keep the balance between word and nonword answers. As a result this gave us the same number of items in each list as for the previous experiment.

**Procedure** The same hardware and software were used as in the previous experiment. Each trial consisted of three visual events. The first was a forward pattern mask consisting of a sequence of '#'. The second event was the display of the prime word for 47 ms. The third event was the presentation of a target word or nonword for 500ms. The prime was in lower case and the target in upper case to make sure that the former was appropriately masked. Subjects were asked to make a quick and accurate lexical decision about the target by pressing a 'word' or 'nonword' key. The experiment lasted about 30 minutes and started with 10 practice trials followed by 10 warm-up pairs and then the experimental trials. There were breaks as in the previous experiment. No subjects reported any awareness of the presence of a prime.

**Participants** Another 42 native French speakers of the same age and from the same population as before took part in the experiment.

### Results

Reaction times higher than 1500 ms were eliminated from the statistical analyses; less than 1% of reaction times were suppressed with this criterion. There were 2% of errors on experimental words. Analyses of variance were conducted on the inverse reaction time data both across subject (F1) and item (F2). Reaction times per condition are presented in Table 3. This also gives the priming effects and their associated significance values.

Table 3: Results of Experiment 2

Note: \*\*  $p < .05$

Comparing first regular conditions and control conditions, we observed an effect of morphological priming ( $F(1,41)=36.74$ ,  $p<.000$ ;  $F(1,92)=59.06$ ,  $p<.000$ ) and an effect of type of verb per subject ( $F(3, 123)=4.73$ ,  $p<.004$ ;  $F(2<1)$ ) but no interaction between the two factors ( $F(1<1$ ;  $F(2<1)$ ). Comparing irregular conditions with control conditions, we observed an effect of morphological priming ( $F(1,41)=22.03$ ,  $p<.000$ ;  $F(1,92)=30.96$ ,  $p<.000$ ) and an effect of type of verb per subjects ( $F(1(3, 123)=7.84$ ,  $p<.000$ ;  $F(2(1, 92)=1.152$ , n.s.) but no interaction ( $F(1<1$ ;  $F(2<1)$ ). Comparing regular and irregular conditions, we observed no effect of the type of priming ( $F(1(41)=2.16$ , n.s.;  $F(2(1,92)=2.09$ , n.s.), an effect of type of verb per subject ( $F(1(3, 123)=4.81$ ,  $p<.003$ ;  $F(2<1)$ ) but no interaction ( $F(1(3,123)=1.31$ , n.s;  $F(2(3,92)=1.18$ , n.s.). In the control condition we found no effect of semantic priming ( $F(1(41)=1.8$ , n.s.;  $F(2(1,21)=1.05$ , n.s.) and no effect of orthographic overlap ( $F(1(41)<1$ ;  $F(2<1)$ ), allowing us to rule out accounts of the results in terms of simple form overlap between prime and target.

These results confirmed the results observed in the cross-modal experiment and show that irregular and regular verb forms prime their infinitive form equally, and that these

priming effects do not vary with the type of verb (irregular vs. regular). The fact that these effects are found in a task which is generally insensitive to semantic relations between prime and target - and where the semantic control condition showed no priming - is good evidence that these are genuinely morphological effects, reflecting repeated access to the same underlying morpheme. This morpheme seems to be accessed equally effectively, regardless of the degree or type of irregularity on the prime word.

## General Discussion

The question asked here was whether French regular and irregular inflected forms show different priming patterns, in the same way as English. The dual mechanism hypothesis postulates a rule-based symbolic processor that supports the representation and generation of regular forms, while an associative rote-memory system is required to account for irregular forms. Pinker (1991) claimed that the different priming effect observed in English for regular and irregular forms support the dual mechanism dichotomy. Using French we found no such difference. The priming generated by regular inflected words did not differ from the priming generated by irregular forms. The facilitatory effects of morphologically related primes are just as strong whether they involve the same or different underlying roots as their targets. Pairs like *aimons/aimer* prime just as well as pairs like *buvons/boire*. These findings seem inconsistent with the predictions of the dual mechanism hypothesis for the processing behaviour of listed forms in a repetition priming task. In the framework of the dual mechanism account, because Conjugation 3 verbal forms are completely idiosyncratic and unpredictable, they will use rote-learning of irregular stems and they will be stored as independent but linked forms in a pattern-associative memory. For a priming task, this predicts reduced priming between prime/target pairs involving different underlying roots, a prediction confirmed in earlier research in English. The results obtained in French contrast with those obtained in English.

The pattern of results observed in French could be explained in terms of connectionist distributed networks, operating sub-symbolically and without syntax (Rumelhart & McClelland, 1986; MacWhinney & Leinbach, 1991; Plunkett & Marchman, 1993). Indeed, the absence of interaction between priming effects observed with regular forms and priming effects observed with irregular forms seems to go against the dual mechanism hypothesis. We could argue that English speakers use rules because the contrast between regular and irregular verbs is sharp, which is not the case in French. In French irregular verbs may often have regular forms in many cases and irregular forms only for particular tenses and persons. As an example table 4 presents the different forms of the irregular verb *aller* for three different tenses and all persons. So for the verb *aller*, while imperfect forms are fully regular (such as *allais*), future forms are all irregular (such as *irai*) and the present forms are both regular and irregular, depending of the person (such as *allons* and *vont*). This complexity and the lack of clear-cut distinction between regular and irregular verbs could discourage

the system from relying on rules. However, the idea that the cognitive system would not be able to use regularities because of the complexity of the verbal system lacks plausibility given the complexity of other processes involved in language understanding.

Also, the result profile observed in French might not, by itself, be an insuperable problem for the dual mechanism account. One possibility is that the processing architecture of French differs from that of English in ways which allow listed allomorphs to prime each other. The idea would be that even if regular forms are retrieved by rule decomposition and not irregular ones, the behavioral output observed (in this case, the priming effect) would be the same even if the underlying processes are different.

Table 4: Verbal forms of the verb *aller* for the three indicative tenses and the three singular and plural persons.

<b>aller</b> <b>(infinitive form)</b>	<b>Present</b>	<b>Imperfect</b>	<b>Future</b>
je (1 sing.)	<i>vais</i>	<i>allais</i>	<i>irai</i>
tu (2 sing.)	<i>vas</i>	<i>allais</i>	<i>iras</i>
il/elle/on (3 sing.)	<i>va</i>	<i>allait</i>	<i>ira</i>
nous (1 plur.)	<i>allons</i>	<i>allions</i>	<i>irons</i>
vous (2 plur.)	<i>allez</i>	<i>alliez</i>	<i>irez</i>
ils/elles (3 plur.)	<i>vont</i>	<i>allaient</i>	<i>iront</i>

Note: sing.: singular; plur.: plural; 1: first person (I or we); 2: second person (you); 3: third person (he/she or they).

Perhaps a more important difference between the idiosyncratic verbal forms in French and the irregular forms in English is that French forms are decomposable while English forms are not. English irregular forms such as *drove* or *gave* are not only irregular but also cannot be further morphologically decomposed. They must be learnt and represented as unanalysable whole forms. In French, even idiosyncratic irregular forms like *buvait* (from *boire*) undergo a regular suffixation procedure: '-ait' is the regular affix for the imperfect third person form. Irregular forms in French are composed of a changed stem plus a regular affix. The irregularity is in the choice of the stem used but the regular suffix procedure applies anyway.

Marslen-Wilson et al. (1995) explain the English results in terms of the inhibitory consequences during acquisition of having to learn, for each irregular stem, to block the application of the default regular suffix. If indeed in English the two possible stems compete with each other during identification in order to block the decomposition process (in case the form that has to be identified is the irregular one), such a process would not be necessary in French. For French irregular verbs, two types of stem would be possible but even if the form presented is irregular there would not be the same type of competition because in both cases decomposition would be necessary to reach identification of the verbal form. Both regular and irregular forms would follow the same processing pathways - which is arguably not the case for regular and irregular forms in English (Marslen-Wilson & Tyler, 1998). If regular and irregular forms can co-exist in this fashion, then both can be linked to the

underlying verbal morpheme without competition from the other - and without the requirement to postulate distinct types of computational procedure to support the generation and analysis of each type of form.

## Abstract

Naming latency studies have recently shown a position-of-irregularity effect (words with early irregularities seem slowed compared to those with late irregularities), for which Dual-Route models of reading can account. Milostan & Cottrell (1998) showed that the initial studies contained a confound between irregularity position and friend/enemy ratio, and that the statistical confound could be captured by connectionist networks which then show the supposed position effect. This paper presents work to disentangle the position/regularity confound through a subject study and additional connectionist explorations. The latency data show that, once friend/enemy ratios are controlled for, the supposed position effect is driven entirely by high-enemy words in the first position. Further, connectionist network simulations show that network error at the first phoneme position only is a better match for naming latency, while overall network error produces a better match to subject error counts.

## Introduction

A major component of the task of learning to read is the development of a mapping from orthography to phonology. In a complete model of reading, message understanding must play a role, but many psycholinguistic phenomena can be explained in the context of this simple mapping task. A difficulty in learning this mapping is that in a language such as English, the mapping is *quasiregular* (Plaut et al., 1996); there are a wide range of exceptions to the general rules. As with nearly all psychological phenomena, more frequent stimuli are processed faster, leading to shorter naming latencies. The regularity of mapping interacts with this variable, a robust finding that is well-explained by connectionist accounts (Seidenberg and McClelland, 1989; Taraban and McClelland, 1987).

In this paper we continue consideration of a recent effect that seems difficult to account for in terms of the standard parallel network models. Coltheart & Rastle (1994) have shown that the amount of delay experienced in naming an exception word is related to the phonemic position of the irregularity in pronunciation. Specifically, the earlier the exception occurs in the word, the longer the latency to the onset of pronouncing the word. Table 1, adapted from (Coltheart and Rastle, 1994) shows the response latencies to two-syllable words by normal subjects. There is a clear left-to-right ranking of the latencies compared to controls in the last row of the Table. Coltheart *et al.* claim this delay ranking cannot be achieved by standard connectionist models. Earlier work (Milostan and Cottrell, 1998) showed that the origin of the effect seen in the Coltheart study lies in a statistical regularity of English, related to

Filler	Position of Irregular				
	1	2	3	4	5

Table 1: Naming Latency vs. Irregularity Position

the number of “friends” and “enemies” of the pronunciation within the word’s neighborhood.<sup>1</sup> The human subject study and network simulations presented in this paper attempt to tease apart the effects of phoneme position and neighborhood ratio.

## Background

Computational modeling of the reading task has been approached from a number of different perspectives. Advocates of a dual-route model of oral reading claim that two separate routes, one lexical (a lexicon, often hypothesized to be an associative network) and one rule-based, are *required* to account for certain phenomena in reaction times and nonword pronunciation seen in human subjects (Coltheart et al., 1993). Connectionist modelers claim that the same phenomena can be captured in a single-route model which learns simply by exposure to a representative dataset (Seidenberg and McClelland, 1989).

In the Dual-Route Cascade model (DRC) (Coltheart et al., 1993), the lexical route is implemented as an Interactive Activation (McClelland and Rumelhart, 1981) system, while the non-lexical route is implemented by a set of grapheme-phoneme correspondence (GPC) rules learned from a dataset. Input at the letter identification layer is activated in a left-to-right sequential fashion to simulate the reading direction of English, and fed simultaneously to the two pathways in the

<sup>1</sup>Friends are words with the same pronunciations for the ambiguous letter-to-sound correspondence; enemies are words with different pronunciations.

model. Activation from both the GPC route and the lexicon route then begins to interact at the output (phoneme) level, starting with the phonemes at the beginning of the word. If the GPC and the lexicon agree on pronunciation, the correct phonemes will be activated quickly. For words with irregular pronunciation, the lexicon and GPC routes will activate different phonemes: the GPC route will try to activate the regular pronunciation while the lexical route will activate the irregular (correct) pronunciation. Inhibitory links between alternate phoneme pronunciations will slow down the rise in activation, causing words with inconsistencies to be pronounced more slowly than regular words. This slowing will not occur, however, when an irregularity appears late in a word since the lexicon will try to activate *all* of a word's phonemes as soon as the word's lexical node becomes active. If an irregularity is late in a word, the correct pronunciation will begin to be activated before the GPC route is able to vote against it. Hence late irregularities will not be as affected by the conflicting information. This result is validated by simulations with the one-syllable DRC model (Coltheart and Rastle, 1994).

Several connectionist systems have been developed to model the orthography to phonology process (Seidenberg and McClelland, 1989; Plaut et al., 1996). These connectionist models provide evidence that the task, with accompanying phenomena, can be learned through a single mechanism. In particular, Plaut *et al.* (henceforth PMSP) develop a recurrent network which duplicates the naming latencies appropriate to their data set, consisting of approximately 3000 one-syllable English words (monosyllabic words with frequency greater than zero in the Kuçera & Francis corpus (Kuçera and Francis, 1967)). Naming latencies are computed based on time-to-settle for the recurrent network, and based on mean squared error (MSE) for a feed-forward model used in some simulations. The structure of the feed-forward network is shown in Figure 1. In addition to duplicating frequency and regularity interactions displayed in previous subject work, this model also performs appropriately in providing pronunciation of pronounceable nonwords. This provides an improvement over, and a validation of, previous work with a strictly feed-forward network (Seidenberg and McClelland, 1989). (Milostan and Cottrell, 1998) then showed that the serial position effect proposed by Coltheart & Rastle could be accounted for by a statistical regularity in English, as measured by the Enemy Ratio (# of enemies in a word's neighborhood divided by the total size of the word's neighborhood). (Milostan and Cottrell, 1998) showed that, for the words used in (Coltheart and Rastle, 1994), words with earlier irregularities had higher enemy ratios, and that the parallel connectionist model of PMSP, exposed to the same statistical regularities, also shows the same left-to-right effect that (Coltheart and Rastle, 1994) claimed it would not.

## Experiment

Intuition suggests that, since English is read from left to right, left-to-right phenomena such as the serial position effect might be seen, independent of statistical confounds. However, as with all assumptions, such effects must be verified through careful testing, and the source of such effects must be carefully delineated within the model hypothesized for the system at hand.

