# The use of a high-dimensional, “environmental” context space to model retrieval in analogy and similarity-based transfer

## Abstract

Current models of the retrieval of analogies from a long-term memory store assume mental representations that are generally either underspecified or implausible. In this paper we conduct two experiments which demonstrate that an ‘environmental’ approach to retrieval can produce appropriate retrieval patterns on cognitively plausible styles of representation, utilising information that can be easily learned from a linguistic environment.

## Introduction: Similarity-Based Transfer

Analogy (and similarity-based transfer) is a central cognitive process that represents a versatile problem-solving and reasoning strategy, allowing agents to bring previous experience to bear on novel problems. Its operation embodies two distinct processes: (i) reminding, or *retrieval*, of appropriate analogs from a long-term memory store; after which (ii) candidate analogs are *mapped* onto the representation of the current problem (the target) to determine deeper relational matches, and to allow inferences to be made (Gentner, Ratterman & Forbus, 1993; Forbus, Gentner & Law, 1995; Holyoak & Thagard, 1995).

The latter mapping process has been shown to rely largely on structural commonalities (Gentner, 1983; Holyoak & Thagard, 1995; Hummel & Holyoak, 1997), and computational models of the mapping processes that determine structural commonalities have been subject to much critical scrutiny (Falkenhainer, Forbus & Gentner, 1989; Holyoak & Thagard, 1989; Keane, Ledgeway & Duff, 1994, Hummel & Holyoak, 1997). In contrast *retrieval* has been subject to less investigation. Here, we subject the relatively more neglected issue of modelling analog retrieval to a more focussed theoretical examination.

## Four Constraints on Retrieval

Empirical studies by Gentner, Ratterman and Forbus (1993) established four primary constraints on the patterns that an appropriate theory of retrieval should produce given a specific context or probe:

1. *Primacy of the mundane*: The majority of retrievals evoked should be literally similar to the context, sharing both surface and structural characteristics (e.g. a

bicycle should call to mind memories of other bicycles).

2. *Surface superiority*: Retrievals based on surface similarity alone (without structural similarity) should also be frequent (e.g. a fairy story about a frog might call to mind other stories about frogs, although the structure of the stories might differ greatly).

3. *Rare insights*: Memories that are structurally similar to the target context should be retrieved only occasionally (e.g. the orbits of the solar system reminding one of electrons orbiting an atom).

4. *Scalability*: The model must plausibly extend to realistically sized memory pools because people typically have vast numbers of memories, and are able to access them in a matter of seconds.

Gentner, Ratterman and Forbus’ (1993) investigation demonstrated that retrieval is sensitive to surface (or ‘semantic’, Hummel and Holyoak, 1997) similarities between a target representation and a base analogy that needs to be retrieved. (As opposed to the shared relational structure that determines an analogical match.) The retrieval process, being relatively computationally cheap, acts as an efficient prefilter to the more expensive process of structural alignment (albeit at the expense of potentially passing over useful analogies that share structural commonalities with the target domain).

## Meeting the Constraints

MAC/FAC (Forbus, Gentner & Law, 1994) and LISA (Hummel & Holyoak, 1997) are the two foremost models of similarity-based transfer. Below we review the approach taken by both models with regards to retrieval, and examine the theoretical basis for each.

## MAC/FAC: Content Vectors

MAC/FAC models retrieval by generating a *content vector* for each representation that is stored in its memory-pool. A content vector summarises the surface features of a representation by recording the frequency with which each *lexically distinct* predicate occurs in it. Thus, the following proposition:

```
(CAUSE (STRIKES-WITH JOHN CUE CUE-BALL)
      (AND (POTS CUE-BALL) (POTS BLACK)))
```

would be assigned the following content vector:

```
((CAUSE . 1) (STRIKES-WITH . 1)
 (AND . 1) (POTS . 2))
```

A measure of the degree that two representations share the same surface features can then be derived by calculating the dot-product of their content vectors (if a particular predicate does not appear in a representation then it is implicit, adopting a sparse-encoding approach, that it has a frequency of zero). It is important to note that only predicates that are *identical* from one another can contribute to the magnitude of a dot-product between two content vectors: there is no potential for multiplying the frequencies of distinct predicates in the dot-product calculation.

Forbus, Gentner and Law (1994) argue that the dot-product between two content vectors provides an empirically adequate measure of the *retrievability* of one representation, given another as a context, because it satisfies the four constraints on retrieval performance.

### A Critique of Content Vectors

In order to model the way that *lexically distinct* items in stimuli prime one another for retrieval, the content vector theory makes a commitment to a theory of mental representation we shall call canonical representation (CR) theory. This presupposes a translation procedure that allows tokens that are lexically distinct but share similar semantic “meanings” to be re-encoded using identical tokens. This translation procedure accounts for cross-lexeme priming effects by identically encoding distinct lexemes that should prime for one another, thus ensuring that they can contribute to the dot-product score between the two representations in which they feature. CR theory assumes that during the process of comprehension (representation building):

“Two concepts that are similar but not identical (such as ‘bestow’ and ‘bequeath’) are decomposed into a canonical representation language so that their similarity is expressed as a partial identity (here, roughly, give).” Forbus, Gentner and Law, 1994, pp. 153

### ‘Canonical Form’?

According to CR theory, complex semantic elements can be recursively decomposed -- or *re-represented* -- until a canonical measure of their semantic significance is reached. Hence CR theory assumes that the mental encoding of semantically complex concepts can ultimately be analysed in terms of a stock of canonical forms. Clearly the correctness or otherwise of this assumption is an empirical matter. However, it does seem worth noting that research into the mental representation of concepts suggests that human conceptual representations are anything but canonical. The proposals for generalised theories of representation that exist in the concepts literature fall well short of providing the kind of “neat” account of concepts that canonical conceptual representation assumes (see Komatsu, 1992; Ramsar & Hahn, 1998 for reviews). Lacking as it does an account of what a canonical conceptual form is, in its current form CR theory is under-specified, and thus fails to operationalise the notion of semantic similarity in a sufficiently tight manner. This prevents specific predictions being made from the theory (e.g. how strongly do ‘cat’ and ‘dog’ prime for one another based on an analysis of the overlap in their shared semantic features?).

### LISA: Semantic Features

The other leading model of analogy in the literature, LISA (Hummel & Holyoak, 1997) also relies upon the notion of semantic units (or links) – and re-representations into ‘semantic primitives’ – in its structured representations to model retrieval. These semantic elements are largely constrained by the representation strategy adopted in LISA (e.g. `\verb+likes1+` or `\verb+likes2+`). Hummel and Holyoak’s claim is that these allow appropriate patterns of retrieval to be produced by their model. However, they offer no empirical support for the selection of their particular set of primitive semantic features. At present, the semantic information in LISA’s representations is *hand-coded*, and ultimately reliant upon humanistic intuitions about similarities of meaning.

### Summary of Current Approaches

Both MAC/FAC and LISA present models of retrieval that are theoretically under-specified. Both accounts rely on the problematic (i.e. currently undefined) notion of re-representation, either into ‘canonical conceptual representations’ (MAC/FAC) or ‘semantic primitives’ (LISA). Ultimately, this means that both models rely on hand-coded information to drive their retrievals. Neither LISA nor MAC/FAC actually *models* the representation of lexical information. They rely instead on imported information (primarily intuition) to underpin their behaviour, thus neither can be said – at present – to offer any real explanation of the role of lexico-conceptual knowledge in retrieval.

None of this means, of course, that the shortcomings that we describe in each of the two theories could not ultimately be addressed. We do, however, feel that in the light of these shortcomings there is room for an investigation of whether another approach to the representation of lexico-conceptual knowledge might be used to ground an alternative theory of retrieval.

### Co-occurrence Models of Semantics

One approach to lexico-conceptual knowledge that seems promising in this respect is the high dimensional modelling of context spaces. This is a data-intensive technique that analyses a set of corpora, and from this derives a summary of the variety of different contexts that different words can be *used* in. There is a growing body of evidence that the frequency with which different lexemes co-occur with one another (that is, are used together within a particular context, such as a paragraph or moving-window) can provide useful information about the semantic properties of those lexemes.

In co-occurrence analyses, a contextual distribution is calculated for each lexeme encountered in a corpus analysis by counting the frequency with which it *co-occurs* with every other lexeme in the corpora being analysed. The contextual distribution of a lexeme can then be summarised by a vector showing the frequency with which it is associated with the other lexemes in a common linguistic environment. One can think of this information as defining a model containing a network of links between the lexemes in a language, each with varying strengths,

and representing the varying contextual co-occurrences of lexemes in that language. Two such co-occurrence models are the *Latent Semantic Analysis* (LSA) model (Landauer and Dumais, 1997; Landauer, Foltz & Laham, 1998), and the *Hyperspace Analog to Language* (HAL) model (Burgess & Lund, 1997).

There is good evidence that co-occurrence analysis extracts information from corpora that can be used to model certain linguistic behaviour. For example, Landauer and Dumais (1997) report that the LSA model can pass a multiple-choice TOEFL synonym test. Lund, Burgess and Atchley (1995) present evidence that co-occurrence data can act as a good predictor of various priming effects. Burgess and Lund (1997) demonstrate that the HAL model can produce clustering in its high-dimensional space of lexemes from differing grammatical categories.

Whilst the exact parameters of LSA and HAL are different, they both adopt the general approach outlined above to generate co-occurrence vectors. We feel that there are a number of attractive benefits to be gained from modelling the semantic information used in analogical and similarity based retrieval in this way:

1. The proposed semantic metric is clearly specified. By proposing that the semantic information used in retrieval is learned from observing the varying contextual co-occurrences of lexemes in a language, we avoid having to postulate entities – such as ‘semantic primitives’ whose theoretical and psychological nature is massively under-specified.
2. The semantic information used could be easily learned from the environment,<sup>1</sup> thus avoiding the problems inherent in positing entities whose learnability is somewhat controversial, and whose innateness might otherwise have to be treated as axiomatic (as canonical concepts seem to be; see Laurence & Margiolis, 1999; Fodor, 1981).
3. An environmental context model contains representationally cheap, summarised information, the usage of which makes only limited processing demands. Thus it allows one to avoid the theoretical problems inherent in theories of re-representation which explain cheap surface matches in terms of semantic decomposition and expensive structural alignment (c.f. Holyoak & Hummel, 1997; Forbus *et al*, 1997).
4. Environmental context models are relatively objective: they do not require that a particular set of ‘semantic features’ are defined before textual analysis begins. Instead the co-occurrence technique takes the lexemes themselves as features, and uses frequency relations between them to define their associativity. This is an advantage given the difficulty we have already highlighted of empirically grounding claims as to the identity of semantic features. Furthermore, the use of

<sup>1</sup> Indeed, despite some of the stronger claims made for co-occurrence models of language (c.f. Landauer & Dumais, 1997) we feel that they are best characterised as being essentially models of the associativity of lexemes in a common linguistic environment, such that we prefer to call them “environmental context models”. It is also worth noting that co-occurrence techniques are also compatible with a neural implementation. Lowe (1997) demonstrates that a co-occurrence model can easily be implemented as a self-organising Kohonen map, and this offers some support for the idea that some form of co-occurrence counting could occur in the brain.

dimensional reduction techniques on the vectors associated with each lexeme (Landauer & Dumais, 1997) offers evidence that, in fact, there may not be a *unique* set of semantic features used in the encoding of semantic relations, but rather that multiple encodings can provide sufficient information to meet empirical constraints

5. Because co-occurrence techniques do not rely on a predefined set of semantic features (such as gender, plurality, animacy and so on), this eliminates subjectivity from the decisions that are made during the process of hand-coding representations during the modelling process.

The success of co-occurrence techniques in accounting for priming effects (c.f. Lund, Burgess and Atchley, 1995), has shown them to be useful models of lexical retrieval. Here, we seek to establish whether these models can be used to account for the retrieval of structured composite representations, and not just individual lexemes, from a memory-pool.

### The ‘Karla the Hawk’ Stories

The experiments detailed below use the ‘Karla the Hawk’ materials as originally used by Gentner, Ratterman and Forbus (1993). The Karla materials consist of twenty sets of stories written in natural language. Each set consists of a base story, and four systematic variations of that story. Two factors are crossed over the four variant stories, as shown in Table 1.

	+ST	-ST
+SF	Literal Similarity	Surface similarity
-SF	Analogy	1st Order Relations

Table 1: The Karla materials

The four story categories systematically vary the commonalities that are shared with the base-story from which they are derived. Each variant can either share or not share surface ( $\pm$ SF) and structural ( $\pm$ ST) commonalities with the corresponding base-story. This 2 x 2 materials design allows for the controlled examination of the sensitivity of various putative measures of retrieval. Gentner, Ratterman and Forbus (1993) found that the prime determinant of retrievability was shared surface commonalities, whilst shared structural commonalities had a nonsignificant effect. This is the pattern of results that we will look for in our experiments. The empirical results reported in Gentner, Ratterman and Forbus (1993) are summarised in Table 2.

	LS	SS	AN	FOR
Retrieval Scores	1.92	1.64	0.44	0.27
Inferential Soundness	4.41	2.70	4.16	2.58

Table 2: The results of the experiments conducted by Gentner, Ratterman and Forbus (1993).

Below, we report two experiments that compare the performance of the content vector (CV) theory of retrieval, as implemented in MAC/FAC, against the measure provided by the LSA model.

## Experiment 1: Stripped Natural Language.

Experiment 1 was designed to determine whether there is sufficient informational content in a reduced representation of the Karla the Hawk stories to produce retrieval patterns conformable to the empirical data.

It is clear from experimental studies that in addition to the accretion of structural information during comprehension, there is a concomitant loss of superficial verbatim information as propositional representations are built up (Sachs, 1967; Gernsbacher, 1985). Since we wanted to simulate retrieval of what subjects in Gentner *et al*'s studies actually stored (and there is good evidence that people do not store texts verbatim), we decided to initially test retrieval on versions of Gentner *et al*'s stimuli that had all of the *closed-class*<sup>2</sup> lexemes removed from them.

Applying this principle resulted in a set of words for each story which constituted the words which are, in some sense, maximally informative about the context that the representation defines. For example, some words (generally the closed-class words) may occur in almost any (and every) possible context (e.g. 'the' can co-occur plausibly with an extremely diverse set of lexemes). Thus encountering such a word in a probe representation has little informational utility with respect to retrieval because it fails to narrow the set of candidate retrievals at all. Such lexemes are unlikely to influence the kind of retrieval studied by Gentner, Ratterman and Forbus (1993).

The original Karla the Hawk base-story after it had been pruned of all closed-class lexemes is given below, as an example of the characteristic 'bag of words' that remained once the natural language representations had been stripped:

Karla old hawk lived top tall oak tree  
afternoon saw hunter ground bow crude arrows  
feathers hunter aim shot hawk missed Karla  
knew hunter wanted feathers glided down hunter  
offered give hunter grateful pledged shoot  
hawk shot deer

### Method

The base story for each story-set of the reduced representations was compared with each of its four variants in turn, using the LSA and CV (MAC/FAC content vector) models. This was done in order to reproduce the experimental format embodied in Gentner's original retrieval experiments. The LSA model was set to compare items in *document-to-document* mode, using the 300 most significant factors extracted by the model from a corpus that approximates the general reading a first year college student is exposed to (which seemed appropriate given the participants in Gentner *et al*'s studies). Because of the 2 x 2 design of the experiment, a repeated-measure ANOVA analysis is the appropriate test to determine which of the factors,  $\pm$ SF or  $\pm$ ST, the two metrics are sensitive to.

### Results

The results of the inter-story comparisons conducted with the LSA and CV models of retrieval are recorded in Table

<sup>2</sup> Closed-class words belong to the set of words which are closed under the grammatical rules of a language.

3. As noted above, each variant story either exhibits  $\pm$ SF and  $\pm$ ST, depending on whether it shares or does not share object-attributes and higher-order relations (structure) with the base story it is derived from. The ANOVA analysis revealed that the CV metric was sensitive to both  $\pm$ SF ( $F(1,19) = 11.965$ ,  $p < 0.01$ ) and  $\pm$ ST ( $F(1,19) = 10.027$ ,  $p < 0.01$ ), with no significant interaction effect ( $F(1,19) = 3.717$ ,  $p > 0.05$ ). For the LSA metric there was a main effect of  $\pm$ SF ( $F(1,19) = 68.985$ ,  $p < 0.01$ ); no effect of  $\pm$ ST ( $F(1,19) = 2.611$ ,  $p > 0.05$ ), and no significant interaction between the factors ( $F(1,19) = 2.428$ ,  $p > 0.05$ ).

	LS	SS	AN	FOR
CV Metric	0.116	0.084	0.057	0.053
LSA Metric	0.442	0.412	0.151	0.152

**Table 3:** Experiment 1 -- The category means for the CV and LSA scores derived from comparing each base-story with its four variants on the stripped ('bag-of-words') representations. All twenty story-sets had closed-class lexemes removed from them, and were used in the comparison.

### Discussion

The clustering in the mean LSA scores for each category of variant (LS-SS and AN-FOR) mirrors the subject data in Gentner, Ratterman and Forbus's (1993) study closely. The same pattern is not observable in the CV metric. Furthermore, the only significant factor in Gentner's original retrieval experiments was  $\pm$ SF and only the LSA scores conform to this pattern. The CV metric was also sensitive to the  $\pm$ ST factor, which indicates that it is sensitive to a factor which has been shown to have little significant impact on retrieval performance. It appears that there is sufficient information remaining in the reduced representation to allow different contexts for retrieval to be discriminated from one another in a way that simulates the empirical findings discussed.<sup>3</sup> Moreover, it seems clear from these results that LSA models the original empirical data more accurately than CV.

## Experiment 2: Faithful Dgroups

Experiment 2 investigated the performance of the CV and LSA measures on a style of representation that explicitly encodes the structural features implicit in the original stories. This structural information is required to be able to complete the mapping phase of similarity-based transfer, and so these experiments were conducted to determine whether a single style of representation would be sufficient to underpin both the retrieval and mapping processes of similarity-based transfer. The style of representation that we chose shares the substantial core of its form with that used in SME and MAC/FAC, but we developed a series of constraints for translating text into these structured representations whilst avoiding any commitment to the CR theory (we call these representations Faithful Dgroups, 'Dgroup' being the usual term used to describe individual – "chunked" – structured representations in the SME literature.).

<sup>3</sup> It should be noted here that the LSA retrieval scores remain more or less unchanged from pilot testing on the full NL versions. The CV scores, however, are significantly reduced from the original NL materials. This seems to indicate that the LSA model is more robust across representations.

### Producing The Faithful Dgroups

Humans are capable of extracting more meaning from language than the basic information that is encoded in the surface structure of texts and dialogues might suggest. To take the following as an example:

John hit Mary; Mary cried. The Headmaster expelled John.

In interpreting this passage, a reader has to infer firstly that John's hitting Mary caused her to cry, and secondly that the relationship between John's hitting Mary, and her crying, caused the Headmaster to expel John. We might express this information in terms of the following nested propositional structure:

```
cause( cause( hit(john,mary), cry(mary) ),
        expel(headmaster, john) )
```

None of this causal information appears explicitly in the original utterance, so it is clear that it must in some way be inferred from a prior source. (The need for inference here is uncontroversial: all theories of comprehension agree that language comprehension requires a great deal of active involvement on the part of the comprehender when it comes to inferring information that is not explicitly encoded in language (e.g. McKoon & Ratcliff, 1992); where they disagree is on what, and how much, inference actually happens.)

Whilst we haven't attempted to make a commitment to a particular theory of comprehension in specifying the procedure for translating texts into Faithful Dgroups, what we have tried to do is to provide the beginnings of a method that requires a minimal amount of inference, and is broadly compatible with the bulk of the available data in this area (again, see McKoon & Ratcliff, 1992).

The basic outline of a procedure for forming the Faithful Dgroups from natural language samples is described below.

#### Algorithm for Construction of Faithful Dgroups

Seeking to maximally preserve closed-class lexical information:

1. Identify the objects that are referred to in the text, and list them using (`sme:defEntity ...`) commands.
2. Identify all the lexeme structures used to express attributes of the objects in the text, and express these as unary expressions.
3. Identify the lexeme structures used to express relations between the identified objects, and express these in the Dgroup form as expressions with two or more arguments, taking only objects as arguments.
4. Now deal with higher-order information (i.e. temporal and causal information that is frequently *implicit* in NL representations). Express this information as expressions taking other expressions as arguments. Note that because this information is often implicit in the NL forms of the stories, a standard (or canonical) lexical identity for each expression must be adopted (this has the effect of minimising the influence of inferred structures on retrieval, which is in accordance with Gentner's empirical findings). The set of inferred

relations should be the minimum set required to articulate the narrative structure of the story.<sup>4</sup>

Thus we sought to minimise unwarranted inferences, and the addition of features not warranted by their inclusion in the original materials. In contrast to the original Dgroups, the Faithful Dgroups incorporate much of the lexical information that is present in the original natural language representations.

#### Method

Faithful Dgroups representing nine of the original story-sets were created.<sup>5</sup> The faithful Dgroup representing the base story for each story-set was then compared with each of its four variants in turn, again using both the CV and LSA models. The LSA model was again set to compare items in *document-to-document* mode, using the 300 most significant factors extracted by the model from the "first year college student, general reading" corpus.

#### Results

The result of the CV and LSA comparisons on the Faithful Dgroups are presented in Table 4 below.

For the CV method there was no significant effect of  $\pm$ SF ( $F(1,8) = 3.647$ ,  $p > 0.05$ ), no significant effect of  $\pm$ ST ( $F(1,8) = 3.383$ ,  $p > 0.05$ ), and no interaction effect ( $F(1,8) < 1$ ). For the LSA method there was an effect of  $\pm$ SF ( $F(1,8) = 66.091$ ,  $p < 0.01$ ); no significant effect of  $\pm$ ST ( $F(1,8) = 2.190$ ,  $p > 0.05$ ); and no significant interaction between the factors ( $F(1,8) = 1.094$ ,  $p > 0.05$ ).

	LS	SS	AN	FOR
CV Metric	0.751	0.718	0.735	0.688
LSA Metric	0.670	0.633	0.466	0.456

**Table 4:** Experiment 2 -- The category means for the CV and LSA scores derived from comparing each base-story with its four variants in the Faithful Dgroups. Nine of the NL story-sets were encoded in this format

#### Discussion

As expected, on representations make no commitment to CR theory – using instead the lexico-semantic information derived from the external representations to drive retrievals – these results demonstrate that the CV method is insensitive to the surface-features of the stories, and thus fails to produce empirically adequate retrieval patterns. This is because the CV method only permits priming between lexically identical items. The LSA method, however, performs much better: its retrievals are only sensitive to the  $\pm$ SF factor, which is what is required to model the empirical evidence.

It is particularly noteworthy that the LSA method assigned high retrieval scores to the LS and SS categories in this experiment, when their representations need not share any *identical* lexemes with their corresponding base representation. It follows that the LSA model is not simply relying on identical lexemes in distinct

<sup>4</sup> Thus, as with other models of similarity-based transfer, some hand coding of representations does occur (though the freedom to make unprincipled coding decisions is greatly reduced in comparison with other models). This procedure was designed to minimise the influence of such hand coding, although our ultimate goal is the automation of this process.

<sup>5</sup> For comparison purposes, we encoded the same set of stories that Forbus, Gentner and Law (1994) coded for MAC/FAC.

representations to facilitate retrievals, but is modelling instead a more complex kind of relationship between the ways that individual lexemes are used in differing linguistic contexts.

## Conclusion

The performance of the LSA measure on both styles of representation offers concrete evidence that it can act as a good predictor of retrieval. That it can do so even when operating on a style of representation that remains faithful to the natural language source of information, and relies on only a psychologically plausible range of inferences for its structure (i.e. a structured, propositional representation that handles lexeme-encoding realistically) is encouraging. As is the fact that we were able to model the empirical data *without* hand tailoring a model of semantics, instead using an objectively, and independently, derived model of lexico-semantic information.

We alluded above to a potential problem in employing the idea of re-representation in retrieval: that studies have shown retrieval to act as a cheap pre-filter for the more computationally expensive – and conceptually rich – process of analogical mapping. Yet the use of re-representation in this process will result in multiple structural mappings being carried out at the conceptual decomposition stage (as many as there are lexically distinct but "semantically" similar items in representations to be mapped). It doesn't take much reflection to realise that will lead to a situation where more structural mapping is required in reconciling semantic differences than in mapping an analogy itself.

At some point mappings between richly represented structure will have to stop, if only because cognitive processing capacity is limited. Our contention is that re-representation – in retrieval at least – is expensive and unnecessary. Structure mappings can be retrieved – and conceptualised – using a far cheaper source of information. Not only does the use of high-dimensional, "environmental" context space to model retrieval in analogy and similarity-based transfer appear to be a plausible approach, it also seems to satisfy Gentner, Ratterman and Forbus' *scalability* constraint better than other models as well.

Given the role structure appears to play in concepts, any *conceptual* solution to matching semantics may suffer from to re-representation problem as well. It may be that *all* conceptualisation – analogical and literal – is about retrieving and mapping the right information in context. Gentner, Ratterman and Forbus (1993) showed that an inexpensive source of information was all that was needed to contextualise retrieval: our results indicate that a of high-dimensional, "environmental" model can provide that context in analogy and similarity-based transfer. Our suspicion is that it might also serve to contextualise broader conceptual processing as well.

## Acknowledgements

We are grateful to Andrew Wishart for his help in coding the Faithful Dgroups, and also for insightful comments on an initial draft of this paper. We would like to thank Lera Boroditsky, Ken Forbus and Dedre Gentner for

helpful discussion of these issues. This work was supported in part by EPSRC Grant GR/M59846

# Organising Principles in Lexical Representation: Evidence from Polish

Agnieszka Reid (agnieszka.reid@mrc-cbu.cam.ac.uk)

William Marslen-Wilson (william.marslen-wilson@mrc-cbu.cam.ac.uk)

## Abstract

Cross-linguistic research into the structure of the mental lexicon potentially allows us to deconfound factors which are language specific from factors which are cross-linguistically universal. In a series of three experiments we provide preliminary evidence for the structure of the Polish lexicon, which belongs to the Slavonic language family. As in English, semantic compositionality plays a crucial role, so that semantically compositional, morphologically complex words are stored in a combinatorial fashion, and semantically opaque words seem to be represented as full forms. At the same time, clear evidence is found for priming between derivational and inflectional affixes, and for interference effects between suffixed words competing for the same underlying stem. Overall the data support a combinatorial and decompositional approach to lexical representation.

## Introduction

To begin to discover the organising principles underlying the representation and processing of lexical knowledge, it is necessary to conduct comparable research programmes across a variety of different languages. In the studies reported here, we take as a starting point a body of research on English (Marslen-Wilson, Tyler, Waksler & Older, 1994), and ask whether the general properties that seem to emerge for English can be found to operate for Polish, a language with a much more complex and developed morphological system.

Two kinds of claim are made for English. The first is that underlying representations of morphologically complex forms, both derivational and inflectional, are fundamentally decompositional and combinatorial in nature. Evidence for this came from three main sources. Marslen-Wilson et al. (1994) report extensive priming, in an immediate cross-modal repetition priming task, between suffixed and prefixed words sharing the same stem. At the same time, they also report the phenomenon of suffix-suffix interference, where semantically transparent pairs such as *government - governor* do not prime, despite sharing the same stem. Marslen-Wilson et al. (1994) interpreted this as evidence for competition between different affixes for attachment to the same underlying stem. Thirdly, and perhaps most compellingly, Marslen-Wilson, Ford, Older & Zhou (1996) demonstrate strong priming between derivational affixes, as in pairs like *toughness/darkness* and *rearrange/rethink*. Affixes like *'-ness'* or *'re-'* appear to be isolable and independent structures in the mental lexicon, participating in a

dynamic and combinatorial manner in the representation of many different words.

The second important claim is that, cutting across this evidence for decompositional morphemically based representation, the further factor of semantic transparency plays a crucial role in determining the representation of morphologically complex words. Marslen-Wilson et al. (1994) found that semantically transparent morphologically complex words, such as *darkness-dark* prime each other, but that morphologically related, semantically opaque pairs, such as *department - depart*, do not, indicating that words such as *department* are stored as full forms. Marslen-Wilson et al. (1994) made the argument that this reflects choices made during the language acquisition process, where the language learner rejects a decompositional analysis of *department* (as *depart + ment*) on the grounds that this delivers the incorrect semantics.

## Cross-linguistic research

The broader status of these claims about the structure of lexical representation – as fundamentally decompositional but conditioned by semantic factors – remains hard to interpret unless comparable bodies of research, using parallel techniques, are conducted across a typologically contrasting sample of the world's languages. Research of this type is only now starting to emerge, and is already suggesting illuminating contrasts with the patterns proposed for English.

A salient example is the contrasting importance of semantic factors in Semitic languages, such as Hebrew and Arabic, as opposed to English. Hebrew and Arabic are characterised by non-linear morphological processes which operate on roots and word patterns. The most striking feature of this morphological system is that morphemes are not combined linearly, but a root, which usually consists of three consonants, is interleaved in a discontinuous manner with a word pattern, to create the phonetic surface form. Deutsch & Frost (1998) demonstrated that in Hebrew, words which are morphologically but not semantically related, prime each other strongly, in contrast to the findings on English. More recently Boudelaa & Marslen-Wilson (2000) demonstrate comparable findings for Arabic, using both cross-modal and masked priming tasks, and finding equally strong priming between prime target pairs sharing the same roots, irrespective of semantic transparency.

The finding that semantic transparency is a crucial factor in the structure of the English mental lexicon, but seems to play no role in the morphological decomposition of Semitic words, is hard to interpret on its own, because of the many

ways in which languages like Hebrew and Arabic contrast with a language like English. One of the goals of the research reported below is to add another typologically distinct data point to these contrasts, asking for Polish not only whether there is comparable evidence here for decompositional representation, but also whether semantic factors play a critical role in determining whether or not complex forms are represented in decompositional format.

## Research on Polish

A striking characteristic of Polish, a member of the Slavonic language family, is the richness of its morphological systems. Almost every word in Polish exists within a very rich paradigm, declensional for nouns, adjectives, numerals and pronouns or conjugational for verbs. The derivational morphology is comparable to English, being based on concatenative processes of prefixation and suffixation, but includes a number of qualitatively very different affixes, for instance verbal aspectual prefixes, aspectual-derivational prefixes and diminutival suffixes. Also, as far as derivational suffixes are concerned, they are considerably more numerous. Polish permits the formation of morphologically very complex words, such as secondary imperfectives described below, which allows a challenging test of claims about combinatorial representation and access.

## Experiment 1

The main goals of the first experiment we report here were to investigate morphological phenomena that are absent in English, as well as to investigate parallel phenomena in the two languages. To do this we used the cross-modal immediate lexical decision task (Marslen-Wilson et al. 1994). In this task subjects hear an auditory prime, at the offset of which, they immediately see a visual target (for 500 ms) and have to decide, by pressing an appropriate button, whether a target word is a real word or a non-word.

Taking advantage of the range of qualitatively different affixes in Polish, we probed their representation in pairs of semantically transparent words, which share the same affixes. The stimuli included (a) 24 pairs of verbs which share the same aspectual prefix, e.g. *skorzystać* 'to benefit, Perfective' - *straciły* 'they lost, Perfective'; (b) 22 verbs which share the same aspectual-derivational prefix, for instance: *nagrzać* 'to heat up, Perfective' - *nakroiła* 'she cut, Perfective'; (c) 18 nouns which share the same diminutive suffix, e.g. *kotek* 'a little cat' - *ogródek* 'a little garden' and (d) 24 nouns which have the same derivational suffix, e.g. *kucharz* 'a cook' - *piłkarz* 'a footballer'. Also, having in mind the difference in findings on English and Hebrew/Arabic regarding words which are morphologically related, but semantically opaque, we included (e) 22 pairs, such as *jalowiec* 'juniper' - *jalowy* 'futile', as a test of whether semantically opaque words prime each other. It seemed plausible that these pairs would prime in a language such as Polish, where the dynamics of morphological processing are much stronger than in English. We will refer to them as [+Morph, - Sem]. We also included a condition (f) 20 pairs which share the same stem, e.g., *szycie* 'sewing' - *szyć* 'to sew'. Because many studies document a robust effect of

stem priming, this condition served as a test of the procedure in our experiment. Finally, we included (g) 20 semantically related pairs, e.g., *kokos* 'coconut' - *banan* 'banana', which also served as a test of the experimental procedure. Many experiments on English found semantic priming in the cross-modal priming. We will refer to them as [-Morph, +Sem]. In addition, to investigate whether any observed priming in affix conditions was due to pure phonological overlap, we included two control conditions where the stimuli were phonologically but not morphologically or semantically related: (h) 18 words with phonological overlap at the onset, e.g. *numer* 'a number' - *nuda* 'boredom' and (i) 18 with overlap at the word offset, e.g. *hałas* 'noise' - *szałas* 'a shelter'.

## Results

6 subjects from version 1 and 4 subjects from version 2 were discarded from the analysis, because of high error percentage on real words (equal to or above 15%) or/and slow mean reaction times to real words (equal to or above 1000 ms). A total of 20 subjects per version was entered into the analysis. All subjects were in their twenties, and were native Polish speakers living and studying in Poland. 7 items were removed from the analysis: 3 because of high error percentage (equal to or above 30% on both versions or equal to or above 40% on one version) and 4 because of homophony. Every reaction time was inversely transformed in order to reduce the influence of outliers. The inversely transformed data were analysed in a Repeated Measures ANOVA separately for items (F2) and for subjects (F1). See Figure 1 for details of the descriptive statistics.

First the overall repeated measures ANOVA with Prime (related, unrelated) and Condition (1-9) was run. There was a main effect of Prime, indicating that RTs were faster for targets when preceded by a related prime than an unrelated prime,  $F(2,163)=22.62$ ,  $p<0.001$ ;  $F(1, 38)=37.32$ ,  $p<0.001$ . The main effect of Condition was significant,  $F(8, 163)=17.82$ ,  $p<0.001$ ;  $F(8, 304) = 162.89$ ,  $p<0.001$ . However, there was also a significant two-way interaction of Condition x Prime  $F(8,163) = 4.49$ ,  $p<0.001$ ;  $F(8, 304) = 7.45$ ,  $p<0.001$ .

The finding that there was 18 ms of priming on average in all the affix conditions treated as a group was explored further in an ANOVA. The results showed that there was a main effect of Prime,  $F(2, 75)=12.06$ ,  $p<0.001$ ,  $F(1, 38)=11.77$ ,  $p<0.001$ . The main effect of Condition was also significant,  $F(3, 75)=19.54$ ,  $p<0.001$ ,  $F(3, 114)=209.88$ ,  $p<0.001$ , with no interaction between Condition x Prime,  $F(3,75)=0.14$ ,  $p>0.05$ ,  $F(3,114)=0.37$ ,  $p>0.05$ . This result indicates that there was a facilitatory effect of Prime in all affix conditions treated as a group.

We then conducted an analysis of simple effects of Prime on each level of Condition in the remaining Conditions. The results show no facilitatory priming for [+Morph,-Sem] pairs,  $F(2,20)=0.56$ ,  $p>0.05$ ;  $F(1,38)=0.72$ ,  $p>0.05$ . There was no priming for either of the Phonological Overlap conditions: Phonological Overlap at the Word Onset,  $F(2,16)=0.05$ ,  $p>0.05$ ,  $F(1,38)=0.62$ ,  $p>0.05$  and Phonological Overlap at the Word Offset  $F(2,16)=2.15$ ,  $p>0.05$ ,  $F(1,38)=3.98$ ,  $p>0.05$ . On the other hand, there

was clear priming in the Stem Condition  $F(2,18)=25.0$ ,  $p<0.001$ ,  $F(1,38)=53.43$ ,  $p<0.001$  and in Semantically, but not Morphologically Related Pairs  $F(2,18)=13.36$ ,  $p<0.01$ ,  $F(1,38)=22.10$ ,  $p<0.001$ .

Figure 1. Priming effects for Experiment 1.

## Discussion

The results of Experiment 1 show clear priming in all the Affix conditions treated as a group as well as in the Stem condition. The absence of priming in the two phonological overlap conditions indicates that the priming obtained in the affix conditions cannot be attributed to simple phonological overlap. The results show that affixes and stems are isolable and independent structures in the Polish mental lexicon. Polish affixes, although qualitatively different from English affixes, seem to be stored in a combinatorial manner. On the other hand, the evidence shows that morphologically related, semantically opaque words do not prime each other, indicating that they are stored as full forms. This indicates that the factor of semantic compositionality determines the representation of morphologically complex words in Polish. This is in line with the findings on English, but is in contrast with Hebrew and Arabic, where semantic compositionality

does not determine the representation of morphologically complex words.

The combinatorial storage of affixes in the Polish mental lexicon is also supported by evidence on a Polish Wernicke's aphasic patient (Ulatowska and Sadowska, 1988). In tests of production, the patient occasionally made mistakes involving derivational morphology. When asked to produce a word denoting a little plate, she produced *tależek*, using an existing, but incorrect diminutival suffix, instead of saying *tależyk*. When verbal aspectual morphology is considered, the patient produced an incorrect form, such as *z-siwiał*, instead of *o-siwiał* 'he got grey', substituting a correct aspectual prefix 'o-' with an incorrect one 'z-' for this verb. Although the origin of these errors may be partially conditioned by phonological deficits in the patient's language output system, it seems to be hard to account for these errors only in these terms. The errors include an incorrect combination of existing morphemes, rather than a combination of non-existing units. Hence, we take this as a further evidence in support for the combinatorial storage of words in the Polish mental lexicon.

## Experiment 2

The findings on affix priming in Polish reported in experiment 1 left us with two further questions. Firstly, does the combinatorial representation of affixed words also hold for much more complex forms? Secondly, will we get more reliable priming, in comparison to the relatively weak priming in the four individual affix conditions in Experiment 1, if two affixes are shared by the prime and target?

Highly polymorphemic, semantically compositional words, such as secondary imperfectives, which occur in Polish, are a particular challenge for the combinatorial view of the mental lexicon. On one hand their complex structure would make them potentially more difficult to parse in comprehension and assemble in production if they are represented as a combination of morphemes, rather than as full forms. On the other hand, the intuition of native speakers of Polish is that they can process highly polymorphemic forms with the same efficiency as the less complex forms. More generally, for productive complex morphological forms, it is generally accepted that simple learning of each complex form is not a plausible language acquisition procedure (e.g., Hankamer, 1989).

We used (a) 30 pairs of secondary imperfectives, which shared the same prefix and suffix, e.g. *roz-pakow-ywa-l-em* (prime) 'to unwrap, 1<sup>st</sup> person sing., masculine, past tense, secondary imperf.' and *roz-walkow-ywa-ć* (target) 'to flatten something using, a rolling-pin, secondary imperf.'. These words consisted of a derivational prefix, e.g. 'roz-', a secondary imperfective suffix '-ywa-', past tense morpheme 'ł' (prime only) and a morpheme '-em' (prime only), which denotes the 3<sup>rd</sup> person singular, masculine. To ensure an appropriate paradigm-check we also included (b) 24 standard stem priming pairs, *myśl-ę* 'I think' - *myśl-e-ć* 'to think'; and (c) 24 semantically related, but morphologically unrelated pairs, e.g. *dom* 'a house' - *garaż* 'a garage', to dissociate the morphological and semantic effects.

Because we wished to avoid possible confounds with semantic priming, we used here a different task. This was an

auditory-auditory priming experiment with 12 items intervening between prime word and target. At these long lags, it is generally found that semantic priming drops away whereas morphological priming does not (Marslen-Wilson & Tyler, 1998).

## Results

10 subjects were discarded from the analysis according to the same criteria as in experiment 1. Data from 23 (version 1) and 24 (version 2) participants were entered into the analysis. One item had to be discarded from the analysis, because of high error percentage on one version. See Figure 2 for the details on the descriptive statistics.

Figure 2. Priming effects for Experiment 2

The reaction time data were prepared for the analysis as described in experiment 1. The overall ANOVA revealed that the main effect of Prime was significant,  $F(2,71)=16.006$ ,  $p<0.001$ ,  $F(1,45)=507.888$ ,  $p<0.001$ . The main effect of Condition was also significant,  $F(2,71)=20.426$ ,  $p<0.001$ ,  $F(1,45)=81.308$ ,  $p<0.001$ . The two-way interaction of Prime and Condition was not significant in the items analysis,  $F(2,71)=2.004$ ,  $p>0.05$ , but it was significant in the subject analysis,  $F(2,90)=72.625$ ,  $p<0.001$ .

We then carried out an analysis of simple effects of Prime on every level of Condition. There was clear priming in the Shared Affixes Condition;  $F(1,28)=4.8$ ,  $p<0.05$ ,  $F(1,45)=7.58$ ,  $p<0.01$ . The results for the paradigm-check conditions were straight-forward: as predicted there was significant priming for the Stem Priming Condition  $F(1,22)=15.48$ ,  $p<0.01$ ;  $F(1,45)=10.98$ ,  $p<0.01$  and there was no priming in the Semantically Related, but Morphologically Unrelated Condition:  $F(1,21)=1.01$ ,  $p>0.05$ ;  $F(1,45)=0.249$ ,  $p>0.05$ .

## Discussion

Firstly, the results show reliable priming for secondary imperfectives, e.g. *roz-pakow.ywa-l-em*, which indicates that they are in fact represented in a combinatorial fashion, de-

spite their morphological complexity. Secondly, it appears that, when two affixes are repeated in prime and target, we obtain a more robust priming effect, of the magnitude of stem priming, in comparison with the relatively weak priming in the affix conditions in experiment 1. This is consistent with claims for combinatorial underlying processing mechanisms, comparable to those claimed for English, and matching the claims for somewhat different forms of underlying combinatorial systems in the non-concatenative morphologies of Hebrew and Arabic.

## Experiment 3

One of the main pieces of evidence in support of the combinatorial approach to the English mental lexicon comes from the finding that semantically transparent pairs which share the same stem and have different derivational suffixes do not prime each other. This finding has been replicated many times in English, since the original report in Marslen-Wilson et al. (1994). For instance Marslen-Wilson & Zhou (1999) show that pairs which exhibit allomorphy, e.g., *sincere-ly* & *sincer-ity* as well as non-allomorphic pairs, e.g., *excit-able* & *excite-ment* do not prime each other either in a cross-modal priming task or in an auditory-auditory lexical decision task with 0 or 8 intervening lags. The results at 8 intervening lags established that the suffix interference effect is robust and can be elicited under conditions where morphological but not semantic factors are likely to be responsible.

Because we found evidence for the combinatorial storage of morphologically complex, semantically compositional words in Polish, we wanted to test whether we would find convergent evidence from suffix interference, tested in a language system where suffixation is one of the main derivational processes.

The stimuli included (a) 32 derived - derived words which shared the same stem, but had different derivational suffixes. Half of the stimuli were deverbal derivatives, e.g. *pis-anie* 'writing' - *pis-arz* 'a writer'. The other half were denominal derivatives, e.g. *balon-owy* 'balloon like, adj.' - *balon-ik* 'a little balloon',  $SR^1 = 8.1$ ,  $SD = 0.5$ ; (b) 32 inflected - derived pairs which shared the same stem. Half of the stimuli had an inflected verb as a prime and a deverbal derivative as a target e.g. *pisa-la* 'to write, 3<sup>rd</sup> person, sing., feminine, past tense' - *pis-arz* 'a writer'. The other half had an inflected noun as a prime and a denominal derivative as a target, e.g. *balon-em* 'balloon, instrumental' - *balon-ik* 'a little balloon',  $SR = 8.4$ ,  $SD = 0.4$ ; (c) 24 stem priming pairs, as before e.g., *mysl-e* 'I think', *mysl-e-c* 'to think' were included as a paradigm check,  $SR = 8.2$ ,  $SD = 0.2$ .

<sup>1</sup> SR denotes a mean score (across 10 participants) on a Semantic Relatedness pre-test, where native speakers of Polish judged on a 9- point scale (where 9 is the highest possible score), to what degree a given pair of words is semantically related. We use these scores as a measure of Semantic Transparency between a prime and target, which is highly correlated with semantic compositionality.

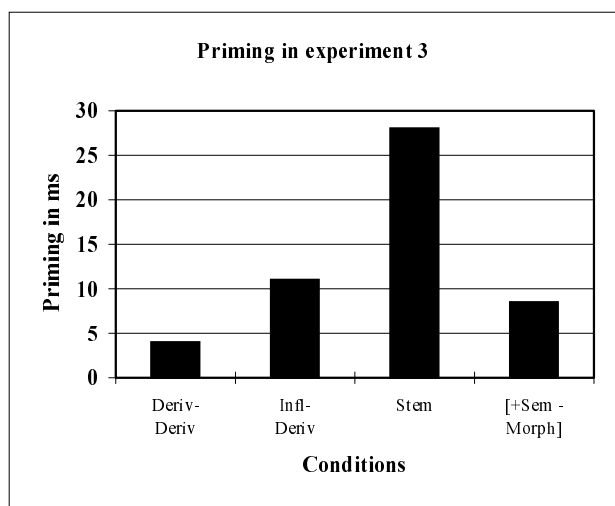

Figure 3. Priming effects for Experiment 3

Both words in the stem condition shared the same stem, the prime had an inflectional ending, denoting person, tense and number, whereas the target was an infinitive and had an infinitival marker 'ć' and (d) 24 [- Morph, +Sem] pairs, included to dissociate the morphological and semantic effects,  $SR = 8.0$ ,  $SD = 1$ . In order to ensure the most rigorous comparison between conditions 1 and 2, the same target was used in both conditions. Experimental items were assigned to 4 versions, so that the same target was preceded by one of the two related primes or one of the two unrelated primes, with one combination of a prime and a target per version. Because we were mainly interested in the morphological effects, we again used an auditory-auditory priming, lexical decision experiment with 12 intervening items to dissociate the morphological from the semantic effects.

## Results

10 participants were rejected on the same criteria as in experiment 1. A total of 89 participants: 22 (version 1), 24 (version 2), 21 (version 3) and 22 (version 4) were entered into an analysis. No experimental items were removed. See Figure 3 for the details of the descriptive statistics.

The overall repeated measures ANOVA analysis with Prime (related, unrelated) and Condition (1-4) revealed that the main effect of Prime was significant  $F(2, 96)=22.2$ ,  $p<0.001$ ,  $F(1, 85)=32.48$ ,  $p<0.001$ . The main effect of Condition was not significant in the item analysis  $F(3, 96)=0.537$ ,  $p>0.05$ , but it was significant in the subject analysis  $F(3, 255)=6.776$ ,  $p<0.001$ . A two-way interaction of Prime and Condition was significant,  $F(2, 1, 3)=2.9$ ,  $p<0.05$ ,  $F(3, 255)=2.71$ ,  $p<0.05$ .

The simple effects analysis was conducted to investigate effect of Prime at each level of Condition. The analysis showed that there was no significant priming in Derived-Derived Condition,  $F(2, 1, 28)=1.35$ ,  $p>0.05$ ,  $F(1, 85)=0.548$ ,  $p>0.05$ , nor in Inflected-Derived Condition,  $F(2, 1, 28)=3.615$ ,  $p>0.05$ ,  $F(1, 85)=2.702$ ,  $p>0.05$ . The remaining analyses on the individual conditions revealed that

there was a strong priming in Stem Condition,  $F(2, 1, 20)=15.24$ ,  $p<0.01$ ,  $F(1, 85)=19.874$ ,  $p<0.001$  and that there was no significant priming for [+Sem, -Morph] Condition,  $F(2, 1, 20)=3.9$ ,  $p>0.05$ ,  $F(1, 85)=1.821$ ,  $p>0.05$ .

## Discussion

The results are clear. There is no priming in Derived-Derived Condition nor in Inflected-Derived Condition while there is robust priming for the Stem Condition and no priming for [-Morph, +Sem] pairs. The findings for the latter two conditions have been replicated in many of our experiments (e.g. experiment 2) and are in line with the predictions.

Not finding priming for semantically transparent suffixed words which share the same stem, but have different derivational suffixes indicates that there must be an inhibitory process between the suffixes. Hearing *pis-anie* 'writing', as a prime inhibits the combination of the root *pis-* with another suffix, e.g. *-arz*, hence the recognition of the target *pis-arz* 'a writer' is slowed, even though the root *pis-* is active. This finding parallels the findings reported for English (Marslen-Wilson et al. 1994).

Interestingly, the results also suggest that there is suffix interference in Inflected-Derived Condition between inflectional and derivational suffixes which are attached to the same stem in semantically compositional pairs. It is hard to see how this could be the case if both types of suffix were not represented in the lexicon.

Most influential linguistic models of word formation in generative grammar assume that inflections are not represented lexically, but they are added by syntactic rules which are outside the mental lexicon. This is supported by data from the lexical decision experiments on English, but not by the findings on Polish. One plausible source of the difference between the findings for Polish and English comes from the characteristics of the Polish inflectional system, which in contrast to English is extremely rich and carries a lot of very complex information. The findings (although from a different paradigm) on Italian (Miceli & Caramazza 1988) which is a morphologically rich language, similarly to findings on Polish support the claim that the inflectional suffixes are stored in the mental lexicon.

The suffix-suffix interference leaves, at the current stage, at least one unresolved issue. All the inflectional suffixes of the primes for deverbal targets in Inflected-Derived Condition were 3<sup>rd</sup> person singular, masculine or feminine, past tense. In our previous experiments, we found priming for pairs which shared the same stem and where prime had a derivational suffix whereas the target had an infinitival ending - 'ć'. The question which arises is: what is special about the infinitival suffix that it does not cause interference with a derivational suffix? One possible explanation is that the infinitival ending does not have the same linguistic status as the inflectional suffixes, which carry a lot of information, e.g. person, number, gender, tense, etc. An issue which has to be resolved in our future research is whether suffix interference occurs for two inflectional suffixes. This will provide a more stringent test of the representation of the Polish inflectional morphemes in the lexicon.

## General Discussion

We have reported the findings on the Polish mental lexicon in a series of three experiments, in an attempt to examine the organising principles affecting the structure of the mental lexicon of a morphologically complex language from the Slavonic family. In the first experiment we concentrated on probing the representation of morphologically complex words, which included affixes which are qualitatively different from English. The findings indicated that affixes are represented in a combinatorial fashion. Secondly, the results show that semantic compositionality is an important factor in determining the lexical representation in the Polish mental lexicon. In the second experiment we confirmed that a combinatorial representation also holds for words with a much more morphologically complex structure, such as the secondary imperfectives, at the same time confirming the existence of strong priming between derivational and inflectional affixes. Finally, in the third experiment we addressed the issue of suffix interference in Polish, finding clear evidence for interference in derived-derived pairs as well as in inflected-derived pairs. This is further evidence for underlying combinatorial representations and processes.

In summary, the overall picture which has emerged as a result of our investigation of the Polish mental lexicon is that, Polish, similar to English and Hebrew is characterised by a combinatorial mental lexicon. However, different factors which condition the structure of the mental lexicon have different 'weightings' in Polish as in comparison with Hebrew and English. The factor of semantic compositionality is crucial in determining the structure of the representation of words in Polish, similarly to English, but in contrast with Hebrew (and Arabic). On the other hand, the factor of the type of inflectional morpheme is important in the structure of the Polish lexicon, in that both types of inflectional morphemes verbal and nominal seem to be represented in the Polish lexicon. This contrasts with English, where neither verbal nor nominal inflections seem to be represented as lexical processing structures.

## Acknowledgements

The research reported here is supported in part by an ESRC research studentship to A. Reid, and in part by the UK Medical Research Council. We would like to thank K. Kowalik, M. Smoczyńska and B. Szymanek for very helpful comments made during the selection of the stimuli. We also would like to thank P. Brzuski who kindly provided the facilities in Poland to run our experiments.

## Abstract

Research has shown that it is effective to combine example study and problem solving in the initial acquisition of cognitive skills. Present methods for combining these learning modes are, however, static and do not support a transition from example study in early stages of skill acquisition to later problem solving. Against this background, we propose a successive integration of problem-solving elements into example study until the learners solve problems on their own (i.e., complete example → increasingly more incomplete examples → problem to-be-solved). We tested the effectiveness of such a fading procedure against the traditional method of employing example-problem pairs. In a field experiment and in a more controlled lab experiment, we found that the fading procedure fosters learning, at least when near transfer performance is considered. Moreover, this effect is mediated by a lower number of errors under the fading condition as compared to the example-problem condition.

## Introduction

Worked-out examples consist of a problem formulation, solution steps, and the final solution itself. Research has shown that learning from such examples is of major importance for the initial acquisition of cognitive skills in well-structured domains such as mathematics, physics, and programming (for an overview see VanLehn, 1996). In addition, novices prefer this learning mode, and they are right: It is quite an effective way of learning. Studies performed by Sweller and his colleagues (e.g., Sweller & Cooper, 1985; for an overview see Sweller, van Merriënboer, & Paas, 1998) showed that learning from worked-out examples can be more effective than learning by problem solving.

Although worked-out examples have significant advantages, their employment as a learning methodology does not, of course, guarantee effective learning. First, the extent to which learners profit from the study of examples depends on how well they explain the solutions of the examples to themselves (Chi, Bassok, Lewis, Reimann, & Glaser, 1989; Renkl, 1997). Second, it is important how the learning materials (examples and problems) are structured (cf. Atkinson,

Derry, Renkl, & Wortham, in press). The second aspect is the focus of this study. More specifically, this study investigates one possible approach to integrating elements of problem solving into example study. We propose that these learning modes can be combined by successively introducing more and more elements of problem solving in example study until learners are solving the problems on their own. This rationale can also be used as a way to structure the transition from studying examples in initial skill acquisition to problem solving in later phases of the learning process.

In the next section, the literature with respect to the issue of combining example study and problem solving is discussed. Then we outline open questions and give preliminary answers that were tested in two studies, first in a field experiment and then in a more controlled lab experiment.

## How to Combine Example Study and Problem Solving? – State of the Art

Empirical evidence has shown that pure example study (i.e., examples alone) is not as effective as learning from examples in which elements of problem solving are integrated. There are two traditional ways to combine example study and problem solving: (1) Making the solutions of examples incomplete and (2) employing example-problem pairs.

### Incomplete Examples

Some researchers argue that incomplete examples, which the learners have to complete, effectively support the acquisition of cognitive skills (van Merriënboer, 1990; van Merriënboer & de Crook, 1992; Paas, 1992; Stark, 1999). Stark (1999) conducted a controlled experiment designed to examine the extent to which the insertion of “blanks” into the solution of examples—which, in a certain sense, forced the learners to determine the next solution step on their own—fostered learning. In his study, half of the participants studied incomplete examples (experimental group), while the other half learned from complete examples (control group). In the experimental group, portions of the example solutions presented to the participants were replaced by “question marks.” The learners were then asked to identify what solution step

was missing. After doing that, or at least making the attempt, the complete solution step was presented so that learners received feedback on the correctness of their anticipation. When compared to studying complete examples, Stark found that incomplete examples fostered the quality of self-explanations and, as a consequence, the transfer of learned solution methods. The results of Stark's study contrast with observations by Paas (1992), who did not find any difference in performance among participants presented with either incomplete or complete examples. However, the main purpose of Paas' study was not to investigate the effects of complete versus incomplete examples. Taken together, the results of Stark (1999) show that making examples incomplete (at least) can support learning.

### Example-Problem Pairs

Sweller and his colleagues (e.g., Sweller & Cooper, 1985) have conducted several classic studies documenting the effectiveness of learning from worked-out examples. However, in these studies the authors did not compare *pure* learning from examples (worked-out solutions only) with *pure* learning by problem solving (problems to-be-solved only). That is, these empirical examinations did not examine the impact of studying examples exclusively with solving practice problems only. Instead, the example condition usually consisted of examples followed by isomorphic problems to-be-solved (example-problem pairs). Thus, the studies of Sweller and colleagues mainly showed that combined learning from examples and problems is more effective than learning by solving problems.