Figure 1: Single Syllable Ortho-to-Phono Network

Figure 2: Hypothetical Position-Only Effect

In a serial system such as the DRC, which by design processes input orthography from left to right, any observed left-to-right irregularity effect is a direct result of the GPC operation. On the other hand, for a parallel model such as the PMSP system, which produces the output phonology all at once, effects of irregularity are driven by neighborhood enemy/friend measures, and serial effects should disappear once these enemy ratios are controlled.

The serial position effect seen by Coltheart & Rastle could be the result of a confound between the position of the irregularity and the statistics of English. Earlier positions appear to have more irregularities. It would be productive, then, to retest the Coltheart & Rastle hypothesis, this time controlling for amount of consistency. If the serial position effect does hold regardless of the enemy ratio of the test words, an effect similar to that shown in Figure 2 would be expected. If, however, the effect is due to enemy ratio alone, the results should be similar to that of Figure 3. The subject experiment and network simulation presented here are an attempt to adjudicate between these options, and stimuli will vary in both position of irregularity, and in enemy ratio, in order to determine the source of the effects.

## Difficulties of GPC rules

One of the major discrepancies between the PMSP work and DRC model is the latter's assumption of the existence of a pronunciation rule system. This rule system *defines* whether a word is regular or not. Thus, all irregular stimuli chosen for experiments on the DRC model are chosen according to the GPC rules. Experiments which attempt to refute the DRC model at any level must also take these rules into consideration when choosing stimuli.

Ideally, the same words that the DRC system uses should

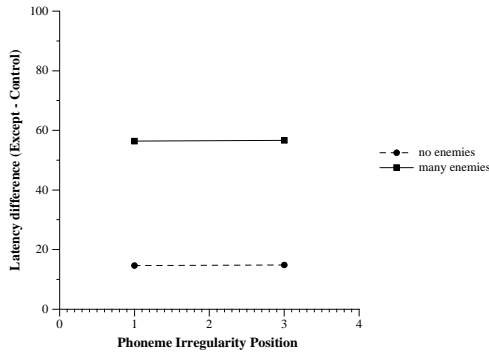

Figure 3: Hypothetical Enemy-Ratio-Only Effect

be addressed. Thus, irregular words for this experiment were identified using the Australian GPC used in the DRC system, and the Australian pronunciations from the MRC database, from which the GPC rules were initially derived. Neighborhood Enemy Ratios were also calculated using the MRC pronunciations. American English would then be used only for identifying errors in subjects' pronunciations.

A program was written implementing the GPC rules of the DRC system as listed in (Rastle and Coltheart, 1999). A word was considered irregular if the pronunciation generated by the rules did not match the pronunciation provided by the MRC database. From the list of identified exception words, homographs where one generated pronunciation was correct were excluded (/wind/ vs. /wInd/), as were Australian words with spellings not commonly used in the United States (gaol). Also excluded were words marked as irregular by the GPC rule which states that word-final /s/ is *always* converted to /z/. This rule causes all words ending in -ace or -ice (face, mice) to be considered irregular.

Overall, the words which were identified by this procedure using the Australian English were also found to be irregular through a similar procedure using the rules of American English pronunciation from (Venezky, 1970). The details of that investigation are reported with a companion study in (Milostan et al., 2000).

### Neighborhoods

Neighborhoods are defined using an extension of the (Taraban and McClelland, 1987) neighborhood rules described in (Milostan and Cottrell, 1998), summarized for single syllable words here:

- Consonant neighborhoods consist of orthographic clusters which correspond to the same location in the word. For one-syllable words, this results in 2 consonant cluster locations: onset and coda.
- Each vowel group is considered within the context of its coda. In order for a word to be in the neighborhood of a test word, it must have the same vowel group ('E' is considered separately from 'EE') and be followed by the same consonant cluster ending that syllable. As an example, the 'OO' neighborhood in 'BOOK' are all those words ending in 'OOK', with the first syllable coda containing only 'K'.
- Consonant cluster neighborhoods include the preceding

Enemy Ratio	Position	
	Front	Back
High	aunt	plaid
Low	earl	fluke

Table 2: Sample Experiment Words

vowel for coda consonants, and the following vowel for onset consonants. As expected, consonant irregularities are by far the minority, and are limited to 'CH', 'TH', 'G', 'C', 'Q', and the silent instantiations such as 'T' and 'H'.

## Methods

### Subjects

Subjects were 23 undergraduate psychology students from University of California San Diego. All subjects had normal or corrected-to-normal vision, and were native North-American-English speakers. They were given course credit for their participation.

### Materials

Sixty-four words with irregular grapheme-to-phoneme correspondences (according to the GPC rules of the DRC model) were chosen. Each target was uninflected and monosyllabic, and had between 3 to 6 letters with Kuçera-Francis frequency between zero and twenty-two.

The chosen words had an irregular grapheme-to-phoneme correspondence in either the first ("front") or third ("back") phoneme position, and were divided into 2 lists on that basis. Each list was further divided into two sublists, based on whether the word had only friends in the neighborhood based on the regularity (Enemy Ratio  $En = 0.00$ ) or mostly enemies at that location (Enemy Ratio  $0.6 \leq En < 1.0$ ). Since a word's neighborhood by our measure includes itself, words with a neighborhood size of one ("loners") were excluded from consideration. These words correspond to Colheart's categorization of "irregular consistent".

Of the eligible words, the front-enemy condition had only 16 candidate words. Each of the other three conditions were randomly pruned down to size 16 in order to balance the conditions. The resulting average word frequency did not differ significantly between conditions ( $M = 4.8281, F(3, 60) = 0.476, p = 0.700$ ). Each irregular word was then matched with a regular control word. Control words were matched to their irregular partners based on initial phoneme (since different phonemes take longer to trigger the microphone) and number of letters. The controls were also in the zero to 22 Kuçera-Francis frequency range.

An example test word from each of the four conditions is shown in Table 2.

## Results

Of the original 25 subjects, data from 2 were unusable (in one case the latency data were accidentally deleted; in the other case the audio recording did not function so errors could not be scored). For the remaining 23 data sets, latencies associated with voice key failures were discarded; if the stimulus was either a test word or a control the associated (control or test) word was similarly disregarded (13 pairs total

Figure 4: Naming Latency Results overall

Figure 5: Error Count Results overall

over all subjects). Latencies for all nonword fillers were also discarded. Words which were pronounced incorrectly, along with the associated match, were removed for separate error analysis.

Naming latency differences were then calculated by subtracting the control word latency from the associated test word latency. Analysis of variance (ANOVA) was then performed on these values. Words in the high enemy ratio condition had significantly greater latency differences than the words in the friend condition ( $F(1, 22) = 18.16, p < 0.0005$ ), and there was a significant interaction between enemy ratio and position of irregularity ( $F(1, 22) = 8.419, p = 0.008$ ). Latency differences for first and third position irregularities, combining both enemy ratio conditions, approached but did not reach significance ( $F(1, 22) = 3.766, p = 0.065$ ). The latency data is shown in Figure 4.

Subjects made a total of 22 errors on control words, and 248 errors on irregular test words. Control words are not considered in the error analysis. Subjects made significantly more errors for front position irregulars than for back position irregulars ( $F(1, 22) = 32.922, p < 0.0005$ ), and more errors for high-enemy words than for low-enemy words ( $F(1, 22) = 326.549, p < 0.0005$ ). Position and enemy ratio also had a significant interaction in number of errors made ( $F(1, 22) = 12.415, p = 0.002$ ). These error data are shown in Figure 5.

## Discussion

From the data collected in this experiment, there is a slight effect of irregularity position, but this appears to be completely

driven by the words with high enemy ratios (see Figure 4). First-position-irregular words with high numbers of enemies in their neighborhood take longer to name than similar words with friends only. This effect has mostly disappeared for those words with third position grapheme-phoneme irregularities.

This makes sense from a cascaded information processing point of view (McClelland, 1979), since it is possible that any (potential) errors late in a word can be resolved by the time the third phoneme is ready to be produced. This difference in time delays can be considered an effect of the temporal nature of the speech process, and the time available to make online corrections. Words with later irregularities have, by definition, *regular* grapheme-phoneme correspondences at the beginning. The subject can begin pronouncing those phonemes immediately, even if she must then make accommodations later. Thus, the initial phoneme in an irregular (high enemy ratio) word may be produced with the same latency as a completely regular word, while the phoneme at the irregular mapping itself may actually be delayed internal to the word. However, there is currently no way of measuring the latencies of each internal phoneme using only the voice key.

## Feed-Forward Network Performance

The feed-forward network of PMSP does not contain a temporal component. Since all phonemes are calculated simultaneously, the irregularity position may not play a part in the latencies calculated from the network as these are actually a measure of the difference between the correct target pronunciation and the network's actual output across the word. Thus, the feed-forward pronunciation network should be affected by enemy ratio alone, as those words with many contradictory spelling-sound mappings will receive less total reinforcement for the correct mapping.

Five feed-forward connectionist networks were trained on 3015 single syllable words as described in (Plaut et al., 1996; Milostan and Cottrell, 1998). This data set is the 2998 words used in PMSP plus 17 additional words used in the current subject experiment. These words were not included in the PMSP data set as they are of frequency rating zero.

Naming latency was then calculated for each test word by using the sum squared error at the output layer, producing the results shown in Figure 6. Unexpectedly, it appears that the back position irregulars take *longer* to name than the front irregulars, regardless of enemy ratio. Remember, however, that naming latency in these feed-forward networks is a measure of error, not of time directly. The representation used for the output layer is a sparse coding of the output phonemes. Of the 62 units, only a small number will be on for any particular word. Thus, the network is exposed to a training set where the majority of the output units are off most of the time. These networks learn how to turn off units very well, and thus there will be less discrepancy between the target and actual output which should be off and is, than for a target which should be on and the related output unit which is actually on. This means that, everything else being equal, training pairs with more units on in the target will inherently produce more error than for those with fewer on targets.

As an example, consider a hypothetical network with 10 output units, and compare the results of two targets, one of

Figure 6: Network Sum Squared Error

which has one unit on and the other of which has two units on. Since the “off” units receive more training, assume that any units off in the target have an activation of 0.1 in the actual network during testing, while the on-units are activated at 0.8. Both of the hypothetical training sets accurately produce the intended output, but in the case where the target has one unit on the network shows an error of  $(0.1^2 * 9) + (0.2^2 * 1) = .13$ , while the target with 2 units on has an error of  $(0.1^2 * 8) + (0.2^2 * 2) = .16$ . This discrepancy becomes more exaggerated as the number of off-units increases. Thus, if there is a systematic difference in the expected number of on-units among the conditions, those targets with more on-units may be unduly penalized. Examination of the output targets for the various test categories reveals that indeed, those in the back position conditions have more on-units than the front position targets, as shown in Figure 7. This means that the words in the back position systematically have one more phoneme than the front-position test words.

In parallel connectionist models, output error is associated with naming latency under the assumption that the more error the output shows, the longer it takes for the system to then converge on a veridical representation for a further stage which will begin the actual production of the speech signal. If the output for each of the ON-bits in the representation can be cleaned up in parallel, then the time required before the next stage may begin is more a measure of the average amount of time required to make the cleanup. Thus, the average ON-bit error provides a more realistic measure of naming latency.

To correct for the bias in number of bits on between first- and third-position words, the total output error for each word was divided by the number of ON-units in that word’s output representation. These results are shown in Figure 8. As in the human data, the networks show a significant effect of enemy ratio ( $F(1,4) = 478.669, p < 0.0005$ ) and a significant interaction between enemy ratio and position ( $F(1,4) = 621.335, p < 0.0005$ ). Unlike the human subjects, however, the networks also show a significant effect of position ( $F(1,4) = 683.588, p < 0.0005$ ). Again, this appears to be mostly driven by the high enemy ratio words. This is actually a bit surprising since the networks produce output in parallel, and thus would not have any time to “correct” for later-position errors. The network results instead reflect the finding that English words are more consistent in endings than they are in onsets (Treiman et al., 1995).

Figure 7: Number of Units ON in Output Representation

Figure 8: Network Error / Number of Phonemes ON

Figure 9: Study #1 Network Error at First Phoneme Only

The corrections made through dividing network output error by the number of ON-bits is reasonable enough, assuming the networks represent a parallel stage which leads to a temporal phoneme-output system. If the motor system were reading off the outputs of this network sequentially, then naming latency would be measured by the error at the first phoneme produced, just as naming latency in subjects is measured as the time to begin the first phoneme. For the networks developed here, then, an even better measure of the naming latency would be the network output error at the first phoneme only. This data is shown in Figure 9. Here there is a significant main effect of both position ( $F(1,4) = 1071.117, p < 0.0005$ ) and Enemy-Ratio ( $F(1,4) = 242.419, p < 0.0005$ ), and a significant interaction between position and ratio ( $F(1,4) = 612.797, p < 0.0005$ ). As can be seen, the data here produce a better match to the human subject latency data, while the total output error (Figure 8) is a better match to the human subject error data (Figure 5). The total network error (driven by the Enemy-Ratio of the words in question) is reflective of the probability that the subject will make an error on the word, while the network first-phoneme-error represents the amount of time it takes for the subjects to begin producing that first phoneme.

### Summary

Subject performance in the naming latency task is driven mostly by the high-enemy-ratio words. Words with irregularities in the first position in the “many enemies” condition are greatly slowed, while there is not much difference in naming latencies for words in any of the other conditions.

When using connectionist networks to model word naming latencies, it is traditional to equate overall output error with latency. The network simulations of this subject study show that, rather, the output error of the first phoneme only is a better model of the subject naming latencies. This implies that a recurrent network which produced the phonemes one at a time, perhaps using a feature-based representation, would result in a better model, defining the output error for the first phoneme as the naming latency.

This study seems to show that the traditional measure of network latency is instead a better predictor of subject error. If the system produces a large overall error, chances of settling into an incorrect attractor basin are increased. Continued experimentation into this idea is currently being undertaken.

The subject study performed here indicates that the enemy

ratio at the first position, not the phoneme position *per se*, is the driving force behind word naming latency.

## Abstract

Instructed category learning studies have shown that categorization practice on a fixed set of labeled training exemplars can cause learners to violate explicitly provided categorization instructions. We have previously proposed a connectionist account of this exemplar-based interference effect — an account which predicts that individuals who display initial difficulty in the application of a categorization rule will exhibit greater exemplar-based interference than good rule-followers. In this paper, we report on a study of human instructed category learning performance intended to test this prediction of the model, and we provide the results of additional connectionist simulations which are fit to the human experimental data.

## Introduction

Instructed category learning studies have revealed that experience with labeled examples can sometimes cause learners to deviate from previously provided categorization instructions, even when the category labels on the training items are perfectly consistent with the given instructions (Allen and Brooks, 1991; Brooks et al., 1991). Such experiments typically begin with the presentation of an explicit rule for categorizing stimuli. These initial instructions are followed by a sequence of trials in which stimuli are presented to the learner, one at a time. The learner is asked to make a categorization judgment for each stimulus, and this judgment is immediately followed by performance feedback, providing the correct category label for the object. After a substantial period of such training, the learner is presented with novel stimuli and is asked to provide category labels for these novel items. Previous studies have discovered that learners may sometimes violate the instructions that they were given when faced with a novel stimulus, assigning the category label of a similar training set exemplar to the novel item in lieu of accurately applying the given explicit rule.

We have previously presented a connectionist model of instructed category learning which explains this exemplar-based interference effect as emerging from the use of an error-correcting learning rule when learning from examples (Noelle and Cottrell, 1996). This model posits the existence of a working memory network which actively maintains a distributed pattern of activity encoding the explicitly provided categorization rule. The model also includes a categorization network — a system which assigns category labels based on stimulus features. The behavior of the categorization network is modulated by activity in the working memory network, allowing explicit instructions to shape categorization performance. Exemplar-based interference appears when connec-

tion weights in the categorization network are modified, by an error-correcting learning rule, as the result of performance feedback on the training exemplars. This mechanism makes a general prediction concerning exemplar-based interference: difficulty in rule-following should result in larger amounts of interference. If the network exhibits substantial residual error when applying a given explicit categorization rule, this error will produce large weight changes during exemplar-based training, and significant interference will arise. This prediction has a number of corollaries. First, the complexity of the categorization rule should impact interference, with more complex rules producing more interference. Second, a corresponding trend should be seen across individual learners, with individuals who are error prone at rule application exhibiting more interference than those who find rule application easy.

In this paper, we investigate these predictions. We report on a human instructed category learning study which investigates individual differences in exemplar-based interference, and we provide the results of detailed connectionist simulations which model the observed human learning performance.

## Individual Differences in Interference

### Method

Undergraduate students were asked to learn to categorize a set of simple geometric line drawings into two categories. Each geometric stimulus involved a circle with a radial line, drawn in green on a black computer screen. The circle stimuli varied along two continuous dimensions: size and orientation. Four different sized circles were used, with radii of approximately 5.0 mm, 7.0 mm, 10.0 mm, and 14.0 mm. The number of distinct orientations was also four, with the radial line of the circle rotated counterclockwise from the right-pointing vector by 30°, 60°, 120°, or 150°. Each of the four angles of rotation could be paired with each of the four sizes, producing a set of 16 different stimulus items. These stimuli may be graphically depicted as points in a two dimensional feature space, as shown on the right side of Figure 1. Of the 16 possible circle stimuli, seven were distinguished as training set items. These items are marked with boxes in Figure 1. Four training stimuli were to be placed in one category, called the “black” category here for convenience, and the remaining three were to be placed in the other, called the “white” category.

A typical experimental trial involved the presentation of a circle in the middle of a blank computer screen. Participants were expected to identify the appropriate category for each stimulus, communicating their judgment by depressing the appropriate key on the computer keyboard. No time pressure

was placed on the learners, and accuracy was stressed in initially provided task instructions. Once a category judgment was made for a given stimulus object, a message appeared above the circle indicating if the given classification was correct or not. The correct category label was also explicitly provided at this time. This feedback remained on the display for 2 seconds, after which time the next trial began.

Participants were randomly assigned to one of two experimental conditions: the simple rule condition or the complex rule condition. In each of these two conditions, the experimental session began with the presentation of an explicit rule for categorizing the circle stimuli. The learners in the simple rule condition were told that circles in the “black” category were those of the smallest size, or of the largest size, or rotated 150°. All other circles were to be placed in the “white” category.<sup>1</sup> Participants in the complex rule condition were given similar categorization instructions, only their rule included an “exception” clause. All circles of the smallest size, the largest size, or rotated 150° were to be placed in the “black” category *unless* they were rotated by 60°. All circles with radial lines at 60° were to be placed in the “white” category, even if they were of the largest or smallest sizes. The instructions were designed to ensure that the rules were clearly understood. The four stimuli sizes and the four angles of rotation were graphically displayed on the same screen with the textually presented categorization rule. The rule was described in plain English, making reference to the graphical examples. Furthermore, participants were not allowed to advance to the next stage of the experiment until they demonstrated an accurate memory of the rule by correctly identifying a reworded version of it in a list of three alternatives. Participants also demonstrated retention of the rule by describing it during an informal debriefing following the experiment.

Once categorization instructions were given, learners were presented with 36 blocks of training trials, each block consisting of one presentation of each of the seven training set items, appearing in a random order. Each trial involved the display of one of the stimuli, a categorization judgment on the part of the learner, and a period of performance feedback which provided the correct category label for the object. At the end of this *training phase*, participants were given a short break, during which time they were told that performance feedback would be suspended for the remainder of the experimental session. They were then presented with 8 blocks of trials incorporating all 16 of the possible stimulus objects. The stimuli were presented in a random order, with the learner providing a category label for each object but receiving no feedback concerning the accuracy of such judgments. Following this *testing phase*, the session was paused once more, and learners were given a new categorization rule to apply. They were told that they would soon be asked to classify circles according to the new rule without the benefit of performance feedback. The new rules involved rotating the structure of the original rules in feature space, keeping the complexity of the rules constant. In the simple rule condition, the new rule placed items in the “black” category if they were rotated to 30°, or to 150°, or if they were of the smallest size. The new complex rule was the same, ex-

<sup>1</sup>The stimuli used here and the simple categorization rule are derived from the experiments of Nosofsky, Clark, & Shin (1989).

cept all circles of the penultimate size (i.e., 10.0 mm radius) were to be placed in the “white” category, regardless of orientation. Following these new classification instructions, 8 more blocks of trials were given, each involving all 16 stimuli, randomly sequenced. The goal of this final collection of trials was to assess the rule-following ability of each learner when no exemplar-based feedback was made available. This final *rule-following phase* was conducted with new categorization instructions to avoid transfer from the earlier training phase.<sup>2</sup> The total number of categorization trials experienced by each participant was 508, and these were typically completed within a period of 45 to 55 minutes.

The performance of participants from a third experimental condition is also reported here. The data for these learners were collected during a previous experiment (Noelle et al., 2000). In this third condition, no explicit categorization instructions were given. Participants were asked to learn to categorize the circle stimuli from feedback on the training items alone. These learners experienced 252 training trials with the seven training stimuli, as the instructed learners did, and they were tested, without feedback, on all 16 objects for 128 trials, as before. Since no explicit instructions were given to these participants, no final rule-following test was conducted.

All of the participants in this experiment were undergraduate students enrolled in psychology or cognitive science courses at the University of California, San Diego during the 1996–1997 academic year. They received course credit in exchange for their participation. Data were collected for 36 uninstructed participants, 28 learners in the simple rule condition, and 27 in the complex rule condition. Some students did not appear to be engaged by the task, exhibiting chance level rule-following performance or chance level performance on the training set items even after the 252 training trials. The data for these participants were discarded, leaving valid data for 34 uninstructed learners, 27 learners in the simple rule condition, and 19 learners in the complex rule condition.

## Results

The mean frequency of classification responses, averaged over the uninstructed learners, are displayed in Figure 1. The mean results for the instructed participants are shown in Figure 2. The chart on the right side of Figure 1 presents the letter labels which will be used to refer to individual stimulus objects in the discussion, below. The other feature space graphs in these two figures show the frequency with which learners identified objects as being in the “black” category during various phases of the experiment.

Exemplar-based interference, if present, should be found in the testing phase categorization frequencies. Such interference involves a change in categorization performance away from that dictated by the rule instructions and towards that suggested by the distribution of training set items alone. The responses of the uninstructed learners may be taken as a characterization of the category structure suggested solely

<sup>2</sup>Previous experiments attempted to assess rule-following ability by testing each participant on the original categorization rule, over all 16 stimuli, without feedback, *prior* to the training phase. It was found, however, that such an initial rule-following test, even without performance feedback, impacted performance during the later training and testing phases in a manner which masked interference.

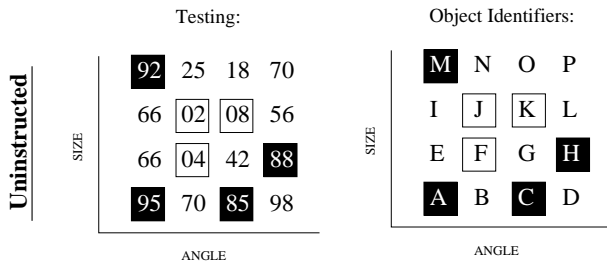

Figure 1: Uninstructed Condition Mean Responses: Categorization results are shown as the percentage frequency with which items were placed in the “black” category. Training set items are marked with boxes, colored according to the assigned category label. Also shown are letter labels for the stimuli, used to reference items in this report.

by the training exemplars. Performance during the final rule-following phase may be used to approximate the accuracy, over all 16 items, with which a learner might have applied the original rule prior to the training phase. Thus, exemplar-based interference may be said to have been present in a given condition to the degree that the pattern of testing phase responding deviated from rule application behavior in the direction of that exhibited by the uninstructed learners.

In order to assess if exemplar-based interference was present in a given experimental condition, careful attention must be given to the amount of error displayed by the participants when they apply an explicit rule without the benefit of exposure to training items. Exemplar-based interference may be said to exist only if deviation from perfect rule application *increases* as a result of performance feedback on the training set. This characterization suggests a quantitative measure of interference involving assessing the deviation from the explicit rule in both the rule-following and testing phases and taking the difference between these two values. Rule-following phase accuracy may be used as an approximation of how well learners might have applied the original explicit categorization rule prior to exemplar-based training. This estimate is compared to categorization accuracy during the testing phase, after training is complete. Using this measure reveals that deviation from the rule did not reliably change in the simple rule condition ( $t(26) = -0.664$ ) but did increase in the complex rule condition, with marginal reliability ( $t(18) = 2.02$ ;  $p = 0.06$ ).

Comparing deviation from the rule across the rule-following and testing phases is not a very powerful test of interference, however. The presence of exemplar-based interference does not entail increased deviation from the rule for *all* stimulus items. Indeed, it is reasonable to expect that the classification performance for some of the stimulus objects will become *more* consistent with the explicit rule as a result of exemplar-based performance feedback, since, for some objects, the category structure suggested by the training items is consistent with that specified by the rule. A more sensitive test of interference would restrict its consideration to those stimulus items for which interference is reasonably expected. A simple operational definition of this expectation can be based upon the uninstructed participant data, expecting

Figure 2: Instructed Conditions Mean Responses: Categorization results are shown as the percentage frequency with which items were placed in the “black” category. Explicitly provided rules are displayed as dashed boundary lines.

interference for those objects which the uninstructed learners, on average, placed in the opposite category as that specified by the explicit rule. The simple categorization rule conflicts with mean uninstructed learner performance at items “E”, “I”, “N”, and “O”. For the complex rule, interference is expected for items “B”, “E”, “I”, and “O”. Restricting our attention to these items, our measure of interference becomes: the increase in mean error, defined as deviation from the rule, from the rule-following phase to the testing phase, averaged only over those items for which interference was expected.<sup>3</sup>

Making use of this more sensitive measure reveals no reliable interference in the simple rule condition ( $M = 0.006$ ;  $SD = 0.244$ ;  $MSE = 0.059$ ;  $F(1, 26) < 1$ ) but substantial interference in the complex rule condition ( $M = 0.220$ ;  $SD = 0.244$ ;  $MSE = 0.060$ ;  $F(1, 18) = 15.478$ ;  $p < 0.001$ ).

Our previous connectionist model of instructed category learning explained exemplar-based interference as the result of connection weight modifications made during the training phase, driven by an error-correcting learning rule (Noelle and Cottrell, 1996). Under this view, large residual errors will produce large weight changes in the network, producing large amounts of interference. Thus, this model gave rise to the prediction that increased error during rule application (estimated by rule-following phase error) should be accompanied by increased exemplar-based interference. Support for this

<sup>3</sup>There may be concern that this measure of interference is inappropriate since different rules were used in the rule-following and testing phases. Indeed, it may seem odd to compare categorization error on a specific stimulus (e.g., item “O”) across the two phases when the relationship of that stimulus to the category boundaries changes between the phases. These concerns may be partially alleviated, however, by noting that none of the significance results reported here change if deviation from the rule is averaged over *all* stimuli in the rule-following phase, and this average deviation is then compared to the average testing phase error on stimuli for which interference is expected.

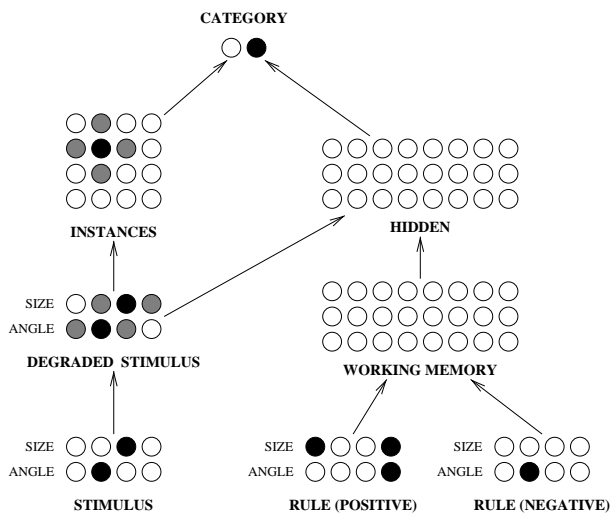

Figure 3: Network Architecture: Each circle represents a standard sigmoidal processing unit, with the units grouped into layers. Arrows represent connections between the units in these layers. Example activations for stimulus “J”, being classified according to the complex rule, are also shown.

prediction may be seen in the difference between the simple rule and the complex rule conditions. The complex rule condition, which elicited a greater degree of rule-following phase error than the simple rule condition (13.5% average error per stimulus object versus 7.9%), elicited a greater degree of interference during the testing phase. This prediction may also be investigated at the level of individual differences. According to the model, poor rule-followers should display more interference than good rule-followers. In order to test this prediction, a correlation was computed over participants in each condition between the mean classification error during the rule-following phase (averaged over all 16 stimuli) and the sensitive measure of interference. A statistically significant positive correlation would verify the prediction. When tested, a marginally reliable *negative* correlation was observed in the simple rule condition ( $r = -0.378$ ;  $t(25) = -2.041$ ;  $p = 0.052$ ), but a robust *positive* correlation was found in the complex rule condition ( $r = 0.629$ ;  $t(17) = 3.340$ ;  $p < 0.01$ ). In brief, the condition which displayed significant interference over all (the complex rule condition) also supported the individual differences prediction of the connectionist model, while the condition which showed no reliable interference (the simple rule condition) revealed a tendency for poor rule-followers to become more consistent with the explicit rule as a result of training.