Studies on learning from worked-out examples performed by other researchers have focussed on pure learning from examples (e.g., Renkl, 1997). Explicit comparisons between pure example learning and learning from example-problem pairs are, however, rare. One such study was performed by Trafton and Reiser (1993), in which the authors designed two treatments, alternating and blocked: Participants in the alternating condition were exposed to six example-problem pairs, where each example was followed directly by a isomorphic problem, while participants in the blocked condition were exposed to the entire set of six examples, followed by the entire set of six practice problems. The authors found that, as predicted, participants in the alternating-example condition took less time and produced more accurate solutions on the transfer posttest than their counterparts in the blocked-example condition. Based on these findings, the authors asserted that "the most efficient way to present material to acquire a skill is to present an example, then a similar problem to solve immediately following" (Trafton & Reiser, 1993, p. 1022).

In a recent study, Stark, Gruber, Renkl, and Mandl (in press) examined whether there might be another effective variation of the traditional method of pairing examples with practice problems. Based on a study of learning diagnostic strategies in medicine in which it was found that it is more effective to learn from a "cognitive model" (which can also be regarded as a kind of worked-out example) after an initial problem solving experience (Gräsel & Mandl, 1993), the authors argued that presenting practice problems first followed by isomorphic examples (problem-example pairs)

should be an effective mode of instruction. Specifically, the authors proposed that initial problem solving difficulties should motivate the learners to process the examples that followed more deeply and, in particular, more focussed with respect to the specific difficulties the individual learners have in solving such problems. In a comparison between pure example learning and learning from problem-example pairs (domain: calculation of compound and real interest), it was found that the combined learning method (i.e., problem-example pairs) substantially fostered active example processing and, as a result, learning outcomes.

Taken together, combining practice problems and examples is obviously more effective than exposing learners to either of the two pure learning conditions, that is, either to sets of practice problems or sets of examples.

### Open Questions and Answers to be Validated

Although there can be little doubt on the effectiveness of a combined learning method, two questions still remain open: (1) Are there more effective ways of combining example study and problem solving than presenting incomplete examples or pairs of examples and problems? (2) What is a sensible rationale for designing the transition from learning from examples in initial stages of cognitive skill acquisition to problem solving in later stages?

Instructional models such as *Cognitive Apprenticeship* (Collins, Brown, & Newman, 1989) propose a smooth transition from modeling to scaffolded problem solving to independent problem solving in which instructional support fades during the transition. The use of incomplete examples, at least as realized in previous studies, has not incorporated such a dynamic fading component. To date, studies incorporating the "pairs arrangement" have also not used a fading component. In fact, these studies typically contain abrupt transitions from examples, as a type of model, to independent problem solving. Against this background, it is sensible to combine problem solving and example study in the following way. First, a complete example is presented (model). Second, an example is given in which one single solution step is omitted (scaffolded problem solving). Then, the number of blanks is increased step-by step until just the problem formulation is left, that is, a problem to-be-solved (independent problem solving). In this way, a smooth transition from modeling (complete example) over scaffolded problem solving (incomplete example) to independent problem solving is implemented. This rationale provides possible answers to the open questions outlined above.

### Experiment 1: Field Experiment

As a first test of our assumptions we conducted a small-scale field experiment in which we tested whether a smooth transition from example study to problem solving (gradual insertion of blanks into the solutions of examples) is more effective than learning by example-problem pairs as they are used in many studies on learning from examples. As a method of fading out the solution steps, we choose to first omit the last solution step, then the last two steps, and finally all three steps ("backward rationale").

## Methods

**Sample and Design.** Two ninth-grade classrooms from a German *Hauptschule* (lowest track of the German three track system) participated in this quasi-experiment. In both classrooms, the same teacher (third author) conducted a physics lesson on electricity based on four examples/problems. In one classroom ( $n = 20$ ) a fading procedure was used and in the other classroom ( $n = 15$ ) traditional example-problem pairs were employed. Each example/problem involved three solution steps. Across both conditions half of the steps were worked-out whereas the other half was to be generated. Thus, learners in both conditions were required to solve the same number of solution steps.

**Learning Environment.** In the experimental phase, the third author (a professional teacher) conducted a 45 minute lesson in each classroom. Both groups worked on four examples/problems in which the cost for running a variety of electric devices for a certain time had to be determined (e.g., "A aluminum factory has a big melting furnace which is run with 1000 V. A power of 20 A has to flow through the furnace in order to melt aluminum. What does the factory have to pay per month when the furnace always runs and the kWh costs DM 0.22?"). Although the examples/problems were printed on work sheets, the problem formulation of each example/problem was read aloud by one of the students from the class. Following the reading of the problem formulation, the students were permitted to ask clarifying questions (of course, no questions on the solution) before working individually on the example or problem. At the end of each incomplete example or problem, the complete solution was presented on an overhead transparency and, if necessary, the students corrected or supplemented their solutions. Then the teacher proceeded to the next example/problem.

In the fading classroom, the teacher presented the instruction in the following order: (1) a complete example, (2) an example with the last solution step left out, (3) an example with the last two steps omitted, and (4) a problem where all three steps were missing. In the example-problem group in contrast, a complete example was presented twice, each time it was followed by a corresponding problem.

**Procedure.** The overall procedure was identical in both classrooms. Basic knowledge of the concepts and rules of electricity was introduced in the context of regular instruction followed by a pretest that tapped into prior knowledge with respect to the ability to apply the abstract rules to domain problems. Two days later, the school lessons in which the experimental variation took place were conducted. Finally, after additional two days, the students worked on a posttest.

**Instruments.** The pretest consisted of four problems from the physics domain of electricity that were structurally equivalent to the problems in the posttest (e.g., "The electronic motor of an electronic locomotive is supplied by a voltage of 0.6 kV. In the average, a current of 18 A flows through the motor. What does an eight-hour trip from Stuttgart to Hamburg cost when you assume that the *German Railway* pays DM 0.12 per kWh?"). For the correct solution

of an item, a maximum of three points was assigned. For partly correct solutions partial credit was dispensed. The score was divided by the theoretical maximum score (12) so that it represent the percentage of points in relation to perfect performance. The pretest had a sufficient reliability (Cronbach's Alpha: .87).

The posttests consisted of six problems. The four near-transfer problems had the same underlying structure (solution rationale) as the examples and problems employed in the learning phase but different surface features (cover story, numbers). Two problems were classified as far transfer because both the underlying structure and the surface features differed (e.g., "Tanja pays for her frig DM 40 per year. One kWh costs DM 0.22. What power does the frig have if you assume that it runs all the time?"). For the correct solution on a posttest problem, which always included three solution steps, three points were dispensed. Partial credit was given for partly correct solutions (1 or 2 points). The scores for both scales were finally divided by the theoretical maximum score (12 or 6 respectively) so that they represented the percentage of points in relation to perfect performance. We obtained sufficient reliabilities (Cronbach's Alphas) for both posttest scales: .85 for near transfer and .60 for far transfer.

## Results

Table 1 shows the means and standard deviations of the two experimental groups on the pretest and the posttest scores. Both groups showed almost identical pretest performance ( $t(33) = 0.01$ ;  $p > .10$ ). Hence, there was no *a priori* difference between groups with respect to prior knowledge.

Table 1: Group means (standard deviations in brackets) of pretest and posttest scores.

	Fading	Example-problem pairs
Pretest	24.06 (28.12)	23.96 (29.02)
Posttest: near transfer	79.38 (27.42)	62.22 (24.82)
Posttest: far transfer	36.25 (37.29)	21.11 (27.61)

With respect to treatment effects we descriptively obtained higher means in the fading group for both near and far transfer. Comparisons between the experimental conditions by means of an ANCOVA (controlling for prior knowledge) yielded a significant difference for near transfer performance ( $F(1,32) = 4.44$ ;  $p < .05$ ). The group difference in far transfer performance failed to reach the level of significance ( $F(1,32) = 2.28$ ;  $p > .10$ ). Thus, the fading procedure clearly fostered near transfer performance. We can not, however, claim that this is also true for far transfer performance.

## Discussion

We obtained a positive effect of our fading procedure with respect to near transfer performance. The far transfer performance was also superior in the fading group, but not at the level of statistical significance. Before theorizing on

possible reasons for potential differential effects of the fading procedure on near and far transfer, we should wait and see whether the respective finding can be replicated.

A replication is necessary because a field study such as the present one always has some factors that might diminish the internal validity of the findings. For example, the teacher that conducted the instruction in both classrooms was not "blind" with respect to the experimental expectations. Furthermore, the present investigation was "merely" a quasi-experiment (no random assignment of participants to the experimental conditions). Hence, the conditions in both classrooms might not have been totally identical except for the independent variable (fading vs. example-problem pairs). Finally, no data on possible processes that mediate the effects of the fading procedure on the learning outcomes were recorded. These issues were addressed in Experiment 2.

## Experiment 2: Lab Experiment

In order to conceptually replicate the results of the preceding field experiment under more controlled conditions, we ran a lab experiment. We also tested for one possible mediating mechanism that may explain the effect found in Experiment 1.

As outlined above, there are quite abrupt changes with respect to the demands placed on the learners in the example-problem conditions. After a first example, the learners have to solve a whole problem totally on their own. In the fading procedure, the first problem solving demand is to generate just a single step, and the demands are only gradually increased. Against this background, we expect that the learners will make fewer errors during learning in the fading condition. In the example-problem condition, in contrast, we expect a relatively high number of errors during learning that may prevent rapid learning progress. This assumption was tested in Experiment 2.

In order to see whether the effects of the fading procedure are robust against variations in its concrete implementation, we did not use a "backward", but a "forward rationale" in this study. This means that firstly the first step was omitted, then the first two steps, and finally all three steps.

## Methods

**Sample and Design.** The participants of this study were 54 students of psychology (Mississippi State University). They were randomly assigned to the fading or to the example-problem condition, respectively ( $n = 27$  in each group). As with our field experiment, the number of unsolved solution steps was held constant across both conditions.

**Learning Environment.** A computer-based learning program was employed that had been originally developed by Renkl (1997), modified by Stark (1999), and finally adapted to the present needs by the second author. It presented worked-out examples and problems from the domain of probability (e.g., "Jonathan has recently bought a new camera. Independently of each other he frequently makes two errors when he takes a picture. He manages to blur the image in 40% of his photos ( $p=2/5$ ) and he forgets to activate the flash in 10% of the photos ( $p=1/10$ ) so that the pictures end up too dark. If you randomly choose one of Jonathan's

developed pictures, what is the probability that it will be flawless?"). The examples/problems were displayed in a step-by-step procedure. On the first page of an example/problem, the problem givens were displayed. The learners could read them and then go to the next page where a first solution step was presented or the learners were required to determine a solution step on their own (or at least to attempt it). After inspecting or determining this solution step, the participants proceeded to the following page where the next solution step was added or required, and so on. When the whole solution of a problem was presented or required, the next page contained the first page of a new example/problem until the lesson was completed. In the case of omitted solution steps, the learners had to type in a solution attempt. Hence, the correctness of the problem solving attempts could be determined. Note that the correct step was always displayed when the learners went to the next page so that there was feedback on the correctness of the learners' problem solving attempts.

On the whole, there were two sets of four probability tasks. Each set consisted of four tasks with the same underlying structure (solution rationale) but different surface features (cover stories, numbers). In the fading group, the first task was a completely worked-out example. In the second task, the first solution step was omitted. In the third task the first two steps were omitted ("forward rationale" of omitting solution steps). The fourth task was essentially a problem-solving task (all three steps were missing). In the example-problem group, two such pairs (i.e., example-problem) were presented.

**Procedure.** The participants worked in group sessions lasting about 90 minutes. They worked individually in front of a computer. First, a pretest on prior knowledge in probability calculation was presented. In order to provide or re-activate basic knowledge that allowed the participants to understand the worked-out examples, an instructional text on basic principles of probability calculation was given to the participants. After reading this instructional text, the participants were to study the worked-out examples and problems provided by the computer program. In this phase, the experimental variation took place (fading vs. example-problem pairs). The time spent for learning was recorded. Finally, the participants worked on a posttest.

**Instruments.** A *pretest* was employed in order to assess prior knowledge. It consisted of nine relatively simple problems involving probability calculation (e.g., "When rolling a 6-sided die what is the probability that '2' or '4' will appear?"). For each correct solution, one point was dispensed (no partial credit). The overall score was divided by the theoretical maximum score (9) so that it represents the percentage of points in relation to perfect performance. We obtained a sufficient reliability of .73 (Cronbach's Alpha).

The learning outcomes were assessed by a *posttest* that included thirteen problems. Besides one very simple warm-up problem, which was ignored for further analysis, we employed six near transfer items and six far transfer items. As compared to the examples/problems studied during the learning phase, the near transfer problems had the same underlying

ing structure (solution rationale) but different surface features (cover story, numbers; e.g., "While preparing a batch of rolls at the local bakery, the baker's assistant forgot to add salt to 30% of the rolls and, independent of this event, he burned 40% of the rolls. If the head baker arrives to examine the quality of his assistant's work by randomly testing a roll, what is the probability that it is edible; that is, that it has the right amount of salt and is not burned?"). Far transfer problems differed with respect to both structure and surface features (e.g., "When driving to work, Mrs. Fast has to pass the same traffic light twice—once in the morning and once in the evening. It is green in 70% of the cases. What is the probability that she can pass through a green light in the morning but has to stop in the evening?").

For the totally correct solution on a posttest problem, which always included three solution steps, three points were dispensed. Partial credit was provided for partially correct solutions (1 or 2 points). The scores for both scales were finally divided by the theoretical maximum score (18) so that they represent the percentage of points in relation to perfect performance. We obtained sufficient reliabilities (Cronbach's Alphas) for both posttest scales: .91 for near transfer and .75 for far transfer.

## Results

Table 2 shows the means and the standard deviations of the two experimental groups for the pretest (prior knowledge), the time spent for studying the examples and problems (learning time), the proportion of correct solutions steps generated during learning, and posttest performance with regard to near transfer and to far transfer. The small difference between the pretest scores in favor of the example-problem group was not statistically significant ( $t(52) = -0.49; p > .10$ ). Hence, the groups were *a priori* comparable with respect to prior knowledge. In addition, the learning time did not significantly differ between groups ( $t(52) = 0.28; p > .10$ ). Thus, possible group differences with respect to learning could not be simply attributed to time-on-task.

Table 2: Group means (standard deviations in brackets) of the pretest, the learning time (min.), the correctness of solution steps during learning (in %), and the posttest.

	Fading	Example-problem pairs
Pretest	55.56 (23.67)	58.85 (25.93)
Learning time	31.15 (10.83)	30.37 ( 9.41)
Correctness of solution steps	66.42 (31.61)	51.81 (33.13)
Posttest: near transfer	53.91 (32.24)	43.83 (35.35)
Posttest: far transfer	38.68 (25.25)	43.42 (24.60)

With respect to treatment effects, we descriptively obtained substantially higher means in the fading group for the proportion of correct solution steps and for near transfer. We used an ANCOVA (controlling for prior knowledge) to make

comparisons between the experimental conditions that yielded a significant difference for near transfer performance ( $F(1,51) = 4.58; p < .05$ ), but not for far transfer ( $F < 1$ ). A third ANOVA revealed that there was also a significant difference between groups with respect to the proportion of correct solution steps ( $F(1,51) = 7.62; p < .05$ ).

In order to test the mediation hypothesis that fading fosters learning outcomes (at least near transfer) because less errors occur during learning, an additional ANOVA for near transfer performance was performed in which the proportion of correct solution steps was included as covariate in addition to prior knowledge. The mediation hypothesis would have been confirmed if the group effect (more or less totally) disappeared in this case (cf. Baron & Kenny, 1986). This proved to be true. The  $F$ -value for the group effect was not only smaller than 1, but was a negligible size of 0.23.

## Discussion

In the present lab experiment, we conceptually replicated the effectiveness of our fading procedure for near transfer. Both studies also yielded consistent results with respect to far transfer: No significant effect was found. We obtained these converging results even though the present study and our first investigation differed with respect to the type of learners ("low-track" students vs. university students), the learning domain (physics/electricity vs. mathematics/probability calculation), the learning setting (school lesson vs. computer-based learning in the lab), and the kind of fading out worked-out solution steps ("backward" vs. "forward"). We interpreted the stability of the findings despite these very different context conditions as an indicator that our fading procedure has a reliable effect.

Something that we did not expect in advance is that the effect of fading is restricted to near transfer. This differential effectiveness of the fading procedure may have something to do with the mediating mechanism that was identified in this study (amount of errors during learning). The analyses showed that the effect on near transfer is more or less totally mediated by the amount of errors committed during learning. Although we did not directly assess self-explanations, this result suggests that the fading procedure did not enhance learning outcomes via fostering self-explanation quality. This also helps to explain the differential effectiveness of fading. For far transfer performance (e.g., Renkl, 1997; see also Atkinson et al., in press), it is of special importance that the learners explain to themselves the rationale of solution steps in an active way so that they become aware of how domain principles can be applied in a domain and how certain goals can be achieved by certain operators. In other words, reflection about the more general aspects of specific problem solutions is necessary for far transfer. However, this process was obviously not elicited by the fading procedure. "Error-avoiding" instructional procedures such as Direct Instruction or drill-and-practice tutorials are known to effectively foster "low-level" level learning (near transfer). As our fading procedure is a method of avoiding errors during learning, it is understandable why it fosters "merely" near transfer performance.

## General Discussion

In the present study, the effectiveness of our fading rationale for designing the transition from example study to problem solving has been affirmed in an highly ecologically valid field experiment as well as in a well-controlled lab study. Thus, we have provided strong evidence that a fading procedure actually fosters near transfer. Nevertheless, there are at least three important questions left that should be addressed in further research:

(1) The results indicate that the effects of fading are more or less totally mediated by the low amount of errors during learning and not by the way in which the examples were processed (self-explanations). In order to obtain more direct evidence for this interpretation, self-explanations should be assessed in a subsequent study on fading in example-based learning. In such a study, the mediation effect involving the amount of errors should be replicated and it should be tested whether there are, as expected, no differences with respect to self-explanations.

(2) In the effort to successively optimize learning from worked-out examples, another issue related to self-explanations should be addressed. If it is true, as argued above, that the quality of self-explanations is especially important for far transfer, it should be tested whether a combination of fading and self-explanation training—such as the one developed and evaluated by Renkl, Stark, Gruber, and Mandl (1998)—can facilitate *both* near and far transfer learning.

(3) We employed two ways of fading out worked-out solution steps, a backward and forward procedure. As the context conditions in our two studies varied substantially, we could not compare the relative effectiveness of these two procedures. In addition, it may well be that other procedures are even more effective. For example, one could first omit the solution step that is the easiest one for the learners to determine, then the second easiest one and so on. Systematic experimentation on this issue is necessary in order to get information on whether different ways of fading have substantially different effects and, if so, which way of fading is the ideal one.

Taken together, this contribution has provided strong evidence for the effectiveness of our "new" rationale for the integration of example study and problem solving. However, in order for us to deeply understand the way this works and to optimize the employment of this rationale, further experiments are necessary.

## Abstract

The way we model semantic similarity is closely tied to our understanding of linguistic representations. We present several models of semantic similarity, based on differing representational assumptions, and investigate their properties via comparison with human ratings of verb similarity. The results offer insight into the bases for human similarity judgments and provide a testbed for further investigation of the interactions among syntactic properties, semantic structure, and semantic content.

## Introduction

The way we model semantic similarity is closely tied to our understanding of how linguistic representations are acquired and used. Some models of similarity, such as Tversky's (1977), assume an explicit set of features over which a similarity measure can be computed, and recent computational methods for measuring word similarity can be thought of as an update of this idea on a large scale, representing words in terms of distributional features acquired via analysis of text corpora (e.g., Brown, Della Pietra, deSouza, Lai, & Mercer, 1992; Schütze, 1993). Other methods, following in the semantic networks tradition of Quillian (1968), focus less on explicit features and more on relationships among lexical items within a conceptual taxonomy, sometimes going beyond taxonomic relationships to also take advantage of frequency information derived from corpora (e.g., Rada, Mili, Bicknell, & Blettner, 1989; Resnik, 1999).

Although some of these approaches are not explicitly designed as cognitive models, we have proposed that prediction of human similarity can provide a useful point of comparison for computational measures of similarity, noting that one must be aware that such comparisons can be quite sensitive to the specific choice of test items (Resnik, 1999). To date, we are only aware of comparisons having been done using noun similarity.

In this paper, we consider the problem of measuring the semantic similarity of verbs. Verb similarity is in many respects a different problem from noun similarity, because verb representations are generally viewed as possessing properties that nouns do not, such as syntactic subcategorization restrictions, selectional preferences, and event structure, and there are dependencies among these properties.<sup>1</sup> This means that particular

care must be taken in selecting items, as discussed below, and it also means that the same computational measures may be capturing different properties for verbs than for nouns. For example, the IS-A relationship in WordNet's verb taxonomy (Fellbaum, 1998), central in the computation of some measures, signifies generalization according to manner, as in *devour* IS-A *eat*; concomitantly, the verb taxonomy is considerably wider and shallower than WordNet's noun taxonomy. Similarly, measures based on syntactic dependencies may be sensitive to syntactic adjuncts, such as locative and temporal modifiers, that occur predominantly with verbs rather than with nouns.

In what follows, we first discuss several different measures of word similarity and their properties. We then describe an experiment designed to obtain human similarity ratings for pairs of verbs, discuss the fit of the alternative measures to the human ratings, and suggest some implications of these results for future work.

## Models of Verb Similarity

We consider three classes of similarity measure, corresponding to three kinds of lexical representation. In the first, verbs are associated with nodes in a semantic network. In the second, verbs are represented by distributional syntactic co-occurrence features obtained via analysis of a corpus. In the third, verbs are associated with lexical entries represented according to a theory of lexical conceptual structure. These classes of representation can be viewed as occupying three different points on the spectrum from non-syntactic to syntactically relevant facets of verb meaning.

## Taxonomic Models

Taxonomic models of lexical and conceptual knowledge have a long history. In this work we use WordNet version 1.5, a large scale taxonomic representation of concepts lexicalized in English. As a model of the lexicon, WordNet's verb hierarchy is limited by design to paradigmatic relations, in explicit contrast to attempts to organize semantically coherent verb classes through shared syntactic behavior.

The simplest and most traditional measure of semantic similarity in a taxonomy counts the number of edges in-

---

be part-of-speech *per se*; one could argue that some nouns carry similar kinds of participant information, observing, for example, that *x's gift of y to z* parallels *x gave y to z*. We are not attempting to address that issue here.

---

<sup>1</sup>Admittedly, the relevant contrast may turn out not to

tervening between nodes (“edge counting”). A distance in edges is converted to similarity by subtracting from the maximum possible distance in the taxonomy, giving the following measure of distance between verbs  $w_1$  and  $w_2$ :

$$\text{wsim}_{\text{edge}}(w_1, w_2) = (2 \times \text{MAX}) - \left[ \min_{c_1, c_2} \text{len}(c_1, c_2) \right] \quad (1)$$

where  $c_1$  ranges over  $s(w_1)$ ,  $c_2$  ranges over  $s(w_2)$ , MAX is the maximum depth of the taxonomy, and  $\text{len}(c_1, c_2)$  is the length of the shortest path from  $c_1$  to  $c_2$ , with  $s(w)$  denoting the set of concepts in the taxonomy that represent senses of word  $w$ . If all senses of  $w_1$  and  $w_2$  are in separate sub-taxonomies of the WordNet verb hierarchy their edge-count similarity is defined to be zero.

The simple edge-counting approach has well known problems, and arguments have been made for the following measure of semantic similarity between concepts in a taxonomy based on shared information content (Resnik, 1999):

$$\text{sim}_{\text{info1}}(c_1, c_2) = \max_{c \in S(c_1, c_2)} [-\log p(c)], \quad (2)$$

where  $S(c_1, c_2)$  is the set of concepts that subsume both  $c_1$  and  $c_2$ , and  $-\log p(c)$  quantifies the “information content” of node  $c$ . This yields a measure of verb similarity

$$\text{wsim}_{\text{info1}}(w_1, w_2) = \max_{c_1, c_2} [\text{sim}_{\text{info1}}(c_1, c_2)], \quad (3)$$

where  $c_1$  ranges over  $s(w_1)$  and  $c_2$  ranges over  $s(w_2)$ , and  $p(c)$  is estimated by observing frequencies in a corpus.<sup>2</sup> Intuitively, the quantity defined in (3) measures the maximum overlap in information between the words being compared. When two words are not very similar, the information content of their most informative subsumer (the node  $c$  maximizing  $-\log p(c)$ ) is low: that subsumer resides high in the taxonomy and thus has high probability, implying low information content. In the most extreme case, the most informative subsumer is just the TOP node of the taxonomy, in which case the probability is 1 and the shared information content (and hence similarity) is 0. When two words are similar, that means there is a node lower in the taxonomy that subsumes them both; being lower in the taxonomy its probability is lower and therefore its information content is higher. Crucially, structural notions such as “lower” and “higher”, and the number of intervening arcs between nodes, play no actual role in this model of similarity. As a result, unlike edge counting, this measure does not fall prey to the rampant variation in density within any realistic conceptual taxonomy, where a single IS-A link could represent a tiny semantic distance (e.g. *ballpoint-pen* IS-A *pen*) or a very large semantic distance (e.g. *toy* IS-A *artifact*).<sup>3</sup>

Lin (1998) argues for an alternative information-based measure of similarity that, when applied to a taxonomy,

<sup>2</sup>For taxonomic measures described in this section, probabilities of nodes in WordNet 1.5 were estimated on the basis of word frequencies in the Brown Corpus (Francis & Kučera, 1982).

<sup>3</sup>Examples are from WordNet 1.5, where *artifact* signifies a man-made object.

closely resembles the measure just described. It differs in normalizing the shared information content using the sum of the *unshared* information content of each item being compared:

$$\text{sim}_{\text{info2}}(c_1, c_2) = \frac{2 \times \log p(\bigcap_i C_i)}{\log p(c_1) + \log p(c_2)} \quad (4)$$

where the  $C_i$  are the “maximally specific superclasses” of both  $c_1$  and  $c_2$ . As a result of this normalization, the measure possesses some desirable properties, such as a fixed range from 0 to 1. Word similarity  $\text{wsim}_{\text{info2}}$  is defined analogously to Definition (3).

## Distributional Co-Occurrence Model

Information-based measures of similarity can be applied to representations other than taxonomic structures. Indeed, Lin demonstrates the generality of the idea by showing how such a measure can be used to measure not only taxonomic distance but also string similarity and the distance between feature sets *à la* Tversky. The latter approach is illustrated by representing words as collections of syntactic co-occurrence features obtained by parsing a corpus. For example, both the noun *duty* and the noun *sanction* would have feature sets containing the feature *subj-of(include)*, but only *sanction* would have the feature *adj-mod(economic)*, since “economic sanctions” appears in the corpus but “economic duties” does not. Because these features include both labeled syntactic relationships and the lexical items filling argument roles, the underlying representational model can be thought of as capturing both syntactic and semantic components of verb meaning.

Lin computes the quantity of shared information as the information in the intersection of the distributional feature sets for the two items being compared. This yields the following measure:

$$\text{wsim}_{\text{distrib}}(w_1, w_2) = \frac{2 \times I(F(w_1) \cap F(w_2))}{I(F(w_1)) + I(F(w_2))} \quad (5)$$

where  $F(w_i)$  is the feature set associated with word  $w_i$ , and where  $I(\mathcal{S})$ , the quantity of information in a feature set  $\mathcal{S}$ , is computed as  $I(\mathcal{S}) = -\sum_{f \in \mathcal{S}} \log p(f)$ .<sup>4</sup> In the experiments described here, we use similarity values obtained for verb pairs using Lin’s implementation of his model, with his feature sets and probabilities obtained via analysis of a 22-million-word corpus of newswire text.

## Semantic Structure Model

Our third method for assessing the semantic similarity of verbs relies on elaborated representations of verb semantics according to the theory of lexical conceptual structure, or LCS (Dorr, 1993; Jackendoff, 1983). LCS representations make an explicit distinction between *semantic structure*, which characterizes the grammatically relevant facets of verb meaning, from *semantic content*, which characterizes idiosyncratic information associated with the verb but not reflected in its syntactic behavior.

<sup>4</sup>Note the assumption that features are independent, permitting the summation of log probabilities.

This difference between semantic structure and semantic content plays an important role in current research on lexical representation (e.g. Grimshaw, 1993; Pinker, 1989; Rappaport, Laughren, & Levin, 1993). We take advantage of this distinction here to derive a measure that focuses exclusively on similarity of semantic structure as disentangled from semantic content.

To illustrate with a simple example, within an LCS representational system *roll* and *slide* might both have semantic structure indicating a change of location, e.g.,

$$\begin{aligned} & (g_{\text{loc}} \text{ x} \\ & \quad (\text{to}_{\text{loc}} \text{ x} (\text{at}_{\text{loc}} \text{ x} y)) \\ & \quad (\text{from}_{\text{loc}} \text{ x} (\text{at}_{\text{loc}} \text{ x} z)) \\ & \quad (\text{manner} \langle \text{M} \rangle)), \end{aligned}$$

and differ only in the value  $\langle \text{M} \rangle$  — an element of semantic content within the semantic structure — indicating the manner of motion (either  $\langle \text{SLIDING} \rangle$  or  $\langle \text{ROLLING} \rangle$ ). Such regularities in semantic structure are argued to provide an explanation for systematic relationships between meaning and syntactic realization (Levin & Rappaport Hovav, 1998).

If those regularities are a part of verb lexical representations, then they also plausibly influence ratings of verb similarity, and the question is how to assess similarity between two such structured representations. Lin’s work provides one plausible answer: decomposing complex representations into (pseudo-)independent feature sets and then comparing feature sets.<sup>5</sup> Our method of decomposition was particularly simple, recursively creating an independent feature from each primitive component of the representation and the “head” of its subordinates. So, for example, the feature set representation of *roll* would contain six features:

$$\begin{aligned} & [g_{\text{loc}} \text{ to}_{\text{loc}} \text{ from}_{\text{loc}} \text{ manner}] \\ & [\text{to}_{\text{loc}} \text{ x} \text{ at}_{\text{loc}}] \\ & [\text{at}_{\text{loc}} \text{ x} y] \\ & [\text{from}_{\text{loc}} \text{ x} \text{ at}_{\text{loc}}] \\ & [\text{at}_{\text{loc}} \text{ x} z] \\ & [\text{manner} \langle \text{ROLLING} \rangle]. \end{aligned}$$

The features of *slide* would be identical but for the last feature, which would instead be  $[\text{manner} \langle \text{SLIDING} \rangle]$ , and the nearly complete overlap between the feature sets for the two verbs captures the fact that the semantic distinction between this particular pair of verbs rests entirely on semantic content and not semantic structure.

Since we had available to us a large lexicon of LCS representations for verbs in English (Dorr & Olsen, 1996, 1997), containing thousands of lexical entries, we estimated the probability of each feature by counting feature occurrences within the lexicon. We define the similarity of two LCS lexicon entries  $e_1$  and  $e_2$  using the shared information content of their feature sets:

$$\text{sim}_{\text{LCS}}(e_1, e_2) = I(F(e_1) \cap F(e_2)) \quad (6)$$

<sup>5</sup>We are grateful to Dekang Lin for suggesting this approach to us.

using  $I(S)$  as in (5), and we compute  $\text{wsim}_{\text{LCS}}(w_1, w_2)$  as the maximum value of  $\text{sim}_{\text{LCS}}$  taken over the cross product of all the words’ lexical entries.<sup>6</sup>

It is worth emphasizing that this similarity measure considers *only* semantic structure, not semantic content, and therefore only syntactically relevant components of meaning enter into the computation. For example, in the comparison of LCS entries for *slide* and *roll*,  $F(e_1) \cap F(e_2)$  will never contain either  $[\text{manner} \langle \text{ROLLING} \rangle]$  or  $[\text{manner} \langle \text{SLIDING} \rangle]$ , and therefore any potential similarities or differences between the content elements — the *physical* aspects of sliding motion versus rolling motion based on real-world knowledge — are excluded from the model.

## Experiment

In order to assess alternative computational models of similarity, we collected human ratings of similarity for pairs of verbs, following a design after that of Miller and Charles (1991). Considering the additional complexities in the verb lexicon, however, the selection of materials required considerable care: we were careful to pay close attention to syntactic subcategorization, thematic grids, and aspectual class information, as described below, in order to limit the possible dimensions across which the two verbs in a pair could differ and to focus on *semantic* similarity. We also designed two versions of the task, with and without presentation of verbs in context, in order to investigate the extent to which contextual narrowing of verbs’ senses affects ratings of similarity.

**Participants.** Participants were 10 volunteers, all native speakers of English, ranging in age from 24 to 53, without significant background in psychology or linguistics. All participated by e-mail.

**Materials.** In constructing the set of verb pairs for similarity ratings, we began with the set of verbs in a large lexicon of LCS entries, containing entries for 4900 verbs. Verb entries in the lexicon contain information about both aspectual features (dynamicity, durativity, telicity; Olsen, 1997) and thematic grid (identifying whether or not a verb takes an agent, theme, goal, etc.) — for example, the verb *broil* requires both an agent and a theme, and is marked as both durative and telic but not dynamic. For subcategorization information, we referred to the Collins Cobuild dictionary (Sinclair, 1995), using the subcategorization frame for the first listed verb sense.

To construct verb pairs, we began by eliminating all verbs whose thematic grid did not require a theme, in order to limit the range of variation in thematic grids.<sup>7</sup>

<sup>6</sup>Although our probability estimate counts features within a set of types (entries in a large lexicon) rather than tokens (verb instances in a large corpus), inspection of the estimated probabilities suggests that frequent features are suitably discounted, having low information content, and rare features are highly informative. Corpus-based estimates are a matter for future work.

<sup>7</sup>All verbs require an agent, so the remaining variation is in the presence or absence of oblique roles such as GOAL.

We then grouped the full set of verbs into eight lists corresponding to the eight possible combinations of the three aspectual features, and restricted our attention to the four most numerous lists.<sup>8</sup> Within each of those four lists, we created 12 pairs of verbs subject to the constraint that the verbs’ associated subcategorization frames had to match, so as to avoid effects of purely syntactic similarity. Items were selected to span the range from low- to high-similarity verb pairs.

In summary, a set of 48 verb pairs was constructed so that (i) both verbs in every pair require a theme, (ii) both verbs have the same subcategorization frame, and (iii) both verbs come from the same aspectual class. Verbs on the list were all given in the past tense. In order to avoid ordering effects, half the subjects in each condition saw items in a random order, and the other half saw the items in the reverse order.

To assess the effects that contextual narrowing of verb senses might have on similarity ratings, the materials as just described were duplicated in order to create *No Context* and *Context* conditions. The conditions were identical except that in the *Context* condition, each item was accompanied by an example sentence for each verb illustrating the verb’s intended sense. Each example sentence came from the corresponding verb entry in the Collins Cobuild dictionary. For example, the example sentence for *loosen* was “He loosened his seat belt.”

**Procedure.** The 10 subjects were split evenly into *Context* and *No Context* groups. Subjects in the *No Context* group were given the set of 48 verb pairs, without example sentences, and asked to compare their meanings on a scale of 0–5, where 0 means that the verbs are not similar at all and 5 indicates maximum similarity. Subjects were explicitly asked to ignore similarities in the sound of the verb and similarities in the number and type of letters that make up the verb. Subjects were also asked explicitly to rate similarity rather than relatedness, with the instructions giving an example of the distinction. (For example, *pay* and *eat* are related in that they are things we do in restaurants, but they are not particularly similar.) Since some verbs in the set have low frequency, a “don’t know” box was included for subjects to mark if they were unsure of the meaning of either verb. There was no time limit on the task, which tended to take approximately 20 minutes.

Subjects in the *Context* group were given exactly the same task, but using the *Context* materials, i.e. with each verb accompanied by an example sentence illustrating the intended sense. As in the previous condition, two orders of presentation were used within this condition to avoid ordering effects.

Each computational similarity measure took the set of verb pairs as input, without context, and computed a similarity score for each.

<sup>8</sup>These were {durative}, {durative,dynamic}, {dynamic,telic}, {durative,dynamic,telic}. Verbs could and did appear on multiple lists.

Table 1: Comparing sets of ratings

wsim	<i>Context</i>	<i>No Context</i>
edge	.720	.675
info1	.779	.658
info2	.768	.668
distrib	.453	.433
lcs	.313	.385
Combined	.872	.785
Inter-rater	.793	.764

**Results and Discussion.** In order to judge the degree to which sets of similarity ratings are predictive of each other, we use a similarity coefficient computed as Pearson’s *r*. Table 1 provides a summary showing *r* for each computational model as compared to the mean of the human subject ratings in the *Context* and *No Context* conditions.<sup>9</sup>

The *Combined* row of the table shows the value of multiple *R* when the five computational measures are compared with human ratings using a multiple regression (see below), and the *Inter-rater* row of the table shows human average inter-rater agreement, measured by *r*, using leave-one-out resampling (Weiss & Kulikowski, 1991).

Examining these figures, we first consider each computational model separately. It is unsurprising that the similarity measure based on LCS representations fares worst, given the design of the experiment: the verb pairs were selected so as to eliminate differences of subcategorization frame, aspectual class, and thematic grid, ruling out *a priori* pairs that differ interestingly with respect to semantic structure. The distributional measure based on syntactic co-occurrence features may be a victim of its dependence on a particular corpus, and of data sparseness — for example, glaring divergences with human ratings include some verb pairs containing some lower-frequency words, such as *embellish/decorate* and *dissolve/dissipate*. Turning to the taxonomic methods, the information-based approaches appear superior to edge counting in the *Context* condition, consistent with previous work on noun similarity, though in the *No Context* condition there are no clear differences. We suspect a difference will emerge with a larger set of items, but this remains to be seen. Our inspection of by-item

<sup>9</sup>From the full set of items, 10 verb pairs were excluded because some participant did not know the meaning of one or the other verb. Moreover, in preparation of the final version of this paper, we discovered that 11 verb pairs inadvertently had been included despite failing to strictly match the criteria described in the Materials section or having other minor errors of presentation, and these are now excluded, as well. Although this is a large number of excluded items, we consider them quite unlikely to have affected participants’ judgments since the excluded pairs were distributed almost perfectly evenly over the four verb lists and varied across degrees of similarity, and since the pattern of results was unaffected. We report all quantitative results in the paper based on only the 27 non-excluded verb pairs.

ratings of the information measures suggests strongly that the differences between the unnormalized and normalized information-based measures are small in comparison to the role played by the structure of the WordNet verb taxonomy.

Comparison of human raters yields several interesting observations. First, a comparison of the *Context* and *No Context* mean ratings by human participants yields  $r = .89$ , which provides some reassurance that subjects in the *No Context* condition are generally interpreting the verbs in the same sense as are subjects in the *Context* condition — where, recall, the context sentence encouraged interpretation according to the first listed verb sense in the Collins Cobuild dictionary. Second, however, average inter-rater agreement in the two conditions (.79 and .76) is much lower than that obtained in a noun ratings experiment using the same method, where leave-one-out resampling yielded an estimate of  $r = .90$  (Resnik, 1999). This may reflect the small sample size in each group ( $N = 5$ ), but we suspect that in actuality it is evidence that word similarity is harder for subjects to quantify for verbs than for nouns. Third, we find that subjects in the *No Context* condition have a very strong tendency to assign higher similarity ratings to the same pair as compared to subjects in the *Context* condition, as determined using a paired  $t$ -test ( $N = 27, t(26) = 4.49, p < .0002$ ).

This last observation is consistent with the idea that subjects in the *No Context* condition are accommodating verb comparisons — allowing for more flexible interpretations of verb meaning — in a way not available to subjects in the *Context* condition because their interpretations are constrained by the context sentence. For example, the verb pair *compose/manufacture* has a mean rating of 2.8 in the *Context* condition, and the context sentences are *He sees the whole, not the various lines that compose it* and *Many factories were manufacturing desk calculators*. In the *No Context* condition, the mean rating for this pair is 4.0, likely indicating that in the process of comparison, subjects focused on available semantic elements of *compose*'s meaning that are closest to *manufacture* (e.g., the notion of composing as creating, *She composed satirical poems for the New Statesman*).

As a preliminary step toward combining models, we performed a multiple regression predicting human ratings using the ratings of the five computational models as independent variables, with the results shown in Table 1 as *Combined*. Although we have not extensively analyzed these data, regressions using all  $2^5 - 1 = 31$  combinations of models show that the highest multiple  $R$  is obtained when all five models are combined, that the two different information-based measures are making essentially the same contribution to the combined model (consistent with our observation that WordNet structure plays the dominant role, rather than details of the measure), and that the LCS measure contributes little for this set of items. Taking these observations into account, the improvement in predictive power when combining models comes from distributional and information-based

models being sensitive to at least some different information.

## General Discussion

The experimental results reflect the fact that similarity measures model different aspects of verb representation and use. Taxonomic similarity measures place little emphasis on verbs' argument structure, emphasizing relationships of semantic content; for example, *drag* and *tug* appear quite close in the taxonomy (under *displace*) although they differ significantly in semantic structure (e.g. in “the tailpipe dragged” and “the donkey tugged” the syntactic subjects have different thematic roles). Conversely, semantic structure is emphasized in the measure based on LCS representations to the exclusion of real-world knowledge, such as the similarity of the physical motions of dragging and tugging. Distributional similarity based on syntactic co-occurrence features is a combination, capturing elements of semantic structure by means of the syntactic relationships (one-versus two-participant relationships), and also indirectly capturing elements of semantic content by means of the lexical items co-occurring in those syntactic positions (*tug* being weighted more heavily against inanimate subjects than *drag*, for example). Based on the performance of the models, and improved predictive power of the multiple regression, we interpret our results as evidence that human ratings of similarity are sensitive to both paradigmatic and syntagmatic facets of verb representation, and we believe the computational models are capturing relevant aspects of verb representation in order to make predictions about similarity judgments.

On a somewhat speculative note, it is interesting to briefly examine cases where the computational models fail to capture similarities identified by the human raters. Consider, for example, items *unfold/divorce*, *chill/toughen*, *initiate/enter*. Based on the WordNet taxonomy, the verbs in these pairs have no common subsumer, so the shared information content is zero; nor do the distributional or LCS measures predict that they are at all similar. The human mean ratings are low (averaging 1.6, 1.4, and 3.2, respectively, in the *No Context* condition), but why are they not zero — and why are they in fact higher than the ratings for some other pairs, such as *open/inflate* (0.6), where one could also identify reasons for believing the meanings have something in common? It would appear that in these cases subjects are finding similarities of meaning according to dimensions that we have not yet formalized. The apparent sense extensions verge on the metaphorical: one can describe divorce as the unfolding of a marriage, observe a person chill and toughen in response to an insult, enter a group by being initiated into it. Capturing those dimensions of similarity in our models will require a better understanding than we have at present of how word meanings are represented and organized.

Even for the time being, however, the work described in this paper offers a method and a testbed for investigating lexical issues that can go well beyond the present experiments. We chose here to tightly control aspect and

syntactic subcategorization while allowing our test items to differ on thematic grids and vary widely with respect to semantic content. Having validated the approach — performance being consistent with what one would predict of the alternative models given the design of the task — the initial work opens the door to other configurations, controlling variation among subcategorization frames, aspectual features, thematic grids, and semantic content in other combinations. What is crucial is that implemented models of similarity, drawing on such theoretical constructs, yield testable predictions that can be verified through careful experimentation.

### Acknowledgments

We are grateful to Dekang Lin and Amy Weinberg for valuable discussions, to Dekang Lin for his kindly computing values of distributional similarity (Definition 4) for the verb pairs in our experiment, and to three anonymous reviewers for their helpful comments. This work was supported in part by DARPA/ITO Contract N66001-97-C-8540.

## Abstract

There have been several reports of faster lexical decisions for words that have many meanings (e.g., *ring*) compared with words with few meanings (e.g., *hotel*). However, it is not clear whether this advantage for ambiguous words arises because they have multiple unrelated meanings, or because they have a large number of highly related word senses. All current accounts of the ambiguity advantage assume that it is unrelated meanings that produce the processing benefit. We report two experiments that challenge this assumption; in visual and auditory lexical decision experiments we found that while multiple senses did produce faster responses, multiple meanings produced a disadvantage. We discuss how models of word recognition could accommodate this new pattern of results.

## Introduction

Many words are semantically ambiguous, and can refer to more than one concept. For example, *bark* can refer either to a part of a tree, or to the sound made by a dog. To understand such words, we must disambiguate between these different interpretations, normally on the basis of the context in which the word occurs. However, ambiguous words can also be recognised in isolation; when presented with a word like *bark* we are able to identify an appropriate meaning rapidly, and are often unaware of any other meanings.

Words can be ambiguous in different ways. The two meanings of a word like *bark* are semantically unrelated, and seem to share the same written and spoken form purely by chance. Other words are ambiguous between highly related senses, which are systematically related to each other. For example, the word *twist* can refer to a bend in a road, an unexpected ending to a story, a type of dance, and other related concepts.

The linguistic literature makes a distinction between these two types of ambiguity, and refers to them as homonymy and polysemy (Lyons, 1977; Cruse, 1986). Homonyms, such as the two meanings of *bark*, are said to be different words that by chance share the same orthographic and phonological form. On the other hand, a polysemous word like *twist* is considered to be a single word that has more than one sense.

All standard dictionaries respect this distinction between word meanings and word senses; lexicographers routinely decide whether different usages of the same spelling should correspond to different lexical entries or different senses within a

single entry. Many criteria (e.g., etymological, semantic and syntactic) have been suggested to operationalise this distinction between senses and meanings. However, it is generally agreed that while the distinction appears easy to formulate, it is difficult, to apply with consistency and reliability. People will often disagree about whether two usages of a word are sufficiently related that they should be taken as senses of a single meaning rather than different meanings. This suggests that these two types of ambiguity may be best viewed as the end points on a continuum. However, even if there is not a clear distinction between these two different types of ambiguity, it is important to remember that words that are described as ambiguous can vary between these two extremes.

In this paper we will review the evidence on how lexical ambiguity affects the recognition of isolated words, and will argue that the distinction between these two qualitatively different types of ambiguity has not been addressed. We then report two experiments that confirm the importance of the sense-meaning distinction, and show that in both the visual and the auditory domains the effects of word meanings and word senses are very different.

## The Ambiguity Advantage

In early studies of semantic ambiguity, Rubenstein, Garfield, and Millikan (1970) and Jastrzembski (1981) reported faster visual lexical decisions for semantically ambiguous words than for unambiguous words. However, these studies did not control for the subjective familiarity of the words, and Gernsbacher (1984) found no effect of ambiguity over and above familiarity. Since then, however, Kellas, Ferraro, and Simpson (1988), Borowsky and Masson (1996) and Azuma and Van Orden (1997) have all reported an ambiguity advantage in visual lexical decision experiments using stimuli that were controlled for familiarity.

Although there does seem to be a consensus in the literature that lexical ambiguity can produce faster lexical decision times, it is not at all clear what type of ambiguity is producing the effect. Is it multiple meanings, or multiple senses that produces the advantage? One way of trying to answer this question is to examine the dictionary entries of the words used in these experiments. As described above, dictionaries make a distinction between words whose meanings are sufficiently unrelated that they are given multiple entries, and those that

have multiple senses within an entry. This provides a convenient way in which to categorise words as being ambiguous between multiple meanings or between multiple senses.

Rodd, Gaskell, and Marslen-Wilson (1999) analyzed the stimuli used in the three studies that report a significant ambiguity advantage in this way, and found that for all three studies the high-ambiguity words have more word senses than the low-ambiguity words. Further, only in the Borowsky and Masson (1996) stimuli did the two groups differ in the number of meanings. Therefore, it appears that it may be multiple senses rather than multiple meanings that are producing the ambiguity advantage. Despite this, all current explanations of the ambiguity advantage assume that the processing benefit arises because of the presence of unrelated meanings.

## Models of the Ambiguity Advantage

One way that the ambiguity advantage has been explained has been to assume that ambiguous words have multiple entries within a lexical network. For example, (Kellas et al., 1988) suggest that the benefit arises because, while the multiple entries for an ambiguous word do not inhibit each other, they both act independently to inhibit all other competing entries, and this increased inhibition of competitors produces the faster recognition times.

Others have assumed that the benefit arises within this type of model by assuming that there is some level of noise or probabilistic activation (Jastrzemski, 1981). Because words with multiple meanings are assumed to have multiple entries, these words might benefit from having more than one competitor in the race for recognition; on average, by a particular point in time, one of these competitors is more likely to have reached the threshold for recognition than a word that has only one entry in the race.

Both these approaches to explaining the ambiguity advantage predict that the effect will occur whenever the different meanings of the ambiguous words are sufficiently unrelated to have separate entries in the mental lexicon; they make no specific predictions about what should happen for words with multiple senses, as it is not clear whether word senses would correspond to separate entries within the network.

An alternative view of word recognition is that words compete to activate a representation of their meaning. There have been several recent models of both spoken and visual word recognition that have taken this approach (Hinton & Shallice, 1991; Plaut & Shallice, 1993; Joordens & Besner, 1994; Gaskell & Marslen-Wilson, 1997; Plaut, 1997). These models use distributed lexical representations; each word is represented as a unique pattern of activation across a set of orthographic/phonological and semantic units.

Within models of this type, the orthographic pattern *bark* must be associated with two different semantic patterns corresponding to its two meanings. When the orthographic pattern is presented to the network, the network will try to instantiate the word's two meanings across the same set of semantic units simultaneously. These competing semantic representations will interfere with each other, and this interference is likely to increase the time it takes for a stable pattern of activation to be produced. Therefore, it appears that these models predict that lexical ambiguity should delay recognition, and not produce the faster response times seen in the literature.

In response to this inconsistency between the ambiguity advantage literature and the predictions of semantic competition models, there have been several attempts to show that, given particular assumptions, this class of model can overcome the semantic competition effect, and show an advantage for ambiguous words (e.g. Joordens and Besner (1994), Borowsky and Masson (1996) and Kawamoto, Farrar, and Kello (1994)). Importantly, these models assume that the effect to be modelled is an advantage for those words with multiple unrelated meanings.

Thus, the ambiguity advantage has been interpreted within a range of models of word recognition. However, all these accounts have implicitly assumed that the ambiguity advantage literature demonstrates that there is a processing advantage for words with more than one, unrelated, meaning. As discussed above, it is not clear that this is the case; the ambiguity advantage may be a benefit for words with multiple *senses* rather than multiple *meanings*. In order to understand fully the implications of semantic ambiguity for models of word recognition, we need to determine which of these explanations is correct.

## Experiment 1: Visual Lexical Decision

### Method

**Experimental Design** This experiment attempts to separate out the effects of lexical ambiguity and multiple word senses by using a factorial design (see Table 1). Groups of ambiguous and unambiguous words were selected to have either few or many senses on the basis of their dictionary entries.

Table 1: Experiment 1: Experimental Design

Ambiguity	Senses	Example
Ambiguous	Few	pupil
Ambiguous	Many	slip
Unambiguous	Few	cage
Unambiguous	Many	mask

**Participants** The participants were 25 members of the MRC Cognition and Brain Sciences Unit subject panel. All had English as their first language, and had normal or corrected-to-normal vision.

**Stimuli** The word stimuli were selected to conform to a 2 x 2 factorial design, where the two factors were ambiguity and number of senses. Words were classed as being unambiguous if they had only one entry in The Online Wordsmyth English Dictionary-Thesaurus (Parks, Ray, & Bland, 1998), and as ambiguous if they had two or more entries. Two measures of the number of senses were used. These were the total number of word senses listed in the Wordsmyth dictionary for all the entries for that word, and the total number of senses given in the WordNet lexical database (Fellbaum, 1998).

Thirty-two stimuli were selected to fill each cell of the factorial design, such that the number of word meanings was matched across each level of number of word senses, and the total number of word senses was matched across each level of the number of word meanings.

The four groups of words were matched for frequency in the CELEX lexical database (Baayen, Piepenbrock, &

Van Rijn, 1993), number of letters, number of syllables, concreteness and familiarity. Concreteness and familiarity scores were obtained from rating pre-tests in which all the words were rated on a 7-point scale by participants who were members of the MRC Cognition and Brain Sciences Unit subject panel, and who did not participate in the lexical decision experiment.

The groups were not explicitly matched for neighbourhood density; however, the number of words in CELEX that differed from each word by only one letter ( $N$ ; Coltheart, Davelaar, Jonasson, & Besner, 1977) was calculated for each word. An analysis of variance (ANOVA) showed that the words in the four groups did not differ significantly on this measure;  $F(3, 124) = 1.02, p > .3$ .

The non-word distractors were pseudohomophones, such as *brane*, with a similar distribution of word lengths to the word stimuli. Pseudohomophones were used because both (Azuma & Van Orden, 1997) and (Pexman & Lupker, 1999) found stronger effects of semantic ambiguity when these non-words were used. In this first experiment, we wanted to maximise the chance of finding significant effects of ambiguity.

**Procedure** All the stimulus items were pseudo-randomly divided into four lists, such that each list contained approximately the same number of words from each stimulus group. Participants were presented with the four lists in a random order, with a short break between lists. Within the lists, the order in which stimulus items were presented was randomised for each participant. All participants saw all of the stimulus materials. A practice session, consisting of 64 items not used in the analysis, was given to familiarise participants with the task. Each block began with 10 stimuli not included in the analysis.

For each of the word and non-word stimuli, the participants were presented with a fixation point in the centre of a computer screen for 500 msec, followed by the stimulus item. Their task was to decide whether each item was a word or a non-word; recognition was signalled with the dominant hand, non-recognition with the other hand. As soon as the participant responded, the word was replaced with a new fixation point.

## Results

The data from two participants were removed from the analysis, because of error rates greater than 10%. The latencies for responses to the word and non-word stimuli were recorded, and the inverse of these response times ( $1/RT$ ) were used in the analyses to minimize the effect of outliers (Ulrich & Miller, 1994; Ratcliff, 1993). Incorrect responses were not included in the analysis. The overall error rate for responses was 3.6%.

Mean values were calculated separately across participants and items. The participant means were subjected to an ANOVA, and the item means were subjected to an analysis of covariance (ANCOVA) with frequency, familiarity, concreteness and length entered as covariates. The mean response times are given in Figure 1.

The ANCOVA revealed significant effects of frequency, familiarity, length and neighbourhood density (all  $p < .05$ ). The effect of concreteness was non-significant ( $p > .5$ ), so this variable was removed from the ANCOVA. The response

Figure 1: Experiment 1, mean lexical decision times

time data revealed a main effect of the number of senses ( $F_1(1, 22) = 14.22, p < .001$ ;  $F_2(1, 120) = 4.51, p < .05$ ). Words with many senses were responded to faster than words with few senses. The effect of ambiguity was marginal in the participants analysis ( $F_1(1, 22) = 3.77, p < .07$ ), but non-significant in the items analysis ( $F_2(1, 120) = 1.67, p > .2$ ). Ambiguous words were responded to more slowly than unambiguous words. There was no significant interaction between these two variables ( $p > .2$ ).

The error data also showed a significant effect of the number of senses; fewer errors were made for words with many senses ( $F_1(1, 22) = 12.2, p < .005$ ;  $F_2(1, 120) = 5.19, p < .05$ ). In the error data neither the effect of ambiguity nor the interaction between the two variables reached significance (all  $p > .4$ ).

## Discussion

This experiment shows that words with many senses were responded to faster and with fewer errors than words with few senses. This advantage for multiple senses is in contrast with a *disadvantage* for words with multiple meanings. Although this disadvantage was not significant, it is clear that contrary to the accepted view in the literature, there is no processing advantage for words with multiple meanings. Moreover, Rodd et al. (1999) did find a significant disadvantage in visual lexical decision for words with more than one meaning, compared with unambiguous words, when the stimuli were selected to minimise the effect of word senses. Thus, previous reports of an ambiguity advantage must be the result of the multiple senses of the high-ambiguity stimuli rather than their multiple meanings.