## A New Connectionist Model

### Simulation Method

Our connectionist model of instructed learning (Noelle and Cottrell, 1996) has been augmented to provide a detailed account of the experimental results reported here, and new model simulations have been conducted. The network architecture used in these simulations is diagrammed in Figure 3. Standard connectionist processing elements were used,

grouped into layers, the activation level of each processing element being the result of applying a logistic sigmoid to the weighted sum of input activity levels. The activity of each unit was, thus, bounded between zero and one.

The network took a representation of categorization instructions and a pair of stimulus features as input and produced a category judgment at the output layer. The input rule representation included eight units corresponding to the four levels of size and the four levels of angle of rotation used in the human learning experiments. Activating one of these units indicated that all stimuli of the given size or of the given orientation were to be placed in the “black” category. These rule input units are shown in Figure 3 as the “RULE (POSITIVE)” layer. Alongside this layer is a collection of inputs, called “RULE (NEGATIVE)”, which encoded “exceptions” to the positive rule terms. Activating one of these eight “negative” units indicated that all stimuli incorporating the given feature level were to be placed in the “white” category, regardless of the category suggested by the positive terms. As an example, the input representation for the complex rule used in our human learning study is shown in Figure 3.

These explicit rule inputs fed activity to a 24 unit working memory layer. When modeling uninstructed learners, the activity levels of these working memory units were set to zero. The weights on the connections from the rule inputs were bound to be non-negative, forcing the working memory layer to encode explicit rule terms by an increase in the activation levels of its processing elements. These weights were initially set to small random values sampled uniformly from the range  $[0.0, 0.4]$ . Complete connectivity extended from the working memory layer to a pool of 24 instruction-sensitive hidden units, and these, in turn, provided activity to the category output units. There were no bounds on these weights. The hidden layer also received complete connections from the degraded stimulus layer, which is described below. All of these unrestricted weights were initialized to small random values, sampled uniformly from the range  $[-0.5, 0.5]$ . Bias values on the working memory and hidden units were initialized to  $-3.0$  in order to encourage sparse internal representations.

Each stimulus was encoded by activating exactly one of the size units and one of the angle units. In order to incorporate perceptual similarity information into the network, this “place coded” stimulus representation was mapped, through connections with fixed weights, to a degraded stimulus representation. In this modified stimulus representation, each unit responded preferentially to a particular stimulus size or stimulus orientation, with partial activity appearing for stimuli of similar sizes or orientations. Levels of partial activation were set to decay exponentially with the number of feature levels separating the given unit from the stimulus. For example, the activity of the “size 2” unit when the stimulus was of “size 4” was set to  $e^{-\beta(4-2)}$ , where  $\beta$  was a gain parameter which could be modified to fit the model to data. Each stimulus dimension, size and orientation, had its own independent gain parameter, making them analogous to the dimensional attention weights used in models like ALCOVE (Kruschke, 1992).

The “instances” layer contained 16 processing elements, with each unit corresponding to one of the possible stimulus objects. Each unit in this layer received input from exactly one size unit in the degraded stimulus layer and from exactly

one angle unit. Unlike other connections in this network, the activity from these two units was multiplied together, rather than summed, to get the resulting activity of the instances layer unit. Thus, each unit in this layer responded preferentially to a unique stimulus object, and activity declined exponentially with city-block distance in feature space. The weights which gave rise to this pattern of activation were fixed. This representational scheme was adopted because of its success in capturing perceived similarity between stimuli in models such as ALCOVE (Kruschke, 1992). The instances hidden layer provided complete connections to the two category output units, with these weights initialized to small random values uniformly sampled from the range  $[-0.5, 0.5]$ . The biases on the output units were initialized to  $-3.0$ .

In order to capture human performance, the network had to be able to apply categorization instructions from the very start of the experimental session. Connection weights which allowed the network to produce accurate categorization decisions immediately following explicit instruction were discovered through a training process conducted during a network initialization phase. During this phase, the network was iteratively presented with a randomly sampled categorization rule along with a randomly sampled stimulus object. It was trained to activate the rule-determined category unit for the given stimulus, modifying weights based on squared error at the output layer using the generalized delta rule (Rumelhart et al., 1986). A learning rate of 0.05 was used, with no momentum term. The gain terms used in the degraded stimulus layer were fixed at 0.8 during this initialization training. This phase continued for 5,000,000 training trials, after which the network consistently demonstrated essentially perfect rule application performance. The distribution of stimuli experienced by the network during this initial training was uniform over the 16 items, but the distribution of categorization rules was skewed towards simple category structures. This biased distribution of rules produced a network which exhibited slightly lower residual error when following a simple rule, as compared to a complex one, and it also encouraged the working memory layer to devote more representational resources to the encoding of simple category structures. The skewed rule distribution also reflected a belief that simple rule structures are much more common in the rule-driven categorization experience of most humans.

Once initialized, the network was presented with the same sequence of trials that was presented to the human learners. When uninstructed, the working memory units were turned off and the network was trained on the seven training items for 252 trials. To measure rule-following performance, the appropriate rule was presented at the input, and category outputs were recorded without performance feedback. To measure performance after both instruction and exemplar-based training, the network was given the appropriate rule at its input and trained on the seven exemplars for 252 trials. The network's performance on all 16 stimuli, without feedback, was then recorded. All exemplar-based training was conducted using the generalized delta rule, with a learning rate of 0.5 and no momentum. Only weights from the instances layer to the output category units, and the bias weights on the output units, were modified during this training process.

To simulate limitations in the cognitive resources applied

to the task, random noise was injected into the activation levels of the processing elements in the working memory layer. During each trial, a random deviant was sampled from a zero-mean normal distribution independently for each unit in the working memory layer and the absolute value of this deviant was subtracted from the activation level of the unit. This caused components of the distributed rule representation held in the working memory layer to become weakened. This use of random noise was intended as a simple and abstract way to capture the temporary failure of the working memory system to actively maintain complete representations of categorization instructions. Resampling the noise on every trial was meant to allow for the possibility of refreshing working memory contents from a longer term episodic memory store.

Network simulations were run 50 times for each experimental condition. Each network was initialized with the same set of connection weights, determined during the initialization phase, but both the injected noise and the order of stimulus presentation was randomized for each simulation. The results of each collection of 50 simulations were averaged to produce figures to be compared to mean human categorization behavior. Four free parameters were adjusted to fit the simulations to data. These included the two gain parameters on the exponential decay used in the degraded stimulus layer representation, the gain parameter used on a Luce choice ratio which converted output activity values to probabilities, and the variance of the noise injected into the working memory layer. A simple grid search was conducted over this parameter space to find values for these four parameters which minimized the squared difference in the probability of "black" category assignment between the human learners and the networks, over all experimental conditions.

## Simulation Results

The best fit of mean simulation results to the human data was had by sharpening the representation of stimulus orientation slightly (gain of 0.9) over the representation of stimulus size (gain of 0.8). This meant that the angle of rotation was slightly more discriminable by the networks than size. The best fit to the mean data required a Luce choice gain of 2.6 on the output activation levels and working memory injected noise with a variance of 0.3. The resulting probabilities of "black" category membership, as predicted by the model, are shown in Figure 4. That diagram also displays the variance accounted for by the model, over stimulus items, for each condition. Notice that, like the humans, the network simulations exhibit no interference in the simple rule case on average (a value of  $-0.017$  in the interference measure previously used with the human data), but they show substantial interference when given the complex rule (0.251).

These simulations involved only a single source of individual variation: the ability to actively maintain an accurate representation of the categorization instructions. Individual differences in exemplar-based interference, then, were to be explained in terms of the weight modifications which were driven by the rule application error introduced by a failure to maintain explicit rules in working memory. Variable working memory ability was reflected by the noise variance parameter in these networks. Thus, in order to examine individual differences in interference, networks with a range of values

Figure 4: Simulation Results: Categorization results are shown as the mean probability with which items were assigned to the “black” category. Training set items are marked with boxes, colored according to the assigned category label. Variance accounted for is listed for each condition separately.

for this noise parameter had to be compared. Given a collection of networks with a variety of noise levels, the correlation between rule-following error and interference may be measured. Recall that human learners displayed a positive correlation when confronted with the complex rule, but showed a marginally negative correlation when given the simple rule.

When the variance on the noise injected into the working memory units was sampled uniformly from a bound range, these simulations matched the human findings. For example, if noise variance was sampled uniformly from the set  $\{0.0, 0.1, 0.2, 0.3\}$ , then the correlation between rule-following error and interference was reliably negative for the simple rule ( $r = -0.283$ ;  $t(198) = -4.15$ ;  $p < 0.0001$ ) and reliably positive for the complex rule ( $r = 0.412$ ;  $t(198) = 6.37$ ;  $p < 0.0001$ ). Similar results were found when the noise parameter was sampled in a manner sensitive to the observed distribution of human rule-following performance. This sampling was done by finding individual network simulations that matched, as closely as possible, the rule-following phase accuracies exhibited by individual human learners. These best match networks were found by varying the noise variance be-

tween 0.0 and 0.4. When correlations between rule-following error and interference were calculated for such participant-matched samples of network simulations, a positive correlation was found for the complex rule case ( $r = 0.545$ ;  $t(17) = 2.68$ ;  $p < 0.05$ ), and no correlation was found in the simple rule case ( $r = -0.166$ ;  $t(25) = -0.840$ ).

## Conclusions

The magnitude of exemplar-based interference was found to be sensitive to the complexity of the explicitly provided categorization instructions, with more complex categorization rules producing more interference. Also, in situations which elicit robust interference, a reliable correlation across individuals is observed: increased error at explicit rule application is paired with increased exemplar-based interference. A connectionist account of these effects, in which interference arises as the result of an error-correcting learning process, was found to fit the human performance data fairly closely.

## Abstract

To understand deep cognitive change, we have to understand how learners can go beyond their own prior knowledge. We propose a *displacement scenario* in which a learner acquires a target idea in a different context and then transfers that idea into a target context. We used virtual reality technology to implement a displacement scenario for teaching 2nd grade children that the Earth is round. The rather large pre- to posttest improvement was stable over four months.

## The Paradox of Deep Learning

Knowledge systems are organized along a center-periphery axis. One or more *central ideas* dominate more peripheral ones. The center-periphery structure is particularly obvious in scientific theories (Lakatos, 1980), but it also plays an important role in cognitive development (Chi, 1992; Vosniadou, 1994), social cognition (Eagly & Chaiken, in press; Rokeach, 1970) and elsewhere.

Changing the peripheral parts of a knowledge system by learning new facts or skills is easy enough, but revising its core concepts -- *deep learning* -- is a different matter (Ohlsson, 1995). Both direct experiences and communications are interpreted in terms of, and with the help of, prior ideas and hence tend to be understood as consistent with them. The result is that people assimilate information that is anomalous or inconsistent with current ideas or beliefs either by misunderstanding the former or by revising peripheral parts of the relevant knowledge system (Chinn & Brewer, 1993; Darden, 1992; Kuhn, Amsel & O'Loughlin, 1988; Strike & Posner, 1992). Consequently, neither direct experience nor communications have much power to change central ideas. Fodor (1976, Chap. 2) has argued that this is necessarily so: A less powerful

representational system cannot, in principle, replace itself with a more powerful one.

This conclusion leads to a paradox (Bereiter, 1985). It implies that central ideas never change, but of course they do. Scientists sometimes revise fundamental theoretical principles and non-scientists undergo radical changes in world view, particularly during childhood. Developmental psychologists have documented deep changes in children's understanding of a variety of domains (see, e.g., Hirschfeld & Gelman, 1994). Gopnic and Meltzoff (1997) argue that such developmental changes share many features with theory change in science.

How is deep cognitive change possible? How does the mind circumvent the learning paradox? One plausible hypothesis is that ideas that are new in one domain are brought into that domain from some other domain. According to this *cross-domain transfer hypothesis*, to acquire a new central idea in a target domain X, the learner must first acquire that idea in some source domain Y in which its acquisition is not hindered by prior knowledge, and then transfer the new idea to X and build a new understanding of X around it. The new understanding will gradually replace the old. This hypothetical three-step process might circumvent the distorting influence of the learner's prior ideas about X.

This hypothesis predicts that we can facilitate the acquisition of a deep idea if we displace the learner's attention from the target domain to some other domain, teach him or her the target idea in that domain, and then prompt him or her to transfer it into the target domain. We implemented this *displacement scenario* in a virtual reality environment for teaching children that the Earth is round. Empirical evaluation in a public school resulted in strong

and lasting improvement in the children's understanding of the shape of the Earth and related facts.

### **Mental Models of the Earth**

All direct experience supports the idea that the ground is a flat surface extending in all directions; hills and valleys are only local perturbations. The sky is parallel to the ground, the ground is always *down* and the sky is always *up*.