Therefore, the results of this experiment together with the results of Rodd et al. (1999) show that the two types of lexical ambiguity have opposite effects on visual word recognition; while ambiguity between multiple meanings may delay recognition, ambiguity between multiple senses is beneficial.

The following experiment will investigate whether this pattern is also seen in the auditory domain. If the above pattern of data is telling us something interesting about the way in which word meanings are stored and processed, we should expect to find the same pattern independent of the input modality.

This experiment will also allow us to establish that these

effects of semantic ambiguity are not contingent on the type of non-word distractors used. In Experiment 1, pseudohomophones such as *brane* were used. There is still debate about how pseudohomophones affect lexical processing (see Pexman & Lupker, 1999 for a review). One possibility is that they simply increase the difficulty of the task, and so increase sensitivity to relatively small effects. However, an alternative explanation is that pseudohomophones strategically effect the way that participants make use of orthographic, phonological and semantic information. The following experiment, which does not use pseudohomophones will attempt to demonstrate that these effects are not due to strategic effects induced by these particular non-words.

Finally, this experiment will also allow us to try and replicate the significant ambiguity disadvantage seen by Rodd et al. (1999).

## Experiment 2: Auditory Lexical Decision

### Method

**Experimental Design** The experimental design was identical to Experiment 1.

**Participants** The participants were 26 students at Cambridge University who had not participated in the first experiment. All had English as their first language, and had normal or corrected-to-normal vision.

**Stimuli** 23 stimuli were selected to fill each cell of the factorial design, such that the number of word meanings was matched across each level of number of word senses. The words were selected on the basis of dictionary entries as in Experiment 1. The number of words in each cell is smaller than was used in Experiment 1, because of the additional constraints used to match the groups. 77% of the words were also used in Experiment 1.

The four groups of words were matched for frequency, number of phonemes, the phoneme at which the word becomes unique, actual length of the words in msec, concreteness and familiarity. Concreteness and familiarity scores were obtained from the same rating pre-test as in Experiment 1. All the words had only one syllable.

The non-word stimuli were created to be as word-like as possible, and to have a similar distribution of word lengths to the word stimuli.

**Procedure** The procedure used was the same as that in Experiment 1, except that now the stimuli were spoken words. Each item appeared 1000 ms after the participants' response to the preceding item. If the participant did not respond within 3000 ms of the onset of a word, the next item was presented.

### Results

The data from four participants were removed from the analysis, because of error rates greater than 10%. Incorrect responses were not included in the analysis. The overall error rate for responses was 5.8%.

As in Experiment 1, inverse response times were used in all analyses. Mean values were calculated separately across participants and items. The participant means were subjected to an analysis of variance (ANOVA), and the item means were

subjected to an analysis of covariance (ANCOVA), with familiarity and length entered as covariates. The mean response times are given in Figure 2.

Figure 2: Experiment 2, mean lexical decision times

The ANCOVA revealed significant effects of familiarity ( $r = -.26, p < 0.05$ ) and length ( $r = -.75, p < 0.001$ ). Concreteness, frequency, number of phonemes and uniqueness point were not significant predictors of response times ( $p > .2$ ), so these variables were not included in the ANCOVA.

The main effect of the number of word senses was significant in both the participants and items analysis ( $F_1(1, 21) = 16.9, p < .001$ ;  $F_2(1, 86) = 4.4, p < .05$ ). Words with many senses were responded to faster than words with few senses. The effect of ambiguity was also significant in both the participants analysis and the items analysis ( $F_1(1, 21) = 27.8, p < .001$ ;  $F_2(1, 86) = 7.4, p < .005$ ). Ambiguous words were responded to more slowly than unambiguous words. The interaction between these two variables was marginal in the subjects analysis but did not approach significance in the items analysis ( $F_1(1, 21) = 3.8, p < .1$ ;  $F_2(1, 86) = 0.4, p > .5$ ).

The error data showed a similar pattern of results to the response time data. Fewer errors were made for words with many senses, although this difference was significant only in the subjects analysis but not in the items analysis; ( $F_1(1, 21) = 10.5, p < .005$ ;  $F_2(1, 86) = 2.7, p = .1$ ). Fewer errors were also made for unambiguous words, although this difference was only marginal in the subjects analysis and did not approach significance in the items analysis; ( $F_1(1, 21) = 4.2, p < .06$ ;  $F_2(1, 86) = 0.7, p > .4$ ). The interaction between the two variables was not significant in either analysis ( $p > .5$ ).

### General Discussion

Both the experiments reported here have shown an advantage for words with many word senses. This advantage for multiple senses was seen alongside a disadvantage for words with multiple meanings. This suggests that the ambiguity advantage reported in earlier studies must have been produced by the high number of related word senses of high-ambiguity stimuli, and not by their unrelated meanings.

What are the implications of this new pattern of results for models of word recognition? Previously, these models had

been required to produce an advantage for words with multiple meanings, but our data suggests they must accommodate exactly the reverse effect. In fact, this is less problematic than might be expected.

The ambiguity disadvantage can easily be explained by models in which words compete for the activation of semantic representations (Hinton & Shallice, 1991; Plaut & Shallice, 1993; Joordens & Besner, 1994; Gaskell & Marslen-Wilson, 1997; Plaut, 1997). As discussed earlier, in these models competition between the different meanings of ambiguous words would delay their recognition. As noted by Joordens and Besner (1994), an ambiguity advantage can only be produced by these models if an additional mechanism is present to overcome this semantic competition. These results suggest that no such mechanism is required.

The other class of model that may be able to accommodate this new pattern of results is those models in which words compete to activate abstract word nodes within a lexical network. Earlier, we discussed how these models could produce an ambiguity advantage by assuming either that ambiguous words are more efficient at inhibiting competitors, or that they benefit from having multiple competitors in the race for recognition.

Surprisingly, these models can just as easily accommodate a disadvantage for words with multiple meanings. As in all experiments of this type, the ambiguous words and unambiguous words in these experiments were matched on total frequency. This means that the frequency of each meaning of the ambiguous words is on average half that of the unambiguous word. This frequency difference could produce faster lexical decisions for the unambiguous words. Similarly, if lateral inhibition were present between all word nodes, including the nodes corresponding to the different meanings of an ambiguous word, this would act to slow the recognition of ambiguous words.

Therefore, it appears that both classes of models considered here can be modified to accommodate the finding of slower responses to words with more than one unrelated meaning. However, Rodd et al. (1999) have shown that at least in the visual domain, the ambiguity disadvantage is modulated by the rated relatedness of the two meanings of the ambiguous words; words whose meanings are sufficiently different to be considered meanings rather than senses but whose meanings are mildly related are responded to more quickly than those whose meanings are highly unrelated. This suggests that semantic representations are actively involved in the process that produces the ambiguity disadvantage, and that the effect cannot be explained solely as the result of a frequency bias for unambiguous words or lateral inhibition between abstract word nodes. Therefore, the ambiguity disadvantage may more easily be explained as the result of semantic competition which is maximal when the competing representations are unrelated.

It is therefore apparently straightforward to explain the observed ambiguity disadvantage. The intriguing question that remains is what causes the advantage for words with many senses?

One possibility is to explain this effect in terms of the attractor basins that develop in a distributed semantic network. The different senses of a word correspond to a set of

highly correlated patterns of semantic activation. As noted by Kawamoto (1993), for a word with many related senses, these senses will create a broad and shallow basin of attraction, containing more than one stable state corresponding to each different sense. It is plausible that within certain architectures, settling into the correct attractor may be quicker for such a broad attractor, compared with the attractor of a word with few senses, or that the multiple stable states within the attractor may lead to faster settling times. This suggestion needs to be assessed by performing the appropriate simulations.

A second possible explanation of the sense effect would be to consider the difference between words with many and few senses as reflecting a difference in the amount of semantic information associated with the two types of words. In other words, a word with many senses may be considered to be semantically rich. This is essentially the same argument that Plaut and Shallice (1993) put forward to account for the processing benefit of concrete words over abstract words. In their computational account of the concreteness effect, the difference between abstract and concrete words is reflected in the number of semantic features in a distributed semantic representation; abstract words are given fewer semantic features than concrete words. This results in concrete words activating more stable representations than abstract words. These stable representations lead in turn to faster settling times for words with more semantic features.

It is not yet possible to distinguish between these (and other) possible explanations of the sense effect reported here. A combination of network simulations and further experiments is required to determine how existing models of word recognition should be modified to accommodate the benefit for words with many word senses. What is clear is that the distinction we have emphasised between word meanings and word senses is critical. In the past, ambiguity has been treated as a unitary property of words; we have shown that this has masked an informative pattern of results that can be used to constrain models of how words are recognised.

More generally, these experiments emphasise how word recognition is inextricably linked with word meanings. Data of this kind places an increasing demand on models of word recognition to incorporate richer semantic representations that reflect the complex structures of the meanings of words.

# Attention to Action: Securing Task-Relevant Control in Spoken Word Production

Ardi Roelofs (ardi@mpi.nl)

Max Planck Institute for Psycholinguistics  
Wundtlaan 1, 6525 XD, Nijmegen, The Netherlands

## Abstract

The Stroop phenomenon is the finding that color naming is inhibited by incongruent color words but word reading not by incongruent colors. When the stimulus onset asynchrony (SOA) is manipulated, maximal inhibition of incongruent words on color naming is obtained when the words are presented within 100 msec of the colors, whereas facilitation of preexposed congruent words is constant. These findings are obtained both with and without task certainty. Whereas existing models explain the basic Stroop effects, they fail to account for the time course findings and for performance under task uncertainty. In this paper, I extend and apply the WEAVERTM model of spoken word production (Roelofs, 1992, 1993, 1997c; Levelt, Roelofs, & Meyer, 1999) to performance on the Stroop task and show that the model accounts for the key findings.

## Introduction

Performance on the Stroop task is of direct relevance to theories of language production and comprehension. The basic modes of language use, namely speaking, listening, reading, and writing, all seem to make use of overlapping sets of basic processing components (e.g., Caplan, 1992; Levelt, 1989; Shallice, 1988). Whereas language perception occurs automatically, hearing or reading a word does not automatically lead to its production but this is under the control of a language user. Similarly, seeing an object does not automatically lead to the naming of it. Furthermore, words do not occur in isolation, but are typically part of a spoken discourse, a text on a page, or appear on objects in the real world. This points to the need to deal with the issue of selectivity. It is generally assumed that performance on the Stroop task can provide evidence on how language is controlled, that is, how a speaker secures task-relevant control over the basic language processes underlying naming and oral reading (e.g., Allport, 1993).

Since Stroop's (1935) experiments in the 1930s, over 700 articles have appeared using his task (reviewed by MacLeod, 1991), which established the following basic empirical picture. Color naming is inhibited by incongruent color words, but word reading not by incongruent color patches. For example, saying "red" to a red color patch on which the word "green" is superimposed proceeds slower than saying "red" in a control condition consisting of a string of Xs. The stimulus onset asynchrony (SOA) between color patch and word has an important effect. Maximal inhibition of incongruent words on color naming is obtained when the words are presented within 100 msec of the colors (e.g., Glaser & Glaser, 1982). Preexposed congruent words yield facilitation, which is constant over SOAs. Whereas color naming is affected by incongruent words,

reading aloud words (e.g., "red") is not influenced by incongruent colors (e.g., green). The asymmetry in effect is not due to a difference in processing speed between words and colors (i.e., reading is some 200 msec faster than color naming), as evident from manipulating the SOA. When a color patch is presented 300 or 400 msec before the word to be read, still no effect of incongruent colors is obtained (e.g., Glaser & Glaser, 1982).

Figure 1: Time course of the Stroop effects (relative to control) in color naming under task uncertainty as measured by Glaser and Glaser (1989): ■ = incongruent, ▲ = congruent

In a standard Stroop experiment, participants are certain about what task to perform. Typically, one group of participants is asked to name the color and to ignore the word, and another group of participants is asked to read aloud the word and to ignore the color patch. Thus, trials are blocked by task. However, in examining the effect of task uncertainty, Glaser and Glaser (1989) asked a single group of participants to perform both tasks. They instructed their participants to respond to the second stimulus component (in the condition with negative SOAs) or the first component (in the condition with positive SOAs). Words had to be read aloud and colors had to be named. Participants can perform this task up to differences in presentation time of 50 msec. The experiment was run with SOAs of -300, -200, -100, -50, 50, 100, 200, and 300 msec (a minus sign indicates preexposure of the irrelevant stimulus). With task uncertainty, Glaser and Glaser obtained the normal patterns of inhibition and facilitation observed with task certainty, for example, with the instruction to name the color and ignore the word. Inhibition increased when the SOA be-

came less negative, peaking at SOAs between -100 and 100 msec. And there was a flat pattern of facilitation at the negative SOAs. Figure 1 shows the SOA curves.

The Stroop phenomenon is not restricted to naming colors and reading color words but appears in many other verbal domains. For example, numerals interfere with the naming of numerosity (e.g., saying “two” to two 6s), but there is no reverse effect (e.g., Flowers, Warner, & Polansky, 1979). Alternating between tasks that exhibit the Stroop conflict (i.e., between color naming and numerosity naming trials) does not yield a greater task switch cost than alternating between tasks that do not yield the Stroop conflict (i.e., between word reading and numeral reading trials), as observed by Allport, Styles, and Hsieh (1994).

## **The Challenge Posed by Task Uncertainty**

### **The Stroop Conflict as Task Conflict**

Recent proposals in the literature (e.g., Rogers & Monsell, 1995) have suggested that the essence of the Stroop conflict is competition between tasks *per se* (i.e., word reading and color naming). The Stroop conflict is explained as inhibition of the “weaker” color naming task by the supposedly “stronger” reading task, while the reverse does not occur. However, task competition fails to explain why the congruent condition (where the same tasks compete) yields facilitation. Furthermore, the fact that task uncertainty has no influence on the SOA patterns poses a challenge. Also, task competition would predict a greater cost for switching between conflict trials with color and numerosity naming than between nonconflict trials with word and numeral reading, but Allport et al. (1994) found no cost difference.

The findings on the time course of the effects and on task uncertainty also pose a challenge to models that do not conceive of the Stroop conflict as a task conflict *per se*. Whereas existing models account for the basic Stroop effects obtained with SOA = 0 msec, they fail to explain the time course findings and they cannot cope with task uncertainty.

### **The Model of Cohen, Dunbar, and McClelland (1990)**

Among the most influential models of the Stroop phenomenon is the connectionist model of Cohen, Dunbar, and McClelland (1990). The model assumes a feedforward network with parallel reading and color naming pathways, which differ in strength. Task relevant control is achieved in the model by task nodes for color naming and reading. These task nodes provide extra input to the color and reading pathway, depending on the task. Each response node in the network is connected with an evidence accumulator. Before the beginning of a simulated Stroop trial, all evidence accumulators are set to zero. A task node is activated and the model is run until the activation of all nodes stabilizes. This allows the system to settle into a “ready state” for the task. Next, the components of a Stroop stimulus are presented with the appropriate SOA. A response is selected when one of the accumulators exceeds a fixed response threshold.

The model of Cohen et al. does well in accounting for the basic Stroop effects obtained with SOA = 0 msec, but there are two major problems. First, as simulations by Cohen et al. (1990, p. 344) showed, the amount of evidence accumulated for the irrelevant stimulus is a positive function of its preexposure time. That is, more evidence is collected at more negative SOAs. Thus, the inhibition in the incongruent condition peaks at the most negative SOA and decreases when the SOA becomes less negative. Similarly, the amount of facilitation in the congruent condition peaks at the most negative SOA and decreases when the SOA becomes less negative. The problem is that these patterns are exactly contrary to the empirical results, where maximal impact of incongruent words is observed when the words appear within 100 msec of the colors and facilitation from preexposed congruent words is constant. The model also predicts a small Stroop effect at negative SOAs in reading aloud, contrary to the real data. The second major problem with the model is that it cannot handle task uncertainty. Before the beginning of a trial, a task node is activated and the model is run until the activation of all nodes stabilizes, which allows the system to settle into a ready state for the task. But with task uncertainty, the task is not known beforehand so that such task-dependent settling of activation is not possible.

### **The Model of Phaf, Van der Heijden, and Hudson (1990)**

Another influential model of the Stroop phenomenon is the connectionist model of Phaf, Van der Heijden, and Hudson (1990), called SLAM (for SeLective Attention Model), which has been developed within the framework of Van der Heijden’s (1992) general theory of attention. The model assumes an interactive-activation network. Input nodes for colors are connected to corresponding hidden nodes for colors, which in their turn are linked to word output nodes. Input nodes for words are directly connected to these output nodes. Thus, unlike the model of Cohen et al. (1990), the model assumes asymmetrical pathways for reading and color naming. Processing occurs through activation spreading from color input via hidden to output nodes, and directly from word input to output nodes, whereby nodes change their activation with time in a continuous, nonlinear manner. There are excitatory links between nodes representing compatible information and there are inhibitory links between nodes standing for incompatible information. All nodes of a particular type within a layer inhibit each other. Selective attention to the color naming and reading tasks is achieved by adding extra external activation to all hidden color nodes for color naming and all output nodes for word reading. The task activation is given from trial onset onward. On each simulated trial, word and color input is given to the network and activation cycles around from one unstable pattern to another until a stable pattern of activation is reached. The excitatory and inhibitory connections push activation of the response nodes into one stable state depending on the inputs provided to the layer (e.g., color and task input). To choose one response or another, activation of the response layer is

input to a sampling and recovery procedure that stochastically favors the most highly activated response node.

The Phaf et al. (1990) model successfully accounts for the basic Stroop effects with SOA = 0 msec, but, again, there are the same two major problems. First, the model does not adequately account for the time course of the Stroop phenomenon that has been observed by Glaser and Glaser (1982) and others. As simulations by Phaf et al. (1990, p. 324) showed, the model predicts that the amount of inhibition of words in color naming does not vary with SOA but remains constant for negative SOAs, contrary to the empirical findings. The reason for predicting a constant SOA effect in color naming is that after perceiving the word, the system quickly settles into a stable state of activation for the response corresponding to the word. By definition, the stable state does not vary with time, and hence making the SOA more or less negative has no effect, until an SOA is used that is too short for the distractor to reach an attractor basin. Consequently, the amount of time it takes for the color name to overcome the inhibition from the word is constant. The second major problem is that the model cannot cope with task uncertainty.

In line with Phaf et al. (1990), Cohen and Huston (1994) discuss an attractor version of the model proposed by Cohen et al. (1990). The behavior of this model is similar to that of Phaf et al. (1990). The amount of inhibition at negative SOAs is constant (see Figure 18.11 of Cohen and Huston, 1994), contrary to the real data. And the new version of the model also cannot cope with task uncertainty.

An alternative to connectionist task control is provided by “production rule system” models (e.g., Anderson, 1983; Anderson & Lebiere, 1998). Below, I show that the WEAVER++ model of word production (Levelt et al., 1999; Roelofs, 1992, 1993, 1997c), which falls into this general class of model, accounts for the findings on task uncertainty. The relevant features of the model are: (1) words are retrieved by spreading activation and (2) task-relevant control is achieved by production rule application.

## Control in the WEAVER++ Model

### Planning Stages

In WEAVER++, naming a perceptual entity such as a color involves a number of processing stages, illustrated in Figure 2. First, there is the conceptual identification of the color based on perceptual input (e.g., red) and its designation as goal concept (i.e., RED(X)). Second, the lemma of the corresponding word is retrieved (i.e., *red*), in the Stroop literature often referred to as response selection (except that it involves here lemmas, which is new). A lemma is a representation of the syntactic properties of a word, crucial for its use in sentences (cf. Roelofs, Meyer, & Levelt, 1998). Third, the form of the word is encoded (i.e., [rɛd]), called response programming. Lemma retrieval and word-form encoding are discrete processes in that only the form of a *selected* lemma becomes activated and selected (Levelt, Schriefers, Vorberg, Pechmann, Meyer, & Haviga, 1991). And finally, the name is articulated, called response execution.

A perceived written word activates its lemma and its

output form in parallel. Oral reading is achieved by a shallow form-to-form route (e.g., from the orthographic form *red* to [rɛd]) or may involve an extra step of lemma retrieval (i.e., from *red* via *red* to [rɛd]), roughly corresponding to what is traditionally called the “semantic” route (e.g., Caplan, 1992; Shallice, 1988). I refer to Levelt et al. (1999) and Roelofs, Meyer, and Levelt (1996) for an extensive discussion.

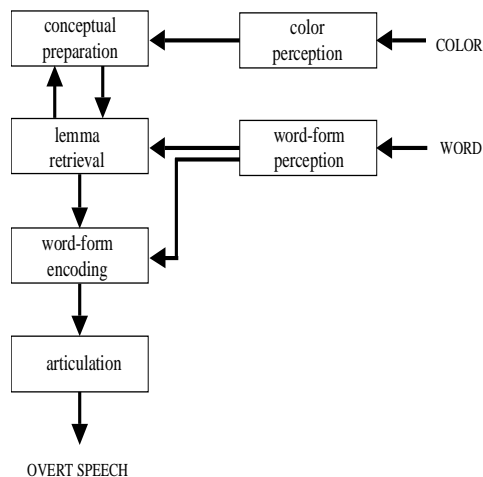

Figure 2: Stages of spoken word planning in WEAVER++

### Network Structure

The model assumes that the mental lexicon is a huge network with information about words, a small fragment of which is illustrated in Figure 3.

Figure 3: Fragment of the lexical network of WEAVER++

The network comprises three major strata: a conceptual, a syntactic, and a form stratum. The conceptual stratum represents concepts as nodes in a semantic network, following Collins and Loftus (1975), and many others. For example, the concept RED is represented by the node RED(X). The syntactic stratum contains lemma nodes, such as *red*, which are connected to nodes for their syntactic

class (e.g., adjective). And finally, the form stratum contains nodes representing morphemes, segments, and motor programs. For an extensive discussion of the theoretical and empirical motivation of these assumptions, I refer to Levelt (1989), Levelt et al. (1999), Roelofs (1992, 1993, 1996a,b,c, 1997a,b,c, 1998, 1999, 2000, submitted), and Roelofs and Meyer (1998).

### Spreading Activation and Production Rule Application

Information is retrieved from the network by the spreading of activation. For example, a perceived color (e.g., red) activates the corresponding concept node (i.e., RED(X)) in the network. Activation then spreads through the network following a linear activation rule with a decay factor. Each node sends a proportion of its activation to the nodes it is connected to. For example, RED(X) sends activation to other concepts such as GREEN(X) and also to its lemma node *red*. Selection of nodes is accomplished by production rules (i.e., condition-action pairs). A rule is triggered when its nodes become active. A lemma retrieval production rule selects a lemma if the connected concept is flagged as goal concept. For example, *red* is selected for RED(X) in case it is the goal concept and *red* has reached a critical difference in activation compared to other lemmas. The actual moment in time of the firing of a production rule whose condition is satisfied is determined by the ratio of activation of the relevant lemma node and the sum of all the others. Thus, how fast a node is selected depends on how active the other nodes are.

### Performing the Stroop Task

In color naming, a production rule like P1 controls general aspects of the task and a rule like P2 achieves the actual lemma selection (and sets a subgoal to encode the word's form, which is omitted here). Word reading is accomplished by a task rule like P3 that maps the orthographic code of a word onto the corresponding articulatory program. Earlier (Roelofs, 1992) I proposed an "intersection" mechanism to achieve selective attention in response selection, which has recently been dropped and replaced by the task production rules (see Roelofs, 2000, submitted).

- (P1) IF the goal is to say the name of the color  
and the concept is the color of the stimulus  
THEN select the concept  
and flag the concept as goal concept  
and enhance its activation
- (P2) IF RED(X) is flagged as goal concept  
and the activation of *red* exceeds threshold  
THEN select *red*
- (P3) IF the goal is to say the name of the word  
and the morpheme is the name of the stimulus  
THEN select the morpheme  
and flag the morpheme as goal morpheme

With task uncertainty, the task itself has to be set during

each trial. This is achieved by production rules like P4 and P5 (in the negative SOA condition).

- (P4) IF the first stimulus is a color  
THEN the goal is to name the word
- (P5) IF the first stimulus is a word  
THEN the goal is to name the color

To assess the Stroop performance of the model, computer simulations were run. The simulations employed a basic set of eight parameters, whose values were the same as in all earlier simulations (e.g., Levelt et al., 1999; Roelofs, 1992, 1993, 1996a, 1997c) except for two parameter values, which were changed slightly to fine-tune the fit of the model to the data. The "distractor duration" was set to 100 msec and the response threshold to 1.6. The distractor duration determines the gain of the distractor input relative to the target input. Roelofs (submitted) gives all the details of the simulations and applies the model to the key findings from over half a century of Stroop research (e.g., reviewed by MacLeod, 1991).

### Illustration of a Simulated Trial

Assume that the task is to name the second stimulus, which may be a color patch or a word. Assume that on a particular trial a red color patch is presented on which the word "green" is superimposed, with the word presented 100 msec before the color patch (i.e., the SOA is -100 msec). The simulation starts with the lemma node of "green" receiving external activation (for 100 msec, the distractor duration). This triggers production rule P5, which sets the goal to naming the color. Activation spreads through the network, with the node *green* sending a proportion of its activation to GREEN(X), and this node in its turn spreads activation to the other concept nodes. After the number of time steps that is the equivalent of 100 msec (the SOA), the concept node RED(X) receives external input from the color. Next, production rule P1 fires, RED(X) becomes flagged as goal concept, and its activation level is selectively enhanced. After the response threshold of the lemma *red* is exceeded, production rule P2 fires and *red* is selected as response.

### Simulation Results

The key finding to account for in this paper is that color naming is similarly affected by color words under task certainty and task uncertainty. Maximal inhibition of incongruent words on color naming is obtained when the words are presented within 100 msec of the colors, whereas the facilitation of preexposed congruent words is constant. Whereas color naming is affected by words, reading aloud is not affected by colors. Again, this holds both for task certainty and for task uncertainty.

Figure 4 shows how WEAVER++ performs. The figure shows the SOA curves of the Stroop effects for color naming under task uncertainty. The curves for task certainty (not shown) exhibit the same patterns. Maximal impact of incongruent words occurs in the model when the words are

presented within 100 msec of the color patches, exactly as empirically observed. For reading aloud in the model, no inhibition and facilitation is obtained at any SOA (also not shown), both for task certainty and task uncertainty, as empirically observed. Thus, WEAVER++ accounts for the time course findings and for the effect of the task certainty manipulation.

Figure 4: Time course of the Stroop effects (relative to control) in color naming under task uncertainty from WEAVER++ simulations:  $\square$  = incongruent,  $\triangle$  = congruent

Why is there no inhibition from colors on word reading? In WEAVER++, lemma retrieval and word-form encoding are discrete. Only the form of a selected lemma becomes activated and selected. Thus, activation does not spread automatically from lemmas to forms but this is under task control. Furthermore, color naming requires both lemma retrieval and form encoding, whereas word reading requires form encoding only. In reading “red” superimposed on a green color patch, the lemma but not the form of “green” becomes active: Because the task is reading and not color naming, the lemma of “green” (corresponding to the color) is not selected and the form of “green” does not become active. The task rule P3 for reading achieves direct selection of the morpheme <red> from the orthographic form *red* rather than indirect selection of <red> by first selecting the lemma *red* and next selecting <red> via the lemma. Thus, selecting <red> from the orthographic form *red* controls the response. Since the form of “green” is not active, planning the form of “red” is unaffected by the color patch.

Independent empirical support for the assumption of a discreteness of stages comes from double-task experiments. Levelt et al. (1991) asked participants to name pictured objects. On one third of the trials (the critical ones), a spoken probe was presented, and participants had to perform a lexical decision on this probe. Peterson and Savoy (1998) also asked participants to name pictures, but on the critical trials in their study written words were presented, which had to be read aloud. The lexical decision and reading latencies showed that in naming a perceptually given entity,

there is no form activation for non-synonymous semantic relatives (i.e., fellow category members) of the target. For example, in naming a cat, there is lemma activation for “cat” and “dog” and word form activation for “cat”, but the word form of “dog” is not activated. By extrapolation, in naming a red color patch, the lemmas of “red” and “green” become active and this also holds for the word form of “red”, but the word form of “green” is not activated. Only the form of a *selected* lemma becomes activated.

O’Seaghdha (1999) argues that the form of “dog” is activated during the naming of a cat, but that the experiments of Levelt et al. (1991) and Peterson and Savoy (1998) were insufficiently powerful to measure this. In support, he refers to a study by O’Seaghdha and Marin, who ran six experiments using word reading with word-word stimuli and an SOA of -500 msec. The effects in the experiments ranged from -2 to +5 msec and were not significant. However, by pooling the observations from the 248 participants in all six experiments, an overall effect of +3 msec was obtained, which reached significance by participants but not by items. By standard criteria, however, such an effect is nonsignificant. Moreover, with large negative SOAs (i.e., -500 msec) expectancy-based priming cannot be excluded (e.g., Neely, 1991). Thus, the findings of O’Seaghdha and Marin do not challenge the discreteness assumption.

## Summary and Conclusions

I have argued that performance on the Stroop task provides evidence on how speech production is controlled, that is, how a speaker exerts task-relevant control over the basic language processes underlying naming and oral reading. Color naming is inhibited by incongruent color words but word reading not by incongruent colors. Maximal impact of incongruent words on color naming is obtained when the words are presented within 100 msec of the colors, whereas the effect of preexposed congruent words is constant. The key observation for the current paper is that these findings are obtained both *with* and *without* task certainty. Whereas existing models (e.g., Cohen et al., 1990; Phaf et al., 1990) explain the basic Stroop effects, they fail to account for time course of the findings and for performance under task uncertainty. In this paper, I have extended and applied the WEAVER++ model of word production to performance on the Stroop task, and I have shown that the model accounts for the findings on the time course as well as for the performance under task uncertainty.

# Non-Linguistic Constraints on the Acquisition of Phrase Structure

Jenny R. Saffran (jsaffran@facstaff.wisc.edu)

Department of Psychology; 1202 W. Johnson Street  
Madison, WI 53706 USA

## Abstract

To what extent is linguistic structure learnable from statistical information in the input? One set of cues which might assist in the discovery of hierarchical phrase structure given serially presented input are the dependencies, or predictive relationships, present within phrases. In order to determine whether adult learners can use this statistical information, subjects were exposed to artificial languages which either contained or violated the kinds of dependencies which characterize natural languages. The results suggest that adults possess learning mechanisms which detect and utilize statistical cues to phrase and hierarchical structure. A second experiment contrasted the acquisition of these linguistic systems with the same grammars implemented as non-linguistic input (sequences of non-linguistic sounds or shapes). These findings suggest that constraints on the mechanisms which highlight the statistical cues which are most characteristic of human languages are not specifically tailored for language learning.

## Introduction

While the idea that surface distributional patterns point to pertinent linguistic structures holds a distinguished place in linguistic history (e.g., Bloomfield, 1933; Harris, 1951), statistical learning has only recently re-emerged as a potential contributing force in language acquisition (though see Maratsos & Chalkley, 1980). This renewed interest in statistical learning has been fueled by developments in computational modeling, by the widespread availability of large corpora of child-directed speech, and most recently by empirical research demonstrating that human subjects can perform statistical language learning tasks in laboratory experiments. For example, computational algorithms can use the co-occurrence environments of words to discover form classes in large corpora (e.g., Cartwright & Brent, 1997; Finch & Chater, 1994; Mintz, 1996; Mintz, Newport, & Bever, 1995). Similarly, individual verb argument structures can be induced by models which track the co-occurrences of verbs and their arguments in the input (e.g., Schütze, 1994; Seidenberg & MacDonald, 1999). Extensive modeling work has also examined the statistical cues available for the discovery of word boundaries in continuous speech (e.g., Aslin, Woodward, LaMendola, & Bever, 1996; Brent & Cartwright, 1996; Cairns, Shillcock, Chater, & Levy, 1997; Christiansen, Allen, & Seidenberg, 1998; Perruchet & Vintner, 1998).

These models provide invaluable explorations of the extent to which statistical information is available, in princi-

ple, to language learners equipped with the right distributional tools. But are humans such learners? A wealth of statistical cues are useless unless humans can detect and use them. In fact, recent research suggests that humans are extremely good at some statistical language learning tasks, such as word segmentation (e.g., Aslin, Saffran, & Newport, 1998; Goodsitt, Morgan & Kuhl, 1993; Saffran, Aslin, & Newport, 1996; Saffran, Newport, & Aslin, 1996).

These results suggest that humans possess powerful statistical language learning mechanisms, which are likely to provide important contributions to the language learning process. At the same time, it is important to recognize that these mechanisms would not be useful in language acquisition unless they are somehow constrained or biased to perform only certain kinds of computations over certain kinds of input. The pertinent generalizations to be drawn from a linguistic corpus are awash in irrelevant information. Any learning device without the right architectural, representational, or computational constraints risks being sidetracked by the massive number of misleading generalizations available in the input (e.g., Gleitman & Wanner, 1982; Pinker, 1984). There are an infinite number of linguistically irrelevant statistics that an overly powerful statistical learner could compute: for example, which words are presented third in sentences, or which words follow words whose second syllable begins with *th* (e.g., Pinker, 1989).

One way to avoid this combinatorial explosion would be to impose constraints on statistical learning which perform only a subset of the logically possible computations. It is clear that learning in biological systems is limited by internal factors; there are species differences in which specific types of stimuli serve as privileged input (e.g., Garcia & Koelling, 1966; Marler, 1991). External factors also strongly bias learning, because input from structured domains consists of non-random information. In order for statistical learning accounts to succeed, learners must be similarly constrained: humans must be just the type of statistical learners who are best suited to acquire the type of input exemplified by natural languages, focusing on linguistically relevant statistics while ignoring the wealth of available irrelevant computations. Such constraints might arise from various sources, either specific to language or from more general cognitive and/or perceptual constraints on human learning.

We have recently begun to explore the possibility that statistical learning itself is constrained. This line of research focuses the acquisition of hierarchical phrase structure. While words are spoken and perceived serially, our representations of sequences of words are highly structured. Consider the sentence *The professor graded the exam*. This sequence of words cannot be grouped as follows – (*The*) (*professor graded the*) (*exam*) – because words that are part of the same phrase are separated. For example, determiners like *the* require nouns; separating these two types of words violates the dependency relations which are part of native speakers’ knowledge of English. The correct groupings, (*The professor*) (*graded the exam*), reflect English phrase structure, which generates a non-linear hierarchically organized structure. Hierarchical phrase structure represents a fascinating learning problem, because the child must somehow arrive at non-linear structure which is richer than is immediately suggested by the serial structure of the input. How do children make this leap? Innate knowledge is one possibility; prosodic regularities may also serve to chunk the input into phrasal units (e.g., Morgan, Meier, & Newport, 1987).

Another type of potentially useful information in the input suggests a statistical learning solution (see also Morgan & Newport, 1981). Linguistic phrases contain dependency relations: the presence of some word categories depends on others. For example, English nouns can occur without determiners like *the* or *a*. However, if a determiner is present, a noun almost always occurs somewhere downstream. This type of predictive relationship, which characterizes basic phrase types, may offer a statistical cue that highlights phrasal units for learners. Research using artificial languages with phrase structure grammars suggests that adult and child learners can exploit predictive dependencies to discover phrases (Saffran, 2000).

These studies suggest that people are skilled statistical learners. But what about the constraints required for the successful acquisition of languages? A particularly useful type of constraint would bias statistical learning mechanisms to preferentially acquire the types of structures observed in natural languages. To address this issue, Experiment 1 assessed the extent to which adults’ ability to acquire an artificial grammar is affected by the availability of predictive dependencies as cues to linguistic phrase structure.

## Experiment 1

**Participants.** 40 monolingual English speaking undergraduates at the University of Rochester participated in this study, and were each paid \$6. Subjects were randomly assigned to the two experimental conditions.

**Materials.** The artificial grammars were adapted from the language used by Morgan & Newport (1981). One of the languages used in this study was a small phrase structure grammar (Language P, for predictive), in which dependencies

between word categories afforded predictive cues to phrases, as in natural languages (e.g., if D is present, A must be present). Importantly, attempts to impose English predictive structure onto the input would mislead learners, as the phrase structure of Language P was head-final while English is head-initial. The second language was equally complex in terms of its size and formal characteristics, but contained a phrase structure unlike natural languages (Language N, for non-predictive). This language did not contain predictive dependencies marking phrases. Rather, it was characterized by overarching optionality: the presence of one word type never predicted the presence of another, which generates statistical properties unlike natural languages (note, however, that this language still possesses phrase structure of a sort – the absence of one word type predicts the presence of another; e.g., if A is not present, D must be present). Each form class (A, C, etc.) included 2 - 4 nonsense words (e.g., the words for the A category were BIFF, RUD, HEP, and MIB).

Table 1. Phrase structure grammars for Experiments 1 - 2. Letters refer to word classes; items in parentheses are optional. In Language N, one member of each phrase type must be present; if both are present, they must be in the order described by the grammar.

<u>Language P</u>	<u>Language N</u>
S → AP + BP + (CP)	S → AP + BP
AP → A + (D)	AP → (A) + (D)
BP → CP + F	BP → CP + F
CP → C + (G)	CP → (C) + (G)

The language generated by Language N is no larger than the language generated by Language P. In fact, Language N contained fewer sentence types (nine) than Language P (twelve). Language N also had shorter sentences on average, presumably making it less daunting to the learner: Language P generated 60% more five word sentences than Language N, and only 40% as many three word sentences. For both languages, only sentence types with five or fewer words were used (eight types for Language P, nine for Language N). Both languages contained the same number of grammatical categories and vocabulary items.

Because the languages were so similar in terms of their non-structural attributes, comparison of learning outcomes is valid. Language P is larger, and contains longer sentences, which could make it more difficult to acquire. However, if predictiveness affects learning, then the structure of Language N might have hindered its acquisition. A trained speaker recorded a corpus of 50 sentences from each language, with uniformly descending prosody but no grouping cues to phrase structure. Subjects were randomly assigned to hear either Language P or Language N sentences. Following approximately 30 min. of auditory exposure to one of the

two languages (the corpus was repeated eight times during exposure), all participants received the same forced-choice test consisting of novel grammatical and ungrammatical sentences, in order to assess acquisition of the rules of the two languages. Importantly, attempts to impose English syntax on either language would hinder performance. No cues other than the statistical information mirroring the underlying phrase structure of the language were available to learners.

**Results.** Each group's overall performance was significantly better than would be expected by chance: for Language P, the total score was 22.8 out of a possible 30:  $t(19) = 10.46, p < .0001$ ; for Language N, the total score was 20.55:  $t(19) = 6.62, p < .0001$  (see Figure 1). The principal hypothesis of interest concerns differences in learning as a function of structural differences between the two languages. To address this question, the scores for the two language groups for items testing each of the five rules were submitted to an ANOVA. The main effect of Language (P versus N) was significant:  $F(1, 38) = 4.2, p < .05$ .

These findings suggest that humans may be constrained to learn most readily via exactly the types of cues present in languages. To the extent that this is the case, the structure of natural languages may have been shaped by the nature of human learning (e.g., Bever, 1970; Christiansen, 1994; Christiansen & Devlin, 1997; Morgan, Meier, & Newport, 1987; Newport, 1990). According to the constrained statistical learning hypothesis, the mechanisms underlying language acquisition are biased to assist learners in detecting the 'right' statistical properties of the input. On this view, human languages have been sculpted by human learning and processing mechanisms – thereby creating input which contains the types of properties most useful for human learners, and rendering a close match between constraints on human learning and constraints on natural language structure.

If learners are biased to preferentially acquire structures where one item predicts another, is this constraint on learning particularly tailored for linguistic input? Biases in learning mechanisms may develop tightly coupled with the particular structure they are designed to acquire. Alternatively, constraints to use predictive statistics may be more generally applied to other types of sequentially presented information, as suggested by the constrained statistical learning hypothesis. Constraints on statistical learning which are not specific to language acquisition, but rather on the acquisition and processing of serial information, may have shaped the structure of natural languages. Experiment 2 thus utilized non-linguistic stimuli from two different modalities: visual shapes and complex sounds. An additional condition included visual linguistic stimuli (written words). As in Experiment 1, we contrasted the acquisition of Language P and N.

## Experiment 2

**Participants.** 154 monolingual English speaking undergraduates at the University of Wisconsin - Madison participated in this study. Forty-four subjects were randomly assigned to the non-linguistic auditory condition, forty subjects to the non-linguistic visual condition, and thirty subjects to the linguistic visual condition. Within each exposure condition, half of the subjects were assigned to Language P and half were assigned to Language N.

**Method.** For the non-linguistic visual condition, we translated the Language P and N grammars shown above into languages of shapes (for a similar methodology, see Goldowsky, 1995). For example, consider the phrase structure rule:  $AP \rightarrow A + (D)$ . In the linguistic version of this language, the category A consisted of 4 nonsense words. In the visual version, the category A consisted of 4 distinct shapes (such as a red circle with stripes). Category membership could not be induced by shape similarity, unlike prior studies by Morgan & Newport (1981). Participants observed the language on a computer monitor: each shape was presented in the middle of the screen, one at a time, with the same timing parameters as the auditory linguistic stimuli used in Experiment 1. Following exposure, participants were tested using a forced-choice test analogous to the linguistic task, in which they saw two shape sequences, one after the other, and decided which shape sequence more closely approximated the exposure stimuli. The linguistic visual condition was identical to the non-linguistic visual condition except that the nonsense words from Experiment 1 were shown typed on the computer screen. In the non-linguistic auditory condition, we translated Language P and N into non-linguistic sounds drawn from the digitized bank of alert sounds provided with Windows 98. Each word corresponded to a different sound, chosen to be maximally discriminable (an ascending buzz, a chord, chimes, etc.). Sound "sentences" generated by Language P and N were presented auditorily at the same rate as the linguistic and visual stimuli. Following exposure, participants received the same forced choice test, translated into non-linguistic sounds. Neither of the two non-linguistic conditions contained any linguistic information.

**Results.** Each group's overall performance was significantly better than would be expected by chance: for Language P Non-linguistic auditory, Nonlinguistic visual, and Linguistic visual,  $p < .0001$ ; for Language N Nonlinguistic visual,  $p < .001$ ; for Language N Nonlinguistic auditory,  $p < .001$ ; and for Language N Linguistic visual,  $p < .05$  (see Figure 1). As in Experiment 1, the principal hypothesis concerns

Figure 1: a. Mean scores from Experiment 1. b. Mean scores from Experiment 2.

differences in learning as a function of structural differences between Language P and Language N. To address this question, the scores for the two language groups for items testing each of the five rules were submitted to an ANOVA. The main effect of Language P versus N was significant for the Nonlinguistic auditory [ $F(1, 42) = 7.72, p < .01$ ] and the Linguistic visual condition [ $F(1, 28) = 4.56, p < .05$ ], but not for the Nonlinguistic visual condition [ $F(1, 38) = .23, n.s.$ ].

In order to ask whether the linguistic or non-linguistic status of the input influenced performance differentially as a function of the availability of linguistic dependencies, we performed a two-way between-subjects ANOVA contrasting Language (P versus N) and Linguistic Status (language versus non-language materials), including the auditory linguistic data from Experiment 1. There was a significant main effect of Language:  $F(1, 150) = 15.17, p < .0001$ . Neither the main effect of Linguistic Status [ $F(1, 150) = 1.09, n.s.$ ] nor the interaction between Language and Linguistic Status [ $F(1, 150) = .71, n.s.$ ] were significant. These analyses indicate that the linguistic status of the input – that is, whether the grammars were implemented in linguistic or non-linguistic tokens – did not affect overall performance. Instead, the dominant factor was whether the input was derived from Language P, which contained predictive dependencies as a statistical cue to phrase structure, or Language N, which did not. This overall non-effect of linguistic status occurred despite the fact that performance on the visual non-linguistic task did not show the predicted difference between Language P and N (see Figure 1). We are currently testing hypotheses concerning why the visual nonlinguistic task patterned differently from the other three conditions included in Experiments 1 and 2.

## General Discussion

These studies ask whether predictive dependencies serve a learnability function in the acquisition of language. The results of Experiment 1 suggest that adult learners are better able to acquire an artificial language which contains predictive dependencies as a cue to phrase structure than a comparable language which does not. Experiment 2 extends these results to demonstrate that the use of predictive dependencies in learning phrase structure is not limited to language learning tasks. These findings mirror prior results suggesting that transitional probability computation in word segmentation tasks can occur when ‘words’ are created from non-linguistic tones (Saffran, Johnson, Newport, & Aslin, 1999) or visuo-motor sequences (Hunt & Aslin, 1998).

Predictive dependencies are a hallmark of natural languages. However, it is of interest to note that these general organizational principles are by no means unique to language. Lashley (1951) observed that hierarchical organization characterizes an enormous variety of behaviors: “the coordination of leg movements in insects, the song of birds, the control of trotting and pacing in a gaited horse, the rat running the maze, the architect designing a house, and the carpenter sawing a board present a problem of sequences of action which cannot be explained in terms of successions of external stimuli” (p. 113). Such observations suggest that learners may be biased to process information in a particular fashion, enabling a learning process which results in phrases and hierarchically structured representations.

The kinds of structure at issue here serve to organize and package serial information into manageable chunks, which then enter relationships with one another. This process presumably maximizes cognitive economy, facilitating the

transmission of more complex information than could be transmitted otherwise. Pinker and Bloom (1990) argue that "hierarchical organization characterizes many neural systems, perhaps any system, that we would want to call complex...Hierarchy and seriality are so useful that for all we know they may have evolved many times in neural systems" (p. 726). When applied to syntax, this kind of argument suggests that grammars look the way they do because these kinds of organizational principles are the human engineering solution to the problem of serial order.

It is conceivable that this type of packaging of serial inputs into higher-order organization facilitates not only language production and processing, but also language acquisition. Systems which are highly organized are more learnable than systems which are not -- as long as the system of organization is consistent with the learner's cognitive structure. We anticipate that future research will be extremely useful in further clarifying the extent to which the constraints observed during the process of language acquisition subserve other learning processes as well.

With respect to linguistic structure, one potential theoretical implication of this research concerns an alternative to the traditional innate universal grammar explanation for the pervasiveness of particular linguistic features cross-linguistically.. If human learners are constrained to preferentially acquire certain types of structures, then some of the universal structures of natural languages may have been shaped by these constraints (see also, e.g., Bever, 1970; Christiansen, 1994; Christiansen & Devlin, 1997; Newport, 1982, 1990). Perhaps languages fit our learning abilities so neatly precisely because languages have no choice. If the pertinent learning mechanisms preceded the advent of languages, then there must have been intense pressure for languages to be learnable, with learnability dictated by the structure of human learning mechanisms. On this view, languages evolve to fit the human learner. To the extent that this type of view is correct, then the striking similarities of human languages may be in part the direct reflections of constraints on human learning abilities.

The present research begins the task of recharacterizing language universals in terms of constraints on learning by recasting the distributional features and dependencies inherent in hierarchical phrase structure into cues detected during the learning process. In the case of the constraint to interpret predictive relations as signaling a linguistic unit, the phrase, we find the beginnings of an explanation for why languages ubiquitously contain the within-phrase dependencies initially characterized by structural linguists. Future research will continue to pursue the hypothesis that constraints on learning play an important role in shaping the structure of natural languages. For example, recent computational research suggests that universal word order typologies may in fact reflect the ease with which different types of systems are learned (Christiansen & Devlin, 1997).

With respect to statistical learning, the present research runs counter to the assumption that statistical language learning accounts -- and any other type of theory which assigns an important role to linguistic input -- are necessarily underconstrained. As animal research has amply demonstrated, learning in biological systems is highly constrained (e.g., Garcia & Koelling, 1966; Marler, 1991). There is every reason to believe that statistical learning is similarly constrained; the purported intractability of statistical learning need not be asserted *prima facie*. What exactly these constraints will turn out to be, and whether they will confer sufficient explanatory power, remain empirical questions. Nevertheless, there are grounds for optimism. Learners are not, and never have been, blank slates. The more we learn about the mechanisms engraved upon that slate, the more we learn about learning.

# Attentional Biases in Artificial Noun Learning Tasks: Generalizations Across the Structure of Already-Learned Nouns

Larissa K. Samuelson (samuelso@indiana.edu)

Department of Psychology and  
Program in Cognitive Science  
Indiana University  
Bloomington, IN 47405

## Abstract

Even though learning noun meanings in a first language should be a difficult task young children learn nouns quickly and often with little effort. Previous research suggests that the task of learning words is made easier by constraints or biases that reduce the problem of finding the correct word-referent mapping to a solvable size. The research presented here examines the relation between the attentional biases young children demonstrate in laboratory noun learning tasks and the pattern of word learning seen outside the laboratory. The comparison suggests that attentional biases in laboratory noun learning tasks are a generalization across the nouns young children have already learned. Further, changing the nouns young children know changes not only the attentional biases they demonstrate in the laboratory, but also their vocabulary development outside the laboratory.

## Introduction

Young children typically say their first word at 1-year-of-age. However, conservative estimates suggest that by 5-years-of-age children have as many as 10,000 words in their productive vocabulary. How do children learn so many words so fast? One suggestion is that the task of learning words is made easier by biases or constraints which reduce the problem of finding the correct word-referent mapping to a solvable size (e.g. Landau, Smith, & Jones, 1988; Markman, 1992; Soja, Carey, & Spelke, 1991). There is strong experimental evidence for the existence of a number of these word learning biases. The research presented here concentrates on two: the shape bias for learning names of solid objects and the material bias for learning names of non solid substances.

Evidence for these two attentional biases comes from artificial noun learning experiments. In these experiments, a young child is presented with a novel object. This exemplar object is then named, i.e. "this is a dax". The child is then presented with novel test objects that match the exemplar in one perceptual dimension, for example in shape only, color

only, or material only. The child is then asked which of these test objects can be called by the same name as the exemplar.

Numerous studies have shown that when the exemplar object is made of a solid, rigid material such as wood or hardened clay, children 24-months-of-age and older generalize novel names to other objects that match the exemplar in shape. This "shape-bias" has been demonstrated in numerous laboratories, with stimuli ranging from real, 3-dimensional objects specially constructed for the experiment (Imai & Gentner, 1997; Landau, et al., 1988), to pictures of familiar objects (Imai, Gentner, & Uchida, 1994). However, when the exemplar object is made from a non solid substance such as hair gel or face cream, children generalize the novel name to test objects made from the same material as the exemplar (Dickinson, 1988; Soja, 1992; Soja, et al., 1991). This "material-bias" has also been demonstrated in numerous studies and laboratories, however this bias does not appear to be robust until after 30-months-of-age (Samuelson & Smith, 1999).

In a series of recent studies, I have examined the relation between these attentional biases, demonstrated in laboratory tasks, and the pattern of noun vocabulary growth seen outside the laboratory (Samuelson & Smith, 1999). These experiments suggest that the attentional biases seen in laboratory word learning tasks may be generalizations across the category structure of already learned nouns. This paper reviews these findings and the suggested hypothesis. Two experiments testing this hypothesis are then presented. The results show that changing the nouns young children know changes the development of attentional biases seen in laboratory word learning tasks, and that this change further alters the trajectory of vocabulary development outside the laboratory

## Attentional Biases and the Nouns Children Know

If the shape and material biases are to help children learn nouns, then these biases need to match the kinds of nouns that young children learn early. That is, if the shape bias helps children learn names for solid objects by directing their attention to within category similarity in shape, then many

of the nouns young children learn early should refer to solid things in categories well organized by shape. Likewise, if the material bias helps children learn names for non solid things by directing their attention to similarity in material substance, then there should also be many names for non solid things in categories well organized by material substance among the nouns children learn early. An important question, then, is what kind of nouns do young children learn early?

To answer this question, I examined the category structures of a corpus of early-learned nouns. The corpus of 312 nouns studied was taken from the Mac Arthur Communicative Development Inventory (MCDI), a parental checklist of 680 words and phrases commonly found in the productive vocabulary of children between 16- and 30-months-of-age. In a series of yes/no judgments, thirteen adult native speakers of English were asked to think of examples of each noun in the studied corpus and say whether the examples were solid, non solid, similar in shape, and similar in material. An 85% agreement criterion was then used to determine the structure of the category referred to by each noun. For example, 85% of the adults agreed that crayons were solid, similar in shape, and similar in material. Thus, CRAYON was classified as referring to a category of solid things similar in both shape and material.

A summary of the findings across the entire corpus can be seen in Figure 1. In the figure, each square represents the 312 nouns studied. The area of each circle represents the proportion of those nouns that fell in each classification. And, the overlapping area of the circles represents the proportion of nouns that fell in the intersection of the classifications. As can be seen in the figure, many of the nouns children learn early name solid things and things in categories well organized by shape. And, there is a large amount of overlap between these classifications; many of the nouns children learn early name solid things in shape-based categories. In contrast, few of the nouns children learn early name non solid substances or things in categories well organized by similarity in material substance. And, there is not much overlap between these classifications; young children do not learn many names for non solid substances

Figure 1: Summary of the category structure of the corpus of 312 early-learned nouns.

in material-based categories (Samuelson & Smith, 1999).

Thus, many of the nouns children commonly learn by 30-months-of-age fit the shape-bias. And, by 30-months-of-age children have not learned many nouns that fit the material-bias. These facts fit with previous findings that children demonstrate a shape-bias in artificial noun learning tasks by 24-months-of-age, but do not reliably demonstrate a material bias until 36-months-of-age. However, this study does not address the developmental relation between these findings. That is, do children demonstrate a shape bias because they know many names for solid things in shape-based categories. Or, do children learn many names for solid things in shape based categories because they have a shape bias? To address this question, I compared artificial noun learning with solid and non solid stimuli in children with a range of vocabulary sizes. Specifically, fifty-eight children between 17- and 31-months of age completed a forced choice artificial noun learning task in which half the exemplars and choice stimuli were made from solid materials such as wood and Styrofoam, and the other half were made of non solid materials such as hair gel and face cream. I also measured each child's productive noun vocabulary via parental report on the MCDI.

Figure 2 presents the key results. As can be seen in the figure, I found that children did not generalize novel names for solid objects to other solid objects by shape at levels reliably above chance until they already had 150 nouns in their productive vocabulary. And, children in the vocabulary range I studied did not generalize novel names for non solid stimuli to other non solid stimuli at levels reliably above chance. Thus, it appears that the shape-bias emerges only after children have already learned many names for shape-based categories. And, the material-bias does not emerge within the vocabulary range I studied (Samuelson and Smith, 1999).

These results suggest that the attentional biases young children demonstrate in artificial noun learning tasks might be the product of their previous noun learning. More

Figure 2: Proportion shape choices by noun vocabulary size for the solid and non solid stimulus sets. Chance responding is .50, \* =  $p < .05$  difference from chance.

specifically, what children do in artificial noun learning tasks is attend to whatever perceptual property has mattered most in learning the nouns they already know. Attentional biases thus appear to be a generalization across the structure of already learned nouns. This hypothesis is tested in the following experiment.

## Experiment 1

Previous results suggest that children's performance in artificial noun learning tasks is a generalization across the structure of already learned nouns. The specific question addressed in this experiment is whether changing the nouns children know changes their attentional biases in artificial noun learning tasks. The idea was to intensively teach nouns to young children who do not have many nouns in their vocabulary and do not yet demonstrate systematic attentional biases in artificial noun learning tasks. If children's attentional biases in noun learning are a product of the nouns they already know, then changing the nouns they know should change their attentional biases.

To this end, two groups of children participated in a nine week longitudinal study. Children in one group were taught twelve names for categories of solid objects well organized by similarity in shape. Another group of children were taught twelve names for categories of non solid substances well organized by similarity in material substance. Two dependent measures were examined: artificial noun learning with both solid and non solid stimuli, and productive vocabulary via parental report. Both measures were taken early in training and, again, later in training. In addition, a follow-up report of productive vocabulary was obtained one month after the experiment was complete.

## Methods

**Participants.** Twenty children between 15- and 21-months-of-age participated (mean 18m 28d, range 15m 20d to 21m 3d). Children were recruited from the child participants file at Indiana University and contacted by phone. All children were learning English as their first language. Children were randomly assigned to either the Shape Nouns or Material Nouns condition such that the mean age and vocabulary across conditions did not differ. Four additional children began but did not complete the experiment. All children received a small prize at each experimental visit and copies of experimental videotapes and T-shirts at the completion of the study.

**Materials.** Conditions differed only in the twelve nouns taught to the children over the course of the longitudinal study. All twenty-four nouns are nouns not usually learned until after 26 months of age. The noun category training sets for each condition consisted of three examples of each of the twelve nouns.

In the Shape Nouns condition, children were taught twelve names for solid things in categories well organized by shape,

for example, bucket, pear, and ladder. In this condition, example items for each category were the same in shape but differed in size, color, and the material they were made from. For example, one ladder was wide and made of red wood, one was taller and made of white plastic and one was short and wide and made of pink metal.

In the Material Nouns condition, children were taught twelve names for non solid things in categories well organized by material, for example, glitter, lotion, and Jell-O. In this condition, example items for each category were made from the same material but differed in amount, color, and shape. For example, the Jell-O was either red, orange or blue and was either presented as a large pile, a couple small piles, or in the shape of a teddy-bear, and these shapes and amounts changed as the child ate the Jell-O.

Eight sets of artificial noun learning stimuli were also constructed—four made from solid materials such as wood and Styrofoam and four made from non solid materials such as hair gel and face cream. Each set consisted of an exemplar object and four test objects. In each set, two test objects were the same shape as the exemplar but were different colors and made from different materials, and two test objects were made from the same material as the exemplar but were different in shape and color. Eight unique nonsense words were created for use in the artificial noun learning task. The pairing of names to stimulus sets was counterbalanced across children.

Twenty unique sets of practice stimuli were also assembled for use in practice artificial noun learning trials. These sets consisted of small toys familiar to most 15-month-olds such as balls, toy cars, and cups. Each set consisted of two identical toys and a third toy that differed in color, shape and size (for example, two purple plastic eggs and a red wooden block).

**Procedure.** Children and their parents visited the lab once a week for nine consecutive weeks. These nine weeks were broken into three blocks of three weeks each. Each block consisted of two weeks of noun category training. On the third week children were tested in artificial noun learning. Productive vocabulary was measured via parent report on the Mac Arthur Communicative Development Inventory at the beginning and end of the experiment and at a follow-up appointment one month after the final experimental session.

During all experimental sessions, the child sat across a large table from the experimenter with his or her parent. Experimental sessions began with two practice trials of the artificial noun learning task. These practice trials were used both to engage the child in the experimental session, and to encourage their participation in the artificial noun learning task. In these practice trials, the experimenter gave the child one set of practice stimuli to examine. After the child had examined the items the experimenter retrieved the toys, put one of the matching pair and the non-matching item on a tray, held up the other matching item and said, "See this,

this is my (name of toy).” She then pushed the tray towards the child saying “Can you get your (name of toy)”. If the child picked-up or gestured towards the matching toy she was praised heavily. If she picked the incorrect toy the experimenter said “Is that the (name of toy)? No! Get the (name of toy)” until the child picked the correct toy.

On noun category training weeks, noun training followed the practice trials. During noun training, the child, experimenter, and parent played with and named the examples of four noun categories. The three examples of each category were played with as a set for approximately three minutes each. The experimenter then put these items away and brought out the examples of the next noun category. The experimenter named each noun category at least 20 times for each child, and encouraged the child to say each noun at least once.

On artificial noun learning weeks, the artificial noun learning task followed the practice trials. This task was identical to the procedure used during the practice trials. The child was given the exemplar, one shape-match test object, and one material-match test object to examine. The experimenter then placed the test objects on the tray, held up the exemplar and said, “See this, this is my bing”, (for example). The experimenter then pushed the tray towards the child and said “Can you get your bing?”. If the child did not respond she was prompted again. The experimenter then proceeded to the next trial for that stimulus set. The parent was asked not to refer to the stimuli during this task but to encourage the child to respond. There were four trials for each stimulus set (each shape-match test object with each material-match test object) and one solid and one non solid stimulus set at each artificial noun learning task. Children never saw the same stimulus set twice. Order of solid and non solid sets was counterbalanced across artificial noun learning tests and order of stimulus sets was counterbalanced across children.

All experimental sessions were video taped for later coding of naming instances and artificial noun learning responses. Three coders blind to the experimental hypothesis coded all artificial noun learning sessions. Coders indicated which test object the child picked on each trial. Twenty percent of the trials were coded by two coders and reliability was greater than 90%.

## Results and Discussion

Figure 3 shows the mean proportion of shape choices in the artificial noun learning task with solid and non solid stimuli for children in the Shape Nouns and Material Nouns conditions at weeks three and nine. A Condition (Shape Nouns v. Material Nouns) X Stimulus Set (Solid v. Non Solid) X Week (3 v. 9) ANOVA revealed a significant main effect of Condition,  $F = 6.854$ ,  $p < .02$ , and significant Week by Condition and Stimulus Set by Week interactions,  $F = 4.695$ ,  $p < .05$ ,  $F = 10.436$ ,  $p < .01$  respectively. As can be seen in the figure, at week three there were no

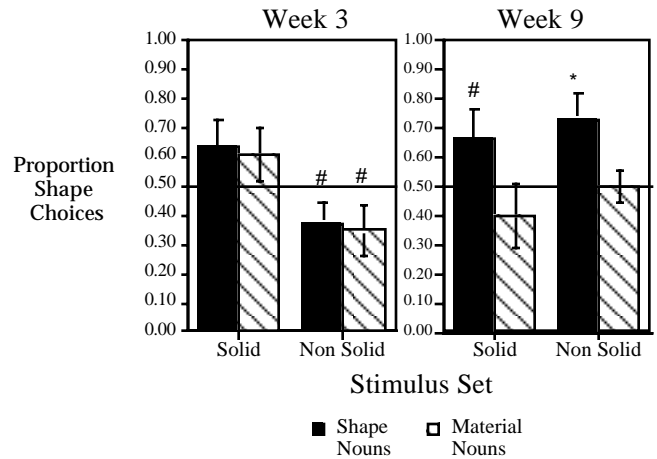

Figure 3. Results of Experiment 1. Chance responding equals .50. \* =  $p < .05$ , # =  $p = .06$  difference from chance.

differences between children in the two conditions in their responding to the solid or non solid stimuli. However, by week nine, children in the Shape Nouns condition picked shape matching test objects more than children in the Material Nouns condition for both the solid and non solid sets, Tukey’s HSD  $p < .05$ . Further, only children in the Shape Nouns condition at week nine picked shape matching test objects at levels significantly above chance. Thus, children who were taught twelve names for solid objects in categories well organized by shape also learned a shape-bias but children who were taught twelve names for non solid substances in categories well organized by material substance did not learn a material-bias.

Importantly, this learned shape-bias demonstrated in the laboratory also influenced children’s vocabulary development outside of the laboratory. Figure 4 presents the mean number of words in the total productive vocabulary of children in each condition at the first experimental session, at the last experimental session, and at the follow-up appointment one month after the experiment had ended. As can be seen in the figure, during the course of the experiment children in both conditions learned new words outside the laboratory at rates that did not differ. However, after the experiment ended, children in the Shape Nouns condition acquired significantly more words by the follow-up appointment. It appears that the twelve shape-biased nouns they were taught in the laboratory somehow accelerated their learning of other words outside the laboratory. It is also possible, however, that the difference in the vocabularies of children in the two conditions at the follow-up appointment was actually due to a suppression of the vocabulary development of children in the Material Nouns condition. Perhaps teaching these children twelve names for non solid things in categories well organized by material substance—categories that even 30-month-old children do not know many of—actually harmed their vocabulary development. This possibility was tested in Experiment 2.

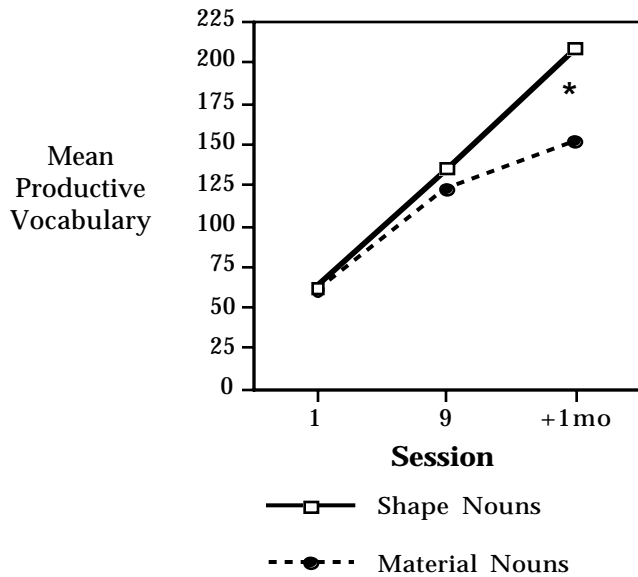

Figure 4. Mean productive vocabulary of children in experiment 1.

### Experiment 2

This experiment provides a control for the possibility that the vocabulary development of children in the Material Nouns condition of Experiment 1 was harmed by the unusual kind of noun categories they were taught. Ten children visited the laboratory nine consecutive weeks but did not receive any noun category training. Children participated in weekly artificial noun learning task practice trials as well as the full artificial noun learning task every third week. As in Experiment 1, the children’s vocabulary was measured at the beginning, end, and one month follow-up appointments. Thus, this experiment provides a measure of the typical vocabulary development of a matched set of children who repeatedly visit the laboratory and participate in the artificial noun learning task.

#### Methods

**Participants.** Ten children between 15- and 21- months-of-age participated (mean 18m 2d, range 15m 9d to 21m 7d). Children were recruited from the child participants file at Indiana University and contacted by phone. All children were learning English as their first language. Children were matched to children from Experiment 1 such that the mean age and vocabulary across experiments did not differ. All children received a small prize each experimental visit and copies of experimental videotapes and T-shirts at the completion of the study.

**Materials.** The same eight sets of artificial noun learning stimuli and 20 sets of practice stimuli used in Experiment 1 were used.

**Procedure.** The procedure was the same as Experiment 1 with the exception that children were not taught any noun categories.

#### Results and Discussion

The key result is pictured in Figure 5. There were no significant differences in the productive vocabularies of children from this experiment and children from the Material Nouns condition of Experiment 1. Thus, teaching children twelve names for non solid substances in categories well organized by material substance did not harm the vocabulary development of children in the Material Nouns condition of Experiment 1. And, thus, teaching children twelve names for solid objects in categories well organized by shape in Shape Nouns condition of Experiment 1 did accelerate their vocabulary growth.

Figure 5. Mean productive vocabulary of children in Experiment 2 (no noun training). Data from Experiment 1 are included for comparison

#### Conclusions

Results from the present experiments comparing early vocabulary growth and the attentional biases seen in laboratory artificial noun learning tasks suggest a clear and sensible developmental story. Early in vocabulary development, children learn many names for solid objects in categories well organized by shape. This learning changes children: they begin to attend to shape when learning novel names in the context of novel solid objects. Thus, it appears that the attentional biases young children demonstrate in artificial noun learning tasks are a generalization across the nouns that they have already learned. In fact, teaching very young children, children who do not yet demonstrate

systematic attentional biases in artificial noun learning tasks, names for solid objects in shape-based categories teaches them a generalizable shape bias. This in turn, promotes the more rapid learning of other words.

There are two important questions that remain unanswered by these results. First, why is there such an advantage for solid-shape-based categories over non solid-material-based categories? One possibility is that this a reflection of the structure of the language children hear (but see Sandhofer, Smith, & Luo, 1999).

The second unanswered question is how do children ever get a material-bias? We know that by three-years-of-age children reliably demonstrate a bias to attend to material substance when generalizing a novel name for a novel non solid substance. However, this bias is not reliable before 30-months-of-age (Samuelson & Smith, 1999). The developmental story for the material-bias may be the same as that for the shape-bias, just more protracted in time. That is, while children are rapidly learning names for solid things, they are also encountering a smaller number of non solid substances and their names. Each of these few substances may have to be individually learned, as an exception, without the boost from past learning given to names for solid objects. But, as vocabulary grows, children may learn enough names for non solid substances that the correlation between the perceptual cues of non solidity and naming by substance cohere to form a generalizable expectation about how substances are named.

# Phrases as Carriers of Coherence Relations

Holger Schauer and Udo Hahn

 Computational Linguistics Division

Freiburg University

D-79085 Freiburg, Germany

<http://www.coling.uni-freiburg.de/>

## Abstract

Coherence relations have mainly been studied as a mechanism for the representation of text structure based on the analysis of clauses and larger text fragments. A closer look at textual data reveals, however, that adjuncts, typically cued by prepositions, also have a coherence establishing function. We discuss empirical evidence for this claim, and outline a framework that integrates the semantic interpretation and recognition of coherence relations covert in prepositional phrases.

## Introduction

Single sentences encode one or more propositions, the semantic content of an utterance. When sentences are grouped together to form a text, this does not just constitute a bag of such propositions. Rather texts are characterized by the property of being coherent.

The glue out of which coherent texts are made is typically attributed to so-called *coherence relations*. Basically, these relations link low-level propositions by causal connections, motivational links (e.g., relating a goal to a sequence of actions intended to accomplish that goal), property descriptions, and argumentative roles. This linkage between several propositions is crucial not only for simple fact retrieval from memory but also for other high-level cognitive tasks. Hence, making coherence relations available lies at the heart of any cognitively plausible approach to modeling human text comprehension and automatic text understanding, as well.

Given the importance of coherence relations for adequate text understanding, the question arises how these relations can be determined by explicit criteria and how this may be achieved by automated systems. The currently dominating approach derives coherence relations directly from particular cue words (i.e., sentence connectives such as ‘*because*’, ‘*alternatively*’, etc. [Knott and Dale, 1994, Marcu, 1998]).

In line with one of the most prominent approaches to coherence, Rhetorical Structure Theory [Mann and Thompson, 1988], such approaches typically take clauses as the elementary coherence bearing units, ignoring the role of more smaller units, i.e., phrases. We will argue that such *interclausal* coherence analysis should be complemented by an analysis of *intraclausal* coherence, in order to obtain more accurate results, both with respect to completeness as well as with respect to correctness of the analyses performed.

When *phrases* are considered as the origin or target of coherence relations, it becomes evident that intraclausal coherence relations are explicitly cued (by prepositions or adverbs), but they also depend on implicit inferences at the semantic level, with references to the underlying common-sense or domain knowledge. While this finding coincides with commonly held views in the cognitive science community [Black, 1985, Meyer, 1985], usually no concrete specifications are supplied for how to compute coherence relations under these assumptions. In this paper, we will first present empirically supported arguments for phrases as the smallest units of coherence analysis, and then discuss explicit nonlexical, i.e., inferential criteria for deriving coherence relations from them.

## Arguing for Phrases as Discourse Units

### Intraclausal Coherence Phenomena

The main claim we make is that coherence relations not only have to be addressed at the *interclausal* but also at the *intraclausal* level of discourse analysis. Unless this finer grain size for discourse units is chosen, we will argue in the following that some coherence relations will not be identified at all, or some of them will be identified but are invalid. Accordingly, we will treat at least some phrase types, *viz.* prepositional and adverbial phrases, as discourse units. Consider the following example:<sup>1</sup>

- (1) a. *Mit dem P6LXZ-A wird Elitegroup aber kaum neue Kunden gewinnen.*  
[With the P6LXZ-A – Elitegroup will hardly attract new customers.]
- b. *Mit einem PCI-Slot bietet das Motherboard zu wenig Platz für Erweiterungen.*  
[With one PCI slot – the motherboard provides not enough space for extensions.]

A straightforward coherence analysis with relations from Rhetorical Structure Theory [Mann and Thompson, 1988]<sup>2</sup> takes (1-b) as a single unit and links it to (1-a), probably via an

<sup>1</sup>In the translations, important phrases keep the syntactic position of the original German sentences and are therefore separated with dashes.

<sup>2</sup>Relations referring to Rhetorical Structure Theory (henceforth referred to as RST) will appear *emphasized* and *Capitalized*.

Evidence	The Satellite, the not so important unit, provides evidence for the situation in the important unit, the Nucleus.
Explanation	The Satellite, which is typically independent of the will of an animate object, explains the Nucleus.
Cause	The situation in the Satellite causes the situation in the Nucleus.
Interpretation	The situation presented in the Satellite interprets (presents a different perspective on) the Nucleus and constitutes the opinion of the writer of the situation in the Satellite.
Means	The Satellite explains the means by which the Nucleus was done.

Table 1: Relations from Rhetorical Structure Theory.

*Evidence* relation, see Table 1.<sup>3</sup> Paraphrasing sentence (1-b) reveals, however, a plausible decomposition into two basic discourse units:

- (2) a. *The motherboard has but one PCI slot,*  
b. *so it does not provide enough space for extensions.*

Obviously, (2-a) gives an *Explanation* for (2-b).<sup>4</sup> From a methodological point of view it cannot be justified to analyze Sentence (2) as being composed of two elementary units, while the prepositional phrase “*with one PCI slot*” should be an indistinguishable part of the whole Sentence (1-b).

Besides *missing* essential coherence relations by not looking at phrases as discourse units, we also have indications that even *wrong* analyses may result. Consider the following sentences:

- (3) a. *Floptical Disks lassen sich nicht wie Festplatten ansprechen.*  
*[Floptical disks cannot be addressed in the same way as ordinary hard disks.]*  
b. *Diese Beschränkung ist aufgrund technischer Unterschiede notwendig.*  
*[This restriction is – because of technical particularities – necessary.]*

One might argue, granting the interpretative force of ‘*because of*’, that (3-b) gives a *Cause* for (3-a). On a closer look, however, this seems to be mistaken, because (3-b) can be said to *Interpret* (3-a). Its main assertions consist of an assessment of (3-a) as being a “*restriction*” and as being “*necessary*”. Obviously, the embedded prepositional phrase (“*because of* . . .”) specifies just the *Cause* for the necessity of the restriction, and is not related to sentence (3-a).

### Criteria for Phrases as Discourse Units

Given that, on the one hand, at least some phrases should be analyzed as discourse units in their own right and that, on the other hand, certainly not all of them figure as discourse units, the question arises which criteria should be set up in order to single out true candidates for discourse units from spurious

<sup>3</sup>In order to avoid a lengthy introduction to RST, the definitions are taken from the manual coming with the tool that we used for our analyses [Marcu et al., 1999]. It makes available an extension of the original RST relations [Mann and Thompson, 1988].

<sup>4</sup>This analysis reflects the impact of the cue word “*so*” in (2-b). More generally, whenever an implicit coherence relation can be made explicit by a paraphrase incorporating a specific cue word, then this coherence relation is always assumed to hold [Martin, 1992, p.184].

ones. While [Grote et al., 1997] recognize that “prepositional phrases are the most compact form” to establish a coherence relation, [Marcu et al., 1999] are among the first who propose to consider those phrases as elementary discourse units that “are unequivocally the nucleus or the satellite of a rhetorical relation that adds some significant information to the text.” However, the restrictions provided by this criterion proved to be too liberal for the choice of possible candidates.

Focusing on the role of prepositional phrases (PPs) in our paper, we propose a mix of two criteria. First, the syntactic criterion requires only those PPs to be candidates for discourse units, which are not syntactically mandatory *complements* of a governing syntactic head, for which we assume a subcategorization frame or a valency list. Phrases which do not match such a schema of their governing syntactic head are syntactic elements we refer to as *adjuncts*.

For example, the PP starting Sentence (1-b), “*with one PCI slot*”, figures as an adjunct. It gives optional information, since the remainder still forms a complete grammatical sentence, “*the motherboard provides not enough space for extensions*”. This stands in contrast to example (4), which contains a true complement:

- (4) *We have to stop pointing our fingers at these kids, he said.*

In Sentence (4), neither should the PP “*at these kids*” be treated as a discourse unit, nor should any other mandatory phrase, such as the subject “*we*”.

At the semantic level we formulate the second major criterion. It is based on the assumption that semantic specifications of lexemes, independent of the specific semantic theory one subscribes to, are confined to “typical” properties, e.g., events are characterized by agents, patients, instruments, locations, time frames, etc. Since any straightforward semantic interpretation must account for these attributes, they should not be part of analyses targeting on coherence relations. Whenever nontypical, unpredictable information pieces have to be accounted for, coherence relations may capture their value-adding semantics. Therefore, only those PPs should be considered as discourse units

- whose straightforward semantic interpretation is precluded because they refer to nontypical properties;
- or whose semantic interpretation partially refers to typical properties, but the intended meaning is not fully covered by them; only additional computations – inferences taking the preliminary semantic interpretation as a starting point – completely account for the intended meaning.

We will illustrate the main criteria which determine whether a PP should be treated as a discourse unit or not by contrasting the sample sentences (1-a) and (1-b). In Sentence (1-a), the PP specifies an instrument for attracting new customers. As it seems entirely reasonable to consider “instrument” as a typical property of “attraction” events, this example should straightforwardly be dealt with by standard semantic interpretation — the conceptual correlate of *P6LXZ-A* will be assigned as the value of a corresponding “instrument” attribute. In particular, this analysis need not take recourse to any notion of coherence relation, although the proponents of RST might consider a *Means* relation as being appropriate.

This typicality consideration does not carry over to an “explanation” of events, which is our interpretation of “with one *PCI slot*” from Sentence (1-b). Rather than being missed at the representational level, accounting for this information adds valuable, ‘heavy’ knowledge. Such a relation, however, can only be computed by additional inferences relating to the underlying domain knowledge base.

### From Prepositional Phrases to Coherence Relations

We now briefly sketch a coherence analysis based on the considerations discussed in the previous section. To make this discussion more concrete, it is embedded in the framework of SYNDIKATE, a text analysis system under development in our lab [Hahn and Romacker, 1999b]. After being submitted to a syntactic analysis the dependency graph for Sentence (1-b) (cf. Figure 1) contains a prepositional adjunct (ppadj) subgraph which holds the phrase “Mit einem *PCI-Slot*”. (This analysis results from the valency specification for the main verb “*bietet*”.) In order to compute a semantic interpretation for Sentence (1-b) (assuming the framework of description logics [Woods and Schmolze, 1992]), the conceptual correlates of its content words are checked for role compatibility.

In this case, the major interpretation constraints derive from the main verb “*bietet*” (*provide*) which is represented as the concept PROVIDE (cf. Figure 2). It has three major conceptual roles, PROVIDE-PATIENT, PROVIDE-CO-PATIENT, and INSTRUMENT. The PROVIDE-PATIENT and PROVIDE-CO-PATIENT roles can be filled by some instance of MOTHERBOARD and SIZE, respectively, in the semantic interpretation phase. This causes conceptual interpretation processes to be triggered linking SIZE and MOTHERBOARD (cf. Figure 2) via the role SIZE-OF.

Figure 1: Dependency Analysis for (1-b)

Figure 2: Semantic Interpretation for (1-b)

Focusing on the analysis of the PP, each preposition specifies *semantic constraints*, see [Hahn and Romacker, 1999a]. In the case of “*mit*” (*with*) they allow an interpretation of the dependency relation *ppadj* in terms of the conceptual INSTRUMENT role, so the corresponding role of SHOW-FEATURE is filled with *PCI-SLOT* during semantic interpretation. Conceptual interpretation, in addition, triggers the computation of a specialization of the PART-OF relation (SLOT-OF) between *PCI-SLOT* and *MOTHERBOARD*.

At this stage, we check whether the preposition might give rise to the computation of coherence relations. Corresponding *discourse constraints* of a preposition specify a set of possible coherence relations it may signal. These constraints were determined empirically, see Section (4). The constraints of permitted coherence relations are checked, taking the already computed semantic interpretation as a starting point. For “*mit*” (*with*) an *Explanation* may be signaled whenever the filler of the INSTRUMENT role stands in a PART-OF relation to the PROVIDE-PATIENT. As SLOT-OF is one of the subroles of the PART-OF relation, an *Explanation* relation is established.

Figure 2 also shows a PURPOSE relation linking instances of PHYSICAL-SIZE and EXTENSION that is due to semantic interpretation, in line with considerations which will be presented in the next section.

### Evaluation of Coherence Data

The basic claim we try to back up by empirical analysis is that focusing on intraclausal coherence leads to more adequate analyses, with respect to both completeness and correctness. In the following we will set out to validate the principal assumptions and criteria and not their implementation. For this task it is necessary to a) closely consider how many and which PPs can be seen as discourse units in their own right (i.e., checking the proposed criteria), b) how many of them have been missed in mainly clause-based analyses, and c) how many of these analyses could be judged as incorrect (similar to example (3)).

### Distribution of Prepositional Phrases in the Corpora

The textual data for our study were taken from two sources – a German-language corpus of test reports from the information technology domain (31 texts, with approximately 7,700 text tokens), and a small set of English texts from the MUC corpus [MUC-6, 1995] (9 texts, with approximately 5,100 text tokens) for comparison purposes.

For our empirical study we used RSTTOOL, a workbench for annotating texts in terms of their underlying coherence relations. The tool makes available an extension of the set of original RST relations. Both the tool and the English texts were kindly supplied by D. Marcu, see [Marcu et al., 1999].

The English texts were already analyzed and contained 795 discourse units connected by 379 relations. We re-analyzed these texts only with regard to prepositional phrases, modifying the original discourse analyses where appropriate. As the German texts were all analyzed with such a focus, we provide the distribution of units and relations in the next subsection.

Our analyses were performed in joint work by one of the authors and one student. During the discourse annotations, for each new clause to be segmented and related, we first determined the syntactic role of prepositional phrases, i.e. whether an identified PP should be seen as an adjunct or mandatory complement of its governing head. Next, when a coherence relation was unequivocally identifiable, the PP was taken as an elementary discourse unit and related with the coherence relation. As a result, we determined for each preposition the set of coherence relations it may give rise to.<sup>5</sup> Otherwise, we just recorded its likeliest interpretation. Obviously, the annotators needed to know about the hypothesis that (prepositional) phrases might trigger coherence relations. Therefore, the data presented below needs to be validated further.

Overall, we determined a total of 611 PPs in the German and 501 PPs in the English corpus. Table 2 lists their syntactic distribution, distinguishing between adjuncts and complements. The leftmost column indicates the syntactic head of the PP, either a nominal or verbal phrase, or an adjective/adverb.

	Adjuncts		Complements	
	German	English	German	English
NP	192	98	60	154
VP	176	128	159	109
Adj	10	5	14	7

Table 2: Syntactic Distribution of PPs in the Corpora

Distinguishing certain and dubious judgements, Table 3 shows the distribution of PPs that were solely analyzed by semantic interpretation, i.e., either no coherence relation could be determined or a semantic interpretation seemed entirely sufficient. We found that in those cases in which a *Means* or *Manner* relation might be used, the interpretation of the PPs just amounted to the assignment of values to reasonable and typical properties, see Example (1-a). Hence we felt that these cases should be dealt with by proper semantic interpretation and not be counted as coherence relations at all, just like locative/spatial and temporal information.

With regard to *Attribute/Restriction*, we found that many PPs that are adjuncts of NPs can be interpreted as specifying

<sup>5</sup>This set can then be used to specify the discourse constraints mentioned in the previous section.

attributes (such as “*the Matrox Millenium graphics card with 4 MByte SDRAM*”) or as stating restrictions for the interpretation of the NP (such as “*a computer with a Pentium is fast enough*”, where the PP picks a specific set of “*computers*”).

Interpretation	German		English	
	Cert.	Dub.	Cert.	Dub.
Locative/Spatial	37	16	25	0
Temporal	16	0	31	1
Means	44	3	4	0
Manner	22	0	4	1
Attribute/Restriction	205	0	226	0
Others	181	1	167	0

Table 3: PPs Not Considered as Discourse Units

Those cases that could neither be addressed by one of the given categories nor be treated as discourse units are listed as *Others*. Mostly these are cases in which the PP is a mandatory complement whose preposition has an almost idiomatic, at least a highly collocational status, see example (4). These phenomena are more adequately dealt with by lexicalized encodings covering the particular reading of the preposition rather than being treated by the general interpretation mechanism for prepositions.

### PPs as Discourse Units in the Corpora

Table 4 summarizes the interpretation of PPs in terms of true coherence relations. For the German texts, we found 66 cases for which coherence relations were unequivocally identifiable, plus 20 dubious cases. In 63 cases, the prepositional phrase appears in the middle of a clause. In this case, two units result from the remainder of the clause that need to be related by an artificial *Same-Unit* relation. Overall, the 66 identified PPs are responsible for 129 relations, including 63 *Same-Unit* relations. For the German texts, a total of 1713 units connected by 869 relations were identified. This means that 14.8% of coherence relations were of the intra-clausal type.

Our re-analyses of the English texts consisted only of additions and modifications of coherence relations due to PPs. This results in 884 units connected by 421 relations. Overall, 40 PPs give unequivocally rise to 51 coherence relations, plus 2 dubious cases. The 40 certain cases of coherence bearing PPs account for 12.1% of the coherence relations.

From those 40 PPs we considered as discourse units in the English texts, only 3 phrases were also analyzed by Marcu. This indicates that the common focus on clauses and larger fragments tends to provoke a certain analytical bias, just as we expected. So, the completeness of coherence analysis seems to benefit from the focus on adjuncts.

With regard to the syntactic criterion, almost all certain cases of discourse units (61 out of 66 in the German texts, 39 out of 40 in the English texts) are due to PPs that we judged as being adjuncts. In contradistinction, most of the dubious cases (15 of 20 for the German texts, 0 out of 2 for the English texts) coincide with the PP in a syntactically mandatory

Relation	German				English			
	Adjuncts		Complements		Adjuncts		Complements	
	Certain	Dubious	Certain	Dubious	Certain	Dubious	Certain	Dubious
Analogy	0	0	0	0	1	0	0	0
Attribution	5	0	0	0	1	0	0	0

Reason	0	0	0	0	2	0	1	0
$\Sigma$	61	5	5	15	39	2	1	0

Table 4: Prepositional Phrases Treated as Discourse Units

position. So the distinction between adjuncts and complements can be seen as a valid indicator for phrases that can be analyzed as discourse units.

With regard to the second criterion, it is necessary to explain the dubious cases. These often coincide with syntactically mandatory complements. As a result, it is often not clear whether the PP should be analysed semantically, although an interpretation in terms of a coherence relation would be possible. As an example, consider the next example, in which the prepositional phrase could be analysed as stating a *Purpose* for the graphics card.

- (5) *Für die nächste Generation an Spielen sind Grafikkarten wie die Spea V7 nötig.*  
 [For the next generation of games – graphics cards such as the Spea V7 are required.]

In contradistinction, for those PPs we unequivocally considered as discourse units, an interpretation solely in semantic terms is usually hard to imagine, see Example (1).

Commenting on the correctness of the original English analyses, we found no cases of errors caused by overlooked PPs, contrary to our expectation. This may be explained by the fact that those cases in German are mainly triggered when the phrase occurs inside a clause – e.g., example (3-b). We found no corresponding example in the English data.

Finally, commenting on the quantitative distribution of coherence relations in Table 4, the large number of *Condition* and *Purpose* relations might largely be attributed to the chosen domain (information-technology). In this domain, judgments are often valid only under certain assumptions and conditions. Also, nearly all actions serve some purpose and are evaluated against it. One might be challenged then to treat *Condition* and *Purpose* as “typical” in this domain; hence they should probably even be treated by the standard semantic interpretation (as already assumed in Figure 2).<sup>6</sup>

<sup>6</sup>See [Linden and Martin, 1995] for an account of the *Purpose*

## Related Work

The notion of coherence relations is dealt with by a variety of approaches — structural ones in which linear text fragments are bracketed and organized in discourse trees by rhetorical relations [Mann and Thompson, 1988], logical ones in which metapredicates provide the inferential basis for linking basic predicate-argument structures [Lascarides et al., 1992], psychological ones in which the level of micropropositions is clustered in terms of conceptually coherent macropropositions [Kintsch and Dijk, 1978, Black, 1985]. Since none of these approaches incorporate syntactic considerations into their analyses (a syntactic analysis is assumed to deliver appropriate text chunks or propositions), they are unable to account for coherence relations encoded via PPs.

There are a few attempts to incorporate the role of cue words in computational approaches to determine coherence relations. These are based on the RST framework [Marcu, 1998], logical interpretations [Hobbs et al., 1993], or extensions of sentence grammars [Webber et al., 1999]. But in these approaches, the level of intraclausal analysis is not an issue. A recent study mentions the role of PPs as carriers of coherence relations [Grote et al., 1997], but only for the purposes of text generation.

Our distinction between semantic and discourse constraints looks similar to the semantic/pragmatic distinction found in [Sanders et al., 1992, Knott and Dale, 1994]. Their distinction, however, addresses the intended effects coherence cues have on the reader, while in our work discourse constraints establish interpretations beyond ‘typicality’ limits.

Another distinction relates to the role of empirical arguments related to coherence relations. Our study deals with the *quantitative distribution* of a set of coherence relations as encoded by various PPs, while in [Sanders et al., 1992] the *plausibility* of certain coherence relations fulfilling a set of

relation in instructional texts that also acknowledges the role of intraclausal coherence.

criteria is judged by a number of subjects.

## Conclusion

We have presented an approach in which the computation of coherence relations is made dependent on the semantic interpretation of a particular class of prepositional phrases, *viz.* adjuncts. The notoriously difficult distinction between complements and adjuncts has been resolved in a pragmatic way such that the syntactic notion of complements is associated with typicality considerations at the semantic level, and, similarly, adjuncts are associated with nontypical properties.

Text interpretation then proceeds via a two-step procedure. First, proper semantic interpretation is concerned with matching parsed utterances to (conceptual) representations in the lexicon. If a match is found (i.e., complements refer to typical properties/relations), one checks, in addition, whether inferential criteria for coherence relations are fulfilled. If no match can be found, an adjunct has been determined which, by definition, constitutes a possible discourse unit and has to be checked for more specific criteria for coherence relations.

One focus of our paper was on finding empirical evidence for the claim that PPs are important at all for coherence analysis. Indeed, we have detected a significant subset of coherence relations encoded as PPs (for the English data roughly 12%, for the German data 15%). These would have been lost if a cue-phrase-only approach were followed, since prepositions cannot be considered reliable predictors of (specific) coherence relations. They would, however, also have been lost with an inference-only approach, since each preposition may signal only some coherence relations. Therefore, they do not seem to be derivable from conceptual representations alone.

Given that this argument is valid, the computation of coherence relations must incorporate both the syntactic and semantic level, as well as inference rules which determine those knowledge structures which have to be superimposed by coherence relations.

## Abstract

Current theories of language production tend to differentiate between a (syntactic) *functional* level and a (surface) *positional* level in the generation of sentences, where functional selection precedes and constrains positional processing. In this paper, we present evidence from a syntactic priming study in German, where position, function, and type of constituent are orthogonally specified for monotransitive and ditransitive verbs. In contrast to findings for English (in which these factors are confounded) we show that previous generation of a ditransitive structure can *inhibit* the production of a further ditransitive when the order of potential arguments differs between prime and target. Our results suggest that positional processing must at the least interact with functional processing in production, and point to the importance of cross-linguistic evidence in the formation of models of language processing.

*Syntactic Priming* is the name given to the tendency that people have to re-use syntactic structure that they have just generated. For example, Bock (1986) demonstrated that, having read aloud a sentence such as *The rock star sold some cocaine to an undercover agent*, participants are more likely to describe a picture with a phrase such as *The girl handed a paintbrush to the man* rather than with the alternative *The girl handed the man a paintbrush*. Current interpretations of these findings tend to emphasise a functional level of sentence production, at which syntactic information (such as subcategorisation properties of verbs) is specified and syntactic roles (such as subject or object) are assigned. The eventual positions of constituents in the utterance are determined by subsequent processes which take as their input the representations built at the functional level (e.g., Bock & Levelt, 1994).

Evidence supporting the existence of a functional level in production has been found in a series of studies by Bock and colleagues (Bock, 1986, 1989; Bock & Loebell, 1990).

- (1a) The secretary baked a cake for her boss.
- (1b) The wealthy widow drove her Mercedes to the church.
- (1c) Susan brought a book to study.

Taking *X primes Y* to mean that utterance *Y* is more likely to be produced by participants who have just produced utterance *X*, it has been demonstrated that *The girl handed a paintbrush to the man* is primed by (1a) (individual lexical items

do not affect priming) and by (1b) (the priming of a prepositional phrase is not affected by its thematic role). However, (1c) does not prime *The girl handed a paintbrush to the man* (prosodic similarity does not affect production).

Starting with this evidence, Pickering and Branigan (1998, henceforth P&B) have recently argued for the specification of syntactic verb information within the production lexicon. Using a localised network model of the production lexicon derived from Roelofs (1992, 1993) they argue that lemma nodes for verbs are linked to additional nodes representing syntactic features such as tense and aspect. These nodes in turn link to ‘lexeme nodes’ on a separate stratum, which represent potential lexical forms of verbs. If the verb lemma <GIVE> and both a past tense node and a perfective aspect node are active, a likely articulation through the lexemic level would be *gave*. The syntactic feature nodes are unique, such that any verb which can be expressed in the past tense is linked to the same past tense node as is <GIVE>. Importantly, P&B also assume that verb lemmas are linked to ‘combinatorial’ nodes which express the constructions in which a verb can be used. <GIVE> would have links to (at least) two combinatorial nodes, representing ‘NP NP’ (give the dog a bone) and ‘NP PP’ (give the bone to a dog) combinations. It is worth noting that (at least) two types of information traditionally described as subcategorisation information are combined by these nodes, since they encode not only the types (syntactic category and case) of arguments used, but also the number of arguments (i.e., the verb’s valence).

Using standard assumptions about decaying activation,<sup>1</sup> the priming of *The girl handed the paintbrush to a man* by *The rock star sold some cocaine to an undercover agent* is accounted for by suggesting that the ‘NP PP’ node retains some activation and thus reaches threshold more easily when making the second utterance. P&B provide support for this model by adopting a novel methodology (see also Branigan, Pickering, Liversedge, Stewart, & Urbach, 1995), in which participants provide written completions for partial sentences. The prime sentences are pragmatically constrained such that the most likely completion is of a given form (e.g., *The racing*

---

<sup>1</sup>P&B’s model deviates from more traditional activation models in that some links, as well as nodes, retain activation over time. However the detail of the model has no bearing on the functional/positional dichotomy to which we address ourselves in this paper.

*driver gave the torn overall* \_\_\_\_ vs. *The racing driver gave the helpful mechanic* \_\_\_\_) but the target sentences end after the matrix verb (e.g., *The patient showed* \_\_\_\_). In line with P&B's predictions, subjects are more likely to produce target sentences with the same syntactic structures as the primes. Moreover, the priming effect becomes stronger when the verb is repeated between prime and target (when activation from both lemma and combinatorial nodes is assumed to contribute to the effect). Finally, syntactic priming is unaffected by differences between prime and target in the verb's tense, aspect, or number, supporting the idea that syntactic feature information is separate from the representations involved in syntactic priming (i.e. lemmas and combinatorial nodes).

However, P&B's evidence lends itself to alternative interpretations. Firstly, it might be possible to account for their findings in terms of *positional* rather than *functional* processing: in English, the positions of the two arguments of a ditransitive verb such as *give* are confounded with the different syntactic structures that are required to realise each possible sequence ('NP NP' vs. 'NP PP'). The same line of reasoning applies to Bock's research: it might even be argued that the irrelevance of thematic role assignment to PP-priming militates against a view where constituents are stipulated at a lexical (argument structure) level, and for a model in which particular constituents like 'NP' or 'PP' are more likely to be reproduced 'in the same linear position'. Evidence for the view that the order of constituents can be primed (where the underlying syntactic representation remains constant) has been recently demonstrated in Dutch (Hartsuiker, in preparation; Hartsuiker & Kolk, 1998b).

Secondly, P&B's experimental findings might be accounted for if they simply reflected the propensity of the production system to reuse particular types of syntactic constituents (for example, PPs). This hypothesis has the attraction of providing a more natural explanation for the priming of *The girl handed a paintbrush to the man* by sentences including optional arguments or modifiers (Bock & Loebell, 1990).<sup>2</sup> Because the experiments do not contain a baseline condition, it is impossible to tell whether both 'NP NP' and 'NP PP' primes have an effect on the sentence produced, or whether, for example, it is only an 'NP PP' prime which affects the standard distribution of responses (see Hartsuiker & Kolk, 1998a, for a similar argument). If previous findings can be accounted for by a mechanism which is simply more likely to use a particular type of constituent, then people may be equally likely to produce sentences where the verb has a different number of arguments but a particular constituent is reproduced, provided that there are no constraints on the verb produced in the target sentence. To make this concrete, consider a situation in which the prime sentence is *The man gave a toy to the child* (which has an 'NP PP' form). If syntactic priming simply reflects the probability of reusing particular constituents (say, a PP), then in the absence of a constraining verb in the target sentence, people may be as likely to produce *The man sang in the bath* as *The man put the soap in its*

*holder* (since both contain PPs).

German provides an interesting opportunity to explore the issues outlined above more fully. In German, ditransitive verbs such as *geben* (to give) take two case-marked arguments: the object given has accusative case, and the recipient has dative case. Importantly, the order of these arguments is (almost) arbitrary, so that *Ich gab dem Mann das Buch* and *Ich gab das Buch dem Mann* are both translated as "I gave the man the book". Therefore, it is possible to explore priming effects at the positional level (as in studies on Dutch: Hartsuiker, in preparation; Hartsuiker & Kolk, 1998b). A second feature of German is that *monotransitive* verbs (which take a single object) can subcategorise for either accusative or dative case objects, providing an opportunity to test whether certain types of arguments (designated by case rather than syntactic category) are reused over consecutive trials. Taken together, this results in a system where number of arguments (1 or 2), type of arguments (accusative or dative NP), and (for ditransitives) order of arguments are orthogonally specified.

## A Completion Experiment on the Internet

The aim of the current study is to exploit these features of German to provide a fuller investigation of syntactic priming, using the sentence completion method pioneered by Branigan et al. (1995) and Pickering and Branigan (1998). In this study, primes consist of ditransitives in each of the possible configurations (which we will refer to as *dat<acc* and *acc<dat*) as well as monotransitives which subcategorise for single accusative (*acc*) or dative (*dat*) arguments. As well as these four primes, we include a baseline condition (where the prime is unrelated to the type of target that can be generated, given experimental constraints). Finally, because we are interested not only in the order of arguments but also in the numbers and types of arguments generated, participants are left free to choose the verb for the target sentence fragment, in contrast to previous studies.

**Participants** The experiment was administered via the World Wide Web. Participants were recruited through advertisements in Usenet newsgroups as well as through links from other web pages. Fifty-eight participants from different regions of Germany, Austria, and Switzerland completed the experiment. All of them acquired German as their first language, and most of them (83%) were university graduates or students of different scientific subjects. Participants' average age was 28.5 years, ranging from 18 to 54 years. Thirty-six of them were male, 22 female.

**Materials** The experiment had a two-factor (5×2) design, using a syntactic priming paradigm in which both primes and targets consisted of sentence fragments for completion. Participants had to complete one of two types of target fragments

---

<sup>2</sup>P&B provide an alternative account of this finding by suggesting that 'combinatorial' nodes encode syntactic rules (such as VP ⇒ NP PP) rather than subcategorisation information.

after having completed one of five types of priming constructions.

The **targets** consisted of pairs of VP-head-final sentence fragments of the forms in (2) below (where \_\_\_ represents the missing material that was to be provided by the participant).

(2a) **accusative target** NP<sub>[nom]</sub> *hat* NP<sub>[acc]</sub> \_\_\_ *wollen*.

(2b) **dative target** NP<sub>[nom]</sub> *hat* NP<sub>[dat]</sub> \_\_\_ *wollen*.

Each target could be completed in one of two ways. The fragments could be completed using a *monotransitive* verb (i.e., a verb which takes a single object NP in the accusative or dative case for (2a) and (2b) respectively). Alternatively, the completion could consist of a second object NP followed by a *ditransitive* verb. For instance, an accusative target like *Der Mann hat den Freund \_\_\_ wollen* (The man has the<sub>[acc]</sub> friend \_\_\_ wanted, cf. (2a)) might be completed with *treffen* (to meet) which subcategorises for a single accusative object NP. Alternatively, a phrase like *seinem Kollegen vorstellen* (to introduce to his colleague) might be used, resulting in a ditransitive construction. Likewise, a dative target like *Der Mann hat dem Freund \_\_\_ wollen* (The man has [to] the<sub>[dat]</sub> friend \_\_\_ wanted, cf. (2b)) could legitimately be completed using *helfen* (to help), which takes a single dative object NP, as well as with a phrase like *seinen Kollegen vorstellen* (to introduce his colleague) as a ditransitive completion. Note that ditransitive completions of examples of the form of (2b) imply a canonical dat<acc ordering of the object NPs. For (2a), on the other hand, ditransitive completions result in less common (though acceptable) acc<dat sequences.

(3a) **acc<dat** NP<sub>[nom]</sub> *hat* NP<sub>[acc]</sub> \_\_\_ V<sub>[ppl; <dat,acc>]</sub>.  
or NP<sub>[nom]</sub> *hat* \_\_\_ NP<sub>[dat]</sub> V<sub>[ppl; <dat,acc>]</sub>.

(3b) **dat<acc** NP<sub>[nom]</sub> *hat* NP<sub>[dat]</sub> \_\_\_ V<sub>[ppl; <dat,acc>]</sub>.  
or NP<sub>[nom]</sub> *hat* \_\_\_ NP<sub>[acc]</sub> V<sub>[ppl; <dat,acc>]</sub>.

(3c) **acc** NP<sub>[nom]</sub> *hat* \_\_\_ V<sub>[ppl; <acc>]</sub>.

(3d) **dat** NP<sub>[nom]</sub> *hat/ist* \_\_\_ V<sub>[ppl; <dat>]</sub>.

(3e) **baseline** NP<sub>[nom]</sub> *war* \_\_\_ *als* NP<sub>[nom]</sub>.

The sets of five **priming** materials were constrained such that the most likely completion would be an object NP (in (3a–d)) or a comparative (in (3e)) (the latter, equivalent to the English ‘NP1 *was* \_\_\_ *than* NP2’, served as the baseline condition). Materials modelled on (3a)—where, in an equal proportion of trials, either the dative or the accusative object was missing—were constructed such that the most likely completion would result in a ditransitive construction with (non-canonical) acc<dat argument order. Condition (3b) was similar to (3a), but a canonical dat<acc ditransitive was the most likely outcome. (3c) and (3d) were most likely to be completed as monotransitive constructions with either a single accusative (3c) or a single dative (3d) object NP. A major constraining factor of the priming materials was the verbs,

which were selected on the basis of their subcat-specifications from the CELEX German Database: for (3a) and (3b), we selected strictly ditransitive predicates, like *gezeigt* (showed), which subcategorise for both a dative and an accusative object; in (3c), predicates which require a single accusative object, like *untersucht* (examined), were used; and for (3d), we chose predicates taking a single dative object like *begegnet* (came across).<sup>3</sup> The copula-verb baseline condition (3e) implied none of these verb frames.

Thirty different item-sets were generated, each comprising two target fragments (cf. (2)) and ten priming fragments (cf. (3)). There were two sentence fragments per priming condition and one sentence fragment per target condition in each item-set, so that the sentence fragments could be arranged in triplets of two primes of the same condition followed by one target. The sentence fragments used for each of the triplets were semantically unrelated.

All possible combinations of priming and target fragments were used, resulting in ten different triplets per item-set. The resulting 300 triplets were randomly allotted to ten treatments such that each treatment contained an equal number of triplets of each type. Each item-set appeared exactly once per treatment, but in a different condition than in the other treatments. A set of 90 filler fragments was also generated—these included intransitives, passives, or copula-verb constructions similar to (3e). The set of fillers was added to each treatment, resulting in a total of 180 sentence fragments per treatment.

Table 1 shows an example triplet consisting of two priming fragments of type (3a), followed by a target fragment of type (2b).

Table 1: Example material set corresponding to conditions (3a) and (2b).

<b>prime 1</b>	Die Mutter hat das Kind ___ anvertraut.
<b>prime 2</b>	Der Dekan hat ___ dem Professor vorgestellt.
<b>target</b>	Der Junge hat dem Mädchen ___ wollen.

**Procedure** Materials were presented using the WebExp experimental toolkit (Keller, Corley, Corley, Konieczny, & Todorascu, 1998).<sup>4</sup> Each sentence fragment was presented

<sup>3</sup>Some dative-object verbs in German select a form of *sein* (to be) rather than *haben* (to have) as their perfect tense auxiliary (cf. (3d)). While this kind of restriction can be useful to elicit the intended response in some of the priming constructions, it needs to be eliminated from the targets. Therefore, we used a modal auxiliary like *wollen* at the end of each target fragment, so that any type of infinitival main verb (instead of a participle) could be inserted. Informed by P&B, we considered the resulting syntactic feature differences between prime and target verbs irrelevant for the priming effects of interest.

<sup>4</sup>A demo is available at [http://www.hcrc.ed.ac.uk/web\\_exp/](http://www.hcrc.ed.ac.uk/web_exp/)

(via a web browser) in a text box, with a series of dashes representing the missing portion: participants were instructed to type one or more words into a second text box such that an *acceptable* sentence was formed from the fragment and the word or phrase that they supplied, where acceptable was defined as grammatically correct and reasonably plausible. There were no further restrictions on how participants completed the sentences, other than their being asked to avoid proper names if possible. Further instructions emphasised that participants should rely on first impressions rather than trying to create witty or original completions.

The WebExp software rotated through the ten sets of materials, so that each new participant saw a different treatment. Within each treatment, the materials were randomised such that each prime-prime-target triple was preceded by three fillers, drawn at random from the ninety available. Completion of an item (by pressing RETURN) resulted in the immediate display of the following item; participants were not able to re-inspect items or responses once they had been recorded. Responses were timed (on the participant's computer) by recording the time taken to make the first keystroke of any response, as well as the time to press RETURN at the end of a response. Completions were required for all 180 items in a given set of materials. At the close of the experiment, participants were thanked for their time and promised a debriefing once the experiment was complete (debriefs were later sent by email).

Two independent judges categorised the responses made to both prime and target fragments, recording the orders and cases of arguments, and the subcategorisation properties of the verbs chosen. The categories were later conflated into *correct* or *incorrect* for primes (reflecting whether the desired response had in fact been elicited) and into *monotrans*, *ditrans* or *other* for targets (reflecting mainly the subcategorisation properties of the verbs chosen). In the few cases where participants had selected a ditransitive verb without including an additional object NP (resulting in an 'implicit argument' construction), target responses were scored as *monotrans*. Grammatically incorrect responses (most of which included wrong case assignments) and responses involving prepositional complements were categorised as *other*.

**Analysis** Effects were examined by testing hierarchical log-linear models (see Howell, 1997, for an overview), adjusting observed cell counts to factor combinations of prime type (cf. (3)), target type (cf. (2)), completion type (*monotrans* vs. *ditrans* vs. *other*),<sup>5</sup> and either participants or items. The analyses including participants or items as random factors are reported as  $LR\chi^2_{(subj)}$  and  $LR\chi^2_{(item)}$  respectively; a further statistic,  $LR\chi^2_{(marg)}$ , refers to an analysis in which the effect itself (i.e., its constituting factor combination) serves as the saturated model, ignoring additional random factors. Technically, the first two statistics represent so-called *partial associations*, whereas the third refers to the *marginal association* of an effect. For main or simple effects only marginal associations ( $LR\chi^2_{(marg)}$ ) will be reported, as the partial associations

are redundant in these cases.

## Predictions

**Priming Effects** Due to the exploratory nature of this experiment, we will skip discussing hypothetical priming effects in favour of a discussion of the theoretical implications of the observed data at the end of this paper. Therefore, we turn our attention to predictions of baseline effects in the following section.

**Baselines** We assumed that the standard distribution of the target responses would be influenced by (at least) two factors: Firstly, the availability of different subcategorisation frames, and secondly, canonical argument ordering constraints. The former was assumed, as a rough estimation, to be a function of the relative sizes of different verb classes in German, given that participants have to choose from these to generate their responses. According to the CELEX German Database, about 63% of the 'common' verbs in German (i.e. verbs with a lemma frequency of at least 10 per million) are monotransitives requiring a single accusative object NP; 23% are ditransitives, taking both an accusative and a dative object NP; and only 4% are monotransitives subcategorising for a single dative object NP (the remaining 10% are either intransitives or verbs requiring other types of complements). Given this distribution of available verb frames (and because participants may avoid generating non-canonical orderings if possible) we predicted that *monotrans* completions should be predominant for accusative targets like (2a). For dative targets like (2b), however, we expected *ditrans* responses to be most frequent, as the set of verbs which take a single dative object NP is relatively small.

## Results

Data from seven participants were excluded from analysis: in five cases, because the proportion of *other* responses was greater than 25% (this may, in some cases, reflect dialectal variations), and in two cases, because median response latencies were extremely slow (at > 20 sec). Target data points from the remaining 51 subjects were excluded if: (a) the immediately preceding prime was categorised as incorrect; (b) the time between the onset of a response to the immediately preceding prime and the onset of the target response lay out with the participant-specific interquartile range. These criteria resulted in the exclusion of 13% of the trials from analysis. Consequently, the results reported are based on a total of 1334 data points.

The frequency of correct trials varied considerably across priming conditions (acc<dat: 68.5%; dat<acc: 88%; acc: 95%; dat: 90%; baseline: 95%), mainly reflecting the fact that participants were more reluctant to produce the intended completion in the non-canonical (acc<dat) priming condition. For the targets, there were 889 (66.6%) *monotrans*, 341

<sup>5</sup>Note that the 'dependent variable' is treated as a factor (as in a standard  $\chi^2$  test).

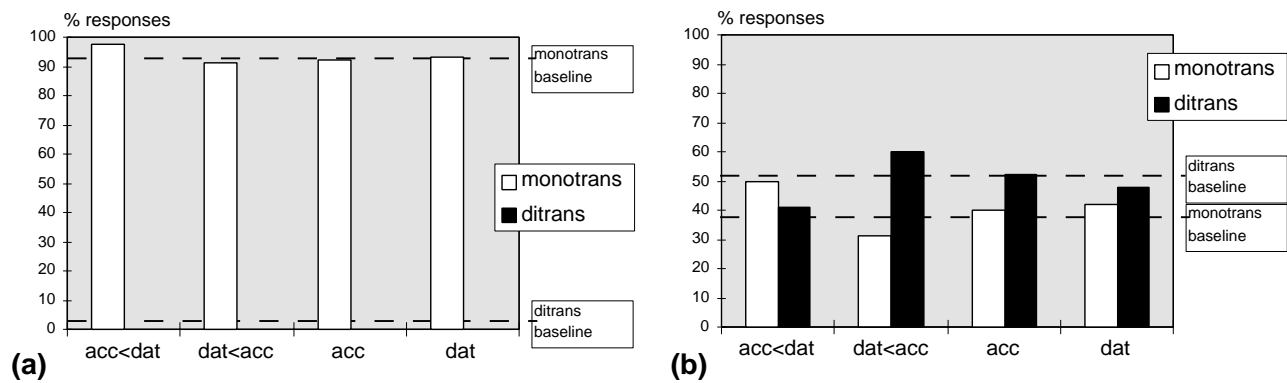

Figure 1: percentages of monotrans and ditrans completions for (a) accusative and (b) dative targets, by type of correctly completed prime.