These ideas partition the universe into two unequal regions, above and below the Earth. They strongly imply that traveling in a straight line will bring the traveler further and further away from his or her starting point, until he or she reaches a boundary where the Earth stops. Furthermore, *down* and *up* do not vary with the observer's location; an arrow pointing upwards in one location is parallel to an arrow pointing upwards in any other location. Also, objects at a distance are hard to see either because they are occluded by another object or because the observer lacks visual acuity. Finally, the location of the sun and the moon when we cannot see them is problematic. Many children in Western (Nussbaum, 1985; Vosniadou & Brewer, 1992) as well as non-Western (Vosniadou, 1994) societies develop some version of this mental model.

The idea that the Earth is spherical has contrasting implications: It suggests that the surrounding space is uniform and it implies that a traveler who keeps going in a straight line will eventually return to his or her starting point. Furthermore, *down* and *up* varies with the observer's location; *up* in New York is not parallel to *up* in Hong Kong. Also, distant objects are invisible because they are occluded by the surface curvature. Finally, the sun and the moon are sometimes invisible because they are occluded by the planet itself.

The shift from a flat Earth to a round Earth view is an instance of deep learning. The two concepts, clearly stated, contradict each other and they influence many other aspects of one's understanding of Earth-related facts and events. Empirical research has shown that this shift takes considerable time, at least two years (Vosniadou & Brewer, 1992, Table 4) and possibly as long as six years (Nussbaum, 1985, Fig. 9.16) when it occurs spontaneously, and it requires one or more intermediate mental models. The question is whether this process can be speeded up with the displacement strategy.

### **A Virtual Asteroid**

Our approach to facilitating the shift from a flat to a round Earth is to teach the idea of a spherical planet in an unfamiliar context, unhindered by prior ideas, and then prompt the learner to apply this idea to his or her knowledge about the Earth. We accomplished the first step in this two-step procedure by using two linked virtual reality (VR) environments. The *Asteroid World* simulates the experience of walking on the surface of an asteroid with approximately 300 yards diameter. The virtual asteroid is roughly spherical

in shape and exhibits a desert-like landscape with a handful of geographical features (a bulge, a canyon, etc.), large rocks scattered here and there and fantasy structures that resemble trees made out of crystal, plus a shuttle-like space ship. The sky is black but features stars and a large, moon-like object. The *Asteroid World* was presented via a so-called *ImmersaDesk*, a VR projection device developed at the Electronic Visualization Laboratory at UIC. The *ImmersaDesk* is roughly 6 feet by 4 feet. The device supports full immersive VR with stereo vision, head tracking, hand tracking and audio; see Czernuszenko, Pape, Sandin, DeFanti, Dawe and Brown (1997) for a technical description.

When the *Asteroid World* user presses the forward-move button on the control stick, he or she has the visual perceptions that would be associated with a physical walk on a real asteroid with the same properties as the virtual one. When the diameter of the world is 300 yards, one can experience its sphericity directly. The horizon is very close, rocks and other large objects appear over the horizon very quickly, the stars in the sky are streaming past at a perceptible pace, objects are difficult to find because they are hidden by the curvature even when close by and circumnavigation is accomplished in a couple of minutes.

Our second environment, called the *Mission Control*, presents a satellite view of the virtual asteroid, projected in stereo on a computer monitor. When the user wears stereo glasses, he or she sees the virtual asteroid as a three-dimensional body floating in space against the background of stars. The various geographical features and the space ship are clearly visible. In addition, the *Mission Control* user sees the user of the *Asteroid World* as an avatar, a small space-suited figure. That is, the *Asteroid World* user and the *Mission Control* user access the same virtual reality at the same time but from different points of view. In particular, *Mission Control* can observe the movements of the astronaut on the virtual asteroid in real time. To remain in visual contact, *Mission Control* can rotate the asteroid (but not change his or her distance from it) by pressing a button on a control stick.

The *Asteroid* and *Mission Control* environments are described in more detail in Johnson, Moher, Ohlsson and Gillingham (1999). By alternating between them, the learner can experience or perceive the uniformity of the surrounding space, circumnavigation, the relativity of up and down, and occlusion by surface curvature. Furthermore, these experiences occur in a context in which the learner has no prior, conflicting ideas about the shape of the world. The second step in our learning scenario -- to transfer and apply this idea to the everyday experience of the Earth -- is described below.

## **Empirical Study**

### **Method**

**Materials** The equipment needed to project the two virtual environments was set up in a large room in a public school in a Chicago suburb. The user of one environment could not see the other environment or its user, but the two users were close enough so that they could talk to each other.

In addition, our instructional procedure required two physical models. One was a foam rubber model of the virtual asteroid, approximately eight inches in diameter, painted and equipped with a model space ship, rocks and other features to make it recognizable as a model of the virtual asteroid as seen in the Mission Control environment. The second physical model was a standard Earth globe purchased in a book store.

**Knowledge test** To assess children's understanding of the shape of the Earth, we developed a structured interview derived from those used by previous researchers (Nussbaum, 1985; Vosniadou & Brewer, 1992). The interviewer (a project team member) asked 18 questions about the shape of the Earth, the content of the region below the Earth, circumnavigation, the relativity of up and down and occlusion by curvature. The children's answers were classified at testing time by the interviewer, using a set of coding categories derived from a pilot study (Johnson, Moher, Ohlsson & Gillingham, 1999). The knowledge test interview took 10-20 minutes. The same test was used as pretest, posttest and delayed posttest.

**Subjects** All fifty second-grade children in the participating class rooms were pretested. The 28 children who answered 10 or fewer pretest questions correctly were included in the *treatment group*. Due to the small number of such students, we preferred to include all of them in a pretest-posttest design over dividing them into two groups in a treatment-control design. The 22 children who answered 11-13 questions correctly will be referred to as the *comparison group*, although it is not a control group in the statistical sense due to the non-random group assignments.

**Procedure** For the children in the treatment group, the procedure consisted of pretest, VR experience, bridging activity, posttest and delayed posttest. For the children in the comparison group, the procedure consisted of pretest and posttest.

(a) **VR experience.** The children were paired into teams of two. During the *familiarization phase*, the two experimenters who acted as guides helped the children put on the stereo glasses and guided them around their respective environments for five minutes. The two children then switched places and the familiarization process was repeated for another five minutes. During familiarization, the guides pointed out visual features related to sphericity (nearness of horizon, objects coming up over the horizon, the avatar seeming to be up side down, circumnavigation, etc.).

During the *game phase*, the children were told that they were stranded on the asteroid for lack of fuel and their task was to find extra fuel cells scattered over the asteroid so that their space ship could return to Earth. The child on the

asteroid collected the fuel cells, but the child in Mission Control assisted by locating fuel cells (the latter were clearly visible in the Mission Control view) and by giving directions to the other child. The children played this game for ten minutes, switched places and continued for an additional ten minutes. Each child thus had a total of 30 minutes (5+5+10+10) of interaction with the two VR environments.

(b) **Bridging dialogue.** Immediately after the VR experience, the two children were escorted to two different rooms for the *bridging dialogue*, a structured conversation with a member of the project team. The purpose of this dialogue was to prompt reflection on the VR experience and to help the child transfer the spherical planet idea to his or her mental model of the Earth. In each phase of the dialogue, the experimenter reminded the child of his or her VR experience with the help of the physical model of the asteroid, re-enacting some facet of that experience (e.g., circumnavigation) with toy figures. The experimenter then shifted the child's attention to the globe of the Earth and told him or her that what was the case on the asteroid is also the case on the Earth, enacting the relevant facet with toy figures vis-à-vis the Earth globe. The conversation then switched back to the asteroid model to cover another facet of sphericity, which was also illustrated with the Earth globe; and so on. The bridging dialogue took approximately 15 minutes.

(c) **Posttest.** The subjects were posttested 24 hours after the learning experience.

(d) **Delayed posttest.** The delayed posttest was administered four months after the learning experience.

## Results

Figure 1 shows the outcome. The performance of the treatment group increased from a mean of 7.3 correct answers on the pretest to a mean of 12.9 correct answers on the posttest. We tested the posttest mean with a single-sample t-test, using the pretest mean as the comparison value. The difference is statistically significant ( $t = 13.68$ ,  $p < .000$ ). Hence, the treatment group improved from pretest to posttest. The magnitude of the improvement is  $12.9 - 7.3 = 5.6$  scale units, which is 1.9 times the standard deviation on the pretest. The mean number of correct answers on the delayed posttest was 11.4. Almost the entire pre- to posttest improvement was retained four months later.

Because the posttest questions were identical to the pretest questions, there is a possibility that the improvement in the children's understanding of the Earth was caused by the test itself. We can use the comparison group to measure the effect of the test. The members of the comparison group were pre- and posttested but did not undergo the VR experience. The mean number of correct answers in this group was 12.2 on the pretest and 14.0 on the posttest. A single-sample t-test of the posttest mean, using the pretest mean as comparison value, showed that the pre- to posttest difference is statistically significant ( $t = 4.6$ ,  $p < .000$ ).

Hence, taking the test prompted some learning, even in the absence of the VR experience. The magnitude of the effect is  $14.0 - 12.2 = 1.8$ , which is .6 times the standard deviation on the pretest. This improvement is considerably smaller than the improvement in the treatment group. Due to the non-random assignment of subjects to groups, the evidence provided by this analysis is admittedly weaker evidence than that provided by a proper control group.

Figure 1. The mean number of correct answers on three test occasions.

A t-test for independent samples shows that the difference between the treatment and comparison groups on the pretest was statistically significant ( $t = 10.71, p < .000$ ). There was no significant difference between the two groups on the posttest ( $t = 1.90, p > .06$ ).

## Discussion

The children in the treatment group almost doubled their understanding of the shape of the Earth, as measured by our knowledge test. The treatment group initially performed considerably below the comparison group, but performed as well as the latter on the posttest. That is, our learning scenario allowed those children who had not spontaneously acquired an understanding of the shape of the Earth to catch up with those who had. Unlike the spontaneous acquisition process, which occurs over several years (Nussbaum, 1985; Vosniadou & Brewer, 1992), the displacement scenario enabled children to acquire the target idea in one day. They retained it four months later.

Why was the displacement scenario successful? An explanation for these results must deal with the paradox of deep learning: Central ideas are seldom transformed by novel input; they are too protected by the surrounding belt of auxiliary ideas and beliefs. So how does deep learning ever come about? The cross-domain transfer hypothesis claims that central ideas are not transformed but replaced by ideas transferred from other contexts, domains or situations (Chi, 1992). In the present study, both our virtual asteroid and the Earth can be said to belong to the domain of elementary astronomy, but the crucial point for learning is that our

subjects had no prior knowledge about the shape of the virtual asteroid but they did about the shape of the Earth.

This model of deep learning differs significantly from other models, e.g., attempts to view deep learning in children as analogous to scientific theory change (Gopnik & Meltzoff, 1997; Hewson & Hewson, 1984; Posner et. al, 1982). One difficulty with this theory theory, as it has come to be known, is that human beings are not conspicuously good at evaluating evidence, presumably the central process in theory change. The theory theory describes cognitive change in logical rather than naturalistic terms (Ohlsson, 2000). It does not explain our results, because we did not present our subjects with evidence of any kind: We familiarized them with a previously unfamiliar environment and then asserted that what was true in that environment is also true about the Earth. The cross-domain transfer hypothesis does better because, unlike the theory theory, it does not claim that dissatisfaction with prior ideas is a prerequisite for learning. Prior ideas are not necessarily falsified or rejected; instead, they fall into disuse when another, more useful idea becomes available.

Unlike the knowledge-in-fragments theory of DiSessa (1988, 1993) and Smith, DiSessa and Roschelle (1995), the present theory does not represent deep learning as a process of clarifying, organizing and systematizing so-called phenomenological primitives. Instead, it claims that a central idea that has been transferred from a different context can serve as a starting point for a new understanding of the target context. One difficulty with the knowledge-in-fragments view is that it is unclear how systematizing and organizing can engender a new idea that directly contradicts one of the ideas available at the outset. For example, it seems implausible that experience of the virtual asteroid would prompt our subjects to organize their no doubt fragmented knowledge of the Earth in such a way that they suddenly realized that it must be spherical.

Although our results are more consistent with the cross-domain transfer hypothesis than with these alternative hypotheses, the present study is limited in several respects. The number of children was small, we had no proper control group and the results do not allow us to separate the effects of the virtual reality experience from the effects of the bridging dialogue. We are currently completing a follow-up study that addresses these limitations.

In addition to its theoretical interest, the cross-domain transfer hypothesis might have practical importance. It is a commonplace in educational discourse that good instruction should connect to the students' prior knowledge and experience. However, this pedagogical tactic is unlikely to be productive in those situations in which the target subject matter conflicts with the students' prior knowledge (Ohlsson, 1999; Strike & Posner, 1992). The alternative is to teach the new idea in a different context and help the student transfer it to the target domain. Because many scientific ideas conflict with ideas derived from experience (e.g.,

inertia), the displacement scenario has the potential to be a useful tool in science education.

## Abstract

This paper attempts to draw a bridge between psychophysics and memory research by proposing a memory-based model of category rating. The model is based on the cognitive architecture ACT-R and uses *anchors* stored in memory that serve as prototypes for the stimuli classified within a response category. The anchors are retrieved by a partial matching mechanism and updated dynamically by an incremental learning mechanism. Anchors also have base-level activations that reflect the frequency and recency of the responses. These mechanisms give rise to sequential effects and nonuniform response distributions. A psychological experiment involving category rating of physical length is reported and the predictions of the model are compared against the empirical data. The psychophysical implications of the model are discussed.

## Introduction

Category rating is a widely used method of data collection in experimental psychology. A category-rating situation arises whenever the participants are asked to assign each stimulus to one of several ordered categories such as *1, 2, ..., 9* or *very dissimilar, ..., very similar*. Procedures of this kind are common for many studies ranging from psychophysical scaling to similarity judgment to personality inventories. Therefore a detailed analysis of the cognitive mechanisms underlying this task is potentially relevant to a diverse set of situations.

Figure 1: Simplified decomposition of the category-rating process. The external stimulus  $S$  maps to an internal magnitude  $M$  which in turn gives rise to the overt response  $R$ .