(25.6%) *ditrans*, and 104 (7.8%) *other* responses in total. Interestingly, participants reused a verb from one of the preceding primes in less than 0.5% of the target completions.

Figure 1 shows the frequencies of *monotrans* and *ditrans* responses (in proportion to the total number of responses per condition) separately for accusative targets (Fig. 1a) and for dative targets (Fig. 1b). Dashed lines indicate baseline response rates. The remaining four prime conditions are represented by data columns.

**Baselines** In the *baseline* prime condition, the predicted biases were confirmed: for accusative targets, *monotrans* completions were clearly predominant (91%, *ditrans* = 3%, *other* = 6%); for dative targets, however, *ditrans* responses were the most frequent (52%, *monotrans* = 38%, *other* = 10%). In fact, irrespective of prime type, there was a significant overall interaction between target type and completion type ( $LR\chi^2_{(subj, item, marg)} > 500$ ;  $df = 2$ ;  $p < .001$ ) which replicates the pattern found in the baseline condition: for accusative targets, *monotrans* completions were the most frequent (93%; *ditrans* = 0.5%, *other* = 6.5%:  $LR\chi^2_{(marg)} > 600$ ;  $df = 1$ ;  $p < .001$ ); for dative targets, *ditrans* completions were the most frequent (51%; *monotrans* = 40%, *other* = 9%:  $LR\chi^2_{(marg)} > 9.950$ ;  $df = 1$ ;  $p < .002$ ).

### Priming Effects

The prime type  $\times$  target type  $\times$  completion type interaction was significant, at least by tests adjusting for subject and item variation ( $LR\chi^2_{(subj, item)} > 27.0$ ;  $df = 8$ ;  $p < .001$ ;  $LR\chi^2_{(marg)} = 15.295$ ;  $df = 8$ ;  $p = .054$ ). Unfortunately, the strong *monotrans* bias in the accusative target condition (there were virtually no *ditrans* responses) rendered any further statistical exploration in this target condition infeasible. Therefore, only the dative target condition was examined in detail. This was done by partitioning the prime type factor into ‘monotransitive’ and ‘ditransitive’ primes.<sup>6</sup>

**Dative Targets** In order to examine the effects of ‘monotransitive’ primes on the distribution of responses in the da-

tive target condition, a reduced model comprising only the *acc*, *dat*, and *baseline* conditions was generated. Testing this model revealed no significant interaction between prime type and completion type ( $LR\chi^2_{(subj, item, marg)} < 0.7$ ;  $df = 2$ ;  $p > .70$ ). Testing ‘ditransitive’ primes via a model including the *acc<dat*, the *dat<acc*, and the *baseline* condition revealed a reliable impact of prime type on completion type ( $LR\chi^2_{(subj, item, marg)} > 7.930$ ;  $df = 2$ ;  $p < .02$ ): as can be seen in Figure 1b, the tendency to produce *ditrans* completions was more pronounced after canonical *dat<acc* primes; the **reverse** tendency, i.e., to produce *monotrans* rather than *ditrans* completions, was found in the non-canonical *acc<dat* priming condition. Statistically, the proportion of *monotrans* and *ditrans* target completions clearly differed between the two ‘ditransitive’ priming conditions ( $LR\chi^2_{(subj, item, marg)} > 6.950$ ;  $df = 1$ ;  $p < .01$ ). Contrasts with the baseline condition were confirmed as statistical trends (*acc<dat* vs. *baseline*:  $LR\chi^2_{(subj)} = 1.903$ ;  $df = 1$ ;  $p < .17$ ;  $LR\chi^2_{(item)} = 4.758$ ;  $df = 1$ ;  $p < .03$ ;  $LR\chi^2_{(marg)} = 3.210$ ;  $df = 1$ ;  $p < .08$ ; *dat<acc* vs. *baseline*:  $LR\chi^2_{(subj)} = 3.638$ ;  $df = 1$ ;  $p < .06$ ;  $LR\chi^2_{(item)} = 2.058$ ;  $df = 1$ ;  $p < .16$ ;  $LR\chi^2_{(marg)} = 4.100$ ;  $df = 1$ ;  $p < .05$ ).

### Discussion

The observed data pattern (at least as established in the dative target condition) bears some interesting implications for the representation of combinatorial information in sentence production (cf. Pickering & Branigan, 1998), and may even challenge some architectural assumptions about the human language production system: it appears that subcategorisation properties of verbs *per se* (in terms of verb valence and case of arguments) are not subject to syntactic priming. This is highlighted by the fact that (a) ‘monotransitive’ primes (*acc* and *dat*) have no significant impact on the distribution of

<sup>6</sup>These analyses considered only the distributions of *monotrans* and *ditrans* completions, as the proportion of *other* responses was totally unaffected by prime type in the dative target condition ( $LR\chi^2_{(subj, item, marg)} < 1$ ;  $df = 4$ ;  $p > .95$ ).

the (dative) target completions, and (b) 'ditransitive' primes (acc<dat and dat<acc) have *facilitatory* as well as *inhibitory* effects on the relative proportions of *ditrans* to *monotrans* responses, dependent on the sequence of arguments specified in the prime. As the latter indicates, there is clear evidence for the importance of positional information in syntactic priming, comparable to recent results from Dutch (cf. Hartsuiker, in preparation; Hartsuiker & Kolk, 1998b).

With respect to representational aspects of a production model, the results could be interpreted as suggesting that combinatorial nodes in the verb lexicon encode subcategorisation information as well as information about the (canonical/non-canonical) sequencing of arguments, i.e., something similar to what is encoded in traditional context free grammar rules (cf. P&B). Unfortunately, our data remain unclear regarding the precise nature of these representations, since the accusative target condition was uninformative (due to a massive bias towards monotransitive responses in this condition): the observed ordering effects could be due to 'canonical vs. non-canonical' argument ordering (i.e., ditransitive verb-frames become more easily retrievable after canonical primes, but less easily retrievable after non-canonical primes) or to a 'match vs. mismatch' in (implied) argument order between prime and target. At this point, we leave this as a question for future research.

Our data do however greatly constrain the range of plausible architectural assumptions about sentence production. Our findings can be taken as strong evidence against a model which claims that processes at the functional level (i.e., verb retrieval and syntactic function assignment) necessarily precede, and therefore determine, positional processing, but not vice versa (e.g., Bock & Levelt, 1994). It appears that positional processing can, under certain circumstances, determine the outcome of processes at the functional level, in such a way that the ease of retrieving a ditransitive verb (in a target trial) is dependent on the argument order specified in a preceding ditransitive priming construction. Note that the retrievability of the verb (or of its corresponding subcategorisation frame) in the prime cannot account for this evidence, since strictly ditransitive prime verbs had already been presented to participants (unlike the target verbs which participants were free to choose). Thus, it must have been the linear order of the arguments that had to be produced in a correctly completed prime that affected the increased or decreased availability of a ditransitive verb frame in the target trials. This is clearly incompatible with (at least) models which claim that there is no feedback from the positional to the functional level of sentence planning (e.g., Bock & Levelt, 1994).

In general, the results of this and other experiments highlight the importance of cross-linguistic research for refining, and possibly revising, existing theories of human language processing, most of which were developed on the basis of English data. The Internet may provide the ideal medium for this kind of research.

**Note** The order of the authors is arbitrary. We wish to thank Ulf Reips, Bernad Batinic, Axel Theobald, and John Krantz for kindly providing links to our web experiment from their host pages. We are especially grateful to Frank Keller for his technical support.

## Abstract

This paper describes a theoretical analysis and experimental investigation of difficulty related distraction by conflicting goal intentions in learning and problem solving with hypertext. Log files are used to capture hypertext navigation in the face of opportunities to implement competing goal intentions. We study how differences in task difficulty influence the volitional protection of the current goal intention. First attempts to integrate volitional processes of action control into cognitive architectures are presented.

## Conflicting Goal Intentions in Hypertext Navigation

The investigation of learning and problem solving with hypertext gains increasing importance as the use of computer-based learning environments and information retrieval systems develops. The term "hypertext" refers to "computer-based texts that are read in a non-linear fashion and that are organized in multiple dimensions" (Landow, 1992, p. 166). A main feature of hypertext is that the user is not reacting to static texts, but is rather choosing according to his or her current intention when and in which order the information is to be presented (Barab, Bowdish, Young & Owen, 1996). Thus, the navigational path through a given hypertext environment depends mainly on the current intentions of the user. Accordingly, Barab et al. (1996) have shown that users' intentions in interacting with hypertext can be predicted from navigational paths captured in log files (computerized records of screens visited that are stamped with the amount of time spent on each screen). The opportunity of navigating through hypertext environments allows for great flexibility and adaptivity of learning and problem solving with hypertext, it is however also responsible for some difficulties. Users tend to be *structurally or conceptually disoriented* in complex hyperspaces and they seem to suffer from *cognitive overload*, if the navigational task consumes too much of their resources (Conklin, 1987).

In this paper we will focus on a further problem concerning navigating through hypertext environments, namely the problem of *being distracted by conflicting goal intentions*. We assume that learning and problem solving are to be analyzed as goal-directed behavior and furthermore that most learners possess numerous waiting goal intentions not related to the current problem. These waiting intentions can be activated by situational cues in the hy-

perertext environment and then compete with the current goal intention for execution. If the user is attracted by these cues, the current goal intention may be suspended in favor of activities related to the competing intention, or in favor of deliberating which of the two intentions should be further pursued. These interruptions and distractions due to conflicting goal intentions should lead to more or less severe efficiency impairments in learning and problem solving depending on the relative strength of the competing goal intentions. As a theoretical basis for analyzing these issues theories of action control are especially useful.

## Cognitive, Motivational, and Volitional Approaches to Action Control

If actions are considered as sequences of activities directed toward a common goal, the term "action control" can be used to describe automatic and controlled processes determining which activity is selected in the next step. Furthermore, action control includes processes that are predominantly *cognitive* (like the selection of a schema or production rule), predominantly *motivational* (like the deliberation of goal values in the course of intention formation), or predominantly *volitional* (like the maintenance of a goal intention in the face of competing intentions). Accordingly, theories from different fields of psychology are concerned with the analysis of action control.

**Purely cognitive approaches** Most of these approaches to action control postulate processing goals, but do not assume that differences in goal values are relevant for action control. Examples are theories of working memory and attention that postulate a supervisory attentional system responsible for intentional shifts of task sets and the control of working memory contents (Norman & Shallice, 1986). On a higher level of abstraction, theories of planning, strategy selection and metacognition are purely cognitive approaches. All of these approaches typically confine themselves to assuming mental representations and cognitive variables describing them, like activation, availability, or subjective probability. Furthermore, most cognitive approaches focus on single task situations and do not consider conflicting goal intentions.

**Approaches with motivational assumptions** Expanding on cognitive assumptions these approaches introduce variables that can be interpreted as goal values or as being dependent on goal values. Examples are theories of motiva-

tion and decision making that postulate expectancy-value-considerations as a basis for choosing between goals and action alternatives. Goal values and success probabilities are combined by calculating resulting motivational tendencies or subjective utilities that serve as a basis for decisions between goals or actions. An example from cognitive science is the cognitive architecture ACT-R (Anderson & Lebiere, 1998). The mechanisms of production rule selection in ACT-R depend on expected utilities of production rules calculated from goal values and success probabilities. A problem of many approaches to action control based on motivational assumptions is that they take differences in goal values for granted without giving further explanations for these values (Anderson & Lebiere, 1998, p. 63).

**Approaches with volitional assumptions** These theories describe control processes that help to initiate goal intentions, to maintain them in the face of difficulties and to protect them against distractions and competing goal intentions. Like motivational theories, volitional approaches are based on variables that depend on goal values (e.g. volitional strength of intentions) but, volitional approaches also describe how these variables change after a goal intention has been formed. They postulate automatic processes of goal protection like the adaptive increase of volitional strength in the face of increasing task difficulty (Gollwitzer, 1990; Heckhausen, 1991) as well as several kinds of volitional strategies to maintain goal intentions (Kuhl, 1987).

Because our paper is concerned with efficiency impairments caused by situational cues for competing goal intentions, theories of volitional action control seem to be best suited for a first analysis. As a framework for the description of volitional control processes we use a condensed and precise version of the rubicon theory of action phases (Gollwitzer, 1990; Heckhausen, 1991) called PART (Heise, Gerjets & Westermann, 1994), which comprises the **P**ivotal Assumptions of the **R**ubicon Theory.

PART allows for the derivation of specific predictions concerning efficiency impairments due to competing goal intentions under different conditions. We designed a hypertext learning environment in order to test these predictions within an experimental setting. PART can also serve as a basis for developing cognitive models of our experimental log file data, because the integration of motivational and volitional aspects of action control into cognitive architectures is easier, if a formalized model of volitional action control is available.

### PART: A Theory of Volitional Action Control

PART describes the entire course of actions from a time-sequential perspective. In addition to analyzing volitional processes, such as maintaining and protecting a goal intention, the theory also handles motivational processes, such as choosing a goal or assessing action outcomes. Within this framework, an action is typically composed of a sequence of four phases, beginning with the *predecisional* action phase and followed by the *preexecutive*, *executive*, and *postexecutive* phases (see Figure 1).

In the predecisional phase, one of several possible goals is chosen as the current goal intention to be pursued. This decision is based on the *motivational tendencies* associated

with the possible goals. In the preexecutive phase, which commences after commitment to a goal intention has been formed, intention-related activities are planned and the intention is maintained until a favorable opportunity for the initiation of these activities occurs.

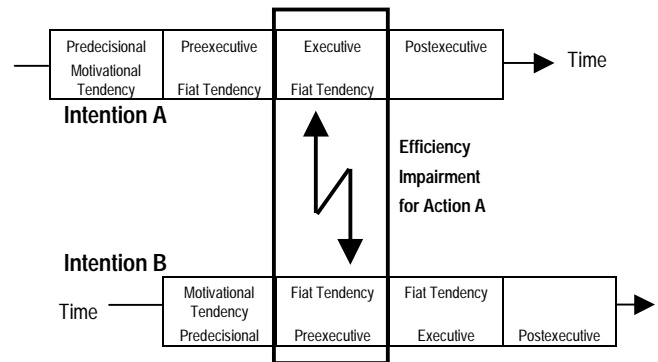

Figure 1: Action phases in PART

The initiation of intention-related activities is controlled by the so called *fiat tendency* and marks the transition to the executive phase. The fiat tendency of an intention depends partly on the suitability of a situation for the implementation of goal-directed behavior. During action execution, the fiat tendency is responsible for the maintenance of the goal intention. If difficulties occur, the fiat tendency of the goal intention increases. This variable is thus of central theoretical importance for explaining volitional action control. It can be interpreted as expressing how strongly an intention demands for implementation in a given situation. The executive phase is followed by the postexecutive phase in which the attained outcome is evaluated.

The theory of action phases is especially suitable for the analysis of action conflicts. In this paper we consider a specific type of conflict that can be described as suspended-intention conflict and is illustrated in Figure 1. It occurs when subjects are instructed to keep working on a task A for a longer period of time, while a competing intention B is waiting to be executed subsequently. In this case, one intention is supposed to remain in the executive phase, while the other is to remain in the preexecutive phase (*pre-executive-executive* conflict). Contrary to the superficially similar task-shift paradigm, where subjects are required to rapidly alternate between the execution of two intentions, no alternation is supposed to take place.

If the fiat tendency of the waiting intention B is strong, then the efficiency of action A should be impaired, because activities related to the competing intention occur or because a process of decision making is initiated in order to determine which intention should be pursued further. The distracting effect of the waiting intention B should be larger the stronger the fiat tendency of B is in comparison to the fiat tendency of the current intention A. The theory of action phases allows for the derivation of several empirically testable hypotheses, from which we chose two predictions that can be easily applied to hypertext navigation:

*Hypothesis of distraction by competing goal intentions:* The efficiency of a currently executed action A will be impaired if a favorable opportunity for the implementation of a competing intention B occurs. This prediction results

from the assumption that an opportunity to realize goal intention B leads to an increased fiat tendency of B.

*Hypothesis of difficulty-related volitional protection:* Efficiency impairments due to waiting intentions should be stronger for a low level of task difficulty than for a high level of task difficulty. This prediction results from the assumption that an increasing level of task difficulty for intention A results in an increased fiat tendency of A.

In several simple reaction time experiments using word classification tasks we were able to confirm both of these predictions (Heise, Gerjets & Westermann, 1997). In the domain of hypertext navigation we can test our predictions within a naturalistic setting, where problems of distraction due to competing intentions are of practical relevance. Furthermore, the use of log files to capture hypertext navigation enables us to investigate whether the distraction effects of a competing goal intention can be traced back to cognitive activities related to the implementation of this competing intention. Finally, we assume that research on hypertext navigation can benefit from insights in the way information processing strategies may change in the face of conflicting goal intentions.

## Experiment

### Method

**Subjects:** 134 students (84 female, 50 male) at the University of Goettingen, Germany participated in the experiment. The average age was 24,8 years.

**Procedure** The subjects' main task (the current goal intention) consisted of a hypertext-based learning and problem-solving task. Subjects had to solve three probability word problems. For each problem the correct solution principle and two correct variable values had to be marked in a multiple-choice form available in the hypertext environment. All three problems were presented at the beginning of the experiment. Subjects were instructed to solve the problems as fast and as correctly as possible using information provided in the hypertext environment. To acquire the relevant knowledge subjects could browse the hypertext environment freely. Six problem categories from the domain of probability theory were explained using worked out examples for illustration. All examples were embedded in interesting cover stories about attractiveness and mate choice (e.g., the probability of guessing the first three winners in a beauty competition between 10 people). The examples and the explanations of the problem categories were available during the whole experiment.

**Design** As independent variables two different levels of difficulty of the word problems to be solved (easy versus difficult problems) and two levels of distraction due to conflicting goal intentions (strong versus weak distraction) were introduced. Both variables of the resulting 2x2-design were varied interindividually. Two further levels of distraction were introduced as control conditions.

In accordance with preliminary studies we manipulated the level of difficulty by using smaller numbers in the easy problems and by stating them in a more familiar way than the difficult problems. The method used to increase difficulty was similar to the one used by Ross and Kilbane

(1997). The cover story and the underlying solution principle of a problem were not affected by this manipulation.

In the *condition with strong distraction* we introduced a competing intention and a favorable opportunity for its implementation. Subjects were informed that they would have to work on a second task within the same hypertext environment after having finished the problem-solving task. The second task consisted of answering three questions about attractiveness and mate choice that were presented briefly at the beginning of the experiment. Subjects were instructed to work on the problem-solving task first and to postpone thinking about the question-answering task until they finished the three word problems. They were assured to have enough time afterwards to browse the hypertext environment for information relevant to the second task. Subjects were told that all information available could be helpful in solving the word problems. As favorable opportunities to execute activities related to the waiting intention we included additional information about attractiveness and mate choice in the hypertext environment. This information was not helpful for solving the probability word problems, but it was related to the topic of the waiting intention. To make this information available during the first task, the examples used to explain the solution principles contained "hot words" linked to that information.

In the *condition with weak distraction* no competing intention was induced. Subjects were only required to solve the three word problems. In order to keep the number of hyperlinks in the learning environment constant, the same amount of irrelevant information was linked to the worked out examples as in the condition with strong distraction. In order to prevent subjects from forming an intrinsically motivated competitive intention to browse the irrelevant information, we replaced the interesting information about attractiveness and mate choice with rather uninteresting information concerning irrelevant terms in the cover story.

To control motivational effects of this replacement a *condition with intermediate distraction* was used. In this condition hyperlinks to irrelevant information about attractiveness and mate choice were inserted but no competing intention concerning that information was induced. If subjects form competing intentions based on personal interest, stronger effects of distraction than in the condition with uninteresting irrelevant information are to be expected.

A *baseline condition* with no hyperlinks to irrelevant information was implemented as a second control condition. This condition was used to estimate additional cognitive costs of navigating hypertext environments containing irrelevant information.

**Dependent variables** To test our hypotheses concerning efficiency impairments we obtained two different kinds of dependent variables. As an outcome measure the percentage of errors for the three word problems was registered. As process measures several time and frequency parameters were calculated from the log file data recorded during subjects' interaction with the hypertext system. Especially, the total amount of time spent on relevant information as well as time spent on irrelevant information was calculated. The latter measure was obtained to test whether efficiency impairments can be traced back to cognitive activities related to the competing intention.

## Results and Discussion

Comparing the conditions with strong and weak distraction yields a significant main effect of distraction on error rates (cf. Figure 2)<sup>1</sup>. In accordance with our distraction hypothesis, subjects with competing intentions and favorable opportunity to initiate corresponding activities show worse performance in the problem-solving. No differences between the condition with weak distraction and the two control conditions were found.

Figure 2: Error rates as a function of task difficulty and distraction (N = 68)

The manipulation of difficulty was successful. The respective main effect is significant. As predicted, the influence of the competing intention on performance depends on the difficulty of the problem-solving task. In the condition with low task difficulty, efficiency impairments due to competing intentions are larger than in the condition with high task difficulty. The respective interaction is significant.

To test whether these efficiency impairments can be traced back to cognitive activities related to the competing intention, we compared the four conditions regarding time spent on irrelevant information (see Figure 3). In the groups with competing intention and opportunity for implementation, the time spent on irrelevant information was significantly longer than in the groups with no competing intention. This was especially the case for the easy word problems. The respective interaction was marginally significant.

Figure 3: Time spent on irrelevant information as a function of task difficulty and distraction (N = 68)

<sup>1</sup> Our specific predictions have been tested using one-tailed *t*-tests. Concerning the general advantage of planned contrasts as opposed to unspecific ANOVA *F*-tests see Hays (1988) or Rosenthal and Rosnow (1988).

These data support the assumption that the observed efficiency impairments under the condition of low task difficulty result from cognitive activities which are relevant for the implementation of the competing intention.

Figure 4: Time spent on relevant information as a function of task difficulty and distraction (N = 68)

In a second step we analyzed time spent on relevant information (Figure 4). As can be seen, higher difficulty of the word problems caused no increase in time on relevant information. Unexpectedly, the groups with a competing intention and opportunity for implementation spent significantly less time on relevant information than groups without such intention. This main effect is caused by differences in the low difficulty task condition. The respective interaction effect is significant.

Taken together, our data support the following conclusions: For high levels of task difficulty no distraction effects can be observed, whereas for low levels of task difficulty the presence of a competing intention leads to an increase in error rates and in time spent on irrelevant information as well as to a decrease in time spent on relevant information. This pattern of results can be interpreted as indicating strategy shifts if a strong competing intention with favorable opportunity is present (speed-accuracy trade-off).

Further analysis of the log file data yields several other strategy shifts under different levels of distraction and difficulty. For example, they concern the time spent on studying the solutions of worked out examples or the order in which the three word problems were solved.

## Summary

The aim of our study was to investigate how conflicting goal intentions can influence learning and problem solving in hypertext environments. As a theoretical background we used a theory of volitional action control (PART) that describes efficiency impairments caused by competing goal intentions under different levels of task difficulty. We used PART to derive two hypotheses about hypertext navigation in the face of conflicting goal intentions. These hypotheses could be confirmed in an experimental study. Furthermore, the experimental log file data show that there are numerous differences between the experimental conditions that cannot be completely explained by our volitional framework (e.g., different kinds of strategy shifts). To further analyze this data, it would be helpful to use a theoretical model that combines volitional assumptions about conflicting goal intentions and more detailed cognitive assumptions about

learning and problem solving behavior. We therefore began to integrate the volitional mechanisms of PART into the cognitive architecture ACT-R (Gerjets, 1997).

## Modeling Volitional Action Control

As illustrated in Figure 5, PART includes detailed assumptions about the interrelations of variables underlying volitional processes.

Figure 5: Interrelations between variables related to fiat tendencies in PART

Each possible goal is associated with a certain *motivational tendency* that determines which of the competing goals in the predecisional action phase will be pursued as goal intention. Each goal intention is assigned a specific degree of *volitional strength* that determines how much effort will be exerted for the implementation of that goal intention. Furthermore, each goal intention is assigned a *fiat tendency* that expresses its demand for implementation. In the pre-executive-executive conflict, the fiat tendencies of the competing goal intentions determine which of the two intentions becomes dominant. The fiat tendency of the current intention A depends essentially on the volitional strength of this intention. The volitional strength, however, not only determines the respective fiat tendency but also the level of effort and the efficiency of the implementing activities. The volitional strength of the current intention is affected by its motivational strength and the level of task difficulty. An increase in task difficulty results in an increased volitional strength of the current goal intention. This dynamic regulation of volition and effort in the face of increasing task difficulty is one of the main volitional mechanisms of the action phase theory and corresponds to the so-called *law of difficulty* (cf. Heckhausen, 1991).

The fiat tendency of the waiting intention B not only depends on its volitional strength but also on the perceived favorability of the opportunity to initiate corresponding activities. If the fiat tendency of the waiting intention becomes sufficiently large (relative to the fiat tendency of intention A), then the efficiency of the current action can be impaired as will be reflected in error rates or reaction times. It can also be assumed that the presence of a waiting intention with a strong fiat tendency will be perceived as an increased level of task difficulty that reactively results in an

increased level of volitional strength. This may at least partly compensate for efficiency impairments. Volitional action control is most adaptive when it results in a balance between shielding a current intention against competing intentions and flexibly responding to situational changes.

Based on our theoretical framework and our experimental findings, there are at least three requirements for the cognitive modeling of volitional action control. First, a cognitive model of our task will have to take into account that learners may simultaneously possess multiple conflicting goal intentions of differing strength. The model has to explain *efficiency impairments* caused by situational cues related to waiting intentions. Second, the model has to reflect the *law of difficulty*. Third, the model has to account for data indicating *strategy shifts* under different levels of distraction and difficulty that cannot be explained at PART's level of abstraction (time spent on different kinds of information, order of solving different problems and trade-offs between speed and accuracy).

As a theoretical basis for cognitive modeling we will refer to Anderson's ACT-R architecture (Anderson & Lebiere, 1998). ACT-R has been developed as a unified theory of cognition applying to domains as diverse as problem solving, learning, or memory. In ACT-R human actions are analyzed in terms of production rules and spreading activation in a network of declarative memory chunks. Production rules are matched to currently activated memory chunks and can be executed if their conditions are sufficiently satisfied. Actions are described as sequences of production rule firings. Action-guiding intentions can be represented by a specific type of declarative memory chunks (*goal chunks*). These chunks are organized by means of a last-in-first-out goal stack and act as temporary sources of activation that guide current information processing by spreading activation to other memory chunks and by thus constraining the set of executable production rules. Most productions are goal specific and can only be executed if the goal referred to in their conditions is the current goal on top of the goal stack.

A major drawback of the ACT-R architecture for our current purposes is that ACT-R is mainly designed as a single-task architecture for modeling tasks in isolation. Processing is completely controlled by the current goal on top of the goal stack. Production rules referring to other than the current goal cannot be selected for execution. Alternative cognitive architectures like EPIC (Meyer & Kieras, 1997) are explicitly designed for modeling dual task performance and multiple goal handling but are however restricted to very simple cognitive tasks lacking complex goal structures. Furthermore, they are not capable of integrating different cognitive components like learning, memory, and problem solving. For that reason, it seems easier to adapt ACT-R to handling multiple goals than to adapt architectures like EPIC for modeling complex cognition.

Our approach for modeling volitional action control in ACT-R comprises two main steps: In a first step we will try to map the concepts and assumptions of PART onto concepts and assumptions of ACT-R. These mappings can be evaluated theoretically (Gerjets, 1997) as well as empirically (Gerjets, Heise & Westermann, 1997). Because dynamic variables like motivational tendency, volitional strength and fiat tendency are of major importance in

PART, the modeling in ACT-R will focus on variables with analogous functional roles, e.g., goal values or source activation. If no satisfying mapping can be found for necessary assumptions of PART, we attempt to develop new concepts and mechanisms based on the ACT-R framework that are compatible with the main assumptions of the theory.

The aforementioned requirements for modeling volitional action control lead to three main subtasks in developing an ACT-R model for our domain.

**Efficiency impairments** Efficiency impairments due to competing intentions cannot be explained in ACT-R without additional theoretical assumptions, since the theory assumes that only the top goal on the goal stack controls performance. To model our data it will be necessary to introduce a new chunk type representing *preexecutive intentions* waiting for implementation. To allow the system to interrupt its performance for information processing related to a waiting intention, we will have to introduce goal unspecific production rules which, in the case of goal conflicts, initiate a decision about which task to pursue further. These *interrupt productions* should be executed whenever declarative memory chunks associated to waiting intentions become activated. Chunks representing waiting intentions can be equipped with additional functional characteristics like an increased base level activation to account for their superior availability in memory (Goschke & Kuhl, 1993).

**Difficulty-related effort allocation** Two interpretations of effort can be modeled in ACT-R. First, high effort can be interpreted as working more accurately. This can be modeled by high goal values, which lead to the selection of production rules with higher probability of success. These rules, however, also yield higher costs for execution. Second, high effort can be interpreted as working faster. This can be modeled by high source activation of goal chunks, which leads to a high amount of activation that spreads to associated chunks in declarative memory. Matching a production rule to chunks in declarative memory will be the faster the higher these chunks are activated. To model the law of difficulty, the concept of task difficulty has to be mapped onto analogous concepts in ACT-R. In our experimental context task difficulty can be best interpreted as missing declarative or procedural knowledge that results in problem-solving impasses. These impasses can be connected to goal values and source activation without violating the ACT-R theory.

**Strategy shifts** As our log file data indicate, level of distraction and difficulty influence the trade-off between speed and accuracy, the order in which test problems are solved, and the time spent on studying the solutions of worked out examples. As aforementioned, speed-accuracy trade-offs can be modeled by goal values and source activation. Time spent on studying worked out examples can be interpreted as reflecting a time demanding strategy with high success probability. Deviations from a given order of test problems can be explained by interrupt productions that react to activated chunks representing waiting intentions. To test whether these ideas suffice to model the influences of difficulty and distraction on strategy selection it will be necessary to develop a detailed ACT-R model of our experimental task.

## Abstract

We investigated the extent to which a collaborative view of human conversation transfers to interaction with non-human agents. In two experiments we contrasted user-initiated and mixed-initiative clarification in computer-administered surveys. In the first study, users who could clarify the interpretations of questions by clicking on highlighted text comprehended questions more accurately (in ways that more closely fit the survey designers' intentions) than users who couldn't, and thus they provided more accurate responses. They were far more likely to obtain help when they had been instructed that clarification would be essential than when they were merely told it was available. In the second study, users interacting with a simulated speech interface responded more accurately, and asked more questions, when they received unsolicited clarification about question meaning from the system in response to their linguistic cues of uncertainty. The results suggest that clarification in collaborative systems will only be successful if users recognize that their own conceptions may differ from the system's, and if they are willing to take extra turns to improve their understanding.

## Introduction

Saying something doesn't guarantee it will be understood. People engage in dialog to make sure that what the speaker intended has been understood—to ground their understanding (e.g., Clark & Brennan, 1991; Clark & Schaefer, 1989; Clark & Wilkes-Gibbs, 1986; Schober & Clark, 1989). People ground their understanding to a criterion sufficient for their current purposes; in casual conversations (e.g., at a cocktail party), people may not need to understand precise details to satisfy their conversational goals, but in other settings (e.g., air traffic control tower conversations, calls to a technical help desk when your computer crashes, or conversations with your ex-spouse about child visitation) the stakes are higher.

This collaborative view of human conversation differs from traditional accounts of language use (what Akmajian et al., 1990 called the "message model" of communication), where listeners interpret utterances directly. The traditional view is that the meaning of an utterance is

contained within the words themselves, and that the process of comprehension involves looking up those meanings in the mental dictionary and combining them appropriately; a collaborative view argues that accurate comprehension also requires dialog so that people can clarify what is meant (see Clark, 1996).

In the studies reported here we investigate the extent to which this collaborative view of human conversation transfers to interaction with non-human agents, and we examine whether a collaborative view can improve user interface design. Examining collaboration in human-computer interaction forces us to specify details of the collaborative view that can test its limits and refine our theories of human communication.

We contrast two approaches to designing collaborative systems that support the clarification of word meanings. Under one approach, clarification is user-initiated—that is, if the user explicitly requests clarification, the system provides it. This requires users to recognize that they need clarification and to be willing to ask for it. Under the other approach, clarification is mixed-initiative—that is the system also provides (or offers to provide) clarification when it diagnoses misunderstanding, based on user behavior. For example, in a desktop or speech interface a system could provide clarification when the user takes too long to act; in a speech interface a system could provide clarification when the user's speech is hesitant or disfluent (containing *ums* and *uhs*, restarts, etc.).

We examine these issues in the context of survey interviewing systems, where systems present questions and users answer them. To our knowledge, current dialog systems for surveys (see Couper et al., 1998 on "computerized self-administered questionnaires") do not allow either user-initiated or mixed-initiative clarification of meaning. Rather, they embody strict principles of standardization developed for human-human interviews, where the interpretation of questions should be left entirely up to respondents (e.g., Fowler & Mangione, 1990). The argument for standardization is that if interviewers help respondents to interpret questions, they might influence responses, but if interviewers read scripted questions and provide only "neutral" feedback, responses are less

likely to be biased. We have demonstrated that in human-human interviews even supposedly nonbiasing feedback by interviewers can affect responses (Schober & Conrad, 1997, in press). More importantly, strict standardization can actually harm data quality because it prevents respondents from grounding their understanding of the questions. This is a problem because people's interpretations of seemingly straightforward questions like "How many bedrooms are there in your house?" can vary enormously; without grounding their understanding of questions, respondents may conceive of questions in unintended ways, and the resulting data may not fulfill the survey designers' purposes (Clark & Schober, 1991). We have shown that responses in strictly standardized interviews can be less accurate than responses in more interactive interviews where respondents can ground their understanding of questions with the interviewers (Conrad & Schober, 2000; Schober & Conrad, 1997).

The task of responding to a computerized survey differs from many human-computer interaction situations. First, in survey systems users provide information to the system rather than retrieving information from the system, as with a database query system or a web search interface. Second, survey system users' need for precise understanding may be lower than when they interact with other systems. Users may care less about precisely understanding the words in survey questions when providing opinions to market researchers (misunderstanding has few consequences for the user) than understanding the words in an on-line job application or an on-line health claims form (where misunderstandings can be costly).

## Experimental Methods

In our studies we assess whether systems that enable users to clarify the survey concepts do actually lead to improved comprehension of questions (and thus improved response accuracy), as a collaborative theory would predict. We examine the effects of clarification on task duration—clarification probably takes more time, and this may offset any benefits. We also examine the effects of clarification on user satisfaction; even if clarification improves comprehension, it could be annoying.

Our first study (Conrad & Schober, 1999) uses a desktop interface, in which the computer displays questions on a screen. The user enters responses and asks for clarification with the keyboard and mouse. Our second study (Bloom, 1999) uses an interface, in which questions are presented in a synthesized voice through a headset. The user answers questions and asks for clarification by speaking into the headset microphone.

In both studies, all users were asked the same survey questions, which had been used in earlier studies of human-human survey interviews (e.g. Schober & Conrad, 1997). We adapted 12 questions from three ongoing U.S. government surveys. Four questions were about employment, from the Current Population Survey (e.g., "Last week, did you do any work for pay?"); four questions

were about housing, from the Consumer Price Index Housing survey (e.g., "How many people live in this house?"); four questions were about purchases, from the Current Point of Purchase Survey (e.g., "During the past year, have you purchased or had expenses for household furniture?"). For each question, the survey designers had developed official definitions for the key concepts, which clarified whether, for example, a floor lamp should be considered a piece of household furniture, or whether a student away at college should be considered to be living at home.

Users answered these questions on the basis of fictional scenarios, so that we could measure response accuracy—that is, the fit between users' answers and the survey designers' official definitions. For each question there were two alternate scenarios, one typical and one atypical. With the typical scenario, the survey question was designed to be easy for users to interpret—to map onto the user's (fictional) circumstances in a straightforward way. For example, for the question "Has Kelley purchased or had expenses for household furniture?", the typical scenario was a receipt for an end table, which is clearly a piece of furniture. With the atypical scenario, it was less clear how the survey question should be answered. For example, for the household furniture question the atypical scenario was a receipt for a floor lamp, which is harder to classify without knowing the official definition of "household furniture."

For each user, half the scenarios described typical situations and half atypical situations.

## Study 1: Desktop interface

In this study, we varied the way the survey system provided clarification. When clarification was user-initiated, users could request the official definition for a survey concept by clicking the mouse on highlighted text in the question. When clarification was mixed-initiative, the system would also offer a definition when users were "slow" to respond. This was defined as taking longer than the median response time for atypical scenarios when no clarification was available. This offer was presented as a Windows dialog box; users could reject the offer by clicking "no" if they didn't think clarification was needed.

We also varied instructions to the users about how precisely they would need to understand the system's questions—that is, we varied the grounding criterion. Some users were told that clarification was essential; they were encouraged to obtain definitions from the computer because their everyday definitions might differ from the survey's. Other users were told merely that clarification was available, that definitions would be available if users wanted them. The five experimental conditions are displayed in Table 1.

54 users, recruited from an advertisement in the Washington Post, were paid to participate. Most (44) reported using a computer every day.

Table 1: Experimental conditions, Study 1.

Type of clarification	User instructed that...
1 no clarification	
2 at user's request	Clarification essential
3 at user's request	Clarification available
4 when user is slow or at user's request	Clarification essential
5 when user is slow or at user's request	Clarification available

## Results

Users' responses were almost perfectly accurate (their responses fit the official definitions) when they answered about typical scenarios. For atypical scenarios, users were more accurate when they could get clarification than when they couldn't (see Figure 1). Response accuracy mainly depended on the instructions to the user about the grounding criterion. When users had been told that definitions were merely available, their accuracy was as poor as when they couldn't get clarification. When they had been told that definitions were essential, response accuracy was much better, whether users had to request clarification,  $F(1,49) = 9.82, p < .01$ , or whether the system also offered it,  $F(1,49) = 14.38, p < .01$ .

As Figure 2 shows, response accuracy was strongly related to how often users received clarification. When users had been told that definitions were essential, they requested clarification most of the time; in fact, they frequently requested it for typical scenarios, when presumably it wasn't necessary. They also requested clarification quickly, which meant that when the system could also provide clarification (conditions 4 and 5) it rarely did. In contrast, users who had been told that clarification was merely available rarely asked for it, and they responded to the questions so quickly that system-initiated clarification was rarely triggered. Apparently, it didn't occur to these users that their interpretation of ordinary terms like "bedroom" and "job" might differ from the system's, and so they answered confidently, quickly, and inaccurately.

As Figure 3 shows, clarification took time. Response times were much longer in cases where users received clarification. As we anticipated, improved accuracy from clarification can be costly.

Users' ratings of their satisfaction with the system suggested two things. First, users who could not get clarification reported that they would have asked for clarification if they could. This suggests that interacting with dialog survey systems that don't allow clarification may be relatively unsatisfying. Second, users' grounding criteria affected their perceptions of the system. System-initiated clarification was rated on a 7 point scale as useful (6.0)

and not annoying (1.0) by "clarification essential" users, and less useful (3.9) and more annoying (4.25) by "clarification available" users. Presumably users who had been told that clarification was available found it jarring for the system to offer unsolicited help for seemingly straightforward questions.

Overall, these results suggest that the success of human-machine collaboration may depend both on users' grounding criteria—how important they believe it is to understand accurately—and also on whether users recognize that system concepts may differ from theirs.

## Study 2: Speech interface

This study used a Wizard-of-Oz technique to simulate a speech interface. Users believed they were interacting with a computer, when actually a hidden experimenter presented the questions and scripted clarification. To enhance believability, we used an artificial-sounding computer voice (Apple's "Agnes" voice).

This study used exactly the same questions and scenarios as Study 1. Users participated in one of four experimental conditions. In the first condition, the system never provided clarification. In the second condition, clarification was user-initiated—the system would provide clarification if users asked for it explicitly. In the third condition, the initiative was mixed—the system would "automatically" provide full definitions when users displayed specific uncertainty markers that had been shown to be more prevalent in atypical situations in human-human interviews collected with these materials (Bloom & Schorer, 1999). These included *ums*, *uhs*, pauses, repairs, and talk other than an answer. In the fourth condition, the system always provided clarification; no matter what the user did, the system would present the full official definition for every question.

40 users recruited from an advertisement in the *Village Voice* were paid to participate.

## Results

As in Study 1, users' responses were almost perfectly accurate when they answered about typical scenarios. For atypical scenarios, users were substantially more accurate when they were always given clarification (80%) than when they were never given clarification (33%),  $F(1,36) = 10, p < .005$ . When users initiated clarification, their response accuracy was no better (29%) than when they were never given clarification, because they almost never asked for it. As in Study 1, it seems likely that it didn't occur to users that clarification was necessary. Response accuracy was better when the initiative for clarification was mixed (59%),  $F(1,36) = 10.11, p < .005$ , although it was not as good as when clarification was given always.

Figure 1: Response accuracy for atypical scenarios, Study 1

Figure 2: How often users received clarification, Study 1

Figure 3: Response time per question, Study 1

System-initiated clarification increased the amount of user-initiated clarification: users were more likely to ask questions in the mixed-initiated condition, presumably because they were more likely to recognize that clarifica-

tion might be useful. These users also spoke less fluently, producing more *ums* and *uhs*. We speculate that this was because these users at some level recognized that the system was sensitive to their cues of uncertainty.

Overall, the users in this study requested clarification far less often than the users in Study 1. This might result from any or all of the differences between our desktop and speech interfaces. In the speech interface, clarification was harder to request; requests had to be formulated into explicit questions rather than being accomplished by simple mouse clicks. Also, in the speech interface the definition unfolded over time (sometimes a substantial amount of time, up to 108 seconds), rather than appearing all at once, and in our application it was impossible to shut off; in the desktop interface, the definition appeared all at once and could be closed with a simple mouse click. Also, unlike in the desktop study, users couldn't reject system-initiated offers of clarification; here the system immediately provided clarification when triggered, without giving the option of rejecting the help.

As in Study 1, clarification took time. The more clarification a user received, the more time the interviews took. Sessions where clarification was always provided took more than twice as long as sessions with no clarification or when it was (rarely) user-initiated (12.8 versus 5.2 and 4.9 seconds per question, respectively); mixed-initiative clarification took an intermediate amount of time (9.6 seconds per question).

Also as in Study 1, users rated the system more positively when it was responsive (user- or mixed-initiative conditions). When the system was not responsive (no clarification or clarification always), users wanted more control and felt that interacting with the system was unnatural. Users didn't report finding system-initiated clarification particularly more annoying than user-initiated clarification—which they almost never used.

Overall, these results suggest that enhancing the collaborative repertoire of a speech system can improve comprehension accuracy without harming user satisfaction, as long as the system provides help only when it is necessary. But these improvements come at the cost of increased task duration, which could make such systems impractical in real-world survey situations.

## Conclusions

Our findings demonstrate that a collaborative view can indeed transfer to interaction with non-human agents. Increased system clarification abilities can improve users' comprehension (and thus their response accuracy), while increasing (or not reducing) user satisfaction. But this comes at the cost of increased task duration, which could lower survey completion rates in the real world.

Our findings also demonstrate that extended clarification sequences are likely to be rare or unnecessary when users' conceptions are likely to be the same as the system's, as in our typical scenarios. The need for building survey systems with enhanced collaborative abilities may depend on the likelihood of potential misunderstandings; if this likelihood is high or unknown, enhanced collaborative abilities may be worth implementing.

The benefits we have shown for collaboratively enhanced survey systems come even with our rudimentary

implementations, which are based on the most generic of user models (see Kay, 1995). A stronger test of collaborative approaches requires more customized interfaces, in which, for example, the system would reason about which parts of definitions would be appropriate to present at any given moment, what particular users are likely to misunderstand, etc. (see Moore, 1995).

Our findings demonstrate that computer implementations of surveys seem to run into exactly the same problems as human-human survey and instructional situations, where people don't always recognize they need help or aren't willing or able to ask for help (e.g., Graesser & McMahan, 1993; Schober & Conrad, 1997).

But our findings also show that in some situations (our desktop interface, when users were told that clarification was essential), users are indeed willing to ask for clarification more often than they are with human interviewers (Schober & Conrad, 1997). This is consistent with findings in other domains that interaction with a computer can lead to better task outcomes than interaction with a person. For example, people may be more willing to accept correction from an intelligent computer tutor than from a human tutor (Schofield, 1995), and people are more willing to admit to undesirable behaviors when asked about them on self-administered computer surveys than in human-administered surveys (Tourangeau & Smith, 1996).

We propose that some of these improvements from interacting with computers don't arise simply from the fact that the computer isn't a person. They arise in part from the fact that the costs and constraints of grounding vary in different media, as Clark and Brennan (1991) argued. Most tutoring and survey systems to date have been direct manipulation or simple (textual) character entry systems like our desktop interface; in such interfaces the user's costs of requesting information from the system can be low. The human interactions to which such systems are often compared are speech interactions, where people have to formulate clarification requests explicitly and clarification takes significant amounts of time. Any differences in task performance may just as likely result from the differences between direct manipulation and speech as from the differences between computers and humans.

We believe our findings also require us to refine a theory of human-human collaboration by explicitly introducing the notion of initiative. Our findings that comprehension success can vary depending on whether the user or system takes the initiative should be extended to the human realm; a collaborative theory should include who takes the responsibility for clarifying meaning. In many cases speakers are responsible for what they mean, and listeners assume that what speakers say is readily interpretable to them in the current context (the "interpretability presumption," in Clark and Schober's [1991] terms). But in situations where the speaker is less competent than the addressee, the addressee may take responsibility for the meaning, and may initiate clarification (Schober, 1998). Who should be responsible under what circumstances, and what determines how speakers decide whose effort should be minimized, are important questions for a theory of collaboration.

Altogether, our results suggest that user-initiated clarification will work only if users recognize that clarification will help, recognize that the system's concepts may differ from theirs, are motivated to understand precisely, and are willing to take the extra turns to ground understanding. Explicit instructions to users can help make this happen—help set a high grounding criterion—but it's unclear whether such instruction is feasible in real-world situations. Our results suggest that system-initiated clarification will work only if users give reliable evidence of misunderstanding and if they are willing to accept offers of clarification. It won't work if users are confident in their misinterpretations.

In general, the opportunity for clarification dialog won't help if users don't recognize it's needed.

Berkeley, CA 94704

## Abstract

A connectionist model capable of performing rapid inferences to establish explanatory and referential coherence is described. The model's ability to perform such inferences arises from (i) its structure, (ii) its use of mutual inhibition among "sibling" types, entities, and rules, (iii) the use of temporal synchrony for representing dynamic bindings, and (iv) its ability to rapidly modify weights in response to convergent activity.

## Introduction

Consider the following simple narrative: "John fell in the hallway. Tom had cleaned it. He got hurt." Upon hearing the above narrative most of us would infer that Tom had cleaned the hallway, John fell because he slipped on the wet hallway floor, and John got hurt because of the fall. These inferences allow us to establish causal and referential coherence among the events and entities involved in the narrative. They help us explain John's fall by making plausible inferences that the hallway floor was wet as a result of the cleaning and John fell because he slipped on the wet floor. They help us causally link John's hurt to his fall. They help us determine that "it" in the second sentence refers to the hallway, and "He" in the third sentence refers to John, and not to Tom. Empirical data strongly suggests that inferences required to establish referential and causal coherence occur automatically during language understanding (see e.g., Just & Carpenter 1977; Keenan, Baillet, and Brown 1984; Kintsch 1988; McKoon & Ratcliff 1980, 1992; Potts, Keenan, & Golding, 1988).

Any system that attempts to explain our ability to establish causal coherence during language understanding must possess a number of properties: First, such a system must be representationally adequate. It must be capable of encoding specific facts and events and expressing general regularities (aka rules) that capture the causal structure of the environment. In particular, the system should be capable of encoding context-dependent and evidential cause-effect relationships. Second, the system should be inferentially adequate, that is, it should be capable of drawing a range of explanatory inferences by combining evidence and arriving at *coherent* interpretations that are quasi-optimal with reference to a cost-function (Hobbs et. al, 1993). Third, the system should be capable of establishing referential coherence. In particular, it should be able to unify entities and events by recognizing that multiple designations might refer to the same entity or event. Fourth, the system should be capable of learning and fine-tuning its causal model based on experience, instruction, and exploration. Finally, the system should be scalable and computationally effective. The causal model underlying human language understanding would be extremely large. Yet we understand language at the rate of several hundred words per minute (Just & Carpenter 1977). Hence, a system for establishing causal coherence should also be capable of encoding

a large causal model and rapidly performing the requisite inferences within fractions of a second.

This paper describes several key extensions to the connectionist model SHRUTI that enable it to draw the sorts of inferences described above. SHRUTI is a neurally plausible system capable of expressing causal knowledge involving n-place relations, limited quantification, and type restrictions. It encodes specific events as well as context-sensitive priors over events. It expresses dynamic bindings via the synchronous firing of appropriate node clusters and performs inferences via the propagation of rhythmic activity over node clusters. This propagation amounts to a parallel breadth first activation of the underlying causal graph, and hence, the reasoning in SHRUTI is extremely fast. The use of weighted links and activation combination functions at nodes allow SHRUTI to encode soft rules and perform evidential inference. SHRUTI supports supervised learning which allows it to fine-tune its causal model in a data-driven manner (Shastri & Ajjanagadde, 1993; Shastri & Grannes, 1996; Shastri, 1999; Shastri & Wendelken, 1999; Wendelken & Shastri, 2000).

In order to carry out inferences for establishing referential and causal coherence, however, SHRUTI's core functionality had to be extended in a number of ways. These include the ability to (i) unify entities and relational instances (events) (ii) posit the existence of entities that are left implicit in the utterance, and (iii) favor interpretations that are more plausible and more likely over others that are less so. These functional extensions were realized in part by introducing mutual-exclusion clusters in the encoding of types and entities and by modifying the behavior of node-types. But more importantly, SHRUTI's inferential behavior was modified by (i) introducing inhibitory interactions among rules sharing a common consequent (effect) and (ii) modeling *short-term-potiation*, a biological phenomena whereby synaptic strengths (link weights) undergo rapid but short-lived changes in response to convergent activity. Both these changes play a critical role in favoring coherent and more-likely interpretations over less coherent and less likely ones.

The rest of the paper is organized as follows. The next section presents SHRUTI's basic representational machinery. This is followed by an elaboration of evidential reasoning in SHRUTI. Next we discuss mechanisms particularly aimed at the problem of establishing coherence and illustrate the functioning of the model with the help of an example.

## SHRUTI's representational machinery

Figure 1 illustrates the encoding of the following fragment of knowledge (expressed in SHRUTI's input syntax):

- (1)  $\forall x:\text{Agent}, y:\text{Location} [\text{slip}(x,y) \Rightarrow \text{fall}(x,y) (600,900)];$
- (2)  $\forall x:\text{Agent}, y:\text{Location} [\text{trip}(x,y) \Rightarrow \text{fall}(x,y) (800,900)];$
- (3) \*TF: trip(Person, Location) 100;
- (4) \*TF: slip(Person, Location) 50;

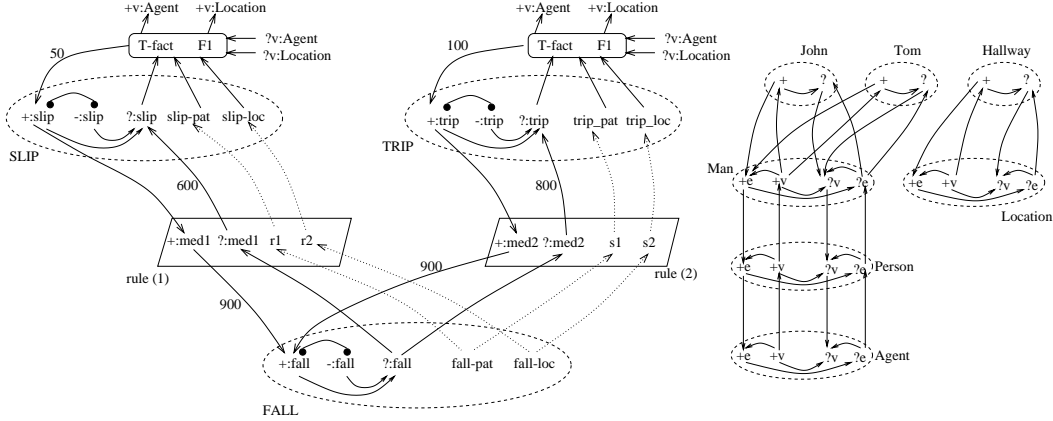

Figure 1: An example SHRUTI network encoding two rules (i)  $\forall x:\text{Agent}, y:\text{Location} [ \text{slips}(x,y) \Rightarrow \text{falls}(x,y) (600,900)]$ ; and (ii)  $\forall x:\text{Agent}, y:\text{Location} [ \text{trips}(x,y) \Rightarrow \text{falls}(x,y) (800,900)]$ ; two T-facts, F1 and F2; and a type hierarchy fragment. Links between mediator and type structures, and inhibitory links between sibling rules, entities, and types, have been omitted.

- (5) is-a( John, Man ); (6) is-a( Tom, Man );
- (7) is-a( Man, Person ); (8) is-a( Person, Agent );
- (2) is-a( Hallway, Location );

Items (1–2) are rules, items (3–4) are taxon-facts (T-facts), and item (5–9) are assertions about types. The first rule states that when an entity of type *Agent* slips at a location, then the latter may fall at that location. The weights (a,b) associated with a rule have an evidential interpretation and we discuss this in the section on evidential reasoning. The weight associated with a T-fact is indicative of the prior probability of the specified event type. All weights lie in the interval [0,1000].

### Encoding Relations, Entities, and Types

Each relation is represented by a focal cluster depicted by a dotted ellipse in Figure 1. Consider the focal cluster for *slip*. This cluster includes an enabler node labeled *?:slip*, two collector nodes labeled *+:slip* and  *-:slip*, and two role nodes labeled *slip-pat* and *slip-loc* for its two roles *patient* and *location*. In general, the cluster for an *n*-place relation contains *n* role nodes. The positive and negative collectors are mutually inhibitory (inhibitory links are depicted by filled circles).

Assume that the roles of *slip* have been dynamically bound to some fillers and thereby represent an active instance of *slip* (we will see how, shortly). The activation level of *?:slip* indicates the strength with which the system is seeking an explanation for the currently active instance of *slip*. The activation levels of *+:slip* and  *-:slip* encode graded beliefs about currently active instance of *slip* ranging continuously from *no* on the one extreme (only  *-:slip* is active), to *yes* on the other (only *+:slip* is active), and *don't know* in between (neither collector is very active). If both the collectors receive comparable and strong activation then both collectors can be active, despite mutual inhibition. This signals a contradiction.

The collector nodes of each relation are connected to the enabler node of the relation. For example, *+:fall* and  *-:fall* are connected to *?:fall*. These links cause *?:fall* to become active whenever *+:fall* or  *-:fall* become active. In effect, these links cause any active assertion about a relation to lead to a query about the assertion. Thus the system continually seeks an explanation for active assertions. The weight on the link from *+:fall* ( *-:fall*) to *?:fall* is inversely proportional to the probability of occurrence (non-occurrence) of an instance of *fall* — the less likely an event, the stronger the search for an

explanation of the event.

The encoding of types and instances is illustrated at the right of Figure 1. The focal cluster of each entity, *A* consists of a *?:A* and a *+:A* node. In contrast, the focal cluster of each type, *T* consists of a pair of *?* (*?:e:T* and *?:v:T*) and a pair of *+* nodes (*+:e:T* and *+:v:T*). While the nodes *+:v:T* and *?:v:T* participate in expression of knowledge (facts and attributes) involving the whole type *T*, the nodes *+:e:T* and *?:e:T* participate in the encoding of knowledge involving particular instances of type *T*. Thus the pair of *v* nodes and the pair of *e* nodes signify universal and existential quantification, respectively. The *levels* of activation of *?:A*, *?:v:T*, and *?:e:T* nodes signify the strength with which information about entity *A*, type *T*, and an instance of type *T*, respectively, is being sought. Similarly, the *levels* of activation of *+:A*, *+:v:T*, and *+:e:T* signify the degree of belief that the entity *A*, the type *T*, and an instance of type *T*, respectively, play appropriate roles in the current situation.

Nodes are computational abstractions and correspond to *small ensembles of cells*, and a connection between nodes corresponds to several connections from cells in one ensemble to cells in the other. Phasic nodes, of which role nodes are an example, produce output spikes in synchrony with their inputs. Temporal-and nodes, such as the enablers and collectors, integrate activity over a broader time window and produce wider output pulses (such a pulse may be identified with recurring high-frequency bursts of spikes).

### Dynamic bindings

The *dynamic* encoding of a relational instance corresponds to a *rhythmic* pattern of activity wherein bindings between roles and entities are represented by the *synchronous* firing of appropriate role and entity nodes (von der Malsburg 1981; Shastri & Ajjanagadde 1993; Hummel & Holyoak 1997). With reference to Figure 1, the dynamic representation of the relational instance (*fall*:  $\langle \text{fall-pat}=\text{John} \rangle, \langle \text{fall-loc}=\text{Hallway} \rangle$ ) (i.e., “John fell in the Hallway”) will involve the synchronous firing of *+:John* and *fall-pat*, and the synchronous firing of *+:Hallway* and *fall-loc*. The entities *+:John* and *+:Hallway* will fire in distinct phases.

### Encoding E-facts and T-facts

SHRUTI encodes two types of facts in its long-term memory: episodic facts (E-Facts) and taxon facts (T-facts). These facts

provide closure between the enabler node and the collector nodes. While an E-fact corresponds to a specific instance of a relation, a T-fact corresponds to a distillation or statistical summary of various instances of a relation and can be viewed as coding *prior probabilities*. T-facts are conditioned on the type of role-fillers. Typically, T-facts involving salient role-filler combinations such as  $[buy(a-Parent, a-Minivan) w1]$  (i.e., the prior probability that a parent buys a minivan is  $w1$ ) as well as more generic T-facts such as  $[buy(a-Person, a-Car) w2]$  would be learned. The priors for role-filler combinations not explicitly encoded would be inherited from generic T-facts.

### Encoding rules

A rule is encoded via a mediator focal cluster (shown as a parallelogram) that mediates the flow of activity between the antecedent and the consequent clusters.<sup>1</sup> The mediator consists of a collector and an enabler node and as many role-instantiation nodes as there are distinct variables in the rule. The enablers of the consequent relations are connected to the enablers of the antecedent relations via the enabler of the mediator. The (+/-) collectors of the antecedent relations are linked to the appropriate (+/-) collectors of the consequent relations via the collector of the mediator. Each of these enabler and collector links for a rule has a weight. The roles of the consequent relations are linked to the roles of the antecedent relations via the corresponding role-instantiation nodes in the mediator. This linking reflects the correspondence between antecedent and consequent roles specified by the rule.

If a role-instantiation node receives activation from the mediator enabler and a consequent role node, it simply propagates the activity onward to connected antecedent role nodes. If the role-instantiation node receives activity *only* from the mediator enabler it sends activity *only* to the node  $?e:T$ , where  $T$  is the type specified in the rule as the role type. This causes node  $?e:T$  to become active in an unoccupied phase. Node  $?e:T$  now conveys this activity to the role-instantiation node which in turn propagates this activity to connected antecedent role nodes. This interaction between the mediator and the type hierarchy, in effect, creates activity corresponding to “Does there exist some role filler of the specified type?” This is the mechanism by which new entities are posited and new phases emerge during the course of inference.

### Evidential Reasoning

The interpretation of link weights and activation values is intentionally underspecified in the core SHRUTI model. The goal has been to provide a flexible and expressive representational structure which can be fine-tuned according to specific modeling and task requirements. The following describes a specific interpretation of link weights in terms of probabilities that leads to satisfactory explanatory inferences.

#### A probabilistic interpretation of weights

Refer to the simplified SHRUTI network shown in Figure 2. The weight of the link from the enabler (?) of a relation to its collector (+) equals the (prior) probability of the occurrence of an instance of the relation. This weight corresponds to the weight of a T-fact associated with the relation. The weight of the link from the collector (+) of a relation to the enabler (?) of the relation is *inversely* proportional to the prior probability of the occurrence of an instance of the relation.

<sup>1</sup>The inclusion of a mediator was motivated, in part, by discussions the author had with Jerry Hobbs.

Figure 2: A simplified depiction of SHRUTI’s encoding of a rule and T-facts. The rule is  $C \rightarrow E$  and the T-facts are the prior probabilities of  $C$  and  $E$ . The negative collector and all roles nodes have been suppressed.

Figure 3: Inhibitory interaction between rules sharing a common consequent.

Now consider the encoding of the rule  $C \rightarrow E$ . The link weight from  $?E$  to  $?C$  equal  $P(E|C)$ , the probability of  $E$  given  $C$ . The weight,  $\Omega$ , of the link from  $+C$  to  $+E$  can be interpreted in several ways, as elaborated below. The simplest of these interpretations is  $P(E|only C)$ , the causal strength of  $C$  for  $E$  (this is essentially the independent component of a noisy-or). Another is  $P(C|E)$ .

When  $E$  is observed to be true, and hence,  $+E$ ’s activity level is clamped to 1.0, the activation of  $?E$  will equal  $1 * (1/P(E))$ , the activation of  $?C$  will equal  $(1/P(E)) * P(E|C)$ , and that of  $+C$  will equal  $(1/P(E)) * P(E|C) * P(C)$ . A direct application of Bayes Rule shows that the activation of  $+C$  reduces to  $P(C|E)$  — the desired degree of belief in  $C$  under a probabilistic interpretation. If there are multiple causes of  $E$ , say  $C1$  and  $C2$ , then subsequent to the clamping of  $+E$ ,  $C1$  and  $C2$  will become active at levels  $P(C1|E)$  and  $P(C2|E)$ , respectively, which is again as desired under a probabilistic interpretation (see Figure 3).

### Evidence combination

Where there are multiple sources of evidence for some predicate, then we must have some way to combine them. Since each source must communicate independently, along a single weighted link, the approach taken follows that of a belief-net noisy-or (Pearl 1988). However, to allow for more flexible evidence combination within this framework than what a single function can provide, a set of evidence combination functions was developed, based on notions of sufficiency or necessity of factors, and also on degrees of correlation.

Interestingly, these functions suggest several different interpretations of the link weights. At one end of this range is the familiar *noisy-or* function  $1 - \prod_i (1 - x_i * w_i)$ , where each weight  $w_i$  is essentially a measure of the sufficiency of each (independent) potential cause for bringing about the effect. At the other end of the spectrum, a sort of *noisy-and* function  $\prod_i (1 - (1 - x_i) * w_i)$  is used where the weight is interpreted as a degree of necessity, the probability that the consequent is false given that the particular antecedent is false (but all other necessary antecedents are true). In between these are *soft-or* (wherein positive correlation is allowed), a set of power averages  $((\sum_i X_i^k W_i) / (\sum_i W_i))^{1/k}$  ranging from *max* down to *min* depending on the parameter  $k$ , and a *soft-and* analogous to the *soft-or* (see Shastri & Wendelken, 1999).

## Mechanisms to support coherence

Several mechanisms have been developed which support the establishment of referential and causal coherence. These include inhibitory connections in the causal model, short-term potentiation, and the ability to create and collapse phases.

### Role of inhibitory connections

The encoding of a rule  $C \rightarrow E$  in SHRUTI involves inhibitory connections from  $+C$  to all the  $? \rightarrow ?$  links that originate from  $? \rightarrow E$  (see Figure 3) and reduce activity at their targets to a degree proportional to the activation of  $+C$ . These inhibitory links serve two purposes. First, they provide a mechanism for *contrast enhancement* since they allow stronger explanations to dominate over weaker explanations. Second, they serve the purpose of *explaining away*.<sup>2</sup> It is well known that combining explanatory and predictive inference can lead to problems in an inference system. For example, a system that can infer “John fell” from “John slipped”, and “John tripped” from “John fell” can also have the unfortunate tendency to infer “John tripped” based on “John slipped”. The inhibitory links prevent such unwarranted proliferation of evidence.<sup>3</sup> The precise impact of inhibition depends on the evidence combination function deployed at the site where the inhibitory links converge.

### Short-term Potentiation

If  $+fall$  receives activity from one of its T-facts it means that  $?fall$  is active, and hence, *fall* is being sought as a possible explanation of some event (say, hurt). If at the same time,  $+fall$  receives concurrent activity from  $+med1$  it means that *fall* is also being predicted as a possible consequence of a *slip* event. In these circumstances, it is *highly likely* that the fall event actually occurred and is both an effect of the slip event and an explanation of the fall event. SHRUTI expresses this increased likelihood via the biologically plausible mechanism of short-term potentiation (STP) (Bliss and Collingridge, 1993). Whenever a collector  $+P$  receives activity from one of its T- or E-fact and concurrent activity from a mediator collector node, then the weights of the links from the mediator collector to  $+P$  and from the active T-facts to  $+P$  increase for a short-duration. Analogous short-term weight changes occur due to convergence of top-down and bottom-up activity at links incident on  $-P$ : and at  $?P$ .

<sup>2</sup>This use of inhibitory connections is motivated in part by Ajanagadde (1991).

<sup>3</sup>The weights of these inhibitory links can be given a probabilistic interpretation. For example, the weight  $\phi(C2 \rightarrow C1)$  in Figure 3 can be viewed as  $[P(E) * P(E|C1, C2) * P(C1|C2)] / [P(E|C1) * P(E|C2) * P(C1)]$ .

With reference to Figure 3, consider a domain where  $A$  is a possible cause of  $C1$ , and hence we have the rule  $A \rightarrow C1$ . Now consider a situation where there is independent evidence for  $A$  and  $E$  and one is interested in determining the probability of  $C1$ ,  $P(C1|A, E)$ . This probability cannot be exactly computed using only information available locally at node  $C1$ . Simply combining the evidence arriving from  $E$  (i.e.,  $P(C|E)$ ) and  $A$  (i.e.,  $P(C1|onlyA)$ ) using an evidence combination function such as *noisy-or* would typically lead to an underestimation of the correct value. However, the short-term potentiation (STP) of links allows SHRUTI to partially offset this underestimation of the probability of an intermediate relation when both the cause and the effect of a relation are observed. At the same time, the unpotentiated weights continue to propagate the correct probability values when only the cause or only the effect is observed.

At a more global level, STP also has the effect of *priming* the whole subnetwork of nodes and links that constitute a coherent interpretation and creating a strong feedback loop of reverberant activity in a subnetwork of causal knowledge corresponding to a coherent interpretation.

Taken together, the short-term associative increase in weights and the inhibitory interactions leading to the explaining away phenomena, provide a powerful and neurally plausible mechanism that enable SHRUTI to prefer coherent explanations over non-coherent ones.

### Mutual exclusion and collapsing of phases

Entities in the type hierarchy can be part of a *phase-level* mutual exclusion cluster ( $\rho$ -mex cluster). Consequently, only the most active entity within a  $\rho$ -mex cluster can remain active in any given phase. A similar  $\rho$ -mex cluster can be formed by mutually exclusive types. Mutual exclusion also occurs in the type hierarchy as a result of inhibitory connections from the  $+$  nodes of a type (or an entity) to the  $?$  nodes of all its siblings. This inhibition leads to another sort of “explaining away” phenomenon. If for example, the type query “Is it a Person?” (i.e., activation of  $?e:Person$ ) leads to the queries “Is it a Man?” and “Is it a Woman?”, then strong support received by  $+e:Woman$  reduces the strength of the query  $?e:Man$ . In essence, the query “Is it a Man?” is no longer considered important by the system since it was seeking a person and it has already found a woman.

SHRUTI allows separate phases to coalesce into a single phase, or new phases to emerge, as a result of inference. The latter is realized by the allocation of new phases resulting from the interaction between role-instantiation nodes in mediators and the type hierarchy, as described above. The unification of phases is realized in the current implementation by the collapsing of phases based on activity within an entity cluster or within a focal cluster. In the first case, phase collapsing occurs whenever a single entity dominates multiple phases (for example if the same entity comes to be the answer to multiple queries). In the second case, phase collapse occurs if two unifiable instantiations of a relation arise within a focal cluster. For example, the active assertion  $+fall(John, Hallway)$  alongside the query  $\exists x:Man ?fall(x, Hallway)$  (Did a man fall in the Hallway?) will result in the merging of the two phases for “a man” and “John” via the inferred assertion  $\exists x:Man +fall(x, Hallway)$ . The same assertion alongside the query  $\exists x:Woman ?fall(x, Hallway)$  would not lead to a similar phase merge because the types Man and Woman are mutually exclusive, and hence, would mutually inhibit one another.

SHRUTI’s ability to readily and flexibly instantiate entities and collapse them into a single entity during inference is due to its use of temporal synchrony to represent dynamic bindings.

## Simulation Result

The activation trace resulting from the processing of the "John fell" story by a SHRUTI network encoding the rules, T-facts, and type hierarchy described in Section is shown in Figures 4 and 5. Figure 4 shows the actual activation levels of the  $+:slip$  and  $+:trip$  nodes as the story is processed by SHRUTI. Figure 5 depicts the activation trace of a larger *subset* of nodes. The depiction in this figure, however, has been simplified to highlight key aspects of the network behavior. In particular, several nodes have been omitted, some intermediate cycles have been omitted and the activation levels of collector and enabler nodes have been discretized to four levels. Please note that due to simplifications made to Figure 5, the time scales along the x-axis in Figures 4 and 5 are not the same. To minimize confusion, we will refer to the times in Figure 4 as cycles and in Figure 5 as steps. The reader may also wish to refer to Figure 1 to ground some of the following description.

Each sentence in the narrative is conveyed to SHRUTI by activating the  $+$  node of the appropriate relation and establishing role-entity bindings by the synchronous activation of the appropriate role and entity nodes. The sentences are presented in sequence and after each sentence presentation, the network is allowed to propagate activity for a fixed number of cycles. For example, the first sentence (S1) is communicated to SHRUTI in step 1 (cycle 0) by activating the node  $+:fall$ , the nodes  $fall-pat$  and  $+:John$  in synchrony, and the nodes  $fall-loc$  and  $+:Hallway$  in synchrony. The firing of nodes  $John$  and  $+:Hallway$  occupy distinct phases —  $\rho_1$  and  $\rho_2$ , respectively.

Activation from the focal cluster for  $fall$  reaches the mediator structure of rules (1) and (2). Consequently, nodes  $r1$  and  $r2$  in the mediator for rule (1) become active in phases  $\rho_1$  and  $\rho_2$ , respectively. Similarly, nodes  $s1$  and  $s2$  in the mediator of rule (2) become active in phases  $\rho_1$  and  $\rho_2$ , respectively. At the same time, the activation from  $+:fall$  activates  $?:fall$  which in turn activates the enablers  $?:med1$  and  $?:med2$  (the activity of mediator nodes, and role nodes of  $slip$  and  $trip$  is not depicted in Figure 5). The activation from nodes  $r1$  and  $r2$  reaches the roles  $slip-pat$  and  $slip-loc$  in the  $slip$  focal cluster, respectively. Similarly, activation from nodes  $s1$  and  $s2$  reach the roles  $trip-pat$  and  $trip-loc$  in the  $trip$  focal cluster, respectively. In essence, the system has created new bindings for the  $slip$  and  $trip$  relations. These bindings together with the activation of the nodes  $?:slip$  and  $?:trip$  encode two queries: "Did John slip in the hallway?", and "Did John trip in the hallway?". At the same time, activation travels in the type hierarchy and activates the nodes  $?v:Man$ , then  $?v:Person$ , and then  $?v:Agent$  in phase  $\rho_1$ , and the  $?v:Location$  node in phase  $\rho_2$ . The coincident activity of  $slip-pat$  and  $?v:person$  node, and the coincident activity of the  $slip-loc$  and  $?v:Location$  nodes leads to the firing of the T-fact F1 associated with slip. The activation of F1 causes activation from  $?:slip$  to flow to  $+:slip$ . The T-fact F2 associated with trip also becomes active in an analogous manner and conveys activation from  $?:trip$  to  $+:trip$ . The level of these activations is a measure of the probability that a person may slip and fall, respectively. At this time, "John tripped" is believed to be a more likely explanation of "John fell" than "John slipped."

While the activation spreads "backwards" from the  $fall$  focal cluster in the manner described above, activation also travels "forwards" to the  $hurt$  focal-cluster (not shown in Figure 1) as a result of the encoding of rule (iii) (also not shown) and leads to the weak prediction that John got hurt.

The introduction of sentence S2 in step 6 (Figure 5) (cycle 40 Figure 4) results in the instantiation of  $clean$  with the bindings ( $\{clean-agt=+:Tom\}$ , and  $\{clean-loc=+:e:Location\}$ ). As a result, Tom gets active in phase  $\rho_3$  and  $+:e:Location$  in phase

$\rho_4$ . Note that now we have two instantiations of a location. The second instantiation gets merged with the first (Hallway) as a result of phase merging. This happens in step 8 (see activity of  $+:e:location$  in Figure 5). The pressure for this merging comes from the strong compatibility, and hence, the strong coherence between the activity of hallway and the new location. Note that in the ongoing activity, hallway and the new location (say, Loc1) are active in parallel assertions such as: "John fell on the hallway floor", "The hallway floor might have been wet", "The hallway floor might have been cleaned" and "The Loc1 floor was cleaned" "The Loc1 floor might be wet", "John might have fallen in the hallway floor." At this time,  $+:wetFloor$  also becomes active as a result of activity arriving from  $+:clean$  via the mediator of rule (4) (cleaning leads to a wet floor).

By step 10 (Figure 5)  $+:slip$  becomes more active as a result of the high activation of  $+:wetFloor$ . The effect of "explaining away" kicks in and causes the activation of  $+:trip$  to go down by step 12. The strength of  $+:slip$  increases even further due to (i) the potentiation of links from the mediator for rule (4) (walking on a wet floor may cause slipping), (ii) the potentiation of the link from  $?:med1$  to  $?:slip$ , and (iii) the effect of explaining away. The effect of these changes on the activation levels of  $+:slip$  and  $+:trip$  may be seen more vividly in the detailed trace shown in Figure 4.<sup>4</sup>

S3 is introduced in step 14 (cycle 80) with the binding ( $\{hurt-pat=+:e:Man\}$ ). This leads to  $+:e:Man$  becoming active in phase  $\rho_4$  and a second dynamic instantiation of  $hurt$  (in addition to the earlier instantiation resulting from the inference  $hurt(John)$ ). These two instantiations get merged immediately, and phase  $\rho_4$  gets merged with  $\rho_1$  (John), in step 15 as a result of the phase merging described in the previous Section.

## Conclusion

SHRUTI shows how explanatory and referential coherence can arise within a neurally plausible system as a result of spontaneous activity in a network. The network's structure reflects the causal model of the environment and when the nodes in the network are activated to reflect a given state of affairs, the network spontaneously seeks coherent explanations. The time taken to perform an inference is simply proportional to the depth of the causal derivation and is otherwise independent of the size of the causal model. The state of coherence is reflected as reverberatory activity around *closed loops*. The system also makes predictive (forward) inferences, but only those predictions that become part of a coherent explanation gain strength and persist. Coherence arises in SHRUTI as a result of (i) inhibitory interactions among sibling entities, types and rules, (ii) short-term increase in link weights resulting from short-term potentiation, and (iii) the dynamic merging and instantiation of entities.

<sup>4</sup>If sentence S2 were delayed, the activity in  $slip$  would lead to the instantiation of an instance of  $clean$  with an entity of type  $agent$  being instantiated as a potential filler of the role  $clean-agt$ . This entity, however, gets unified with  $Tom$  upon the introduction of S2.

Figure 4: The activation trace of collector nodes  $+:slip$  and  $+:trip$  during the processing of the “John fell” story. X-axis is time. The activity of these collectors around cycle 12 is due to associated T-facts. Since tripping is more likely than slipping (100 versus 50),  $+:trip$  has a higher activation. Activity from the *clean* predicate arrives (via *wetFloor*) at the *slip* collector at cycle 50 due to the introduction of S2 at cycle 40, giving  $+:slip$  a significant boost. >From here onwards the associative weight changes along highly active pathways into  $+:slip$  result in a large increase in values at around cycle 55. The potentiation of the path from  $?:fall$  to  $?:slip$  also contributes to this increase. At the same time, the “explaining away” phenomena leads to the decrease in the activation of  $+:trip$ . The activity stabilizes around cycle 100. Note that each cycle in SHRUTI roughly corresponds to twice the period of  $\gamma$  band activity, i.e., about 40-50 msec. (see Shastri & Ajjanagadde 1993).

## Abstract

A recent study of infant familiarization to artificial sentences claimed to produce data that could only be explained by symbolic rule learning and not by unstructured neural networks. Here we present successful unstructured neural network simulations showing that these data do not uniquely support a rule-based account. In contrast to other neural network simulations, our simulations cover more aspects of the data with fewer assumptions using a more realistic coding scheme based on sonority of phonemes. Our networks show exponential decreases in attention to a repeated sentence pattern, more recovery to novel inconsistent sentences than to novel consistent sentences, some preference reversals, and extrapolation.

One of the most simulated phenomena in developmental psychology is a data set that was claimed to be immune from simulation by unstructured neural networks (Marcus, Vijayan, Bandi Rao, & Vishton, 1999). Although the authors maintained that their results could only be explained by explicit rules and variables, there are now at least eight connectionist simulations of the data, most of which do not use explicit variable binding and none of which use explicit rules. Here we present additional neural simulations of these data, arguing that our model may provide the currently most satisfying account. The paper reviews the relevant infant data, presents various interpretations and models, and then focuses on our current model.

## The Infant Data

The relevant experiments familiarized 7-month-old infants to three-word artificial sentences and then tested them on novel sentences that were either consistent or inconsistent with the familiar pattern. The design of these experiments is shown in Table 1. In Experiment 1, infants were familiarized to sentences with either an ABA pattern (e.g., *ni la ni*) or an ABB pattern (e.g., *ta gi gi*). There were 16 of these sentences, constructed by combining four A-category words (*ga*, *li*, *ni*, and *ta*) with four B-category words (*ti*, *na*, *gi*, and *la*). After infants became familiar with a sentence pattern, they were tested with two sentences having novel words

that were either consistent or inconsistent with the familiar pattern.

Table 1: Marcus et al. (1999) experiments.

Pattern	Experiments 1 & 2		Experiment 3	
	Cond. 1	Cond. 2	Cond. 1	Cond. 2
Familiarize	ABA	ABB	ABB	AAB
Consistent	ABA	ABB	ABB	AAB
Inconsistent	ABB	ABA	AAB	ABB

When an infant looked at a flashing light to the left or right, a test sentence was played from a speaker situated next to the light. Each test sentence was played until the infant either looked away or 15 s elapsed. Infants attended more to inconsistent novel sentences than to consistent novel sentences, showing that they distinguished the two sentence types.

Experiment 2 was the same except that the words were chosen more carefully so that phoneme sequences were different in the familiarization and test patterns. Experiment 3 used the same words as Experiment 2, but in contrastive syntactic patterns that each duplicated a consecutive word: AAB vs. ABB. The idea was to rule out the possibility that infants might have used the presence or absence of consecutively duplicated words to distinguish sentence types.

In all three experiments, infants attended more to inconsistent than to consistent novel sentences. Our concern is with the best theoretical account of these data. Is the infant cognition based on rules and variables or on connections?

## A Rule and Variable Interpretation

Marcus et al. (1999) argued that these grammars could not be learned by the statistical methods common to standard neural networks. They also tried some unsuccessful neural network simulations using Simple Recurrent Networks (SRN). The authors proposed that only a rule-based model could cover their data. "We propose that a system that could account for our results is one in which infants extract algebra-like rules that represent relationships between placeholders (variables) such as 'the first item X is the same as the third

item Y' (p. 79)." They allowed that their data might also be accounted for by structured neural networks that implement explicit rules and variables in a neural style: "The problem is not with neural networks per se but with the kinds of neural networks that are currently popular. These networks eschew explicit representations of variables and relations between variables; in contrast, some less widely discussed neural networks with a very different architecture do incorporate such machinery and thus might form the basis for learning mechanisms that could account for our data (pp. 79-80)."

### **Psychology of Familiarization**

A leading psychological analysis of familiarization assumes that infants build categories for stimuli (Cohen, 1973; Sokolov, 1963). Subsequently, they ignore stimuli that correspond to their categories, and concentrate on stimuli that are relatively novel. These processes are often discussed in terms of recognition memory. If there is substantial recovery to a novel test stimulus, then it is considered novel. But if there is little or no recovery, then the stimulus is considered to be recognized as a member of a familiar category. During familiarization there is typically an exponential decrease in attention.

### **Familiarization in Neural Networks**

Encoder networks that learn to reproduce their inputs on their output units can simulate familiarization and novelty effects in infants (Mareschal & French, 1997). Relations among stimulus features are encoded in hidden unit representations, and accuracy is tested by decoding these hidden unit representations onto output units. Discrepancy between output and input representations is network error. Familiar stimuli produce less error than novel stimuli, which presumably deserve further learning. Such hidden unit representations enable prototypes, generalization, and pattern completion (Hertz, Krogh, & Palmer, 1991).

### **Other Neural Network Models**

There are at least eight alternative computational models of the Marcus et al. (1999) data, all of them connectionist models, presumably attracted by the challenge that ordinary connectionist models would not be able to simulate the data. Most of these models are ordinary unstructured connectionist models without explicit rules and variables. All eight of these models cover the basic finding of the Marcus et al. (1999) experiments, namely noticing the difference between consistent and inconsistent sentences. It is beyond the scope of this brief paper to thoroughly review all of these models, many of which are as yet only sketchily reported. However, we can briefly characterize each model and identify what we believe to be its best virtue and most significant limitation.

Four of the unstructured models use the SRN architecture, construing the network's task to be prediction of the next word in a sentence. Negishi (1999a, b) used an SRN without

hidden units, coding each word in analog fashion with place of consonant articulation and vowel height. This is a simple network requiring no unusual hand-wired assumptions or pre-experimental experience. However, Marcus (1999a) claimed that it essentially implemented variables by using continuous values on the input units that are transmitted directly to the outputs, thus arguably disqualifying the model from meeting the challenge that variable binding is required.

Following an argument that Marcus et al.'s (1999) SRNs failed because they lacked normal phonemic experience (Seidenberg & Elman, 1999), Elman (1999) pre-trained an SRN to distinguish whether each word differed or not from the previous word. Each word was coded on 12 binary phonetic features. Although 7-month-olds obviously know something about phonemes and it may be reasonable to include such knowledge in models, it is unlikely that infants receive any target signals about phonemic sameness and difference. More seriously, the network's task in both the pre-training and habituation phases of the simulation was discrimination rather than habituation as it was for the infants.

Christiansen and Curtin (1999) pre-trained an SRN on word segmentation. The network learned to predict the identity and stress of the next phoneme in sentences from information on 11 binary phonological features and the stress and utterance boundaries of individual phonemes. Presented with the Marcus et al. test sentences, the network then showed slightly better prediction of words occurring in inconsistent than those occurring in consistent sentences. Again, the use of prior knowledge seems reasonable. However, it is unclear why the network would perform better on inconsistent sentences, with which it is less familiar, than on consistent sentences whose pattern it has just learned.

Altmann and Dienes (1999) used SRNs with an extra encoding layer between the input and hidden layers. Unlike some models, this one does not require any questionable pre-training and is performing the habituation task. On the negative side, Marcus (1999b) reports that only when somewhat unconventional correlation and distance measures are used can the network discriminate between consistent and inconsistent sentences. It would be more typical to measure error or relative output activation for such networks.

Gasser and Colunga (1999) used a specially-designed network with micro-relation units whose activations correlated with inputs from two different syntactic categories. Hard-wired connections caused similar syllables to be synchronized, producing low activations on the micro-relation units, and dissimilar syllables to be desynchronized, producing high activations on the micro-relation units. No pre-training was necessary, but the hardwiring of connection weights is of questionable psychological validity.

Shastri and Chang (1999; Shastri, 1999) designed a structured connectionist model with explicit variable binding, implemented by temporal synchrony of activations on units representing sequential position and other units representing arbitrary binary word features. The network learned to represent an ABA pattern by firing the first position unit synchronously with the third position unit. This network would seem to generalize well to any novel sentences of

three words, regardless of the particular features of the words used. But the network is extensively hand-built, and the critically important feedback signals about the position of words in a sentence are psychologically implausible.

None of the foregoing reports of models include evidence on the course of habituation or provide predictions that could be tested with infants.

Shultz (1999) used an encoder version of the cascade-correlation algorithm with arbitrary analog coding of syllables. With an encoder network, the task is construed as word and sentence recognition. Besides covering the consistency effect, these networks learned the training patterns with an exponential decrease in error and showed occasional reversals of preference that were found with the infants. Because the coding was arbitrary, however, it was not possible to simulate the detailed phonetic differences between Marcus et al.'s (1999) Experiments 1 and 2.

### Our Model

Here we present a simulation like that of Shultz (1999), but with phonetically realistic encoding of the input sentences using a continuous sonority scale. A successful result would suggest that such coding could be used by infants in their sentence processing. Sonority is the quality of vowel likeness, and can be defined by perceptual salience (Price, 1980) or by openness of the vocal tract (Selkirk, 1984). The coding scheme is shown in Table 2. The specific numbers are somewhat arbitrary, but their ordering is based on phonological work (Selkirk, 1984; Vroomen, van den Bosch, & de Gelder, 1998).

Table 2: Sonority scale with examples in IPA.

Phoneme category	Examples	Sonority
low vowels	/a/ /æ/	6
mid vowels	/e/ /e/ /o/	5
high vowels	/i/ /i/ /u/ /u/	4
semi-vowels and laterals	/w/ /y/ /l/	-1
nasals	/n/ /m/	-2
voiced fricatives	/z/ /v/	-3
voiceless fricatives	/s/ /f/	-4
voiced stops	/b/ /d/ /g/	-5
voiceless stops	/p/ /t/ /k/	-6

Sonorities range from -6 to 6 in steps of 1, with a gap and change of sign between the consonants and vowels. Each word was coded on two units for the sonority of its consonant and that of its vowel. This is similar to Negishi's (1999b) coding, except that we place consonants and vowels on a single scale, rather than on separate scales. We coded each sentence in the artificial language with six units, two for each one-syllable word. For example, the sentence *ni la ni* was coded as (-2 4 -1 6 -2 4).

Our learning algorithm, cascade-correlation, grows during learning by recruiting new hidden units into the network as required to reduce error (Fahlman & Lebiere, 1990). Recruited

hidden units are installed each on a separate layer, receiving input from the inputs and from existing hidden units. The candidate hidden unit that gets recruited is the one whose activations correlate best with current error. After recruiting a hidden unit, the network returns to the phase in which weights feeding the output units are adjusted to reduce error. An encoder option to cascade-correlation (Shultz, 1999) freezes direct input-output connections at 0 to prevent trivial solutions in which weights of about 1 are learned between each input unit and its corresponding output unit.

The cascade-correlation algorithm has been used to simulate many other aspects of cognitive development, including the balance scale (Shultz, Mareschal, & Schmidt, 1994), conservation (Shultz, 1998), seriation (Mareschal & Shultz, 1999), discrimination shift learning (Sirois & Shultz, 1998), pronoun semantics (Oshima-Takane, Takane, & Shultz, 1999), and integration of velocity, time, and distance cues (Buckingham & Shultz, in press).

In these models, network behavior becomes rule-like with learning, but knowledge is clearly not represented in rules and cognitive processing is definitely not accomplished by explicit variable binding and rule firing. Instead, rules are viewed as abstract, epi-phenomenal characterizations of processes occurring at the sub-symbolic level of unit activations and connection weights (Smolensky, 1988).

There are several advantages of implementing rule-like behavior with neural processes, including the acquisition of psychologically realistic non-normative rules, integration of perceptual and cognitive phenomena, natural variation across problems and individuals, and achievement of the right degree of crispness in knowledge representations. In many cases, universally quantified rules are too crisp to model knowledge representations in children.

Neurological justification for generative networks such as cascade-correlation is provided by recent findings on learning-driven neurogenesis and synaptogenesis throughout the lifespan (Quartz & Sejnowski, 1997). Although neurogenesis and neural migration may be too slow to account for learning within the time frame of the typical infant familiarization experiment, there is evidence that synaptogenesis can occur within seconds (Bolshakov, Golan, Kandel, & Siegelbaum, 1997).

Like most models of higher cognition, cascade-correlation is not a model of detailed neural circuits. Instead, it is an abstracted and simplified model that is partly inspired by neural principles. Individual units in cascade-correlation networks may correspond roughly to groups of biological neurons, and connection weights may correspond roughly to neural pathways.

### Results

Mean network error on test patterns for the three experiments is shown in Table 3. Main effects of consistency were significant at  $p < .0001$ . The results show more network error to inconsistent test patterns than to consistent test patterns

for each experiment. On the assumption that error represents a need for further cognitive processing, these results capture the infant data.

Table 3: Mean error on test patterns.

Expt.	Patterns	Consistent	Inconsistent
1	ABA v. ABB	8.2	14.5
2	ABA v. ABB	13.1	15.8
3	AAB v. ABB	12.9	15.3

The proportion of networks showing a reversal of the consistency effect was .0667, which is close to the .0625 obtained with infants.

A plot of mean error over epochs for a representative network from the ABB condition of Experiment 1 is shown in Figure 1. The first few epochs are omitted for clarity because error started so high, at around 350. Such plots reveal exponential decreases in error on the training patterns over time, similar to the shape of declining attention in infant familiarization. The epochs at which hidden units are installed are shown with diamond shapes just above the training error. As in most cascade-correlation simulations, error decreases sharply after a hidden unit is recruited. After training, error is higher on inconsistent test patterns than on consistent test patterns.

Figure 1: Error reduction in one network.

Generalization tests show that the consistency effect actually grows larger with increasing distance from the training set, a prediction quite different than universally quantified rules would make.

Network analysis revealed that hidden units used sonority sums of consonant and vowel to represent sonority variation first in the duplicated-word category and second in the single-word category. Networks decoded this hidden unit representation with virtually duplicate weights to outputs representing the duplicate-word category.

## Discussion

Like other neural models, our model easily captures the consistency effect. In contrast to alternate models of these data, ours has several features to recommend it. Our model does not require extensive pre-experiment experience (Christiansen & Curtin, 1999; Elman, 1999), extensive hand-wiring of networks (Gasser & Colunga, 1999; Shastri & Chang, 1999), external feedback signals not available in the stimuli (Elman, 1999; Shastri & Chang, 1999), unusual interpretation of outputs (Altmann & Dienes, 1999), or explicit variable binding (Shastri & Chang, 1999). On grounds of theoretical parsimony, the more unsupported assumptions that a model requires the less plausible it becomes.

Unlike some alternate models (Shastri & Chang, 1999; Shultz, 1999), our model uses a realistic coding of the stimuli. Like Negishi (1999b), we used an analog coding of inputs based on the manner in which the phonemes are produced. But our representation scheme is a bit more compact and uniform because we use a single sonority scale for both consonants and vowels, whereas he used two separate scales, one for place of consonant articulation and another for vowel height. Moreover, our use of hidden units with non-linear transfer functions ensures that any possible variable binding at the input level is lost as activation is propagated forward through the hidden layers.

Our model is the only one so far to capture the other feature of the Marcus et al. (1999) infant data, the occasional reversal of preference for novel patterns. It is unclear how easily other models might be able to capture these reversals, but there are hints that it might be difficult for some models. Elman's (1999) model, for example, had such a strong consistency effect that reversals of preference would be unlikely: mean activation to ABB sentences was 123 times higher than to ABA sentences. Likewise, the Shastri and Chang (1999) model learns a very strong representation of serial position. The correlation between weights to position nodes were .9993 for positions 1 and 3 in networks habituated to ABA sentences, and .9998 for positions 2 and 3 in networks habituated to ABB sentences. This rather crisp representation produced 3.4 times more error to inconsistent than to consistent sentences in the ABA condition of Experiment 1, which would seem to preclude reversals.

Although it is not known why infants show occasional reversals, our simulations show that they can be a natural part of learning. With limited exposure, as in both the psychological experiments and our simulations, exceptions naturally occur. This is a parsimonious explanation of reversals because it does not require assumptions of any extraneous processes.

In summary, our model might be currently preferred because it covers more of the infant data, with less pre-experimental experience, less network design, and more realistic stimulus coding than alternate models. It also uses a general learning algorithm that has been applied successfully to several other phenomena in cognitive development.

With so many successful neural models of the consistency effect, there is no question that ordinary, unstructured neural networks can cover these data. The modeling shows

that some of the functionality of symbolic rules and variable binding can be constructed from sub-symbolic processes without having to be explicitly built in. The time is now ripe to generate and test predictions from these alternate models.

## Abstract

The consonance constraint-satisfaction model, which has simulated the major paradigms of classical cognitive dissonance theory, is here extended to deal with more contemporary findings concerning self-affirmation phenomena in dissonance reduction. The key addition to the model, which has also figured in recent simulations of arousal phenomena, is to lessen activity level within the neural network model in self-affirmation conditions. These and other simulations continue to show that dissonance phenomena can be explained in terms of constraint satisfaction.

## Introduction

One of the fundamentally important theories in social psychology is cognitive dissonance theory, which has generated a literature of more than 1000 studies over the past 40 years (Festinger, 1957; Thibodeau & Aronson, 1992). We have recently modeled a number of the central dissonance phenomena using constraint-satisfaction neural networks (Shultz & Lepper, 1996, 1998a&b, 1999a&b). Our so-called consonance model covered insufficient justification, free choice, arousal, and some self-concept phenomena. The model also predicted new free-choice effects that were subsequently confirmed by further psychological experimentation (Shultz, Léveillé, & Lepper, 1999). In this paper, we report on an extension of the model to deal with a prominent self-concept effect in dissonance called self-affirmation.

Dissonance is hypothesized to occur when behavior is inconsistent with self-concept (Steele, 1988; Thibodeau & Aronson, 1992). Because most people have a positive self-concept, behaviors such as lying or trying to persuade others of a position that one does not agree with arouse dissonance and lead to attitude change that reduces the dissonance. However, if important aspects of the self-concept have been recently affirmed, even aspects irrelevant to an experimentally induced inconsistency, there may be no need to reduce dissonance via attitude change. Steele (1988) presented experiments in which fairly subtle self-affirmation manipulations eliminated dissonance effects. Some of these experiments concern insufficient justification via forced compliance, and others deal with free choice. We return to these experiments after reviewing the consonance model used in the simulations.

## The Consonance Model

The consonance model holds that dissonance reduction is a constraint satisfaction problem. The motivation to reduce dissonance stems from the various soft constraints on the beliefs and attitudes that an individual holds. A consonance network corresponds to a person's representation of the situation created in the conditions of a dissonance experiment. Activations of network units represent the direction and strength of a person's cognitions. Weights between cognitions represent psychological implications. These unit activations and weights may vary across the different conditions of a single experiment.

Consonance is the degree to which similarly evaluated units are linked by excitatory weights and oppositely valued units are linked by inhibitory weights. More formally, consonance in a network is defined by

$$\text{consonance} = \sum_i \sum_j w_{ij} a_i a_j$$

where  $w_{ij}$  is the weight between units  $i$  and  $j$ ,  $a_i$  is the activation of the receiving unit  $i$ , and  $a_j$  is the activation of the sending unit  $j$ .

Activation spreads over time cycles by two update rules:

$$a_i(t+1) = a_i(t) + \text{net}_i(\text{ceiling} - a_i(t)) \text{ when } \text{net}_i \geq 0$$

$$a_i(t+1) = a_i(t) + \text{net}_i(a_i(t) - \text{floor}) \text{ when } \text{net}_i < 0$$

where  $a_i(t+1)$  is the activation of unit  $i$  at time  $t+1$ ,  $a_i(t)$  is the activation of unit  $i$  at time  $t$ ,  $\text{ceiling}$  is the maximum activation,  $\text{floor}$  is the minimum activation, and  $\text{net}_i$  is the net input to unit  $i$ , defined as:

$$\text{net}_i = \text{resist}_i \sum_j w_{ij} a_j$$

where  $\text{resist}_i$  refers to the resistance of receiving unit  $i$  to having its activation changed.

At each time cycle,  $n$  units (normally the number of units in the network) are randomly selected and updated. The update rules ensure that consonance increases or stays the same across cycles. Consonance increases because positive net inputs drive unit activations toward the ceiling and negative net inputs drive them toward the floor. Consonance increases until units reach extreme values or net inputs fall to 0. When consonance reaches asymptote, updating stops.

Consonance networks are hand-built to implement particular dissonance experiments using a set of five principles that map dissonance theory to the consonance model:

1. A cognition is implemented by the net activation of a pair of negatively connected units, one of which represents the positive aspect and the other the negative aspect of the cognition.
2. Cognitions are connected to each other based on their causal implications.
3. Dissonance is the negative of consonance divided by the number of nonzero inter-cognition relations.
4. Networks settle into more stable, less dissonant states as unit activations are updated.
5. Unit activations, but not connection weights, are allowed to change, and some cognitions are more resistant to change than others. In particular, beliefs, behaviors, and justifications are more resistant to change than are evaluations and attitudes.

Additional details about the consonance model and its assumptions are available in our previous papers (Shultz & Lepper, 1996, 1998a).

### Forced Compliance

Forced compliance is the most popular dissonance technique within the most prominent dissonance paradigm of insufficient justification. Insufficient justification concerns cases in which a person does something inconsistent with his or her attitudes without much justification. The less the justification, the more cognitive dissonance is created.

In a forced-compliance experiment (Steele, 1988, p. 272), college students were selected for their strong opposition to an increase in tuition fees. They were then persuaded to write essays supporting a substantial tuition increase. In one condition, they were given a choice about whether to write the essay; in another condition, they were given very little choice about whether to write the essay. When a person freely agrees to argue against personal beliefs, this creates dissonance, which can be reduced by changing attitudes in the direction of the argument. There should be little or no dissonance when one is pressured to make such arguments.

Before measuring post-experimental attitudes, some participants were first asked to complete the political sub-scale of the Allport-Vernon Study of Values. One-half of them had been previously assessed as having a strong economic-political value orientation, whereas the others did not have this value orientation. Completing the political value scale was supposed to affirm a valued self-concept only for those students with a strong economic-political value orientation.

As shown by the solid line in Figure 1, there was the familiar dissonance effect of more attitude change under high choice than under low choice. Moreover, as predicted, self-affirmation eliminated attitude change, even under high choice conditions. Two other experiments with minor variations yielded similar results (Steele, 1988).

### Method

Network specifications for the three conditions are shown in Table 1. There are two relevant cognitions, attitude and es-

say, and relations between them. As in our previous simulations, each cognition is implemented with a pair of negatively related units, one to represent the positive aspect of the cognition and the other to represent the negative aspect. Net activation for a cognition is computed as activation on the positive unit minus activation on the negative unit. Positive relations between cognitions are implemented by positive weights between their positive units and between their negative units, and negative weights between the positive unit of one cognition and the negative unit of the other cognition. All weights are bi-directional.

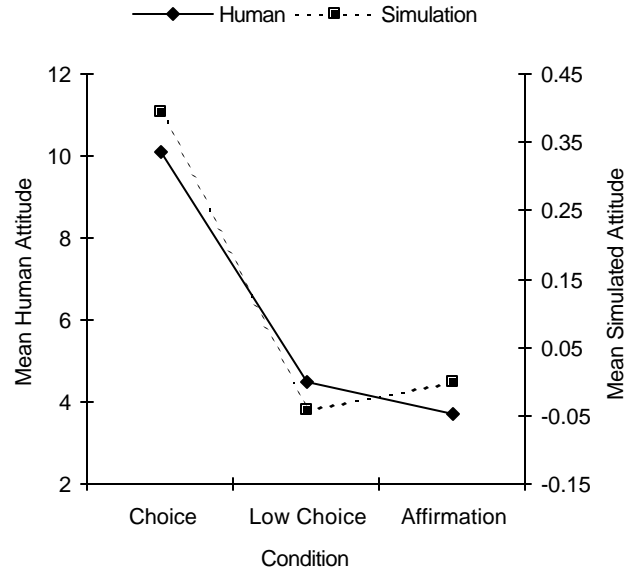

Figure 1: Mean attitude following forced compliance.

All weights and initial unit activations are assigned either high (0.5) or low (0.1) values, according to the five mapping principles described earlier and the descriptions of the experiments being modeled. The floor parameter is 0; the ceiling parameter for positive units is set to 1, and that for negative units is set to 0.5. A *cap* parameter is set to -0.5. This corresponds to the value of the weight between each unit and itself and it prevents activations from growing to ceiling. The *resist* parameter is set to 0.5 for low resistance, and 0.01 for high resistance. These parameter settings are standard across all our dissonance simulations, and some justification for them is provided in our longer papers, (Shultz & Lepper, 1996, 1998a, 1999a).

Table 1: Network specifications for forced compliance.

Condition	Attitude	Essay	Relation
Choice	-0.5	0.5	0.5
Low Choice	-0.5	0.5	0.1
Affirmation	-0.25	0.25	0.25

In this experiment, there is a positive relation between attitude and essay because the more positive one's attitude toward tuition increases, the more likely one would be to

agree to write an essay in favor of tuition increases. This relation is high in the choice condition and low in the low-choice condition. Initially, attitude is given a high negative value to reflect students' initial attitudes; and essay is given a high positive value because the essay was indeed written by all students. An activity-level scalar of 0.5 (the same value used in our other simulations of arousal and self concept) reduces initial activations and weights in the self-affirmation condition, relative to the no-affirmation conditions. The theoretical justification for using a scalar in this way is that self-affirmation is hypothesized to reduce the importance of a dissonant situation (Steele, 1988, p. 292).

All initial unit activations and weights are randomized for each network by adding or subtracting a random proportion of their initial amounts. The three proportion ranges in which additions or subtractions are randomly selected under a uniform distribution are .1, .5, and 1. This increases psychological realism because not everyone can be expected to share the same parameter values. It also allows a test of robustness of the model. Twenty networks were run in each condition at these three different levels of parameter randomization. Networks were run for 30 cycles, which was sufficient to approach asymptotic activation levels.

## Results

Mean attitude toward the view espoused in the essay is presented, in the dashed line in Figure 1, for networks at the .5 level of parameter randomization. As with Steele's (1988) subjects, attitudes are more positive under choice than under the other two conditions. An ANOVA with condition as the single factor revealed significant main effects of condition,  $F(2, 57) = 67, p < .001$ . A contrast  $F$  with weights of +2 for choice, -1 for low choice, and -1 for self-affirmation is significant  $F(1, 57) = 135, p < .001$ , with no significant residual,  $F(1, 57) < 1$ . Proportion of total variance accounted for by this  $F$  is .99.

Figure 2: Mean dissonance following forced-compliance.

Mean dissonance scores over time cycles, for networks run at .5 parameter randomization for the three conditions, are shown in Figure 2. Dissonance starts high in the choice

condition and is greatly reduced over time. In contrast, there is minimal dissonance in the other two conditions and very little dissonance reduction. Similar results were obtained at parameter randomization levels of .1 and 1.

## Discussion

The consonance networks provide a good fit to the attitude change data reported by Steele (1988). There is considerable attitude change in the choice condition, but very little in the low-choice and self-affirmation conditions. There is also a close correspondence between amount of attitude change and plots of dissonance reduction in that the condition with sharp dissonance reduction is also the one with the most attitude change. Examination of dissonance plots is a bonus of computer simulations -- there is no known way to measure dissonance directly in humans. Such plots of simulated dissonance can help to understand the more indirect attitude-change effects that occur as a way of reducing dissonance.

### Free Choice

Steele (1988, p. 276) also presents a free-choice experiment that shows self-affirmation effects. Participants rated and ranked 10 music albums and were then given a choice to keep either their fifth- or sixth-ranked album. Choosing between qualitatively distinct objects creates dissonance because the chosen object is less than perfect and the rejected object has some desirable features that are forgone when an irreversible choice is made. The dissonance arising from a free choice is typically reduced by increasing evaluation of the chosen object and decreasing evaluation of the rejected object (Brehm, 1956; Shultz et al., 1999).

In Steele's experiment, one-half of the participants had been previously selected for having a strong scientific-value orientation and for indicating that a lab coat symbolized these values. The others did not share these values. One-half of the participants in each of these groups were asked to wear a lab coat for the rest of the experiment, during which they rated the albums again, after making their choices.

Post-decisional spread of alternatives was measured by adding the increase in the value of the chosen item and the decrease in the value of the rejected item. There were three control conditions, one with participants not having a science orientation and not wearing a lab coat, another with participants not having a science orientation but wearing a lab coat, and a third with participants having a science orientation but not wearing a lab coat. There were identical dissonance effects in all three control conditions, but not for the self-affirmed, scientifically-oriented students wearing a lab coat. Mean spread of alternatives was higher in the control conditions than in the self-affirmation condition, as shown by the solid line in Figure 3. Once again, apparently irrelevant self-affirmation precluded dissonance reduction.

## Method

Network specifications for these two groups of conditions are shown in Tables 2 and 3. There are three cognitions: a decision and evaluations of the chosen and the rejected objects. Because the decision is public and irreversible, it has

high resistance and high initial activation; the two evaluations have low resistance. Initial evaluation of the chosen object is somewhat higher than that for the rejected object because people generally choose items that they rate higher.

Figure 3: Mean spread of alternatives following free choice.

The relation between the decision and the chosen object is positive because the better-liked object is chosen. The two objects are negatively related because they compete for an exclusive choice. Both relations have high values in the control condition. To implement self-affirmation, initial activations and weights are scaled by .5. Networks in each condition were run for 40 cycles, which was sufficient for saturation. As is customary in our simulations, all weights and initial unit activations were randomized at up to .1, .5, or 1 of the values shown in Tables 2 and 3. Other parameter settings are also the same as in our other dissonance simulations.

Table 2: Initial net activations for free choice.

Cognition	Condition	
	Control	Affirmation
Chosen	.30	.15
Rejected	.20	.10
Decision	.50	.25

## Results

Spread between evaluations of the two choices was computed as in Steele (1988). Change in evaluation of each object is the difference between initial evaluation and evaluation after 40 cycles. Spreading of alternatives is the sum of the increase in evaluation of the chosen alternative and the decrease in evaluation of the rejected alternative. Mean spreading of the alternatives is plotted, on the dashed line in Figure 3, at the .5 level of parameter randomization. There is a larger spread of the alternatives in the control than in the self-affirmation condition,  $F(1, 38) = 76, p < .001$ .

Mean dissonance scores across time cycles in networks at .5 parameter randomization are shown in Figure 4 for the two conditions. Although dissonance starts low in both condi-

tions, it drops only in the control condition. Similar results were found at parameter randomizations of .1 and 1.

Table 3: Relations between cognitions for free choice.

Relation of chosen to Rejected	Condition	
	Control	Affirmation
Decision	.50	.25
Rejected	-.50	-.25

## Discussion

Consonance networks yield greater separation of alternatives in the control than in the self-affirmation condition, as found with human participants (Steele, 1988). Dissonance reduction is also greater in the control than in the self-affirmation condition, consistent with the idea that attitude change is driven by dissonance reduction.

Figure 4: Mean dissonance following free choice.

## General Discussion

These simulations extend the consonance model to rather subtle aspects of dissonance reduction involving the self-concept, using the same conventions, mapping principles, and default parameter values as in previous simulations. In all of these cases, dissonance arises when constraints between simultaneously held cognitions are unsatisfied. Dissonance is reduced as the constraints are satisfied, typically by changing evaluations of entities in the situation defined by the dissonance experiment. The self-affirmation phenomena considered here had not previously been simulated and were not generally seen as being closely related to other contemporary dissonance phenomena on emotional arousal. As in earlier simulations, the consonance model is here shown to be robust against parameter variation, as revealed by the fact that even a high degree of parameter randomization does not affect the pattern of overall results.

A key, unifying concept in simulating contemporary dissonance phenomena in self-concept and arousal is that of activity level. An activity scalar adjusts the overall level of activation in networks that represent dissonant situations. In the present simulations, the activity-level scalar operates

much like a tranquilizing drug in arousal simulations (Shultz & Lepper, 1999b), by decreasing activation of the representation of the dissonant situation.

Self-affirmation manipulations are thus hypothesized to decrease the relative importance of being in a dissonant situation. When you feel good about yourself, being in a dissonant situation is not nearly so bothersome, and you become immune to the effects of dissonance reduction. This reveals a somewhat unexpected theoretical communality between arousal and self-concept effects.

This analysis is consistent with recent results on *trivialization* as a mode of dissonance reduction (Simon, Greenberg, & Brehm, 1995). Merely making salient to participants asked to write counter-attitudinal essays the contrast between issues they believe to be of great consequence and the less important topic of their own essays reduces attitude change in the direction of the position advocated.

At the level of the brain or an artificial neural network, the key theoretical notion is that of activity level. Dissonance effects are enhanced by increases in activity level and dampened by decreases in activity level. There are a variety of ways to modulate activity level, including general manipulations such as drugs (Cooper, Zanna, & Taves, 1978) and specific manipulations such as attention to particular cognitions (Read & Miller, 1998a). Consequently, activity level has the potential to unify theoretical understanding of several apparently different dissonance phenomena.

The general success of the consonance model enables a theoretical reinterpretation of dissonance that stresses commonalities with other psychological phenomena that result from constraint satisfaction. Phenomena such as analogical reasoning, person perception, schema completion, attitude change, and dissonance reduction can all be understood in terms of the dynamics of constraint satisfaction (Holyoak & Thagard, 1989; Read & Miller, 1998a, b; Rumelhart, Smolensky, McClelland, & Hinton, 1986; Spellman & Holyoak, 1992; Spellman, Ullman, & Holyoak, 1993; Thagard, 1989).

## Abstract

The paper presents a model suggesting that inductive generalizations in young children could be a function of similarity among compared stimuli. Predictions derived from the model were tested in two experiments where young children and preadolescents were presented with triads of schematic faces (a Target and two Test stimuli) that varied in perceptual similarity, with one of the Test stimuli sharing a linguistic label with the Target. Participants were taught a biological property about the Target and asked to generalize the property to one of the Test stimuli. Results from both experiments support predictions, indicating that for young children, proportions of label-based generalizations varied with featural overlap among the compared stimuli. There were also developmental differences found in effects of labels: while for young children these effects varied with featural overlap, preadolescents relied solely on linguistic labels when performing inductive generalizations.

## Introduction

Inductive generalization is an important component of human thought. Furthermore, some believe that it the most important component because "inductive inference is the only process... by which new knowledge comes into the world" (Fisher, 1935). Therefore, understanding of the development of induction is an important step in understanding of human thought.

One theoretical proposal suggests that induction starts out as a category-based process (see Gelman & Coley, 1991; Gelman, Coley, & Gottfried, 1994, for reviews and discussions). In this case, independent of similarity, generalization within a theoretically-defined category is more likely than generalization across categories. For example, a person is more likely to generalize a property (e.g., the ability to drink) from a bird to another dissimilar looking bird than from a bird to a similar looking airplane (Mandler & McDonough, 1998; Gelman & Markman, 1986; Gelman & Coley, 1991).

The alternative, similarity-based approach, suggests that induction starts out as a special case of the "universal law of generalization" (Shepard, 1987). The law states that the probability of generalizing a response (e.g., fear) from one stimulus to another stimulus varies with featural similarity between the stimuli.