A rough decomposition of the process of category rating is presented in Figure 1. (This diagram is by no means complete or accurate; it is provided for expository purposes only.) The *perceptual subsystem* maps the external stimulus  $S$  onto an internal representation  $M$  on a psychological continuum. In this paper the internal representation is called *magnitude*. The magnitude  $M$  then serves as a basis for generating an overt response  $R$  on the category scale. The latter

transformation is the responsibility of the *central* (or *cognitive*) *subsystem*. Both subsystems are characterized with internal states that unfold in time and may differ from trial to trial. Thus each box in Figure 1 has underlying dynamics and the whole system is more complex than the open-loop pipeline suggested by the diagram.

The present paper focuses on the central subsystem and the computational mechanisms converting subjective magnitudes into external reports. While the perceptual aspects of the process are certainly important, they are not central to the research reported here. Therefore the research strategy has been to try to minimize the contribution of the perceptual subsystem so that the properties of the central one can show through. This dictated the choice of a modality for which the perceptual transformation is as simple as possible—physical length.

The empirical relation between stimulus intensities  $S$  and averaged category ratings  $R$  tends to follow a power function:  $R = k \cdot S^n$  (Stevens, 1957). The exponent  $n$  is characteristic of the perceptual modality. For physical length, this exponent is very close to 1.0 (Stevens, 1957). In other words, the scale is linear. Thus it seems reasonable to assume that the perceptual subsystem delivers veridical representations of physical length, with little if any systematic distortions (Krantz, 1972). Under this assumption, any patterns in the category-rating data for length are largely due to the central subsystem.

The psychophysical literature reports several phenomena related to category rating. The most basic finding is that the participants are able to perform this task without major difficulties and provide robust and regular data: the average rating values vary smoothly with stimulus intensity (Stevens, 1957). This is true whether or not feedback is provided (e.g. Ward & Lockhead, 1970). The second major finding is Stevens' power law stated above. In addition to these first-order results, there are several second-order effects as well.

The *sequential effects* are of special interest here because they shed light on the dynamics of the rating process. Numerous studies have indicated that the successive trials in a rating experiment are not independent (Ward & Lockhead, 1970; Jesteadt et al., 1977; Petzold, 1981; Schifferstein & Frijters, 1992). The responses, regarded as a time series, show autocorrelational structure. Typically the data are analyzed using multiple regression in which the stimulus  $S_{t-1}$  and the response  $R_{t-1}$  on the preceding trial enter as predictors after the contribution of the current stimulus  $S_t$  has

been partialled out. A robust finding is that current responses tend to be contrasted (i.e. negatively correlated) with previous stimuli and assimilated (positively correlated) toward previous responses. Moreover, there is an interaction between the two time-lagged variables  $S_{t-1}$  and  $R_{t-1}$ . The assimilation towards the previous response seems to be modulated by the difference between the two consecutive stimuli  $S_{t-1}$  and  $S_t$  (Jesteadt et al., 1977; Petzold, 1981). The closer the stimuli, the stronger the assimilation.

Theoretical analysis of the task also invites the hypothesis that some form of memory is involved in the rating process. Consider a trial in a category-rating experiment. The presentation of the stimulus evokes some subjective percept in the participant. The participant is then faced with the problem of communicating this subjective percept using the particular response scale chosen by the experimenter. There is no a priori correspondence between the subjective magnitudes and the response categories. Such correspondence must be established at the beginning of the experiment and then applied consistently until the end. This is a role for memory.

This hypothesis is supported by a study of Ward and Lockhead (1970). The experiment involved 8 sessions on 8 consecutive days. Feedback was provided at the end of each trial. Unbeknown to the participants the feedback was manipulated so that the response categories were associated with different stimuli on different days. This caused systematic shifts in participants' responses.

The thesis of the present paper is that memory plays an important role in category rating and in particular in the transition from internal magnitudes to overt responses. Memory maintains the consistency of responses over periods of hours and even days. Moreover, the hypothesis is that failures to achieve perfect consistency—manifested as response drifts, sequential effects, and context effects—are due to the plasticity of the memory system and reflect the dynamics of its operation.

This paper reports the initial steps towards a memory-based theory of category rating. The theory is instantiated in a computational model called ANCHOR and the predictions of the model are compared with empirical data.

## Psychological Experiment

The ANCHOR model makes detailed predictions on a trial-by-trial basis. To estimate the parameters of the model and evaluate its adequacy as a psychological theory one needs empirical data at the same level of granularity. The psychophysical literature cited in the introduction reports aggregate data only and hence falls short of this standard. Therefore, a psychological experiment was carried out. In addition to providing the necessary data, it replicates the sequential effects from the literature and tests the assumption of linearity of the scale of physical length.

## Method

**Stimulus Material.** The stimuli were pairs of white dots presented against black background on a 17-inch Apple-Vision monitor. The only independent variable in the experiment was the distance between the two dots measured in pixels. The distance used on each trial was drawn independ-

ently from a uniform distribution ranging from 250 pixels (80 mm) to 700 pixels (224 mm). The viewing distance was approximately 500 mm. The imaginary segment formed by the dots was always horizontal and was randomized with respect to its absolute horizontal and vertical position on the screen. The stimulus set for each participant was generated and randomized separately. The maximal distance representable on the monitor was 1000 pixels (320 mm). Each dot was roughly circular in shape with a diameter of 16 pixels (5 mm).

**Participants:** 24 students participated in the experiment to satisfy a course requirement.

**Procedure.** The participants were asked to rate the “distance between the dots” on a scale ranging from 1 to 9. The participants entered their responses on the numeric keypad of the computer keyboard. Each trial began with a 500 ms beep followed by 3300 ms stimulus presentation followed by 200 ms inter-trial interval. There were 17 demonstration and 450 experimental trials divided into 10 blocks with short rest periods between the blocks. The demonstration presented stimuli of length 275, 325, 375, ..., 625, 675, 625, ..., 275 pixels and the participants were encouraged to practice pressing the keys 1, 2, ..., 8, 9, 8, ..., 1. No feedback was given during the experimental trials. The whole procedure lasted about 40 minutes.

## Results and Discussion

The data are analyzed at the level of individual participants.

**Linearity of the Scale.** To estimate the exponent of Stevens' power law, a function of the form  $R = a + k \cdot S^n$  is fitted to the data of each individual participant. The exponents  $n$  range from 1.01 to 1.12 in the sample of 24 participants, with mean 1.06. Thus the exponent is empirically indistinguishable from unity for all participants. (The correlations between the functions  $S^{0.95}$ ,  $S^{1.00}$ , and  $S^{1.10}$  are greater than 0.99 in the domain [250;700].) This suggests that the assumption of linearity of the scale is correct, at least within the precision of measurement.

**Overall Accuracy.** The linearity of the scale allows the data to be analyzed by simple linear regression of  $R$  on  $S$ . The squared correlation coefficient  $R^2$  is a measure of the accuracy of the respective participant. It ranges from 0.65 to 0.91 for the 24 participants, with mean 0.80 and std.dev. 0.070. In other words, the immediate stimulus accounts for full three quarters of the response variance, sometimes up to 90%.

**Response Distributions.** Even though the stimuli are uniformly distributed, the responses are not. Figure 2 shows the response distributions for two representative participants. A marked feature of these distributions is the predominance of responses in the middle of the scale at the expense of extreme ones. The response standard deviation ranges from 1.20 to 2.44, with mean 1.96 and s.d. 0.28. For comparison, if the 450 responses were evenly distributed in 9 categories, the standard deviation would be 2.58.

Figure 2: Response distributions for two representative participants.

It seems unlikely that the perceptual subsystem maps the uniform stimulus distribution onto a highly non-uniform distribution of internal magnitudes. Therefore the shape of the response distribution appears to be largely due to the cognitive subsystem. It is possible that the participants reserve the extreme responses for distances that are very short (close to zero) or very long (filling the width of the screen). Such extreme stimuli are not presented during the experiment and this may be one of the reasons for the non-uniformity of responses. However, this explanation does not address the peak in the middle of the scale. The memory-based theory of category rating offers an alternative explanation in terms of self-reinforcing buildup of strength for the frequent responses and corresponding loss of strength for the infrequent ones.

**Sequential Effects.** A multiple linear regression is performed with the following variables entering as predictors: the current stimulus  $S_t$ , the previous stimulus  $S_{t-1}$ , and the previous response  $R_{t-1}$ . The signs of the regression coefficients of the time-lagged variables are of special interest. For the previous stimulus  $S_{t-1}$ , the standardized coefficient  $\beta_s$  ranged from  $-0.53$  to  $-0.08$ , with mean  $-0.25$  and s.d.  $0.10$ . Conversely, the standardized coefficient  $\beta_r$  for the previous response  $R_{t-1}$  ranged from  $+0.15$  to  $+0.55$ , with mean  $+0.30$  and s.d.  $0.10$ . Thus all 24 participants without exception show evidence of stimulus-driven contrast and response-driven assimilation.

Additional regression analyses involving interaction terms replicate the finding of Jesteadt et al. (1977) that the assimilation towards  $R_{t-1}$  is modulated by the difference between the two consecutive stimuli  $S_{t-1}$  and  $S_t$ . These analyses are not reported here because of lack of space.

## Memory Based Model of Category Rating

As argued in the introduction, memory seems to play an important role in the category-rating process. The remainder of this paper outlines one particular proposal about the computational mechanisms that may carry out this process. The ANCHOR model proposed here is based on a general theory of memory incorporated in the ACT-R cognitive architecture (Anderson & Lebière, 1998). The ACT-R theory is consistent with a broad range of memory phenomena. Thus ANCHOR draws a bridge between psychophysics and memory research. The following two subsections describe the model first in general terms and then with details and equations.

## Main Principles of the Model

The centerpiece of the ANCHOR model is the construct of an *anchor*. An anchor is an association between an internal magnitude and a category on the response scale. There is one anchor per category and it can be construed as an internal representation of the prototypical member of this category.

The collection of all anchors defines a mapping from the continuum of magnitudes to the discrete categories of the response scale. This mapping is partly constrained and partly arbitrary. The constraints come from the demand for homomorphism implied by the category-rating task. There is intrinsic ordering of the intensity of the physical stimuli and hence of the magnitudes on the subjective continuum. Also, there is ordering of the response categories. When reporting their subjective magnitudes, the participants try to align the ordering of the two domains.

Another constraint implied by the task is to maintain consistency over time. If, for whatever reason, a stimulus is labeled with a particular response on a given trial, there is pressure to label this stimulus with the same response on subsequent trials. This extends not only to the stimulus that happened to be presented but to other stimuli that evoke similar subjective magnitudes.

These constraints motivate the following mechanisms of the ANCHOR model. When a stimulus is presented and encoded as an internal magnitude, a *partial matching mechanism* activates an anchor whose magnitude is similar to the magnitude of the target stimulus. In so far as anchor magnitudes are relatively stable, categorization of the stimuli is consistent over time.

The partial matching is stochastic and depends on other factors besides similarity (viz. recency and frequency, discussed below). Therefore it is not guaranteed to retrieve on each trial the anchor that best matches the target magnitude. In the cases when there is large discrepancy between the target magnitude evoked by the stimulus and the anchor magnitude retrieved from memory, a *correction mechanism* may increment or decrement the response suggested by the anchor. The correction mechanism is stochastic and error-prone too but it does tend to enforce homomorphism between magnitudes and responses.

Phenomenologically, an introspective report of a category-rating trial might run like this, “I see the dots... The distance looks like a 7... No, it’s too short for a 7. I’ll give it a 6.”

So, the stimulus has been encoded, matched against anchors, and a response has been produced. Is this the end of the trial? According to the ANCHOR model and the broader ACT-R theory (Anderson & Lebière, 1998), the answer is no. The cognitive system is plastic (within limits) and each experience seems to leave a mark on it. It is impossible to step into the same river twice. The model postulates an obligatory *learning mechanism* that pulls the magnitude of the relevant anchor in the direction of the magnitude of the stimulus that has just been presented. Thus each trial results in a slight change of the magnitude of one of the anchors—namely the one that corresponds to the response given on that particular trial. The notion of obligatory learning is similar to the ideas of Logan (1988), although ANCHOR learns prototypes rather than individual instances.

The implications of this incremental learning mechanism are worth considering in detail. After a long sequence of trials, each anchor magnitude ends up being a weighted average of the magnitudes of all stimuli classified in the corresponding response category. Thus the anchors are true prototypes. However, recent stimuli weigh more heavily than earlier ones, introducing bias. The influence of the initial instructions and demonstrations gradually wash away.

More importantly, the performance of the system on each trial depends on the history of its performance on previous trials. This makes it a dynamic system capable and even forced to exhibit gradual shifts, sequential effects, and self-reinforcing preferences. Each run of the model becomes idiosyncratic in systematic ways apart from the random noise even when tested on the exact same sequence of stimuli.

One final aspect of the model remains to be introduced. There is abundant evidence that the human memory system is sensitive to the frequency and recency of the encoded material. These two factors enter the ACT-R theory and the ANCHOR model through a construct called *base-level activation* (BLA). Each memory element, anchors included, has some base-level activation that goes up and down with time. The partial matching mechanism is sensitive not only to the similarity between the target magnitude and the anchor magnitudes but also to the activation levels of the anchors. Overall, anchors with high BLA are more likely to win in the matching process than anchors with low BLA, the target stimulus notwithstanding.

The form of the base-level learning equation (Eq. 6 below) entails that when a response is produced on a trial the BLA of the corresponding anchor receives a sharp transient boost followed by small residual increase. On the other hand, when some response is not used for a long time the activation of the corresponding anchor gradually decays away. In terms of observable behavior, the rapid transient manifests itself as sequential response assimilation and the long-term overall strength leads to rich-gets-richer differentiation of the response frequencies.

## Details and Equations

Figure 3 shows a schematic diagram of the various quantities used in the model and the dependencies among them.

Figure 3: Schematic diagram of the quantities used in the model: physical intensity of the stimulus  $S$ , target magnitude  $M$ , anchor magnitude  $A$ , increment  $I$ , and overt response  $R$ .