Although the similarity-based approach seems to be more

appealing on the basis of parsimony, it has been often criticized for the failure to constrain the notion of similarity (e.g., Goodman, 1992/1972). Indeed, with the increase of the complexity of predicate structure, it becomes unclear which of these predicates will be used in computing similarity.

Recently, we proposed a model suggesting that for young children, linguistic labels might be an important constraining factor (Sloutsky & Lo, 1999). In a series of experiments, we demonstrated that linguistic labels have larger weights in similarity judgment of young children than other perceptual attributes. We argued that similarity between stimuli patterns decreases as a function of exponential decay (cf. Estes, 1994; Medin, 1975). That is similarity between two labeled stimuli patterns could be calculated using Equation 1:

$$Sim(i, j) = S_{Label}^{1-L} S_{Vis.attr}^{N-k}$$

where  $N$  denotes the total number of visual attributes,  $k$  denotes the number of matches,  $S_{vis.attr}$  denotes values (weights) of a mismatch on a visual attribute,  $S_{Label}$  denotes values of label mismatches, and  $L$  denotes a label match. When there is a label match,  $L = 1$ , and  $S_{Label} = 1$ ; when there is a label mismatch,  $L = 0$ , and  $S_{Label} < 1$ . Because  $S$  varies between 0 and 1, similarity equals to one when there are no mismatches, otherwise it is smaller than 1.

We also suggested that when a child is presented with a Target feature pattern (T) and Test feature patterns (A and B) and asked which of the Test patterns is more similar to the Target, the probability of choosing B could be predicted using Equation 2:

$$P(B) = \frac{Sim(T, B)}{Sim(T, B) + Sim(T, A)}$$

In this paper, we present evidence that the model can account not only for similarity judgement, but for inductive inference of young children as well.

Of course, it could be argued that reliance of young children on linguistic labels when performing induction is an indicator that they perform induction in a category-based manner, because they use linguistic labels as category markers. There is an important caveat, however. If they rely on linguistic labels as category markers, labels should affect induction in a qualitative "all-or-none" manner (i.e., presence or absence of the shared label should be a critical factor in

induction). We predict an alternative course: labels affect induction in a quantitative manner, in accordance with equations 1 and 2. In other words, proportions of label-based generalizations in young children should vary, with the number of visual attributes shared between the compared entities.

## Experiment 1

### Method

**Participants** A group of 87 children aged 4 to 12 years participated in the study. The participants represented three age groups: (1) 32 four-to-five year-olds ( $M = 4.5$  years,  $SD = 0.56$  years; 14 boys and 18 girls), 30 seven-to-eight year-olds ( $M = 8.1$  years,  $SD = 0.5$  years; 15 boys and 15 girls), and 25 eleven-to-twelve year-olds ( $M = 11.8$  years,  $SD = 0.5$  years; 15 boys and 10 girls). The participants were recruited from daycare centers, elementary and middle schools located in middle class suburbs of Columbus, Ohio.

**Materials** The materials included triads of 2" by 2" schematic faces, two of which were Test stimuli and one of which was a Target. Each schematic face had three distinct attributes (shape of head, shape of ears, and shape of nose), and each attribute had three values (e.g., "curve-lined" nose, "straight-lined" nose, and "angled" nose). These materials were identical to those used in Part 1 experiments (Sloutsky & Lo, 1999). Materials also included 36 artificial bi-syllable labels (e.g., *Bala*, *Gula*, and so forth) and a set of unobservable biological properties of the Target. These properties were as follows:

1. Has pink bones
2. Has green brain
3. Has white heart
4. Has orange stomach
5. Has blue fat
6. Has yellow blood

Participants were asked which of the Test stimuli was more likely to share a biological property with the Target.

**Design and Procedure** The experiment had a mixed design with age and labeling condition (label vs. no-label) as between-subject factors and a stimulus pattern condition as a within-subject variable. For both levels of the labeling condition, participants were presented with the same triads of schematic faces, two of which were Test stimuli and one of which was a Target. The only difference was that in the label condition all stimuli were labeled, whereas in the no-label condition these stimuli were not labeled. The stimulus pattern condition included six levels, T-00, T-11, T-22, T-01, T-12, and T-02. Note that T refers to the Target, the first digit refers to the number of attributes shared by Test B with the Target, and the second digit refers to the number of attributes shared by Test A with the Target. In the label condition, the Target always shared labels with Test B and always had labels different from Test A. A female researcher interviewed children in a quiet room in their schools. Before the experimental task, children were introduced to some warm-up questions and were given feedback. In the warm-up

tasks, children were presented with Test and Target stimuli and were asked to choose the Test stimulus that shared a biological property with the Target.

**Warm up Trials.** In the first warm-up trial, participants were presented with a Target (a shark) and two Test stimuli (a bear and a tree branch). In the second warm-up trial, they were presented with a rabbit as a Target, and an apple and a dog as Test stimuli. In the third warm-up trial, children were presented with a fish as a Target, and a turtle and a spider as Test stimuli. In all these warm-up trials, children were first told that the Target stimuli either had bones, blood, or skeleton inside the body. Children then were asked to determine which of the two Test stimuli has the same thing inside the body as the Target. If a child failed to answer induction questions, the researcher explained how each of the Test stimuli could have the same thing as the Target.

**Experimental Trials.** If a child was capable of giving correct answers in two out of three warm-up trials, the researcher proceeded to the main experiment. No child was eliminated from the study since all participants provided satisfactory responses in at least two out of three warm-up trials. In the Label condition, children were first introduced to the labels for the Target and Test pictures and asked to repeat them. All labels used were the same artificial names (e.g. *Bala*, *Guga*) as in Part 1 experiments. After each stimulus was labeled, children were asked to repeat these labels. No labels were introduced in the no-label condition. Children were then introduced to an unobservable biological property that belonged to the Target stimuli and were asked which of the Test stimuli was likely to have this property. Positions of the two Test pictures were counterbalanced across the experimental trials. After children answered the questions, they were asked to provide their justification for their choices. In both conditions, participants of the two older groups had 24 experimental trials (6 within-subject stimulus patterns with 4 trials each), while participants of the youngest group had 18 experimental trials (6 within-subject stimulus patterns with 3 trials each). This reduction in the number of trials was important to avoid fatigue that could lead to random responding in young children. The order of presenting of stimulus patterns was randomized within participants.

Figure 1: Example of stimuli presented in one trial in the T-1-2 condition: The Target shares the overall shape and the nose with Test A and the size of the ears with Test B.

## Results and Discussion

Results indicate that in the no-label condition, participants of all age groups based their inductive inferences on available perceptual information. Proportions of Test B choices broken down by stimulus pattern condition and age groups are presented in Figure 2. Recall that B-choices refer to the selection of the Test stimulus that in the label condition shares the label with the Target. As predicted (see Table 1), for all indeterminate stimulus pattern conditions, when the Target shared equal numbers of attributes with each Test stimulus (i.e., T-00, T-11, and T-22), the proportions of B-choices for all age groups were at chance (one-sample t-tests, all  $ps > .25$ ). Also as predicted, in all determinate stimulus pattern conditions where Test B shared fewer attributes with the Target than Test A (i.e., T-01, T-12, and T-02), the proportions of B-choices for all age groups were below chance (one-sample t-tests, all  $ps < .01$ ).

Figure 2: Induction in the No-Label condition broken down by stimulus pattern condition and age group.

To examine the direction of differences among the stimulus pattern conditions in the no-label condition, proportions of B-choices were subjected to a two-way ANOVA with age as a factor and stimulus pattern condition as a repeated measure. Because proportions of B-choices across the T-00, T-11, and T-22 conditions were very similar (all  $ts < 1$ ), proportions of B-choices were averaged across these conditions into a new aggregated variable T-Equal ("T" stands for the Target and "Equal" indicates that each of the Test stimuli shared equal number of features with the Target). While there were no significant differences in proportions of B-choices among the age groups,  $F(2, 35) = .8, p = .45$ , there was a significant main effect due to the stimulus pattern condition,  $F(3, 105) = 13.5, MSE = 0.1, p < .0001$ . Planned comparisons indicated that T-Equal exhibited the largest proportion of B-choices (46%), whereas T-02 exhibited the smallest proportion of B-choices (11%), all  $ts > 2.2, ps < .05$ . At the same time, T-12 and T-01 did not differ significantly,  $t < 1$ . These results indicate that when only perceptual information was available, participants based their inductive inference on this information: in all age groups inductive inference was a function of the number of attributes shared by the Target with Test stimuli.

Introduction of labels, however, dramatically changed the proportions of B-choices that had been observed in the

no-label condition. Recall that in the label condition, Test B always shared the label with the Target. Proportions of B-choices (i.e., label-based generalizations) in the label condition broken down by age group and stimulus pattern condition are presented in Figure 3. In the oldest group, all participants on all trials, with the exception of one participant on one trial, used labels as the only basis of their induction. At the same time, effects of labels in the two younger groups varied across stimulus pattern condition. Because participants in the older group exhibited no variability in their responses (311 out of 312 responses were label-based generalization), while participants in the two younger groups exhibited variability, the former were not included in the analysis of label-based generalizations across stimulus pattern condition.

Figure 3: Induction in the Label condition broken down by stimulus pattern condition and age group.

Proportions of label-based choices across stimulus pattern condition in the two younger groups were subjected to a two-way (age by stimulus pattern condition) ANOVA with stimulus pattern as a repeated measure. Because proportions of label-based generalizations across the T-00, T-11, and T-22 conditions were statistically equivalent ( $t < 1$ ), these proportions were averaged across these conditions into a new aggregated variable T-Equal. The analysis indicates a significant main effect due to stimulus pattern condition,  $F(3, 102) = 2.8, MSE = 0.06, p < .05$ , whereas neither main effects of age group, nor the interaction of the two factors were significant ( $p = .15$  and  $p = .8$ , respectively). Planned comparisons pointed to significant differences between the T-Equal condition and the T-12 and T-02 conditions, all  $ts(35) > 2.1, ps < .05$ . In short, as predicted, in the oldest group the proportion of selecting Test B did not vary across the stimulus pattern conditions, whereas this proportion did vary as a function of stimulus pattern condition in the two younger groups. Although differences among the stimulus pattern conditions may appear relatively small (in particular, differences between T-02, on the one hand, and T-01 and T-12, on the other hand, fell short of statistical significance), the direction of these differences, except for the T-02 condition in the middle group, closely match predictions derived from Equations 1 and 2.

Overall fit between predicted probabilities and observed frequencies is presented in Figure 4. Each data point in Figure 4 represents responses of to each stimulus pattern

averaged within age groups. Note that Figure 4 depicts performance of children in the two younger groups in the label and no label conditions. In addition to a high correlation between the predicted and observed probabilities ( $r = .96$ ), the proposed theoretical model accounts for approximately 92% of the observed variance ( $R^2 = .919$ ). These findings support the notion that for younger children labels contribute to specific induction in a quantitative manner and that this contribution varies with the number of attributes shared by Test A and Test B with the Target. Note that Figure 4 does not include performance of the oldest group, because their induction was not derived from Equations 1 and 2. On the contrary, their induction was predicted to be category-based, as opposed to similarity-based induction of younger children.

Figure 4: Theoretical probabilities (computed from the model using Equations 1 and 2) and observed probabilities of generalization of biological properties to Test B. Note: parameter  $S$  was estimated from our previous research.

Findings of this experiment support our predictions regarding quantitative contribution of labels to inductive inferences of young children. In the absence of labels, participants of all age groups based their inductive inference on perceptual information. However, when labels were introduced, the pattern of choices changed dramatically: preadolescents based their induction solely on labels, whereas younger children based their induction on a combination of labels and the number of overlapping attributes. Therefore, it seems reasonable to infer that preadolescents performed induction in a category-based manner, whereas younger children performed induction in a similarity-based manner.

However, it could be argued that these findings strongly support predictions for preadolescents' induction, while providing only tentative support of predictions for young children's induction. The support is tentative because some differences among the stimulus pattern conditions, while all in predicted directions, failed to reach significance. Because of this, we deemed it necessary to conduct a second experiment, replicating the current experiment for young children while simplifying the task, and increasing the sample sizes and the number of trials.

## Experiment 2

### Method

**Participants** A group of 30 four-year-old children ( $M = 4.3$  years,  $SD = 0.5$  years; 19 boys and 11 girls) participated in the experiment. The participants were recruited from daycare centers located in middle class suburbs of Columbus, Ohio.

**Materials** The materials included triads of schematic faces identical to those used in Experiment 1.

**Design and procedure** The design and procedure were identical to that in Experiment 1 with three exceptions. First, the current experiment included only a label condition. Second, the "why" questions that accompanied children's choices in Experiment 1 were dropped. Finally, the number of trials within each stimulus pattern condition was increased from three to four.

### Results and Discussion

Proportions of label-based generalizations across the stimulus pattern conditions are presented in Figure 5. Because proportions of label-based generalizations in T-00, T-11, T-22 conditions were statistically equivalent (87%, 85%, and 87% respectively,  $ts < 0.5$ ), participants' responses were averaged across these conditions into a new variable T-Equal. Proportions of label-based generalizations in T-Equal, T-01, T-12, and T-02 conditions were subjected to a one-way repeated measures ANOVA. The analysis points to significant differences among the stimulus pattern conditions,  $F(3, 87) = 16.744$ ,  $MSE = 1.15$ ,  $p < 0.0001$ . Planned comparisons pointed to the following order among the conditions in the proportion of label-based generalizations: T-Equal (86%) > T-12 (63%) = T-01 (56%) > T-02 (39%). All indicated differences were significant, all  $ts > 3.5$ , Bonferroni adjusted  $ps < .01$ , while the difference between T-12 and T-01 was not significant,  $t < 1$ . These results clearly indicate that the proportion of label-based generalizations varied as a function of the number of features shared by the Target with each of the test stimuli, thus further supporting the notion of similarity-based specific induction in young children.

Figure 5: Proportions of label-based generalizations across the stimulus pattern conditions.

## General Discussion

Results of the two reported experiments are as follows. In Experiment 1, when labels were not provided, 4-5 year-olds, 7-8 year-olds, and 11-12 year-olds relied on perceptual similarity when making specific induction with novel entities. At the same time, when labels were introduced, preadolescents made inductive inferences based solely on the basis of the provided label, whereas specific induction of younger children varied with the number of attributes (which includes labels) shared by the Target and Test stimuli. Results of Experiment 2 further indicated that proportions of label-based generalizations in young children varied as a function of visual attributes shared by the Target with each of the Test stimuli. These results fit predictions, indicating that the model proposed by Sloutsky & Lo (1999) can account for specific induction of younger children and that specific induction of the younger children is similarity-based.

The results of the no-label condition indicate that for all three age groups, similarity-based specific induction is the default mechanism (cf. Keil, 1989). When no other information was available, participants of all age groups used perceptual similarity to generalize biological properties from the Target to Test stimuli. Therefore, if similarity-based induction is the default mechanism, it seems likely that it might developmentally precede category-based induction. This contention was supported by results of the label condition.

The results of the label condition supported the notion of different mechanisms underlying specific induction in young children and preadolescents, thus allowing the resolving of an apparent paradox of specific induction. The paradox is as follows. On the one hand, if specific induction is category-based, it should be dependent on general induction and the ability to perform induction-deduction coordination. On the other hand, even three year-olds are capable of performing specific induction (Gelman & Markman, 1987). The reported results suggest that specific induction does not have to be category-based -- it may start out as similarity-based and develop into category-based later. The reported experiments support this notion, suggesting that this shift may occur sometime between nine and eleven years of age. Indeed, while specific induction of 7-8 year-olds appeared to conform to the proposed model and to vary with a number of perceptual attributes shared by the Target and Test stimuli, specific induction of 11-12 year-olds appeared to be independent of shared attributes and to be a function of labels.

It is also important that for younger children, labels exert similar effects on similarity judgment and specific induction. At the same time, in preadolescents these effects are fundamentally different. While labels had no effect on similarity judgment of preadolescents (Sloutsky & Lo, 1999), in specific induction preadolescents relied solely on labels. These findings further support the possibility of a developmental shift from similarity-based to category-based induction occurring between 9 and 11 years of age.

This developmental shift may be a function of the

development of a categorical structure: when two objects share a label they are more likely to be considered members of the same category than to be considered members of different categories. When a categorical structure is in place, the probability that two remotely similar entities that have the same label would be considered members of different categories could be estimated by the base rate of homonyms (and homophones), and therefore is negligibly small. In fact, we drew a random sample of 200 most frequently used English nouns from Francis and Kucera (1982) and asked three native English speakers to mark those that have homonyms and homophones. While the overall rate of homonyms and homophones appeared to be relatively high (ranging from 20% to 30%), many of these homonyms and homophones were adjectives and verbs (e.g., horse/hoarse or board/bored). At the same time, the rate of noun-noun homonyms (e.g., case/case) was around 5%. Furthermore, the rate of a noun having a homonym within the same ontological class (e.g., living creature having a homonym that indicates a completely different living creature) was practically nonexistent. Hence, remotely similar entities that share the label should be interpreted as members of the same category and, therefore, to share unobservable properties as well. In short, the label-as-attribute model proposed by Sloutsky & Lo (1999) can account not only for similarity judgment of younger children, but also for their specific induction.

While the model provides a reasonable account of specific induction with artificial stimuli that are relatively similar on the overall scale, it remains unclear whether or not the model is capable of handling more naturalistic and diverse set of stimuli. Our most immediate concern is to test the model with these kinds of stimuli. Because our stimuli were quite similar overall (all pictures represent human-like faces) it is possible that results might have been different had the stimuli been more different. It is also possible that results might have been different if stimuli were not human-like: infants and young children have been shown to develop different types of representations of humans and animals (Quinn & Eimas, 1998). While the former could be represented as individual exemplars, the latter may have summary (i.e., category-based yet perceptual) representations. However, we believe that introduction of more different and more diverse stimuli would make differences between younger and older children even more apparent, because stimuli would increase perceptual-similarity-based variance in the younger groups without increasing this variance in the older group.

If induction in young children is based on overall similarity among compared entities then introduction of new attributes (both perceptual and non-perceptual) that contribute to overall similarity, should also contribute to inductive generalizations. It would be important to test this prediction and to estimate weights of different classes of attributes. It would be also important to trace changes in these weights with development and learning. Finally, it would be necessary to test the model on younger participants and have more dense developmental observations.

Because the proposed model is capable of formulating specific predictions, these predictions can be tested in future research. For example, we contend that specific induction in young children is similarity-based, whereas preadolescents it is category-based. If this is true, then for younger children specific induction should be easier than general induction, while for older children it should be more difficult (because category-based specific induction requires more mental steps than general induction). However, if specific induction in younger children is also category-based, then in both younger and older children specific induction should be more difficult than general induction.

Recall that the label-as-attribute model also affords the computation of specific probabilities of inductive generalizations across stimuli that vary in overall similarity. In future research, we plan to test these predictions of the model with respect to naturalistic stimuli. Because it is impossible to individuate features and to precisely calculate featural overlap with complex naturalistic stimuli patterns, we will manipulate similarity by "morphing" naturalistic pictures into each other in a fixed number of steps.

## Abstract

It has been well established that experts and novices focus on different aspects of problems, with novices focusing more on surface features rather than on deep principled features of a problem. What is less clear are the mechanisms that underlie these differences in construal of problem representation. The current study, which uses an 'old/new' recognition procedure, examines expert and novice representation of arithmetic equations in which the deep relational properties (i.e., principles of commutativity and associativity) were well known to both groups. Results indicate that both novices and experts encode both surface and principled features in the same serial manner, with surface features preceding principled features for both. At the same time, only for novices and not for experts, surface features compete with deep features, thus requiring additional resources to inhibit this attentional competition.

## Introduction

Mental representation is a central component of several fundamental cognitive processes, including categorization, reasoning, decision making, and problem solving. For example, the way an entity is categorized depends on the content of an organism's mental representation regarding this entity and the similarity of this representation to a composite representation stored in memory (Estes, 1994; Nosofsky, 1988). In addition, the way people reason from propositions and what they infer from these propositions depends on the manner in which these propositions are mentally represented (Byrne, 1989; Johnson-Laird & Byrne, 1991; Johnson-Laird, Legrenzi, Girotto, Legrenzi, & Caverni, 1999). Finally, the content of a mental representation determines the approaches and strategies people use when they attempt to solve problems (Kaplan & Simon, 1990; Larkin & Simon, 1987; Newell & Simon, 1972). Of course, the content of mental representation may depend on knowledge of the conceptual and relational structure of the domain, and transformational procedures and algorithms (Anderson, 1982; 1990; Case & Okamoto, 1996; Gelman & Meck, 1986, 1992; Hebert & Lefevre, 1986; Rittle-Johnson & Alibali, 1999). For example, the problem "Bill has eight marbles and Jill has six times more" would be represented as " $8 \times 6 = ?$ ", only if

the person has knowledge of and can abstract basic multiplication algorithms.

As noted above, there is a distinction between the content of a mental representation (or what is represented) and the process of construing this content (or what is attended to, encoded, and stored). The process of construing mental representations remains largely unknown, and is the focus of this paper. However, there are several important regularities that have been established with respect to the content of mental representation that are important for the study of the process of construing of mental representation.

In Part 1 of this paper (Yarlas & Sloutsky, 2000) and elsewhere (Yarlas & Sloutsky, 1999), we describe a large body of literature indicating that in problem solving, reasoning, learning and transfer, and problem categorization, novices and experts construe representations that differ in their content. In particular, novices tend to focus on surface features of the problem, whereas experts tend to focus on deep relational features (e.g., Chase & Simon, 1973; Chi, Feltovich, & Glaser, 1981; Gentner & Toupin, 1986; Kotovsky & Gentner, 1996; Larkin, 1983; Simon & Simon, 1978; Yarlas & Sloutsky, 1999). These effects have been demonstrated across a variety of knowledge-rich and knowledge-lean domains.

However, in spite of these well-established expert-novice differences, it remains unclear what accounts for these differences. Do differences occur because experts have knowledge of deep relational properties and novices do not? Do they occur because novices are less intelligent or younger than experts are, and they cannot grasp deep relational properties? Do experts and novices differ in processes underlying the construal of a problem representation? Or do differences stem from a combination of these factors?

In Part 1 of this paper (Yarlas & Sloutsky, 2000), we focused on expert-novice differences in the content of mental representations. It was demonstrated that when tasks are sufficiently simple and deep relational properties are well known, neither differences in knowledge, intelligence, nor development can fully account for the observed differences between novices and experts. In a series of experiments designed to distinguish among these possibilities, tasks were constructed that included principles of arithmetic familiar to novices, and surface features that were completely superfluous with respect to deep relational features. In particular,

they asked participants varying in age and degree of expertise to sort mathematical equations that could have common surface elements (e.g., commonality of numbers or the same number of constituent addends in the equation) or common deep mathematical principles (e.g., commutativity or associativity). Results indicated that only mathematics experts consistently focused on principles, whereas novices, regardless of age and intelligence, focused mostly on surface features. However, elimination of surface features led to substantial increase in focusing on principles. Interestingly, the reintroduction of surface features reduced participants' focus on principles to their original low levels. These and other manipulations allowed us to argue that differences between novices and experts stem from differences in processes underlying the construal of a problem representation. However, if novices have knowledge of the principles in question yet still fail to represent them, then several questions arise about processes underlying problem representations in novices and experts. Do novices initially encode both deep and surface features, but later discard the deep relational properties, or do they simply fail to encode the deep relational properties? And what are the processing mechanisms underlying problem representations in experts: do experts encode and discard surface features, or do they ignore these features from the very beginning?

To answer these questions, we used an 'old/new' recognition paradigm in the current experiment. This paradigm affords the creation of a set of foils, such that patterns of hits and false alarms point to which aspects of problems have been encoded and committed to memory and which aspects have been left out. In the study phase, participants were presented with a set of arithmetic equations. These equations all utilized a principled property, either associativity or commutativity. The former states that for addition, subtraction, and multiplication, constituent parts can be decomposed and recombined in different ways (e.g.,  $a + b = [a - c + c] + b$ ). The latter states that the order of elements is irrelevant for addition and multiplication (e.g.,  $a + b + c = b + c + a$ ). In addition, these equations all used consistent levels of two surface elements: all equations used numbers ranging between 1 and 9, and all used either 5 or 6 numbers in the equation. In the recognition phase of the experiment, in addition to 'old' items, four combinations of 'new' equations were presented as foils. Half of these foils, which we refer to as 'feature +' foils, maintained the same levels of surface features as used in the learning phase (i.e., numbers ranging between 1 and 9, and either 5 or 6 numbers in the equation), while the other half of the foils, which we refer to as 'feature -' foils, violated these categories (i.e., numbers greater than 9, and either 4 or 7 numbers in the equation). Also, half of the foils, which we refer to as 'principle +' foils, maintained the use of one of the two principled properties, while the other half, which we refer to as 'principle -' foils, did not use any principled properties in the equation. The two levels of the two kinds of properties (feature being either + or -, and principles being either + or -) were fully-crossed, thus creating four combinations of foils: feature + /principle + (F+/P+), feature + /principle - (F+/P-), feature -/principle + (F-/P+), and feature -/principle - (F-/P-). For example, for the equation  $5 + 3 + 6 = 3 + 6 + 5$  in the study phase, the

following foils were presented in the recognition phase: (1)  $5 + 3 + 6 = 3 + 6 + 5$  (Old), (2)  $7 + 4 + 2 = 4 + 2 + 7$  (F+/P+), (3)  $5 + 3 + 6 = 3 + 4 + 7$  (F+/P-), (4)  $11 + 9 = 9 + 11$  (F-/P+), and (5)  $14 + 7 = 9 + 12$  (F-/P-).

The goal of this paper is to elucidate processes underlying problem representations in novices and experts. In this article, we consider and test a number of possible processing models for both novices and experts, which are summarized in Table 1.

Table 1: Summary of considered processing models

Novice Model 1	Encode only surface features with no encoding of deep structural features
Novice Model 2	Encode both surface and deep structural features; attentional competition between surface and structural features, with surface features winning
Expert Model 1	Encode only deep structural features with no encoding of surface features
Expert Model 2	Encode both deep structural and surface features; attentional competition between structural and surface features, with structural features winning
Expert Model 3	Encode both deep structural and surface features; no attentional competition

For this task, if novices encode only surface features and not relational features, they should rapidly respond "Old" when surface features are present and they should rapidly respond "New" when surface features are absent (Novice model 1). Similarly, if experts encode only principles and not surface features, they should rapidly respond "Old" when principles are present and they should rapidly respond "New" when principles are absent. If either group encodes both principles and features, they should exhibit more complex patterns of responses (Expert model 1).

There is preliminary evidence (Yarlas & Sloutsky, 1999) that novices do encode both surface and deep features, but discard the latter in the course of attentional competition (Novice model 2). However, while processing mechanisms underlying problem representations in novices require further clarifications, these mechanisms in experts remain unclear. One possibility is that experts start construing problem representations from deep rather than from surface (Expert model 2). An alternative possibility is that experts construe representations in a manner similar to that of novices, except that there is no attentional competition in experts (Expert model 3). Of course, it is also possible that experts construe representations in a parallel manner, in which case their response latencies should exhibit small or no differences across the foils.

The alternative response patterns derived from the models summarized in Table 1 are presented in Table 2. These predictions are based on the following two assumptions: (1) both experts and novices process properties of problems in a serial manner and (2) each additional step in processing leads to increase in latencies. Both assumptions were previously corroborated using this task with novices (Yarlas &

Table 2: Patterns of responses and latencies predicted by alternative models for novices and experts

Models of responses	Foil Types and Patterns of Responses				
	Old targets	F+/P+	F+/P-	F-/P+	F-/P-
Novices Model 1 (Response type)	OLD	OLD	OLD	NEW	NEW
Novices Model 1 (Latency)	Fast	Fast	Fast	Fast	Fast
Novices Model 2 (Response type)	OLD	OLD	NEW	NEW	NEW
Novices Model 2 (Latency)	Slow	Slow	Very Slow	Fast	Fast
Experts Model 1 (Response type)	OLD	OLD	NEW	OLD	NEW
Experts Model 1 (Latency)	Fast	Fast	Fast	Fast	Fast
Experts Model 2 (Response type)	OLD	OLD	NEW	NEW	NEW
Experts Model 2 (Latency)	Slow	Slow	Fast	Slow	Fast
Experts Model 3 (Response type)	OLD	OLD	NEW	NEW	NEW
Experts Model 3 (Latency)	Slow	Slow	Slow	Fast	Fast

Sloutsky, 1999). Because of these assumptions, the parallel processing model is absent from Table 1; however we do not discount the possibility of parallel processing in experts. Note that predictions presented in Table 2 are qualitative, in that they do not specify accuracy or latency across the conditions, but rather point to (a) patterns of recognition responses and (b) directions of differences in latencies.

Note that the tables have two critical components. First, in novices, responses to F+/P- foils afford either corroboration or elimination of Model 1 for novices (see Table 1), whereas in experts, responses to F-/P+ foils afford corroboration or elimination of Model 1 for experts (see Table 1). Second, within experts and novices, patterns of differences in latencies afford the selection of the more plausible model as well as the description of specific processing components. Specifically, latencies in experts' responses to F+/P- items will allow for discriminating between Model 2 and Model 3 for experts. In short, patterns presented in the table should allow us to distinguish between processing models in novices and experts presented in Table 1.

## Method

### Participants

Two samples, representing novices and experts, were used in this study. The novice group included twenty-three undergraduates in an introductory psychology course at the Ohio State University who participated for partial course credit. This sample had an average age of 19.2 years ( $SD = 0.9$  years), with 12 women and 11 men. The expert group included twelve graduate students in the Mathematics Department at the same university who participated for a payment of twenty dollars. This sample had an average age of 27.6 years ( $SD = 5.8$  years), with 3 women and 9 men.

### Materials and Procedure

The materials and procedures used in this study were identical for participants in both the novice and expert samples. All participants were run individually with stimuli presented by a personal computer using SuperLab software (Cedrus Corporation, 1999).

The experiment consisted of three phases: the study phase, the distraction phase, and the recognition phase. In the study

phase, participants were presented with thirty arithmetic equations, which they had been instructed to memorize. All thirty equations used addition, used numbers ranging from 1 to 9, contained either 5 or 6 numbers, and used either the associative or commutative principle (half for each). Each equation was centered and presented in dark type on a white screen for ten seconds, with a two-second interval between each, during which only the white background was seen. The order of equations was randomized across participants.

A distraction phase followed the study phase for the purpose of clearing participants' short-term memory. For the distraction task, participants were presented with ninety letters, for which they had been instructed to indicate whether the letter was a vowel or a consonant. This phase took approximately three minutes.

Following the distraction phase was the recognition phase. Participants were told that they would be presented with a number of arithmetic equations, some of which had been presented to them earlier and some of which had not been presented earlier, and that they were to decide whether each equation was 'old' or 'new'. There were a total of sixty equations presented in the recognition phase. The order of equations presented in this phase was randomized across participants. There were five categories of foils, with twelve exemplars for each category. Recall that these foils included: (1) Old targets that had been presented earlier in the learning phase, (2) F+/P+ equations, which used similar surface features and used either the commutativity or associativity principle as in the original equations, (3) F+/P- equations, which used similar surface features as the original equations but did not use either the commutativity or associativity principle, (4) F-/P+ equations, which used surface features different from those used in the original equations but used either the commutativity or associativity principle, and (4) F-/P- equations, which used surface features different from those used in the original equations and did not use either the commutativity or associativity principle.

## Results and Discussion

In this section, we will first discuss the accuracy of recognition and latencies of responses for novices, and then for experts. For each group, we will first examine overall accu-

curacy of response to the foils (i.e., correct acceptance of Old targets and correct rejection of all foils). We will then compare participants' "Old" responses and latencies across the foil types. Note that for all foils except F+/P+, we compared latencies for correct responses only. Because we expected a large number of false alarms for F+/P+ foils, for these foils, latencies for both correct and incorrect responses were used in the analyses.

Novices exhibited high overall accuracy for most of the foils, correctly accepting Old targets and correctly rejecting F-/P+, F-/P-, and F+/P- foils. They mostly false alarmed, however, on F+/P+ foils. The latter finding is expected because F+/P+ foils were categorically indistinguishable from Old targets, since both surface features and principled features present in Old targets were also present in F+/P+ foils. More specifically, results indicate that accuracy rates (i.e., hits for Old Targets and correct rejections for the other foils) for F+/P- ( $M = 0.69, SD = 0.35$ ), F-/P- ( $M = 0.93, SD = 0.20$ ), F-/P+ ( $M = 0.97, SD = 0.16$ ), and Old targets ( $M = 0.84, SD = 0.15$ ) were significantly higher than chance (all  $t(22) > 9.4, ps < .001$ ), whereas for F+/P+ ( $M = 0.36, SD = 0.26$ ) accuracy was significantly lower than chance,  $t(22) = -6.4, p < .001$ . These results indicate that these participants took the task seriously and were providing rather accurate responses.

Percentages of "Old" responses and latencies for novices are presented in Figure 1. A one-way repeated measures ANOVA points to significant differences among foils for novices ( $F(4, 88) = 53.9, MSE = 542.7, p < .0001$ ). Paired-samples t-tests indicated the following the following direction in the proportion of "Old" responses: Old targets  $>$  F+/P+  $>$  F+/P-  $>$  F-/P+ = F-/P-, all  $t(22) > 3$ , all Bonferroni adjusted  $ps < .05$  for differences.

Novices' latencies to different foils are also presented in Figure 1. These measures were also subjected to a one-way repeated measures ANOVA. The analysis indicates significant differences among the foils,  $F(4, 76) = 15.48, p < .001$ . Planned comparisons revealed that F+/P- latencies were significantly higher than those for Old targets,  $t(20) = 3.4, p < .005$ , whereas latencies of F-/P- and F-/P+ foils were significantly lower than those of the Old targets,  $t(21) > 3.5, ps < .005$ .

These data allow us to rule out Model 1 presented in Table 1 -- novices did not base their responses solely on the presence or absence of surface features. When surface features were absent (F-/P- and F-/P+ foils) participants produced fast and accurate "New" responses; however, when surface features were present, novices did not always produce "Old" answers. Rather, novices' responses were mediated by the presence or absence of principled features. In particular, when both surface and principled features were present (Old targets and F+/P+ foils) novices generally responded "Old". These responses were slower than those for F-/P- and F-/P+ foils. Finally, when surface features were present but principles were absent (F+/P- foils), participants in general accurately rejected these foils, but latencies for these correct rejections were significantly higher than latencies for Old targets. These findings support the notion of the attentional competition between the two types of features (see Table 1, Novice model 2), pointing to a relative difficulty for partici-

pants to inhibit the salient surface feature and reject the foil. Of course, these data raise an interesting question of whether or not experts would also exhibit attentional competition between deep relational and surface features.

Figure 1. Proportion of novices' "Old" responses and response times (in milliseconds) across foil types in the recognition phase.

Similarly to novices, experts exhibited high overall accuracy for most of the foils, correctly accepting Old targets and correctly rejecting F-/P+, F-/P-, and F+/P- foils. They too mostly false alarmed, however, on F+/P+ foils. More specifically, accuracy rates (i.e., hits for Old Targets and correct rejections for the other foils) for F+/P- ( $M = 0.96$ ,

$SD = 0.06$ ), F-/P- ( $M = 1.00$ ,  $SD = 0.00$ ), F-/P+ ( $M = 0.98$ ,  $SD = 0.04$ ), and Old targets ( $M = 0.90$ ,  $SD = 0.05$ ) were significantly higher than chance (all  $t_s(11) > 58$ ,  $p_s < .001$ ), whereas for F+/P+ ( $M = 0.15$ ,  $SD = 0.09$ ) accuracy was significantly lower than chance,  $t(11) = -5.1$ ,  $p < .001$ . These results indicate that experts also took the task seriously and provided rather accurate responses.

Percentages of "Old" responses and latencies for experts are presented in Figure 2. A one-way repeated measures ANOVA points to significant differences among foils for experts ( $F(4, 44) = 768.5$ ,  $MSE = 34.2$ ,  $p < .0001$ ). Paired-samples t-tests indicated the following the following direction in the proportion of "Old" responses: Old targets = F+/P+ > F+/P- = F-/P+ = F-/P-, all  $t_s(22) > 23$ , all Bonfer-

oni adjusted  $p_s < .0001$  for differences.

Figure 2. Proportion of experts' "Old" responses and response times (in milliseconds) across foil types in the recognition phase.

Experts' latencies to different foils are also presented in Figure 2. These measures were also subjected to a one-way repeated measures ANOVA. The analysis indicates significant differences among the foils,  $F(4, 44) = 18.60$ ,  $p < .001$ . Planned comparison revealed that, in contrast to novices, F+/P- latencies for experts were not significantly different from those for Old targets,  $t(11) = 0.2$ ,  $p = .85$ , but that latencies for F-/P- and F-/P+ foils were again significantly lower than those of the Old targets,  $t_s(11) > 4$ ,  $p_s < .005$ .

The analysis of hits and false alarms allows us to eliminate Model 1 of expert responses presented in Table 1. Indeed, according to this model, experts should have responded "New" when principles were absent, and respond "Old" when principles were present. However, the F-/P+ foils almost invariably generated "New" responses, thus eliminating Model 1. Similarly, the analysis of latencies affords the elimination of Model 2. Recall that according to this model, experts should have more rapidly answered "New" when the principle was absent than when the feature was absent. However, the observed findings are consistent with Model 3 and not with Model 2, given that F-P+ foils were rejected faster than F+P- foils. Therefore, results of the experiment support Model 2 for novices and Model 3 for experts.

These findings point to important processing similarities and differences in experts and novices. First, both experts and novices exhibited serial processing. In addition, when construing problem representations, both experts and novices encode features first. At the same time, only novices experience competition between salient surface features and less salient deep principles. For the majority of novices, well known deep principles end up winning the competition; however, the competition takes time and effort. At the same time, experts represent both deep and surface features of the problem and do not experience such attentional competition. Recall that the experiment employed a very simple recognition task. In more resource demanding tasks, such as categorization, reasoning, or problem solving, deep relational features in novices may lose attentional competition to salient surface features. This loss would manifest itself in novices' tendency to focus on surface feature, while ignoring deep relational features (Chase & Simon, 1973; Chi, Feltoich, & Glaser, 1981; Gentner & Toupin, 1986; Kotovsky & Gentner, 1996; Larkin, 1983; Simon & Simon, 1978; Yarlas & Sloutsky, 1999).

The results have several potential implications. First, they lead to a better understanding of expertise, indicating that expert-novice differences persist even with most simple tasks (it is reasonable to expect that more complex tasks would result in more dramatic expert-novice differences). Second, the results have important educational implications, suggesting that salient surface features may deter rather than promote learning.

## Conclusion

The reported findings indicate that even when a task is very simple, experts and novices construct problem representations differently. While both experts and novices encode deep as well as surface features of the problem, only

for novices and not for experts, surface features compete with deep features, thus requiring additional resources to inhibit this attentional competition. These findings may or may not hold for less familiar deep principles or more complicated tasks. However, these results allow us to conclude that even when a task is very simple and deep principles are well known, experts and novices differ in processes underlying the construal of problem representations.

### Abstract

These experiments were designed to discover whether untrained speakers produce prosodic cues that are sufficient to allow listeners to interpret ambiguous PP-attachments. A referential communication task was used to elicit productions of ambiguous sentences and determine whether listeners could use prosodic cues to correctly interpret these ambiguities in context. In Experiment 1, the referential context supported both potential interpretations of the ambiguity. Acoustic analyses indicated that Speakers produced potentially informative prosodic cues. Listeners' responses to the ambiguous sentences strongly reflected the demonstration the Speaker had seen, indicating that they were able to use this information. However, post-experiment interviews revealed that Speakers were aware of the ambiguous situations. Experiment 2 manipulated Speaker awareness by altering the Speaker's referential context to support only the intended meaning, and by making the resolution of the ambiguity a between subjects variable. Although Listeners' contexts were unchanged from Experiment 1, Listeners now showed no sensitivity to the Speakers' intended meaning. Acoustic analysis indicated that the strong prosodic cues provided in Experiment 1 were absent in Experiment 2. The experiments suggest that informative prosodic cues depend upon speakers' knowledge of the situation: speakers provide prosodic cues when needed; listeners use these prosodic cues when present.

### Introduction

One of the current challenges for research on prosody and syntactic ambiguity is to bring together what we know about the listener with what we know about the speaker. In doing so, we can begin to understand whether the prosodic cues that are available in speech can influence a listener's interpretation. The research reported here attempts to address this challenge by examining how a speaker uses prosody in the face of ambiguity and whether an accompanying listener is able to interpret the speaker's intended meaning. We will propose from this research that prosodic cues in adult-to-adult speech often depend upon the speakers' knowledge of the referential context. In particular, the choice to provide helpful prosodic cues depends upon whether or not the referential situation furnishes other cues that could help resolve the ambiguity.

Prior research on prosody and syntactic ambiguity has focused almost exclusively on either the speaker or the listener, and only rarely on the interaction between the two.

This division of labor has led to important advances in our understanding of prosody; we know a fair amount about what listeners can do with prosodic cues, and what prosodic cues speakers can produce.

Numerous language comprehension studies have demonstrated that prosodic manipulations of the linguistic input can influence comprehenders' on-line and off-line decisions about syntactic ambiguity (for reviews see, Warren, 1996; Kjelgaard & Speer, 1999). These studies have used a wide variety of experimental techniques, including cross-modal naming, lexical decision, word monitoring, and sentence judgments, and have found effects of prosody on the interpretation of a variety of temporary and global ambiguities. Likewise, studies of language production have found that the prosody of an utterance often reflects its syntactic structure (Cooper & Paccia-Cooper, 1980). Moreover, informed speakers can mark different meanings of an ambiguous string through prosodic grouping (Lehiste, 1976; Allbritton et al., 1996). These studies suggest that speakers of a language share knowledge about prosodic cues to syntax, and can use this information in decisions about production.

Curiously, most comprehension and production studies have relied upon distorted and/or artificial manipulations of prosodic information. In comprehension studies prosody is typically manipulated by splicing silent pauses into speech to indicate clause boundaries, manipulating synthesized speech, or asking trained speakers to produce particular prosodic variants of an utterance. Production studies have relied upon data from trained speakers, such as radio announcers, who have been explicitly instructed to contrast the alternate interpretations of an ambiguous sentence. Notably, few studies of prosody and syntax have examined how untrained listeners respond to the speech of untrained speakers in contexts in which the participants are attempting to communicate about a shared situation.

In naturally occurring speech, syntactic structure is only a weak predictor of prosodic variation (for review see Fernald & McRoberts, 1996) This is because prosodic patterns are affected by many other factors, including the length and stress pattern of words, speech rate and discourse factors such as contrastive stress (Selkirk, 1984). Unsurprisingly, a number of researchers have found that naïve speakers produce less consistent prosodic cues for syntactic disambiguation than the informed speakers typically used in comprehension experiments (Lehiste, 1973; Wales & Toner, 1979;

Allbritton, McKoon, & Ratcliffe, 1996). In the most relevant of these studies, Allbritton et al. (1996) compared situations in which speakers were uninformed or explicitly informed about potential ambiguities. In the uninformed case, untrained speakers (undergraduate students) and professional speakers (radio announcers) were asked to read paragraphs containing globally ambiguous sentences (e.g., “They rose early in May”) which had been disambiguated by the prior context. In the informed case, radio announcers were provided with the same globally ambiguous sentences without a disambiguating context, both of the meanings were explained to the speaker, and he/she was asked to read the sentence twice, to convey each of these meanings.

Recordings of these utterances were played for a separate group of subjects who were given both meanings and asked to identify the one that the speaker was attempting to convey. The findings from this judgment task revealed, in the words of the authors, that “most speakers trained or not, did not produce prosodically disambiguated utterances for most sentences. Trained, professional speakers reliably produced appropriate disambiguating prosody only when they were shown the two meanings of the sentence side by side and were explicitly asked to pronounce the sentence twice.”

There are three plausible explanations of the Allbritton et al. findings, each of which has different implications for the role of prosody in syntactic ambiguity resolution. First, it is possible, as the authors claim, that speakers only produce reliable cues when instructed to do so. However, this would suggest that prosodic cues to structure are rare in natural speech, raising questions about how listeners become sensitive to these cues. Second, the results could be interpreted as evidence that speakers only produce reliable cues when the surrounding context does not disambiguate the utterance. In the Allbritton et al. study, experimental naïveté and contextual constraint were confounded. Perhaps, as Lieberman (1967) suggested, speakers don’t bother to divide up an utterance into informative prosodic chunks if other cues are present to disambiguate structure. Finally, it is possible that speakers do not produce reliable prosodic cues when reading connected text, regardless of whether that text provides a disambiguating context.

Recently, Schafer, Speer, Warren & White (1999) have presented data which challenges the Allbritton findings. They elicited prosodic variants of temporary and global ambiguities from uninstructed subjects by having them play a game that used a set of scripted commands. These utterances were submitted to acoustic and phonological analyses and a judgement task parallel to that conducted by Allbritton et al. (1996). In all three analyses Schafer and colleagues found evidence that speakers produced consistent prosodic cues to the intended structure. They attribute the divergent findings to differences in the tasks that were used, suggesting that the subjects in the earlier study were reading and had no clear communicative intentions.

The current paper attempts to explore the role of prosodic cues in language production and comprehension. In particular, we examine the situations under which untrained speakers can produce reliable prosodic cues that will allow listeners to resolve attachment ambiguities. The critical sentences are ones that contain globally ambiguous preposi-

tional phrase attachments, such as “Tap the frog with the flower”. Out of context, the phrase “with the flower” can be taken as Instrument (VP-Attachment) indicating what to use for the tapping, or the phrase can be taken as a Modifier (NP-attachment) indicating which frog to tap.

These experiments were conducted using a referential communication task, in which a Speaker and a Listener were separated by a divider, allowing for only verbal communication between the two participants. Under discussion in these studies was the movement of objects, with Speaker attempting to have the Listener perform actions upon an identical set of objects on the other side of the screen. This situation provided two advantages of over other common tasks. First, the referential context was highly salient, and was defined by the set of objects in front of the speaker and listener. Memory considerations for referential factors (e.g., what a speaker remembers about a story) are not relevant in such a task since the reference world is co-present with the production task. Second, the separation of the Listener and Speaker allowed us to manipulate independently the referential context of the Speaker and the Listener, allowing us to disentangle referential effects on the task of production and the task of comprehension.

In Experiment 1, we examined the use of prosodic cues when the referential context of the Speaker supported either meaning of the target sentence. In Experiment 2, we examined prosodic cues when the referential context of the Speaker strongly supported the intended meaning of the utterance. If prosodic choice is affected by Speaker’s knowledge of the referential context, we would expect to see decreased use of helpful cues when the referential context provides other cues to disambiguate the utterance. If on the other hand, knowledge of the referential context is not relevant, we would expect similar performance across the two experiments.

## Experiment 1

### Methods

**Participants** Thirty-two pairs of participants from the University of Pennsylvania community volunteered for the experiment. They received extra course credit or were paid for their participation. In each pair, one participant played the role of Speaker and the other played the role of Listener. All Speakers were female whereas half the Listeners were male and half were female. All participants were native speakers of English.

**Procedure** During the experiment, the Speaker and Listener sat on opposite sides of a vertical screen. On each trial they were given identical bags containing toys, which they laid out on the trays in front of them. As the Speaker and Listener removed toys from their bags, the Experimenter introduced each toy using indefinite noun phrases (e.g., This bag contains a dog, a fan...).

Next, the Experimenter showed the Speaker a demonstration of the target action. This action could not be seen by the Listener. The Speaker then received a card containing a

written sentence describing this action. Speakers memorized the sentence and returned the card to the Experimenter. After seeing a second demonstration, the Speaker produced the sentence. The Listener responded by attempting to perform the correct action with his or her own set of toys. Speakers were told that the primary goal of the experiment was to say each sentence in such a way as to get the Listener to perform the same action on the other side of the screen. Each Listener was told that her job was to perform the action that she believed had been demonstrated to the Speaker.

During the course of the experiment, interaction between the Speaker and the Listener was limited. Once the Speaker produced the sentence, the Listener could not ask for any clarification. Listeners' actions were videotaped and the Speakers' utterances were audiotaped. After the study was completed the Listener and Speaker were separated and each was interviewed to assess their awareness of the experimental manipulation and the ambiguity in the critical items.

**Stimuli** On critical trials, the target sentence contained an ambiguous Prepositional Phrase attachment, as in (1a) and (1b) below. Identical bags of objects were given to both participants. On each trial the bag contained: 1) a Target Instrument, a full scale object that could be used to carry out the action (e.g., a large flower); 2) a Marked Animal, a stuffed animal carrying a small replica of the instrument (e.g., a frog holding a little flower); 3) an Unmarked Animal (e.g., an empty-handed frog); and 4) two unrelated objects (e.g., a giraffe in pajamas and a lego block). The set of toys supported both interpretations of the ambiguous sentence by providing a potential direct object (plain frog) and instrument (large flower) for the VP-attachment and a potential direct object for the NP-attachment (frog holding flower).

The Experimenter demonstrated one of two possible actions: an Instrument action (e.g., the Experimenter picked up the large flower and tapped the plain frog) or a Modifier action (e.g., using her hand, the Experimenter tapped the frog that had the small flower). Ambiguous sentences were compared with unambiguous sentences (1c and 1d).

1a. Tap the frog with the flower. (Amb, Inst)  
*Action involves the unmarked frog and the instrument.*

1b. Tap the frog with the flower. (Amb, Mod)  
*Action involves the marked frog and not the instrument.*

1c. Tap the frog by using the flower. (Unamb, Inst)  
*Action involves the unmarked frog and the instrument.*

1d. Tap the frog that has the flower. (Unamb, Mod)  
*Action involves the marked frog and not the instrument.*

Four presentation lists were constructed so that each of the 16 target trials appeared in only one of the four possible conditions on a given list but appeared in each of the conditions across lists (resulting in four target trials in each condition per subject pair). The target trials were interspersed with thirty distractor trials. Four additional lists were generated by reversing the order of trials in each list.

**Coding** The videotapes of Listeners' actions were edited to include only the actions on the sixteen target trials, and all audio was removed. Coders, who were blind to the condition of each trial, judged whether the Listener made an Instrument response (performed the target action using the Target Instrument or the miniature instrument).

## Results

**Listener's Actions** The percent of Instrument responses in each of the four conditions is presented in Figure 1. Listeners' actions in response to the ambiguous instructions were affected by the action demonstrated to the Speaker ( $F(1,16) = 63.42, p < .001$ ;  $F(1,12) = 77.31, p < .001$ ). When an Instrument action had been demonstrated to the Speaker, Listeners produced an Instrument action 66% of the time. When a Modifier action had been demonstrated, Listeners produced an Instrument action only 24% of the time.

Figure 1: Experiment 1 Listener's Actions

Also, as expected, unambiguous instructions (the left-hand portion of Figure 1) resulted in extremely accurate performance by Listeners. The interaction between Ambiguity and Demonstration Type was reliable ( $F(1,16) = 81.91, p < .001$ ;  $F(1,12) = 113.71, p < .001$ ). As can be seen in the figure, this interaction arose because Listeners were more accurate at reproducing the demonstrated action when the utterance was syntactically Unambiguous than when it was Ambiguous. This pattern suggests that the prosodic cues produced by Speakers were highly informative to Listeners, but not as informative as unambiguous sentences.

**Speaker's Prosody** To verify that our Listeners were glean- ing this information from prosodic cues provided by the Speaker, we conducted acoustic analyses of the ambiguous target sentences. The audio recordings were digitized and a

speech waveform display was generated for each target utterance. Coders, who were blind to the condition, measured the duration of the Verb Composite (verb plus the postverbal pause, if any) and the Noun Composite (the direct object noun plus the following pause, if any). The onset or offset of a word was initially estimated by using visual information from the speech waveform display. This estimate was revised by listening to gated regions of the waveform.

Figure 2: Experiment 1, Mean Durations from Speakers' Utterances

As Figure 2 suggests there is a reliable and substantial effect of demonstration on the mean duration of both the Verb Composite ( $F(1,24) = 12.92, p < .001; F(1,12) = 50.59, p < .001$ ) and Noun Composite ( $F(1,24) = 52.71, p < .001; F(1,12) = 290.42, p < .001$ ). When Speakers saw Instrument Demonstrations, they tended to lengthen the direct object noun and they paused between the noun that the with-phrase on 68% of the trials. This prosodic pattern suggests that the major phrase boundary is located between the direct object and the prepositional phrase and is thus consistent with a verb-phrase attachment of the prepositional phrase (instrument interpretation) but not with a noun-phrase attachment (modifier interpretation). In contrast, when Speakers saw Modifier Demonstrations, they tended to lengthen the verb and paused after the verb 40% of the time. This prosodic pattern suggests that the major phrase boundary is located between the verb and the direct object noun phrase and is more consistent with a noun-phrase attachment.

**Ambiguity Awareness** Listeners' actions in response to ambiguous instructions suggest that prosodic cues were a highly effective but imperfect means of syntactic disambiguation. However the results of the postexperimental interviews raised some concerns about the generality of these findings. 97% of the Speakers in our experiment and 91%

of the Listeners reported being aware of the ambiguity. As mentioned earlier, Allbritton and colleagues (1996) found that ambiguity awareness affected radio announcers' ability to generate useful prosody. Although our participants were not trained radio announcers, we thought it necessary to explore if ambiguity awareness, and more generally knowledge of the referential situation, were influencing the kinds of prosodic choices made by our Speakers.

## Experiment 2

In this experiment, we attempted to decrease Speaker awareness of ambiguity. This was accomplished by making two changes to the previous experiment. First, we altered the Speakers' referential context, so that only the intended meaning of the ambiguous phrase was supported. This was done in hopes that the alternate interpretation would not be considered by the Speakers if it was not suggested by the context itself. Second, we made the type of Demonstration a between subjects variable.

All other aspects of Experiment 2 were the same as Experiment 1. It is especially important to note that the Listeners' context was the same as that used in Experiment 1. And, as in Experiment 1, participants were told in advance that on each trial the Speaker and Listener would receive an identical set of toys. However, in Experiment 2 this was a deception, to be explained at the end of the study.

## Methods

**Participants** Thirty-two pairs of participants from the University of Pennsylvania community received extra course credit or were paid for their participation. All Speakers were female, 17 of the Listeners were male. All participants were native speakers of English and none had participated in Experiment 1. Two additional pairs of subjects participated but were not included in the analyses because of experimenter error (1) or failure to follow instructions (1).

**Procedure** The procedure was the same as Experiment 1 except that the contents of the bags were not listed aloud, to prevent the subjects from discovering that their bags contained different sets of objects. Instead a card listing the objects was included in each bag and the participants were told to check the contents of the bags against the card to insure that all of the toys were present.

**Stimuli** The stimuli and experimental design were the same as in Experiment 1, with the following exceptions. When the Experimenter performed an Instrument Demonstration, the Speaker's bag of toys did not include a Marked animal (e.g., the frog holding the flower) but instead included a second unrelated animal (e.g., an elephant wearing a hat). Hence, a modifier interpretation of the with-phrase should be less available to the Speaker. When the Experimenter performed a Modifier Demonstration, the Speaker's bag of toys did not include the Target Instrument (e.g., the large flower) but instead included a second unrelated object (e.g., a leaf). Hence, the Instrument interpretation of the with-phrase should be less available to Speakers in this context.

In addition, we excluded the unambiguous conditions in this experiment, because these sentences had been uniformly interpreted and coded correctly in Experiment 1. To equalize the number of ambiguous sentences that subjects received in each experiment, we divided the 16 critical sentences into two lists. The items on each list appeared in a pseudo-random order embedded in the same twenty-four distractor trials. In addition, reverse-order lists were generated.