The perceptual subsystem (cf. Figure 1) is modeled by a single equation [1]. It transforms the physical intensity of the stimulus  $S$  into an internal magnitude  $M$ . The transformation is linear, with some multiplicative noise. The magnitudes are arbitrarily scaled between 0.25 and 0.70, given that  $S$  varies between 250 and 700 pixels. The random variable  $\epsilon$  is normally distributed with zero mean. Thus the term  $(1+\epsilon)$  is centered around 1.0. The standard deviation of

the noise is a free parameter of the model. In the simulation experiments reported in the next section this parameter was set to 0.050. The multiplicative relationship between the scale value (i.e. the mean of the magnitude distribution induced by a given stimulus  $S$ ) and the noise term implements Ekman's law (Ekman, 1959).

$$M = S \cdot (1 + \epsilon) / 1000 \quad [1]$$

There are 9 anchors with magnitudes  $A_1 \dots A_9$ , respectively. The partial matching mechanism has to select one of them according to their similarity to the target magnitude  $M$  and their base-level activations  $B_1 \dots B_9$ . This process is governed by two equations. First, a *score* is produced for each anchor according to Eq. 2. Second, one anchor is chosen according to the *softmax* Equation 3.

$$Score_i = B_i - MP \cdot |M - A_i| \quad [2]$$

The *mismatch* (or dissimilarity) between two magnitudes is simply the absolute difference between them. The mismatch is multiplied by a *mismatch penalty factor*  $MP$  and subtracted from the base-level activation of the anchor to produce the combined score for this anchor.  $MP$  is a free parameter of the model that scales the mismatches relative to the activation values. It was set to 7.0 in the simulations.

$$P_i = \exp(Score_i / t) / \sum_j \exp(Score_j / t) \quad [3]$$

Equation 3 converts scores into retrieval probabilities.  $P_i$  is the probability of retrieval of anchor  $i$  and  $\exp(\cdot)$  denotes the exponentiation function. The *temperature*  $t$  is a free parameter of the model controlling the degree of non-determinism of the partial-matching process. It was set to 0.40 in the simulations.

Having retrieved an anchor, the model has to determine the correction  $I$  to produce the final response. Under the current settings of the model, the correction can be 0,  $\pm 1$ , and occasionally  $\pm 2$ . The correction depends, stochastically, on the discrepancy between the target magnitude  $M$  and the anchor magnitude  $A$ . One free parameter of the model— $d$ —defines a set of five *discrepancy reference points*  $\{-2d, -d, 0, d, 2d\}$ . They are compared with the algebraic difference  $(M - A)$  to produce *correction scores*:

$$CorrScore_k = |d_k - (M - A)|, \quad k = -2 \dots +2 \quad [4]$$

The correction scores are converted to choice probabilities by an equation analogous to Eq. 3. The only differences are that the correction scores enter with negative signs, thus transforming the softmax rule into softmin, and that a separate temperature parameter is used. In the simulations this parameter was set to 0.040. The discrepancy reference parameter was  $d=0.090$ . To illustrate these settings, suppose the anchor magnitude  $A$  is 0.050 below the target magnitude  $M$ , which is roughly the width of one response category. Then there is 51% chance that the model will increment the anchor response by +1, 39% chance to leave it unchanged, and marginal chance to increment it by +2 or decrement it.

The final response  $R$  is the algebraic sum of the anchor label and the increment, clipped between 1 and 9 if needed.

At the end of the trial the learning mechanism updates the magnitude of the anchor corresponding to the response  $R$ . (Note that this does not necessarily coincide with the anchor retrieved from memory.) The anchor magnitude  $A$  is updated according to Eq. 5, which is a form of competitive learning.

The learning rate  $\alpha$  weighs the most recent trial relative to earlier ones. The simulation experiments used  $\alpha=0.50$ .

$$new\_A = \alpha \cdot M + (1-\alpha) \cdot old\_A \quad [5]$$

The base-level learning equation is somewhat less transparent. The ACT-R theory postulates Equation 6a which contains an explicit term for each instant the anchor is updated (Anderson & Lebière, 1998, p.124). Suppose a particular response has been given at time lags  $t_1, \dots, t_n$  from the present trial. Then the base-level activation  $B$  of the corresponding anchor is the logarithm of a sum of powers [6a], where  $d$  is a decay parameter.

$$B = \ln \left( \sum_i t_i^{-d} \right) \quad [6a]$$

Because Equation 6a is computationally expensive, the model uses Eq. 6b which closely approximates the theoretical formula. The approximation disregards the detailed update history and retains only the time lag since the last usage  $t$ , the lag  $T$  since the beginning of the experiment, and the total number of times the corresponding response has been given up to the current trial. In the simulation experiments the decay parameter was set to  $d=0.5$ , which is a default value used in many ACT-R models. The duration of each trial was 4 sec, as in the psychological experiment.

$$B = \ln \left[ t^{-d} + n \cdot (T^{1-d} - t^{1-d}) / [(1-d)(T-t)] \right] \quad [6b]$$

Equations 2, 3, 4, and 6a are taken verbatim from the ACT-R architecture (Anderson & Lebière, 1998) and thus establish continuity between the ANCHOR model and a broad spectrum of memory-related models. Equation 1 is ANCHOR's connection to Stevens' and Ekman's psychophysical laws.

## Evaluation of the Model

### Simulation Experiment

In order to test the model, its computer implementation was run on the 24 random sequences of stimuli used in the psychological experiment. To mimic the effect of the introductory demonstration, the magnitudes of the anchors were initialized as follows. Anchor 9 was set to 0.800—a compromise value between the longest stimulus presented on the demonstration (675 pixels) and the total width of the screen (1000 pixels). Anchor 1 was initialized to 0.150 and the remaining anchors were evenly spaced in between. The other parameters were set as reported in the previous section. The model generated 24 sequences of responses which were then analyzed in the same way as the psychological data.

Table 1: Comparison of the performance of the model and the psychological data. See text for details.

Statistic	Human data				Model			
	min	mean	max	s.d.	min	mean	max	s.d.
Accuracy ( $R^2$ )	.65	<b>.80</b>	.91	.07	.65	<b>.76</b>	.84	.05
Resp. std.dev.	1.20	<b>1.96</b>	2.44	.28	1.58	<b>1.81</b>	2.57	.21
Multiple $R^2$	.67	<b>.83</b>	.93	.07	.73	<b>.78</b>	.84	.03
Increase in $R^2$	.00	<b>.02</b>	.06	.01	.00	<b>.02</b>	.10	.02
$\beta$ for $S_t$	.80	<b>.90</b>	.93	.04	.80	<b>.87</b>	.92	.03
$\beta$ for $S_{t-1}$	-.53	<b>-.25</b>	-.08	.10	-.47	<b>-.23</b>	-.10	.09
$\beta$ for $R_{t-1}$	+.15	<b>+.30</b>	+.55	.10	+.13	<b>+.25</b>	+.53	.10

Table 1 summarizes the outcome of these various analyses and compares the performance of the model with the human data. The overall accuracy of the model, operationalized as the squared correlation between stimuli and responses, ranges from 0.65 to 0.84 in the sample of 24 runs, with mean 0.76 and standard deviation 0.046. The mean  $R^2$  for the psychological data is 0.80. The degree of non-uniformity of the response distribution is reflected in the standard deviations reported in the second row of Table 1.

The remainder of Table 1 summarizes the multiple regression analysis of the response  $R_t$  on the current stimulus  $S_t$ , previous stimulus  $S_{t-1}$ , and previous response  $R_{t-1}$ . The model shows the same pattern of sequential effects as the psychological data.

Overall, the results of the simulation experiment suggest that the ANCHOR model closely matches human category-rating behavior. The biggest discrepancy between the two data sets is that the model responses are less variable. The human data, however, includes both within-subject and between-subject variability whereas the parameter settings of the model were fixed for all 24 runs. Individual differences can be modeled by using different parameter settings for the different runs.

### Explanation of the Empirical Phenomena

The fact that a model fits the data indicates that its computational mechanisms hang together and can be brought in line with the empirical observations. A much more acid test for the utility of the model, however, is the degree to which it contributes to the theoretical understanding of the psychological phenomena. This closing section discusses the empirical effects in light of the ANCHOR model.

**Nonuniformity of the Response Distribution.** The model shifts the level of theorizing from aggregate scale values to individual responses. At that level of granularity the entire response distribution becomes important. Two salient features of this distribution appear to be the predominance of responses in the middle of the scale and the relative infrequency of extreme responses (Figure 2). Several factors conspire to produce such distributions in the model. The base-level learning mechanism (Eq. 6a/b) tends to differentiate the response frequencies—more frequent anchors build up strength which in turn makes them more likely to be retrieved in the future. This makes flat distributions unstable—small differences tend to grow. This self-reinforcing dynamics cannot go out of hand, however, because of three stabilizing factors. First and foremost, the immediate stimulus controls about 75% of the response variance and hence the responses cannot stray too much from the stimuli. Second, the correction mechanism redistributes the strength among neighboring anchors. This inhibits the formation of isolated spikes or gaps in the distribution, making the smooth unimodal shape the most stable configuration. The third stabilizing factor is related to the context effects discussed below.

**Context Effect.** If the stimuli control 75% of the response variance and the base-level learning tends to amplify inequalities, what happens when the stimuli are unevenly

distributed themselves? It may appear that the model would produce responses that are even more skewed. This would directly contradict the finding of several studies (Parducci, 1965; Parducci & Wedell, 1986; Schifferstein & Frijters, 1992). Empirically, the responses tend to be less skewed than the stimuli, not more so. However, simulation experiments with the ANCHOR model that are too long to be detailed here indicate that it produces context effects consistent with the empirical data. In a nutshell, this is due to the anchor adjustment Equation 5. Because the anchors are prototypes, they tend to cluster in those regions of the magnitude continuum that are densely populated with stimuli. In turn, this reduces the skewness of the response distribution.

**Sequential Effects.** The positive autocorrelation between responses on successive trials is a direct consequence of the recency component of base-level activations (Eq. 6a/b). When a particular response is given, the BLA of its corresponding anchor goes up, which in turn improves the probability of retrieving the same anchor on the next trial. This produces assimilation towards the previous response. However, the increase of the activation level matters only when the two successive stimuli are similar enough (cf. Eq. 2). If they are too far apart, the response on the first trial primes an anchor that is too remote from the target on the second trial to have any influence on the final outcome. The closer the two consecutive stimuli, the stronger the assimilation.

Another sequential effect is the negative correlation between the response  $R_i$  on a given trial and the stimulus  $S_{i-1}$  on the previous trial. Part of this effect is probably due to the perceptual subsystem and its tendency to enhance contrasts. The ANCHOR model, however, has a deliberately simplified front end that precludes any interaction between the stimuli at the perceptual level. Still, the model exhibits contrast effects due to the plasticity of anchor magnitudes (Eq. 5) and the discrepancy penalizing aspect of the partial matching mechanism (Eq. 2). The magnitude of the past stimulus  $S_{i-1}$  is averaged into the magnitude of one of the anchors, which then serves as a proxy of that stimulus on subsequent trials. The anchor magnitudes  $A_i$  are subtracted from the new target magnitude  $M$  during the partial matching process. In other words, one of the  $A_i$  terms in Eq. 2 is positively correlated with  $S_{i-1}$ ,  $M$  is positively correlated with  $R_i$ , and  $A_i$  and  $M$  are subtracted from each other. This creates negative relationship between the response  $R_i$  and the previous stimulus  $S_{i-1}$ .

**Memory-Related Effects.** The anchors are stored in memory and decay only slowly with time. Therefore, the mapping from stimuli to responses implicit in these anchors can influence the performance hours and even days later.

This paper argues in favor of the hypothesis that category ratings are produced in a memory-based manner. A range of category-rating phenomena seem to arise naturally from a set of principles that are also consistent with a large body of memory research. In so far as the ANCHOR model is successful, it illustrates the advantages of its integrative methodology and the utility of general architectures for cognitive modeling.

## Acknowledgments

This research is supported in part by grant AFOSR F49620-99-10086 awarded to John Anderson. The authors thank Stefan Mateeff, Stephen Gotts, and two anonymous reviewers for their valuable comments on the paper. The contribution of Stefan Mateeff is especially gratefully acknowledged.

## Abstract

We present an approach towards a simple, explicit model of saccadic selectivity in visual search tasks. The model in its present state includes weights for target-distractor similarities and fixation field size as its only adjustable parameters. Based on these, the model predicts the statistical distribution of saccadic endpoints for any given visual search display. Besides providing an explicit and complete mathematical specification of the model, we demonstrate the performance of its computer simulation in a triple-conjunctive search task. The model successfully simulates empirical data reported by Williams and Reingold (in press).

## Modeling Visual Search

How do we detect a prespecified target item among a set of distractors? Numerous studies employing the paradigm of *visual search* have attempted to answer this question (see Treisman, 1988 and Wolfe, 1998, for reviews). In a typical visual search task, subjects have to decide whether a search display contains a designated target item, indicating their decision by pressing either a “yes” or a “no” button. In most studies, reaction times (RTs) and error rates were analyzed as a function of the number of items in the display (display size). The majority of current models of visual search were based on data obtained within this paradigm.

An early attempt to model visual search is the Feature Integration Theory (Treisman & Gelade, 1980; Treisman, 1988). This theory proposes the existence of preattentive *feature maps*, one for each stimulus dimension such as color or shape. These maps are created in parallel after stimulus onset and allow immediate target detection if the target is defined by a unique feature in any single dimension (feature search). If the target is defined by a specific combination of features (conjunctive search), attention is necessary to locally combine the information of the corresponding feature maps. As a result, subjects have to inspect the display in an item-by-item fashion until target detection or exhaustive search. The Feature Integration Theory thus explains the finding that reaction time tends to increase with display size in conjunctive search tasks, while it is almost constant in feature search tasks.

A more recent approach is the Guided Search Model (Cave & Wolfe, 1990; Wolfe, Cave & Franzel, 1989; Wolfe,

1994), which proposes a two-stage model of visual search. In the first, parallel stage, an *activation map* containing likely target locations is created on the basis of both top-down and bottom-up sources of activation. The second, serial stage uses the activation map to guide visual attention from item to item, starting with the item with the highest activation, then proceeding to the second highest, and so on, until the target is found or the current activation falls below a certain threshold (see Chun & Wolfe, 1996).

Besides many variations of these two models, there are also more complex approaches like the one by Grossberg, Mingolla and Ross (1994). Their model uses artificial neural networks to achieve perceptual grouping of search displays into subregions. Visual search is assumed to proceed serially between these subregions and in parallel within them.

Recently, several researchers have analyzed participants' eye movements during visual search to supplement traditional RT and accuracy measures (e.g. Findlay, 1997; Hooge & Erkelens, 1999; Jacobs, 1987; Luria & Strauss, 1975; Motter & Belky, 1998; Rayner & Fisher, 1987; Scialfa & Joffe, 1998; Shen, Reingold, & Pomplun, in press; Viviani & Swenson, 1982; Williams, Reingold, Moscovitch, & Behrmann, 1997; Williams & Reingold, in press; Zelinsky, 1996; see Rayner, 1998, for a review). Some of these studies have further examined *saccadic selectivity*, i.e. the proportion of saccades directed to each distractor type, by assigning saccadic endpoints to the closest display item. Such studies have found a strong selectivity towards distractors sharing a particular feature with the target item (e.g. Findlay, 1997; Hooge & Erkelens, 1999; Luria & Strauss, 1975; Motter & Belky, 1998; Scialfa & Joffe, 1998; Shen, Reingold & Pomplun, in press; Williams & Reingold, in press; but see Zelinsky, 1996). Given that eye movements are usually accompanied by shifts of attention (see Hoffman, 1998, for a review), it seems that subjects can selectively attend to a critical subset of items in the display rather than perform an item-by-item search as suggested by the original Feature Integration Theory.

To date, no explicit model has been proposed which allows for simulating saccadic selectivity in visual search. In the present article, we propose such an approach, referred to as the Area Activation Model. Following the description of

the model, we examine its performance by simulating the saccadic selectivity findings reported by Williams and Reingold (in press).

### The Area Activation Model

The Area Activation Model is based on assumptions concerning three aspects of visual search performance: (1) the extent of available resources for processing, (2) the choice of fixation positions, and (3) the scan-path structure.

**Processing resources** - The extent of available resources for processing is determined by a two-dimensional Gaussian function with its peak centered at the current gaze position (e.g. Pomplun, Ritter & Velichkovsky, 1996). The standard deviation  $\sigma_f$  of the Gaussian function would be affected by a variety of factors such as task difficulty, item density, and item heterogeneity, but in essence should be a function of the area from which information is extracted during a fixation (henceforth “fixation field”). For example, if the target and distractors are easily discriminable and the density and heterogeneity of items are low, we would expect the fixation field to be larger than when discriminability is low and density and heterogeneity are high. This theoretical measure is likely to be correlated with the number or density of fixations in a given area. If the fixation field is smaller, we would expect more fixations per display area. In fact, in the current simulation we are using the empirically observed number of fixations per trial to adjust  $\sigma_f$ .

**Fixation positions** - Fixation positions are chosen to optimize the amount of information acquired. However, the execution of saccades entails a certain amount of error, which causes fixations to deviate from these optimal positions. Another source of error in empirical data is related to inaccurate measurement of eye movements. It is important for a valid comparison between empirical and simulated data to consider both saccadic error and measurement error.

For every point in the display it is possible to calculate its informativeness or relevance to the search task, creating an activation map. In the present simulation, we use weights corresponding to features along several dimensions to determine activation for individual items. A variety of models may suggest different activation maps (e.g. Cave & Wolfe, 1990; Wolfe, 1994).

In order to make the method transparent and applicable to a wide variety of tasks, we provide a general, explicit specification of the model. A search display consists of  $N$  items with positions  $(x_n, y_n)$  and features  $f_n^{(d)}$  along  $D$  dimensions,  $n \in \{1, \dots, N\}$ ,  $d \in \{1, \dots, D\}$ . The search target has the features  $t^{(d)}$ . Each dimension  $d$  is assigned a weight  $w^{(d)}$ , which currently has to be estimated on the basis of the results from a pilot-study. If, for example, subjects rely entirely on color, the color weight should be set to 1 and all other weights set to 0.

If an item  $n$  is identical to the target in dimension  $d$ , the item's feature activation  $a_n^{(d)}$  is set to the weight of that dimension:

$$a_n^{(d)} = \begin{cases} w^{(d)}, & \text{if } f_n^{(d)} = t^{(d)} \\ 0, & \text{otherwise} \end{cases}, \quad n \in \{1, \dots, N\}, \quad d \in \{1, \dots, D\}$$

The total activation of item  $n$  is then calculated as the sum of its feature activations, implying the possibility of simultaneous guidance of attention by two or more dimensions:

$$a_n = \sum_{d=1}^D a_n^{(d)}, \quad n \in \{1, \dots, N\}$$

In a triple-conjunction search task, for instance, with color, shape, and orientation weighted 1, 0.5, and 0 respectively, a distractor item of the same color and shape as the target would receive a total activation of 1.5, surpassing those distractors with single-feature correspondence. Results from empirical studies support the hypothesis of combined activation across dimensions (see Williams & Reingold, in press).

As argued above, the activation map function  $m(x, y)$  should reflect the amount of information that could be processed during a fixation at any position  $(x, y)$  in the display, given a Gaussian distribution of resources for processing. In the current model,  $m(x, y)$  is calculated as the sum of total activations of all the items, with each item weighted by the amount of resources it receives, as a function of its distance from  $(x, y)$ :

$$m(x, y) = \sum_{n=1}^N a_n \cdot \exp \left[ -\frac{(x-x_n)^2 + (y-y_n)^2}{2\sigma_f^2} \right]$$

The fixation targets are chosen as those maxima (peaks) of  $m(x, y)$  that are greater than or equal to the activation of a single target item, i.e. those coordinates  $(x_p, y_p)$  meeting the following two requirements:

$$\exists \varepsilon > 0: |x - x_p| + |y - y_p| < \varepsilon \Rightarrow m(x_p, y_p) > m(x, y) \forall x, y$$

$$m(x_p, y_p) \geq \sum_{d=1}^D t^{(d)}$$

While the first requirement achieves a plausible selection of fixation points for most efficient acquisition of information, the second requirement simulates a subject's ability to give a negative response even before attending to every item in the display. According to this equation, subjects can decide whether a peak in the activation map is high enough to possibly contain a target item. They can thus stop the search after inspecting all relevant peaks, without directing their attention to the irrelevant ones.

After calculating the fixation targets, the actual fixation points are determined by simulating normally distributed saccadic error and measurement error. Saccadic error is assumed to increase with a larger fixation field, which corresponds to faster search, longer saccades, and a more diffused activation map. Accordingly, in the present

simulation, we set the saccadic error parameter to equal the fixation field parameter  $\sigma_f$ . Measurement error is set to a constant standard deviation  $\sigma_m$  corresponding to the precision of the eye tracker used in the empirical study. The actual fixation point for an activation peak  $(x_p, y_p)$  is thus determined on the basis of the following probability distribution  $p(x, y)$ :

$$p(x, y) = \frac{1}{2\pi(\sigma_f^2 + \sigma_m^2)} \cdot \exp\left[-\frac{(x-x_p)^2 + (y-y_p)^2}{2(\sigma_f^2 + \sigma_m^2)}\right]$$

**Scan paths** - The structure of scan paths is governed by the principle that every fixation target, i.e. every relevant peak in the activation map, is visited exactly once. The order in which these fixation targets are inspected is chosen in terms of spatial optimization, as suggested by empirical results (e.g. Zelinsky, 1996). Among the unvisited peaks, the current implementation of the model always chooses the one that is nearest to the current gaze position. This type of local scan-path minimization - also termed the "Greedy Heuristic" - has been shown to resemble human scanning strategies without assuming extensive planning processes (see Pomplun, Carbone, Koesling, Sichelschmidt & Ritter, submitted).

Turning back to the distinction between feature and conjunctive search, the current model makes the following predictions: If the distractors' activations are too weak to form peaks that exceed the target activation - for example, if the target has a unique feature in one dimension (feature search) - the target item produces the only relevant peak in the display, yielding a highly efficient "pop out" search. In contrast, increasing target-distractor similarity (e.g. conjunctive search) leads to more fixations and a stronger influence of display size on search performance. These predictions of the model are consistent with empirical results.

## Empirical Validation of the Model

The Area Activation model is illustrated by simulating saccadic selectivity findings reported by Williams and Reingold (in press). The authors reported two visual search experiments with 32 participants in each experiment. Participants were presented with displays of 6, 12, and 24 items, half of them containing a target item defined by a unique combination of three dimensions - color, shape, and orientation. Each experiment consisted of a single-feature (SF) and a two-feature (TF) condition, in which the distractor items shared one or two dimensions respectively with the target item. While both experiments used the same colors (red and blue) and orientations (upright and rotated clockwise by 90 degrees), the stimuli differed in the discriminability of the shape dimension. Experiment 1 employed the similar letters E and F (low discriminability), whereas Experiment 2 used the distinct letters T and C (high discriminability). Figure 1 (upper row) presents a sample stimulus for each of the two experiments. Eye movements

were measured with the SR Research Ltd. EyeLink system. The measurement error in this study was determined as  $\sigma_m = 0.6$  deg.

In our comparison of empirical and simulated data, only target-absent trials were analyzed in order to avoid the disruptive influence of target items (see Zelinsky, 1996). In the present article, only the results for display size 24 were simulated.

Since we had no a-priori knowledge about the subjects' fixation field in each of the four conditions (SF and TF conditions in Experiments 1 and 2), we used an iterative algorithm to adjust the model's fixation field parameter  $\sigma_f$  in such a way that the simulated number of fixations per trial matched the empirical one.

Another problem was to determine the weights  $w^{(d)}$  for the color, shape, and orientation dimensions. We used the SF conditions in both experiments to adjust these weights and we tested their generality by applying them to the TF conditions. In the SF condition of Experiment 1, subjects showed strong saccadic selectivity towards color and equally low selectivity towards shape and orientation (see Figure 2, top row). This suggested that only the color dimension induced feature guidance, while shape and orientation were irrelevant to the search process. Consequently, for both the SF and TF conditions in Experiment 1, the weights were set to 1, 0, and 0 for color, shape, and orientation respectively. Experiment 2 differed from Experiment 1 only in the shape discriminability. Therefore, a larger shape weight was required in Experiment 2, but the other two weights had to be the same. We adjusted the shape weight to 0.6 in order to match the empirical saccadic selectivity towards the shape dimension in the SF condition of Experiment 2.

With these adjustments, the computer simulation of the Area Activation Model attempted to address several important questions: Is the model able to quantitatively reproduce the empirical saccadic selectivity? Does the implemented concept of simultaneous guidance by multiple dimensions match the human data, i.e. do the parameters for the SF conditions predict selectivity values in the TF conditions? Do the simulated gaze trajectories correspond to the empirical ones, as indicated by the distribution of saccade amplitudes?

Figure 1 (lower left) shows the activation map calculated by the computer simulation for the sample stimulus of Experiment 1. It reveals four peaks induced by groups of distractors sharing the target color blue, since in this condition only color features contribute to the activation map. As shown in Figure 1 (lower right), the simulation fixates once in the vicinity of each peak while always choosing the nearest unvisited peak as the next saccade target.

Figure 2 allows a comparison between simulated and empirical results, with each row referring to one of the four conditions. The first row shows a remarkable correspondence in the SF condition of Experiment 1, for both the amplitude and the feature selectivity of saccades.

Figure 1: Sample stimuli and illustration of the Area Activation Model. Blue and red items are displayed in black and gray respectively. Upper left: Experiment 1, SF condition, target is a blue, upright “F” (absent). Upper right: Experiment 2, TF condition, target is a red, upright “T” (present). Lower left: Activation map (“activation landscape”) calculated for the sample stimulus of Experiment 1. Lower right: Scan path generated by the model for the same stimulus. The four fixations correspond to the four peaks in the activation map.

The same is true for the TF condition, as shown in the second row. Despite a profound difference in search efficiency between these two conditions (3.77 versus 10.41 fixations per trial), the distribution of saccades and their selectivity is well predicted with the same set of parameters used in the SF condition.

With regard to the SF condition of Experiment 2, the model's saccadic selectivity once again closely resembles the empirical one, whereas the saccade histogram indicates a significant mismatch. The empirical data revealed a peak at an amplitude of approximately 3 degrees, but the model produced a smoother distribution extending further towards

higher amplitudes. This discrepancy might be related to the high search efficiency in this condition (only 2.59 fixations per trial).

Finally, the TF condition, which is substantially less efficient (6.31 fixations per trial), showed an excellent correspondence between simulated and empirical data. The same parameters that failed to replicate the distribution of saccade amplitude in the SF condition almost perfectly reproduced the empirical amplitude histogram in the TF condition. Again, the model precisely predicted the effect of simultaneous guidance by two dimensions.

Experiment	1
Condition	SF
Fixations per Trial	3.77
Fixation Field Size	1.05 deg

Experiment	1
Condition	TF
Fixations per Trial	10.41
Fixation Field Size	0.96 deg

Experiment	2
Condition	SF
Fixations per Trial	2.59
Fixation Field Size	1.82 deg

Experiment	2
Condition	TF
Fixations per Trial	6.31
Fixation Field Size	1.06 deg

Figure 2: Comparison between empirical and simulated data with each row corresponding to one of the four experimental conditions. Left column: Empirical number of fixations per trial and simulated visual span size required to match the number of fixations. Middle column: Comparative histograms of saccade amplitude. Right column: Comparative diagrams of saccadic selectivity towards different distractor types.

## Conclusions

In all four conditions, empirical saccadic selectivity was precisely replicated, supporting the concept of simultaneous guidance by multiple dimensions. Moreover, saccade amplitude produced by the model was remarkably accurate. One exception found was the SF condition in Experiment 2. This is perhaps due to the fact that search in this condition was highly efficient. It may be the case that highly efficient searches induce a qualitatively different saccadic scanning behavior. For example, if it is always possible to detect the target from the central gaze position, an efficient strategy could be to avoid any eye movements to the periphery. Another factor could be an increased amount of corrective saccades due to faster scanning of the display. Further research is necessary to investigate this issue.

As indicated by the model's accurate saccadic selectivity, not only the area-based activation map, but also the implementation of saccadic error - as identical to the fixation field size  $\sigma_f$  - have passed their first test. The generally successful replication of saccade amplitude supports the hypothesis of spatial scan-path optimization within the relevant display areas.

All in all, the current version of the Area Activation Model can be considered a promising approach towards an explicit, quantitative model of saccadic selectivity in visual search.