Finally, the type of Demonstration was manipulated between subjects. In the Instrument Condition, all target items were ambiguous and involved an Instrument demonstration (and an Instrument context for the Speakers). In the Modifier Condition, all target items were ambiguous and involved a Modifier demonstration (and a Modifier context for the Speakers).

**Results**

**Ambiguity Awareness** Listeners in Experiment 2, like those in Experiment 1, usually reported that they were aware of the ambiguity. This is to be expected, given that the same referential contexts were presented to Listeners in both experiments, and it suggests that the between-subjects design does not, by itself, affect ambiguity awareness.

Speaker awareness of ambiguity did change across experiments. In particular, only one speaker in the Instrument condition (6%) reported being aware of the ambiguity. Interestingly, and in contrast, nine of the Speakers in the Modifier condition, or 56%, reported being aware of the ambiguity. This pattern was unexpected; we were hoping that few if any of the Speakers would be aware of the ambiguity. This difference may be related to the fact that Modifier attachments are dispreferred by readers, especially with action verbs (Spivey-Knowlton & Sedivy, 1994). Conflicts between lexical and referential cues in the Modifier condition may brought the ambiguity into awareness. As we shall

Figure 3: Listeners' Responses to the Ambiguous Sentences in Experiments 1 & 2  
see, this unexpected result is serendipitous, because it allows us to compare the performance of the Listeners who heard utterances from aware and unaware Speakers.

**Listener's Performance** The percent of Instrument responses for each conditions of Experiment 2 appear on the right hand side of Figure 3. Listeners in Experiment 2 were clearly unaffected by the type of Demonstration performed by the ( $F(1,24) < 1, p > .3$ ;  $F(1,12) = 1.88, p > .3$ ), suggesting that Speakers were not effective in helping Listeners resolve the ambiguity. To compare performance in the ambiguous conditions of Experiments 1 and 2, ANOVAs were conducted on the percent correct for items and subjects with Experiment as a between subjects and within items factor. Unsurprisingly, Listeners in Experiment 1 performed significantly better than those in Experiment 2 ( $F(1,62) = 11.76, p < .001$ ;  $F(1,14) = 19.91, p < .001$ ).

**Speaker's Prosody** The audiotapes were digitized and coded in the manner described above. As Figure 4 suggests, there was no reliable effect of condition on the duration of the Verb Composite ( $F(1,24) < 1, p > .6$ ;  $F(1,12) = 1.69, p > .2$ ). The effect of condition on the Noun Composite was not significant in the subjects analysis ( $F(1,24) = 1.66, p > .2$ ) and was small but reliable in the items analysis ( $F(2,1,12) = 7.71, p < .05$ ).

Figure 4: Experiment 2, Mean Durations from Speakers'

**General Discussion**

When the Speakers' context strongly supported the intended meaning of an ambiguous utterance, Listeners showed complete insensitivity to the intended meaning of the utterance. This stands in contrast to Experiment 1, where Listeners had

the same referential context, but were highly sensitive to the intended meaning. There are two possible explanations to these findings. First, the findings may be attributable to Speakers' awareness of the ambiguity (Allbritton et al, 1996). Speakers in Experiment 1 were almost always aware of the ambiguous sentences while those in Experiment 2 were usually unaware. Second, the findings may be due to the change in the referential context of the Speakers. In the first experiment, Speakers were given a context that supported either meaning of the ambiguous sentence, whereas in Experiment 2 Speakers were provided with a context that supported only the relevant interpretation. Perhaps speakers only produce informative prosody when the context doesn't disambiguate the sentence for them (Lieberman, 1967).

Because a subset of the subjects reported being aware of the ambiguity in the Modifier condition, we can test if ambiguity awareness per se is driving the results of Experiment 2. Ten additional subject pairs were tested to gather sufficient data for this comparison. We found no reliable differences between responses to aware speakers and those to unaware speakers ( $F(1,23) < 1, p > .8$ ;  $F(1,15) < 1, p > .9$ ). When the referential context disambiguated the sentence, awareness of the **potential** for ambiguity did not lead speakers to provide adequate prosodic cues.

The substantial difference in performance across the studies and the absence of an effect of awareness within Experiment 2, suggest that referential context itself is critical in determining whether speakers will produce strong prosodic cues. In Experiment 1, the Speaker's referential context supported both interpretations of the "with" phrase and thus the sentence was, in the absence of prosodic cues, ambiguous in context. Under these conditions, Speakers produced prosodic cues that were not only consistent with the intended structure but also inconsistent with the competing interpretation. Listener's were able to use these cues to determine the intended meaning, albeit imperfectly. In Experiment 2, the Speaker's referential context supported only the relevant interpretation, disambiguating the sentence and making strong prosodic cues unnecessary. Listeners, who did not have access to this disambiguating referential context, were able to find nothing in the Speakers' prosody to guide them. These data, therefore, support Lieberman's hypothesis that speakers only produce informative prosody when the context doesn't do the work for them.

This conclusion and these results appear to conflict with those of Schafer and colleagues who find that untrained, uninformed speakers produce consistent prosodic cues regardless of whether the context of the utterance provides disambiguating information (1999). To add to the confusion the tasks appear to be quite similar: both experiments use variants of the referential communication task and ask speakers to produce scripted, memorized commands to achieve concrete results. The two experiments, however varied in several critical respects. First, in the Schafer study, there is a higher degree of uncertainty about the listener's referential context. The speaker knows both that the listener has information about the context that the speaker lacks and that the listener's context will change as the experiment progresses. Second, the participants are given the set of commands, which contains both interpretations of the ambi-

guity, at the beginning of the study and are exposed to situations in which each meanings is applicable. Thus it seems likely that these speakers were aware of the globally ambiguous sentences and believed that there was the potential for referential ambiguity.

In this paper, we have suggested that a speaker's knowledge of the referential situation affects her ability to disambiguate otherwise ambiguous utterances. In particular, we propose that when a speaker recognizes that an utterance is ambiguous in context, she will disambiguate it by making prosodic choices that are consistent with the relevant interpretation and inconsistent with the alternatives.

## Abstract

A recent eyetracking experiment has indicated that, while staring at a blank white display, participants engaged in imagery tend to make eye movements that mimic the directionality of spatial expressions in the speech stream (Spivey & Geng, 2000). This result is consistent with a spatial mental models account of language comprehension (e.g., Johnson-Laird, 1983), adds a *motor* component to evidence for activation of *perceptual* mechanisms during visual imagery (e.g., Kosslyn, Thompson, Kim, & Alpert, 1995), and fits with claims regarding the embodiment of cognition (e.g., Varela, Thompson, & Rosch, 1991). However, some methodological concerns remain. We report some preliminary observations, and a controlled experiment, in which these methodological concerns are resolved. We demonstrate that, even when the speech includes no instructions to imagine anything, and even when participants' eyes are closed, participants tend to make eye movements in the same direction (and especially along the same axis) as the described scene when listening to a spatially extended scene description.

## Introduction

More than three decades ago, Donald O. Hebb (1968) suggested that the very same eye-movement scanpaths associated with *viewing* an object may be automatically triggered (via transcortical cell assemblies) when a person is *imagining* that object -- and some empirical support for this claim has recently been reported. When viewing a blank screen and being instructed to imagine a previously-viewed block pattern, observers produced scanpaths that bore some resemblance to the scanpaths elicited during original viewing of the actual block pattern (Brandt & Stark, 1997).

Such oculomotor behavior in the absence of visual input is consistent with the notion that, when imagining or remembering an object or event, we often develop a mental representation of that object or event that has a distinctly spatial structure to it. This spatial format of representation is thus able to take advantage of properties inherent to Cartesian space, such as topography and metric relationships. During the construction and interrogation of such spatial mental models (e.g., Bower & Morrow, 1990; Bryant, 1997; Johnson-Laird, 1983, 1996), cognition often uses linguistic input to activate memory representations, and imagery may then use those memory representations to partially activate perceptual representations (e.g., Farah, 1995; Finke, 1986; Kosslyn et al., 1995).

The present study demonstrates that, even in the absence of any visual stimulus at all, such "perceptual simulations" (Barsalou, 1999) often trigger corresponding oculomotor responses. In a sense, one might say that *thinking* of something often involves *pretending to look at it*. This finding contributes to the developing "embodied" view of the mind (e.g., Ballard, Hayhoe, Pook, & Rao, 1997; Brooks, 1995; Varela, Thompson, & Rosch, 1991), in which an adequate characterization of cognition requires special attention to the repertoire of actions available to the organism or agent.

## Looking at Objects that Aren't There

In a recent study, Spivey and Geng (2000, Experiment 1) had participants simply listen to pre-recorded instructions to imagine visual scenes while looking at a blank white projection screen and wearing a headband-mounted eyetracker. Each of the descriptions had a specific directionality (rightward, leftward, upward, and downward) to the manner in which new objects or events were introduced in the scene. In addition, a control scene description was presented, in which no particular directionality was present.

Pilot results with this methodology produced eye movement patterns very much in accordance with the directionality of the scene description, however most participants developed rather accurate suspicions of our experimental hypothesis. Although eye movements are relatively automatic, and usually not very susceptible to voluntary control, the concern remained that participants may not have produced such behavior if they hadn't known that their eye movements were being recorded.

To avoid potential strategy effects, we introduced a sham task (of following instructions to move objects around on a table), and referred to the imagery session as a break from the experiment during which the eyetracker would be turned off ("but don't take off the headband because then we'd have to recalibrate the tracker when we return to the experiment"), Although two participants suspected that their eyes were still being tracked, and two participants closed their eyes during the imagery session, the remaining six participants produced eye movement patterns that were remarkably consistent with the directionality of the scene descriptions. Figure 1 shows example data from the Control (left panel) and Rightward (right panel) scene descriptions.

Figure 1: Polar coordinate plots of the average proportion of saccades in various directions while listening to stories. In the control story, participants made an approximately equal proportion of eye movements in all directions. In the rightward story, .2 and .14 of all saccades were in the two rightward directions (15° and 345°, respectively).

Despite remarkable direction-selectivity in saccades during the imagery instructions (for all four directionally-biased scene descriptions), some concerns about this methodology remained. To begin with, the scene descriptions began with an explicit instruction to "imagine" the scene, which may be importantly different from normal language use. Moreover, because they knew that eye movements were involved in the rest of the experiment, participants' eye movement behavior may still have been somehow unnatural. Ideally, these findings needed to be replicated under circumstances where there were no explicit instructions to imagine something, and where the participant had no idea that his/her eye movements were being recorded.

### Observation

We have been developing a methodology for recording a participant's eye movements with an ISCAN, Inc. remote eyetracking camera without the participant's knowledge. With a benign deception, great care is taken to prevent participants from discovering that their eye movements are being recorded, while still protecting their rights. For our purposes, the deception involves telling participants that the camera directed at them is recording subtle thermal changes in the face as a result of emotional arousal. They are encouraged to sit as still as possible during the experiment in order to allow an accurate thermal image.

### Control Story

### Rightward Story

Figure 2: Example scanpaths from a participant while listening to the Control and Rightward scene descriptions.

For calibration, we use five pseudo-Rorschach images mounted on the corners and center of a black foam core board spanning 20 X 30 degrees of visual angle. With the cover story being that we must first collect some baseline thermal readings, participants are asked to look at each of the pseudo-Rorschach images and report what they see, during which time we record those five eye positions as calibration points. The ISCAN system then interpolates between those calibration points to provide an eye position signal with an accuracy of better than 1 degree of visual angle. In order to reduce the amount of visual information in the environment that participants might fixate during the time that they listen to the pre-recorded stories, the poster is then flipped over to display the black-colored board.

Table 1: Pre-recorded scene descriptions

---

### CONTROL STORY

"You are on a hill looking at a city through a telescope. Pressing a single button zooms a specific block into view. Another button brings a gray apartment building into focus. Finally a third button zooms in on a single window. Inside you see a family having breakfast together. A puppy appears and begs for a piece of French toast."

### RIGHTWARD STORY

There is a fishing boat floating on the ocean. It's facing leftward from your perspective. At the back of the boat is a fisherman with a fishing pole. The pole extends about 10 feet to the right beyond the edge of the boat. And from the end of the pole, the fishing line extends another 50 feet off to the right before finally dipping into the water."

### DOWNWARD STORY

"You are standing at the top of a canyon. Several people are preparing to repel down the far canyon wall across from you. The first person descends 10 feet before she is brought back to the wall. She jumps again and falls 12 feet. She jumps another 15 feet. And the last jump, of 8 feet, takes her to the canyon floor."

### LEFTWARD STORY

"There is a train extending outwards to the left. It is pointed to the right, and you are facing the side of the engine. It is not moving. Five cars down is a cargo holder with pink graffiti sprayed on its side. Another six cars down is a flat car. The train begins to move. Further down the train you see the caboose coming around a corner."

### UPWARD STORY

"You are standing across the street from a 40 story apartment building. At the bottom there is a doorman in blue. On the 10th floor, a woman is hanging her laundry out the window. On the 29th floor, two kids are sitting on the fire escape smoking cigarettes. On the very top floor, two people are screaming."

---

The pre-recorded auditory stimuli consist of ten short stories, each story lasting approximately thirty seconds. Half of the stories are filler stories which contain no directional cues, but which are intended to be slightly emotionally-engaging, in order to divert the participants from suspecting the actual experimental hypothesis. The five test stories are derived from Spivey & Geng (2000), but do not begin with an instruction to "Imagine...". The test stories contain systematic directional cues (see Table 1), and are not emotional in content. The order of the ten stories is pseudo-randomized, with one filler story interleaved between each pair of test stories. After about five minutes for calibration, the listening session begins with a filler story, and lasts another five minutes.

At the end of the session, participants are debriefed and thoroughly questioned as to their beliefs about the nature of the study. With the thermal camera cover story, very few of the participants have correctly guessed the experimental hypothesis -- almost all participants were surprised that their eye movements were being examined rather than patterns of thermal change on the face.

In developing this methodology, we have encountered numerous complications in acquiring and testing an accurate calibration of the eyetracking system without betraying the deception. Due to blinks and other movements, an accurate calibration with the remote eyetracking camera occasionally requires multiple fixations of some of the five calibration points. As the calibration period drags on with more and more inventive questions regarding the five pseudo-Rorschachs, participants can become suspicious of the cover story. Moreover, following an acceptable calibration, head movements during the listening phase of the experiment can make it difficult for the software, or a human controller, to maintain a centralized camera image of the eye.

Despite the complications, some preliminary observations from this methodology are available and worth reporting. It is already clear that listeners make a greater number of saccades during the directionally-biased stories compared to the Control Story. Although these eye movements are not always in the specific direction of the directionally-biased story, they do tend to be limited to the appropriate axis of orientation; see Figure 2. This should be expected if one considers the fact that a listener simply couldn't make rightward or upward eye movements indefinitely as the story continues to add rightward or upward expressions. At some point, an eye movement in the opposite direction is necessary to "re-center" the imagined scene in head-centered coordinates. (It is possible that this might occur less frequently if participants were allowed to turn their heads.) In any case, there is nothing stopping the listener from voluntarily "examining", or "looking back to", previously described elements of the scene.

Further development of this methodology, with more accurate tracks from additional naive participants, will allow averaging of saccades in polar coordinates (as shown in Figure 1). Preliminary data appear likely to confirm the findings of Spivey and Geng (2000), under circumstances where there are no explicit instructions to imagine anything, and participants are completely unaware that their eye movements are being recorded.

## Experiment

The described complications with the above methodology (as well as concerns about participants looking at objects in the visual field beyond the 20° X 30° black display board) point to a methodology with which it is easier to collect data from more reliably naive participants, but which produces data that is admittedly more difficult to analyze. In this experiment, participants were instructed to close their eyes while they listened to the same ten stories; the stories in Table 1 as well as the five filler stories. A standard video camera was directed at the participant's face, and the camera's image of the participants' closed eyes was later used to estimate incidence and direction of eye movements. (One could, in principle, record movements of closed eyes with electrooculography [surface electrodes near the eyes] or a search coil [a contact lens with a copper wire and loop, the position and orientation of which is precisely determined via an electromagnetic field in which the participant sits]. However, it might be difficult to convince such participants that their eye movements were not being recorded.)

## Method

**Participants** Eleven Cornell University undergraduates participated in the study for extra credit in Psychology courses. None of them had previously participated in an eyetracking experiment.

**Stimuli and Apparatus** This experiment used the same pre-recorded scene descriptions as described in the previous methodology. A standard video camera was positioned in front of the participant, with a black curtain as background. Stories were presented in a pseudo-randomized order, with each test story preceded by a filler story.

**Procedure** Participants were asked to relax in their seat, but to remain still and to close their eyes while listening to the ten short stories. They were informed that we would be examining their facial expressions as related to story content. Participants were told that their shoulders and face were being videotaped while the stories were being played. Upon achieving a well-focused image of the participant's closed eyes through the video camera, recording began. The stories were played from a cassette player. Each session lasted approximately five minutes. At the end of each session, participants were debriefed and thoroughly

questioned as to their beliefs about the nature of the study. None of the participants correctly guessed the study hypothesis, and all were surprised that their eyes movements had been of interest.

**Coding** Coding was made easier by focusing on the movement of a round spot of luminescence on each of the participant's eye lids. The spot of light reflectance on the eye lids corresponded to the protuberant round area of the cornea directly over the pupil sitting beneath the lid. Movements of the eye were considered to be clearly visible shifts in the spot of reflectance on each lid (as opposed to ambiguous twitches in the lid, or jitters in the positioning of the spot of reflectance that were too small in distance and too short in duration to be easily interpreted.) See Figure 3, where dark lines are added to indicate the points of inflection due to the corneal bulge. Such eye movements are much easier to discern when multiple frames are seen in real-time (<http://node15.psych.cornell.edu/home/eyesclosed.html>). A definite movement of the eye ball was considered to be a movement of the spot of reflectance lasting for 3 video frames or longer and of such a distance that the direction of movement was unambiguous to 2 independent trained coders. Assessment of start time and direction of eye movements involved pinpointing the movements on video tape by playing approximately 10 frames of tape at a time, then comparing the previous position of the spot of reflectance with the new position. It was frequently necessary to rewind or forward the position of the tape one frame at a time to specify as precisely as possible when each eye movement took place. Inter-rater reliability for the two coders was high, as measured by a Pearson correlation;  $r=.84$ . It is difficult to estimate how large a saccade (in degrees of visual angle) is detectable with this coding method. However, it is likely that many small eye movements are being made in this task, the direction of which cannot be determined with the present method.

## Results

For each scene description, proportion of detectable eye movements in each of eight directions was averaged across all eleven participants. Two of the eleven participants made no detectable eye movements during the entire experiment. Consistent with the previous observations, only three of the eleven participants made any detectable eye movements

Figure 3: Examples of a detectable rightward eye position (left panel) and leftward eye position (right panel).

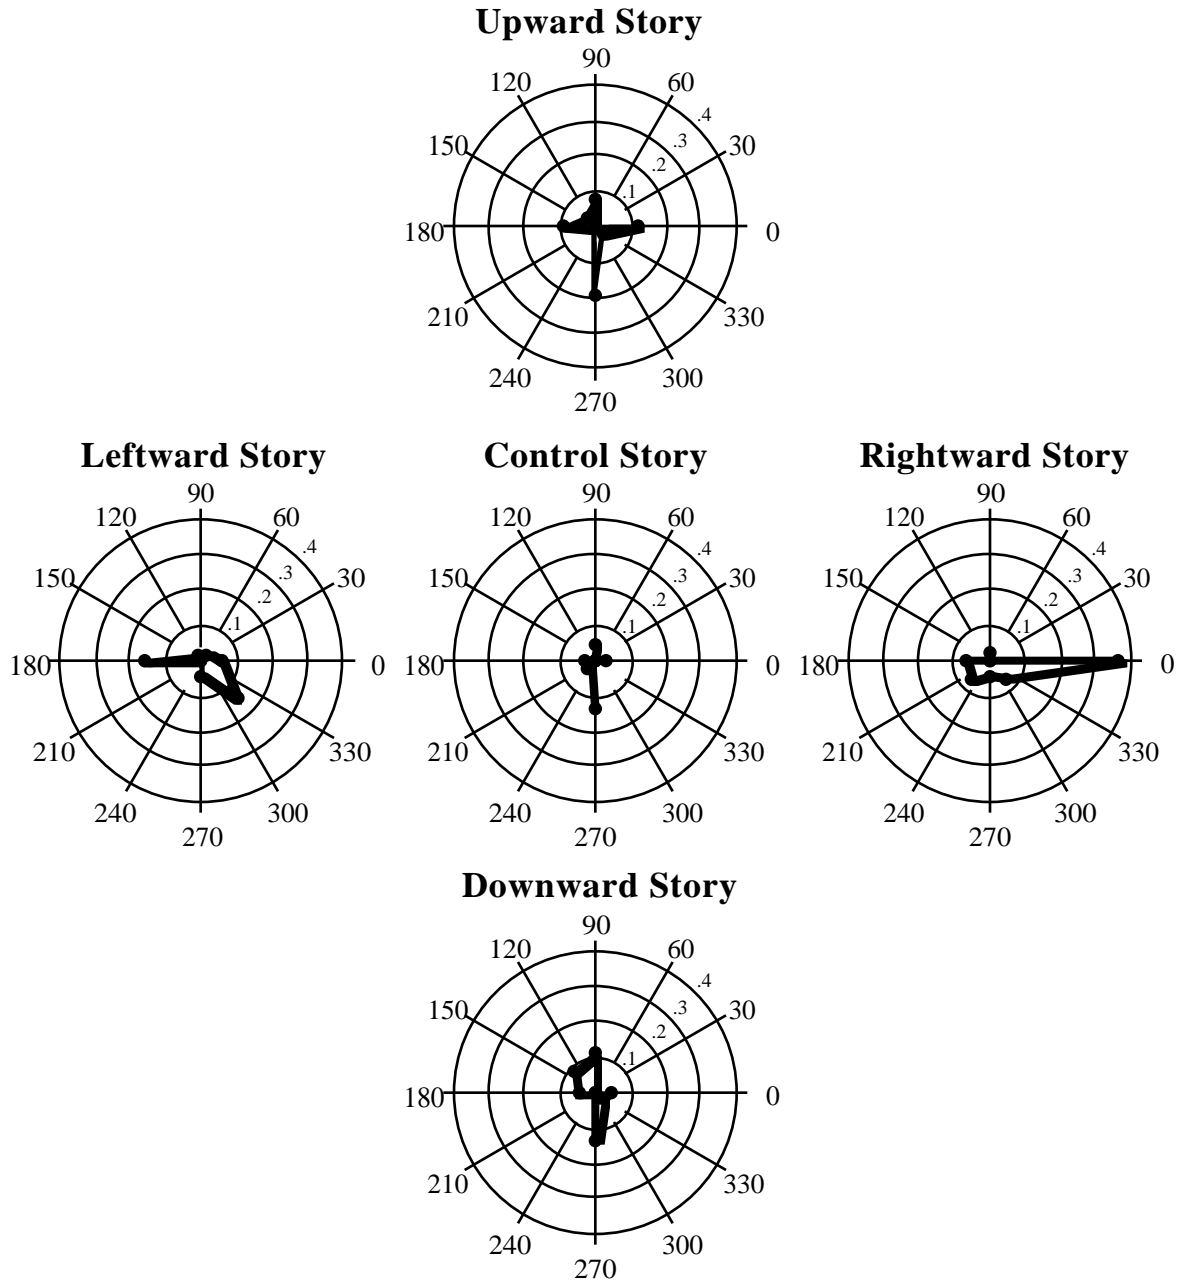

Figure 4: Polar coordinate plots of the average proportion of detectable eye movements in eight directions while participants listened to scene descriptions with their eyes closed.

during the Control Story. Unfortunately, this contributes to a rather unreliable estimate of the direction-selectivity profile for that story. Figure 4 shows polar coordinate plots of the eye-movement direction-selectivity profiles for the five scene descriptions. It is noteworthy that when the detectable eye movements were in the unpreferred direction, they were frequently in the exact opposite direction. Thus, even when the eye movements do not follow the specific directionality of the scene description, they nonetheless tend to be limited to the appropriate axis of orientation (horizontal or vertical), suggesting that an entire axis of a reference frame, rather than simply one direction, may be activated (e.g., Carlson-Radvansky & Jiang, 1998; Demarais & Cohen, 1998). In a

paired t-test, the average proportion of eye movements in a preferred direction was significantly greater than the average proportion of eye movements in the unpreferred directions;  $t(10) = 4.49, p < .01$ .

### Discussion

These results demonstrate that, even when participants' eyes are closed, they tend to move their eyes in directions that accord with the directionality of the scene being described. Although comprehension of these scene descriptions may involve some of the same mechanisms involved in imagery tasks (e.g., Kosslyn et al., 1995), the present results do not

rely on explicit instructions to imagine anything. We suggest that comprehension of scene descriptions employs a decidedly spatial format of representation, and that oculomotor coordinates may be an important component of that representation.

## Conclusions

With no visual information available, participants constructing mental models of complex scenes tend to make eye movements that mimic the kinds of eye movements that would be made when viewing that actual scene. In a similar vein, Spivey and Geng (2000, Experiment 2) and Richardson and Spivey (in press) report experiments in which participants attempting to recall visual or auditory information tend to make eye movements to the region of space (now empty) where that information was first encoded. In conjunction with results in visuomotor coordination by Ballard et al. (1997) and in attention by Pylyshyn (1994), this work suggests that the mind/brain exploits useful properties inherent to spatial formats of representation by relying on oculomotor pointers to spatial indexes out in the world or, in the present case, perceptual simulations of them. This perspective may point to a pivotal role for space, independent of perceptual modality, in all mental representations (cf. Bryant, 1997).

One could possibly interpret our findings as a tangential endorsement of a sort of 'Cartesian Theater' account of the mind (cf. Dennett, 1991): that when we imagine something, it is like viewing it "in our mind's eye", and that (perhaps epiphenomenally) our real eyes simply echo the motion of our internal spectating. However, it is well known that this kind of interpretation too easily falls into the infinite regress of a homunculus inside the mind. Therefore, we prefer to place these results in the light of Ryle's (1949) comment that "[A person picturing his nursery in his mind's eye] ... is not being a spectator of a resemblance of his nursery, but he is resembling a spectator of his nursery." That is to say, we would argue that our data are indicative of an embodied system that naturally activates 'lower level' motor actions to accompany 'higher level' cognitive processes because, rather than being separate functions that are triggered by a mental state, motor actions are fundamental components of the mental state.

In such an embodied view of the mind, action determines cognition as much as perception does. Indeed, a number of researchers have suggested that an important aspect of *perceiving* an environment is knowing *how to interact* with it (e.g., Brooks, 1995; Gibson, 1979; Milner & Goodale, 1994; Turvey & Carello, 1996). Perhaps we can add to this embodied view of perception that part of *perceiving* a scene is also knowing *how to look at it* -- even when it's not there.

## Acknowledgments

We are grateful to Michael Tanenhaus, Mary Hayhoe, and Dan Earley for helpful discussions of this work, and to Jessica Evett-Miller and Koji Park for assistance with data collection and analysis. Supported by a Sloan Foundation Fellowship in Neuroscience and a grant from the Consciousness Studies Program at the U. of Arizona.

## Abstract

Conceptual learning in maths and science involves learning to coordinate multiple representation systems into smoothly functioning heterogeneous reasoning systems composed of sub-languages, graphics, mathematical representations, etc.. In these heterogeneous systems information can be transformed from one representation to another by inference rules, and learning coordination is learning how and when to apply these rules. Heterogeneous reasoning has a particularly important role to play in teaching students how to apply formalisms to real world problems, rather than merely teaching formalism-internal calculation.

This paper analyses three learning incidents which happened in groups of students engaged in learning the mathematics and biology involved in modelling biological populations, from the perspective of the heterogeneous reasoning involved. Greeno, Sommerfeld & Weibe (2000) and Hall (2000) analyse incidents from the same curriculum intervention from other points of view, in this volume.

We observe both learning successes and failures that cannot be understood without understanding the seams joining the representation systems involved, and the inference rules and operations required to get from one to another. One conclusion is that even apparently homogeneous natural language has to be seen as heterogeneous in its fully contextualised application.

## Introduction

The coordination of multiple representation systems is frequently instrumental in conceptual learning (see e.g. van Someren et al. 1999; Barwise & Etchemendy 1994; Stenning, Cox & Oberlander 1995). In particular, learning mathematics and science concepts involves learning to coordinate multiple formalisms (numerical, graphical, algebraic, terminological), but it also involves learning how to apply formalisms in contexts. It is all too possible for students to succeed at the first and to fail at the second—to learn the internal operation of some formalism without learning how to apply it to new problems. Barwise and Etchemendy have used the term ‘heterogeneous reasoning’ for reasoning using multiple coordinated representations, and have applied heterogeneity of representation in order to improve students’ grasp of the application of formalisms in computer environments such as Hyperproof. Another related curriculum response to this problem of teaching the application of formalisms to real world problems has been a move toward project-based approaches which teach formalisms in close relation to their context of application—in particular teaching scientific concepts along with the mathematics that goes with them.

The purpose of this paper is to use some example episodes from project-based group learning to illustrate how the concepts of heterogeneous reasoning present themselves in the classroom setting in less formal contexts than Hyperproof. This investigation underscores how local the semantic interpretation of representations is in context. Words change meaning frequently and systematically, and the information they carry is moved into and out of other representations. The investigation also provokes examination of the relation between heterogeneity and localness of interpretation (e.g. Moravcsik 1998). With diagrams, it is usually quite evident to users that the diagram has a local interpretation and that the naive user needs to learn this local interpretation, even though there are regular features of such diagrammatic systems from use to use. With natural language, we are often so practiced at making the contextual interpretation of its local semantics that it is easy to fail to realise that this is what we do. Examining learning discourse in context raises the question whether heterogeneity should also be extended to cases where the linguistic part of the discourse has to be treated as multiply interpreted.

Our longer term aim is to coordinate this approach with others which focus on discourse practices and students’ recruitment of material from their diverse experiential worlds. Greeno, Sommerfeld & Weibe (2000) and Hall (2000) take these respective perspectives on material from the same group learning curriculum intervention. The advantage of pursuing several parallel analyses of the same data for cognitive theory may share something with the advantages of the project-based approach for the students. Applying several kinds of the theory to the same episodes turns up new questions about how the theories relate to each other, and thus may induce conceptual learning and improved ability to apply the theories in novel circumstances.

## Heterogeneous reasoning

Theories of human reasoning have begun to pay more attention to how representational systems are selected or constructed, and the variety of systems that may be used in solving a single problem, rather than conceiving of reasoning as a system internal activity. Barwise & Etchemendy have called this use of multiple coupled systems of representation *heterogeneous* reasoning, and have developed several computer environments for teaching heterogeneous reasoning. For example, Hyperproof presents a graphical window containing diagrams of a blocks-world inhabited by regular solids on a chequerboard, and a sentential window containing first order

logic sentences. The proof rules of the heterogeneous system incorporate the inference rules of the conventional sentential calculus, augmented by rules for moving information between diagram and sentences, in both directions. For example, the user can *observe* a feature of the diagram as the basis for inferring a sentence; or may *apply* information from a sentence by inferring (and constructing) a new feature of the diagram. *Observe* and *apply* are two (of about a half dozen) of the heterogeneous inference rules which coordinate the diagrammatic and sentential representations into a heterogeneous system.

Fundamental semantic distinctions between how diagrammatic and sentential representation systems express abstraction have been shown to play an essential part in analysing the learning that occurs as students master the construction of proofs in Hyperproof's heterogeneous environment, allowing the learning to be characterised as learning strategies of representation selection and use (Stenning, et al. 1999). Whether students benefit from the diagrammatic facilities of Hyperproof is determined to a great extent by their facility at grasping useful strategies for using Hyperproof's expressions of graphical abstraction.

Hyperproof reveals an important property of representational systems in use. Its semantics, both of its sentences and its diagrams are *partially interpreted*. That is, the system has some of its meaning fixed while other parts are defined in episodes of reasoning. This contrasts with the usual presentation of first order logic as an entirely uninterpreted language. In Hyperproof, even the sentences of the first order calculus have to be given a partial local interpretation because the predicates and relations have to coincide with those of the diagrams.

Partly diagrammatic systems of representation like Hyperproof reveal the need for coordinating diagrammatic and sentential representation systems, but lead to the further realisation that in situations of real language use, the apparently homogeneous languages in play are in fact often heterogeneous in the fundamental sense that many schemes of interpretation are in play at once. Even when natural language is the only modality, the reasoning systems in operation must be thought of as heterogeneous because the apparently single language can only be understood in terms of overlapping language fragments, each constituting a distinct system of representation.

To illustrate this point, this paper takes some classroom interactions of a group of students learning to model biological populations in terms of mathematical functions, and analyses the multiple partially interpreted representation systems which are in play. The students' representational resources and activities include at least the following: worksheet filling, graph drawing, computer operation, calculator use, group speech and gesture, reference material, and teacher interventions.

The educational issue in focus is the learning about modelling, and particularly learning about the process of formalisation and interpretation. A recurring theme is the struggle to coordinate formalism internal operations (calculation) and formalism external correspondences (semantics). We will analyse both successes and failures of coordination.

## The educational setting

The data we analyzed comes from an 8th grade Middle-school Mathematics through Applications (MMAP) classroom in the San Francisco Bay Area. The purpose of MMAP is to have students use math to address real-world problems, often with the assistance of computer applications. In the approximately 30 day unit we will discuss, called Guppies, students created mathematical models of biological population growth. As part of this unit students were to learn both about how to construct mathematical models of population growth and about the exponential functions that underlie them. Our analyses focus on a group of students, Manuel, Lisa, Kera & Nick whose improvement on pre/post assessments placed them about midway in learning of the half a dozen focus groups videotaped by Rogers Hall and his colleagues (Hall, 1999) during this unit in a variety of classrooms. These students are chosen to reflect roughly average performance for the class. For more information about the design of the study, please see Hall (2000, this volume).

## Three learning incidents

The three following incidents were chosen from videotapes because they illustrate both successful and problematic learning episodes. The initial incident from the pre-test phase sees the students make at least part of one of the fundamental conceptual discoveries of this field—that population models have a recursive characteristic that leads to exponential growth if unchecked—Malthus' equation.

The second incident, from the body of the course, is of interest because it contains an attempt to creatively diverge from the structure of the assigned worksheet by taking a short cut in the calculation. On the one hand this divergence reveals the germ of another important insight—that functions can be composed. But in the circumstances, the insight is not fully worked out and leads to error and confusion.

The third incident is chosen to illustrate that the confusion that is not resolved in the previous incident appears to persist into the much later post-test phase of the course. It consists of another attempt to calculate a birthrate for a new modelling problem.

In all of these incidents, the students struggle to coordinate multiple representations. We examine some of the coordinations in detail seeking to reveal how some episodes are successful and others not. For this short paper, the transcriptions are compressed by leaving out material which does not relate to our analysis.

### Pre-test insight—'babies have babies'

When the group discovers the recursive nature of population growth, they are engaged in constructing a model of a mouse population. They have obtained an initial number of 20 adults from the worksheet, and estimated a birthrate of four per couple. They are now calculating what the population will be after eight breeding seasons. The group initially adopt a linear model implicit in multiplication of a fixed birthrate. Only when they turn to the graphing activity dictated by the worksheet do they begin to think of the process which the calculation is intended to reflect.

60: M. so there's ... equals 40 babies each season

65: M. it's three hundred and twenty

- 66: K. (inaudible) is that including adults?  
 67: M. no, three hundred and twenty plus twenty  
 69: M. by the end of the winter  
 70: M. three hundred and forty mouse ...mice ... mices.  
 OK.  
 73: M. Now we need to make a graph of it  
 ...  
 182: M. so let's see ... the first season is over here  
 (making a mark on the graph)  
 183: L. xxxxxx wait a minute  
 186: M. and then sixty plus is going to be a hundred  
 189: L. wait a minute its forty (gestures a triangular  
 shape) OK its forty right?  
 190: L. and then you have to pair those up (brings hands  
 together) and then they have kids (spreads hands apart,  
 while K and M look at her confused)  
 192: M. oh yeaah (embarrassed, laughing at himself)  
 we were doing it ...  
 194: L. That's a lot of mice  
 195: K. gosh that's a lot of nasty mice

The interchange on lines 65/66 is an example of the frequent need to coordinate numbers with their semantics—adults still have to be included in the population, and “three hundred and twenty” is the number of babies in eight seasons just calculated. Similarly line 69 is a further reiteration of the semantics of the number “three hundred and twenty plus twenty”—the number represents a population at a time. Line 73 is an appeal to the authority of the worksheet for what has to be done next. What is interesting about this introduction of a new representation (the graph) is that it appears to be what triggers the new thinking that reveals the error (adopting the linear model) that they have all made. M. makes a mark of sixty on the Y axis at the origin representing the starting population. But L has realised that something is wrong (line 183). M continues calculating the next graph point. But L persists. She starts by reiterating the number and asking for acknowledgement of it (line 189). The number is the number of first season babies. She then states that these have to be paired up, and themselves reproduce (line 190). The gesture is intuitively an important part of her communication that she has a new insight, both for herself and for the group. M fairly rapidly sees their mistake too. They all realise that this is going to make the growth of the population much more rapid though they don't have any number for it. They immediately refer back to the experiential world of ‘nasty mice’. Perhaps the reality of reproduction lies behind the affective tone of the incident. It wasn't just a mathematical mistake, but a failure to apply the ‘facts of life’?

The original adoption of the linear model arises within the ‘mathematical world’. It is, in some sense, the obvious calculation to do—forty babies a season for eight seasons is going to give 320 babies. After all, multiplication is something we learn so as to avoid having to do multiple additions. It is not until the graphing activity makes them break this calculation down into a series of calculations that L sees the error. She thinks about what happens in the world of mice—about the semantics. Her insight is adopted rather rapidly.

### An attempt at creative construction—‘discovering function composition’

When the group brushes up against function composition, they are constructing one of their early models of a population. They have a worksheet entitled *Building the Birthrate* which gives them a procedure for calculating, or recording from reference sources, the various parameters of the situation (brood size for different ages, birthrate, survival rate). Parts of this worksheet and the computer interface are condensed into Figure 1.

The worksheet has its own sequence of activities, though it should be noted that this is not the sequence in which this group performs them. The worksheet's (see Figure 1) first table implements the calculation of the total population births in a season from data from reference sources. At Step 2 the percentage *survival rate* is entered from a reference source and, at Step 3, applied to the total from the table to give a number surviving. The lines represent page breaks in the work booklet. Step 4 then converts the total surviving fry into a percent *birthrate* for the computer. The relevant part of the interface appears next. The bottom table of the figure (over the page on the worksheet) keeps track of the model, and will hold several trial models later on.

The group's sequence of work is actually to start by fulfilling steps 1, 2 and 3, followed by entering the result into the computer and recording the model. Step 4 is circumvented initially and is only filled in retrospectively the next day.

The incident opens with M proposing to take a shortcut in the calculation. This is at first taken by L to be a mistake. She requests an explanation and receives one that she finds satisfying. However, she appears to appreciate that there is consequent bookkeeping which needs to be taken care of, but fails to deflect the group from continuing to the entry of data into the computer model.

444: M. hey wait wait wait ... no but listen. If 4% of the fry survive why don't we just forget about the fry survival and just put that amount for the, for how much are born ...

445: L. because the number born are not how much survived

446: M. yes. yes, the ones who survive are the ones we count, not the ones who are dead because we don't make room for the ones that are dead

453: M. OK you know how 4% the whoooooo fry who were born survive so why don't we just put 4% on the guppies birth because that's how many are going to survive

454: L. I get what you're saying because why put however many more guppies in when they're just going to die anyway?

455: K. so why not just put 4% because that's how many are surviving/ that's how many we're going to count

497: L. but what's that 4% ?

498: K. the ones that survive

499: M. The ones that actually survive fryhood

501: L. Yeah, I know, but how many of the guppies are 4% ?

502: M. we don't know, we'll let that mechanical thing

## Building the Birthrate

**Step 1**

age	# males	# females	# fry	total
young	2	1	4	4
mature	4	2	50	100
old	0	1	0	0
total	6	4		104

**Step 2** What percent of fry born survive? What happens to the ones who don't make it?

*5% of fry survive. They are eaten*

**Step 3** Use this survival percent and the total number born to calculate the number that survive.

*5.16*

**Step 4** So what's the birthrate? Now that you have calculated an assumed number of fry that survive past birth, you need to convert this into something that Habitech can use as a birth rate. As you know, Habitech works with percents or constant numbers. You will be using a percent birth rate.

BASED ON YOUR ASSUMPTIONS YOUR BIRTHRATE IS

Congratulations! Now take this birth rate and the death rate you will use and head to Habitech to make your model. Remember this birth rate is based on certain assumptions. If you change an assumption, it will affect your model.

**Step 5** Entering numbers into the Habitech interface:

### Recording of Models

Initial #	Birth rate %	Death rate %	Years	Descr.
10	4%	4%	2 year	< 13

Figure 1: Parts of the worksheet and computer interface. The numbers in the tables, equation and the italicised answers were entered by the students

work and tell us

At 444, M opens with a proposal to collapse two stages of calculation into one. In fact, this proposal is perhaps something akin to what is embodied implicitly in the worksheet, and is potentially a creative proposal embodying a concept rather close to one of the core aims of this curriculum—the understanding of mathematical functions. M is proposing to compose two functions into a single function taking the argument of the first and the value of the last. L objects to this proposal and justifies her objection by pointing out that ‘the number born are not how much survived’. In fact we will see that in the terminology of the worksheet, the number of fry surviving expressed as a percentage of the whole population *is* the birthrate, which plays its part in this confusion. M appears to understand the objection and explains his proposal's departure from the worksheet with some success. L accepts the sense of the innovation even though she expresses reservations about its coordination with the worksheet. The activity is turned over to the superior calculating powers of ‘that mechanical thing’—the computer program Habitech.

Unfortunately, the ‘mechanical thing’ does not understand the creative proposal—L's reservations are well motivated, but, lacking a clear understanding herself, her intervention does not deflect the group (see Greeno, Sommerfeld & Weibe (2000) for further analysis). There are numerous problems of coordination between the representations in Figure 1. The survival rate of 5% at Step 2 gets copied into the model table as 4% (possibly a memory error, or a correction later). But the serious error is in shortcutting the calculation at Step 4 and entering the 4% rate directly into the birthrate box at the end. The algebraic ratio part at Step 4 is returned to only later next day when trying to comply with having the whole thing filled in.

What has gone wrong as the group struggles with the welter of representations and numbers? It is hard to give a crisp interpretation of a murky confusion, but we can suggest some of the contributing factors. An important source may be a divergence of the ordering of biological events and the calculation events that refer to them; another is the terminology. In the fish world, fry are born, and then the vast majority are eaten, and then at the end of the season they are counted. In the calculation world, first the number of births are calculated; then a survival rate is applied; and a census number of surviving fry results. So far so good. But turning the page after Step 3, and after recording model parameters on the next page, the students arrive at a further calculation of the ‘birthrate’, where ‘birthrate’ now means ‘birth-and-survival-to-year's-end rate’.

So, at Step 1, the birthrate is a set of numbers representing the brood size of the average guppy at different ages (namely the numerals 4, 50, 0); at Step 2, the birthrate is the number (namely the numeral 104) of fry born to the whole population. In steps 3 and 4 *birthrate* is the birth and survival to end of season rate expressed as a percentage of the whole population (namely the numeral 4). The same idea, a very tangible idea, is represented each time by a number, but each time the number counts different kinds of thing, and complex calculations constitute the inference rules which ‘move the number from box to box’.

Unfortunately, M's insight that two functions can be composed requires attendant housekeeping to keep the ontology straight. Perhaps a contributing factor is that because the pre-survival birthrate in Step 1 is never put into the form of a percentage (1040%), M does not appreciate that, after Step 3, it already has been implicitly composed with the survival rate, and the calculation at Step 4 is intended only to get back to a percentage form. The terminology unfortunately exacerbates this problem of 'backward causality'—first calculating a survival rate (using births) and then calculating a birthrate from that figure.

### Post-test—the persistence of a confusion

We now present an incident from the post-test in which the group displays evidence that the episode of confusion just described has not been fully resolved. Although in the intervening couple of weeks the group has made good progress in understanding population models, as is illustrated in Hall (submitted to this volume), it is of some concern that the particular confusions surrounding the derivation of birthrate from raw data appear to persist.

The group is working on the post-test problem of constructing a model for a mouse population preyed on by cats. This episode is from fairly early on when they are settling on a birth rate for mice and have not yet considered predation:

- 76: M. four, five or six? per adult?  
77: K. If we're going to go four, five or six, let's go four.  
78: L. actually lets use five. Its four through six. Let's use five.  
82: M. OK how do we find out the birthrate? (grabs a piece of paper) We do the ... five is what we decided on. How many did we start out with (looks at the computer)  
83: L. Twenty  
86: M. I'm not sure that this is right (as he writes  $5/20 = X/10$ )  
87: M. What's 500 divided by twenty?  
88: L. What are you doing?  
89: M. Finding out the birth rate  
90: L. Oh yeah.  
91: M. What's 500 divided by 20? (K hands him the calculator and M starts punching in numbers)  
92: M. 25% I could have figured that out myself (K laughs; M goes back to the computer) 25% right? (enters it into the birthrate) and how many die?

Segment 82 illustrates the pervasive struggle with the semantics of numbers. M accepts that they will use 5 (babies per litter per season) which one might think *is* a birthrate, but in this context, 'birthrate' is a specific number that can be entered into certain boxes on worksheet and computer screen. The birthrate, in this sense, they correctly appreciate they do not have, and this is precisely where they had problems before. The number they seek is a percentage. At 87, M has implicitly multiplied the 5 by 100 and is now explicitly going about dividing by twenty (the number in the initial population). L not surprisingly doesn't understand where the 500 came from and asks for clarification, but receives only the description at the completely unhelpful level "finding out the birthrate". The problem is then accepted as a calculation problem, and the semantics is left unaccessed. Why should

the number of babies in one litter divided by the total number adults in the population multiplied by 100 yield a percentage birthrate? The answer would appear to be that the based on some dim memory of a ratio formula (Step 4, Figure 1).

The group is content to continue to the next stage of the problem and does not question the reasonableness of the figure of 25%. This is testimony to the insulation of the numbers from what they mean. If each couple has 5 babies, the actual number is 250%. But the group do not discuss finding this number or acknowledge that adults have to be paired up. The group does not even apply the qualitative reasoning that since the parents are outnumbered by their babies, the birthrate must be more than 100%. Such qualitative inferences are only available if the numbers are treated as standing for something other than themselves—numbers. Even when the model actually turns out to extinguish the mice in short order, the problem is not traced to the low birthrate. It is all too easy for a problem to hide in a complex model. The whole point of models is that many parameters contribute to their outcome. But this means that there are many possible culprits when the outcome is unacceptable.

### Discussion

Nothing by way of inferences about the causalities or even correlations between the kinds of events observed here can emerge from an analysis of these few isolated examples. Nor is redesign of a curriculum usefully based on analyses of single incidents. It is clear from other studies of this curriculum that it is highly effective. Indeed, this very group of students shows a considerable mastery of modelling at the post-test phase. The group repeatedly alters parameters of complex models (including not just birth and survival rates but also predation) in the qualitatively correct direction in response to over- or under-shooting of the desired population outcome.

But we believe that these analyses do make clear just what a sea of semantic complexities the group swims in. They are awash with numbers, and those numbers have to travel from one representational system to another to achieve the problem solving task at hand. As they travel, they change their meanings and their names, and their values. Birthrate is rarely the same thing on two occurrences. The whole system cannot be understood as anything other than heterogeneous, and the interpretations as anything other than highly local. If we were to go through the transcript spelling out after each occurrence of a numeral, the type of the entities it enumerates, we would wind up with some splendid and totally incomprehensible sentences. Nor are numerals the only problem. Simply spelling everything out is *not* to be recommended other than as a way of exposing complexity. But we cannot understand the students' problems until this complexity is exposed.

From a theoretical perspective, this may seem either banal or outrageous. Once we are fluent at the skills of transformation required for coordinating the sub-systems of representation, the whole system appears to take on a transparency and homogeneity which is completely illusory. We cease to notice how the very same number means something quite different from occurrence to occurrence, as do many of the other words. We therefore can either forget that the system is heterogeneous (and respond with outrage to the claim), or we can, as theoreticians, claim that there is nothing deep in the

coordinations that are required (and respond with a yawn).

The students do not have the luxury of mastery. For example, one of the banal consequences of the instability of the meanings of the numerals is that there is a huge memory load as evidenced in the repeated mis-recalls of numbers from sheet to sheet of their workings. We do not believe that there is any way out of the heterogeneity. Learning mastery of the coordination of representation systems is a requirement of learning mathematics and science (and probably most other things). But what we can strive to do is to educate both teachers and students into the quirks of the representational furniture they find themselves surrounded by.

Our research experience in classrooms indicates that teachers are rather wary of taking an explicitly metalinguistic stance. They do not often point out the dangers of shifts in meaning of words during an argument. The critical thinking lecturer warns students about equivocation—the same term being used with different meanings in different occurrences in an argument—but only at college. Prevarication is treated as a fallacy, usually assumed to be eradicable, and therefore is perhaps thought to be eliminable from well-kept classrooms. Our analysis in terms of heterogeneity and localness of interpretation strongly suggests that prevarication is not eliminable. We cannot use unique terms for every meaning, and should not if we could. The use of the same term is often essential to anchor the term to the shared concept as the details shift through its various guises. Perhaps signalling when this is likely to be a problem would help? And perhaps teaching teachers to detect the seams that have become transparent for them between systems is an important aim?

But these observations from the classroom are just as important for theories of the semantics of representations. The conventional response to the kind of observations of language we have made here is that everyone knows that natural language is ambiguous. It is easy to acknowledge heterogeneity if a system contains language and diagrams—here the heterogeneity is on the surface. But the idea that natural language consists of many heterogeneous sub-systems is generally resisted, and explained away as polysemy at the lexical level. There are at least two problems with this explanation. The number of polysemous readings required is essentially infinite, and the meaning of one word is systematically related to that of others. Words in these discourses do not function atomistically—they are part of subsystems. If ‘birthrate’ is construed one way, then its contrasting terms such as ‘deathrate’ and ‘survivalrate’ will also be construed in related ways—at least until there is a shift to a different subsystem. Recently, (e.g., Moravcsik, 1998) theories of lexical meaning have paid more attention to the considerable distance between the generalities of the lexicon and the details of contextualised language use. These stratified theories are much more conducive to understanding real language use and the heterogeneous nature of most reasoning.

In learning to get from a real world problem into a formalism, and back out from the formal results of calculation to an implication about the real world, students must cross many experiential worlds and, when working in groups, negotiate complex patterns of authority for knowledge which determine what the group actually does. In these tapes, we again and again see transitions between the world of numbers and the

world of fish and mice. At one point the discourse is entirely numerical and insulated from the real world consequences, as witnessed by the acceptance of completely implausible values. At others, there is a sudden jumping out of the mathematical world to references to the death of a pet fish, or gee, that’s a lot of nasty meeces! Although formalisms distance proceedings from affective states, when we reason about the world, our reasoning should still be animated by affect. We will not understand conceptual learning until we can give an account of how representations, the social arrangements for authority in discourse, and our experiential worlds are all coordinated.

# Inducing hybrid models of task learning from visuo-motor data

Devika Subramanian

## Abstract

We develop a new hybrid model of human learning on the NRL Navigation Task (Gordon et. al. 1994). Unlike our previous efforts (Gordon & Subramanian, 1997) in which our model was crafted from verbal protocols and eyetracker data, we demonstrate the feasibility of using visuo-motor data (time series of sensor-action pairs) gathered during training to construct models of a subject's strategy. The goal of our cognitive modeling is to provide a sufficiently detailed description of the subject's strategic misconceptions in real-time, in order to tailor a personalized, task training protocol. Using a small-parameter hybrid model that can be estimated directly and efficiently from the visuo-motor data, we study the deviation of the subject's action choices from that dictated by a near-optimal policy for the task. This model gives us a clear description of the subject's current strategy relative to the near-optimal policy, thus directly suggesting performance hints to the subject. We also provide evidence that our model parameters are sufficient to account for individual differences in learning performance.

## Introduction

Our goal is to build computational models of humans learning to perform complex visuo-motor tasks. By a model of human learning, we mean an explicit representation of the human's action policies (mapping from the perceptual inputs to motor actions) and its evolution over time. The models will be used in designing personalized training protocols to help humans achieve high levels of competence on these tasks. This intended use places constraints on the class of models we can consider and the methods for evaluating them. In particular, the models need to be detailed enough to pinpoint problems in a subject's learning; yet be coarse enough to be unambiguously built from the available visuo-motor learning data. Our criterion for evaluating models is empirical: (i) they must accurately identify incorrect aspects of the subject's strategy, and (ii) when used in place of the human, they must yield comparable performance.

A major challenge in this endeavour is the fact that the visuo-motor data are at an extremely low

level. One approach to modeling in such a situation is to start with a cognitive architecture, and then to find parameter settings for that architecture which recreate the available low-level data. This tactic is adopted by Newell in UTC, Anderson in ACT\* and in EPIC by Kieras and Meyer. We take an alternative approach here based on behavioral cloning (Sammut et. al., 1998). In our approach, the low-level visuo-motor data is taken as the ground truth, and using ideas from machine learning and data mining we "compress" the data in the form of a policy which maps sensors to actions. If there are high level regularities at the policy level in the learning data, they will be reliably extracted by our learning algorithms. This approach has the advantage that cognitive modeling constructs arise endogenously from the data, rather than being stipulated *a priori*.

Our task domain is the NRL Navigation task (Gordon, et al., 1994) developed by Alan Schultz at the Naval Research Laboratory (NRL). It requires piloting an underwater vehicle through a field of mines guided by a small suite of sonar, range, bearing and fuel sensors. Sensor information is presented via an instrument panel that is updated in real-time. The sensors are noisy. Decisions about motion of the vehicle (speed and turn) are communicated via a joystick interface. The task objective is to rendezvous with a stationary target before exhausting fuel and without hitting the mines. The mines may be stationary or drifting. A trial or episode begins with the vehicle being randomly placed on one side of a mine field and ends with one of three possible outcomes: the vehicle reaches the target, hits a mine, or exhausts its fuel. Reinforcement, in the form of a scalar reward dependent on the outcome, is received at the end of each episode. Since the mine configurations vary from episode to episode, it is fruitless for subjects to memorize a

sequence of actions that will get the vehicle to the target. To solve the task, subjects must learn a policy for choosing actions based on the sensor values presented to them.

The Navigation task belongs to the family of partially observable Markov decision processes. With the addition of the last action taken, we can transform it into a fully observable Markov decision process (MDP). This transformation lends theoretical tractability because deterministic optimal decision procedures exist for MDPs. However, the size of the state space is about  $10^{18}$  and there are 153 choices of action at each time step, which make the Navigation task extremely challenging both for humans as well as for present-day learning algorithms like reinforcement learning (Sutton, 1988).

There are four major sources of complexity in the Navigation task from a cognitive perspective: (1) the need for rapid decision making with incomplete information, (2) the sheer number ( $10^{18}$ ) of distinct sensor configurations for which an action choice has to be computed, and the need to learn a partition in the sensor space while acquiring a policy, (3) limited binary feedback at the end of each episode, and, (4) a tightly coupled action space in which the different components (turn and speed) cannot be learned independently. Together, these make the task difficult for our human subjects; one out of every three never acquires the task with our current training protocols.

Our data was gathered as follows. Five subjects ran the Navigation task with a configuration of 60 mines, small mine drift, and low sensor noise.<sup>1</sup> Subjects trained for five days, spending an hour each day running consecutive episodes. The number of episodes per hour varied from around 60 to 160. Each episode varied from 40 to 200 time steps. At the beginning of the first session, subjects were told they had to navigate through a minefield to get to a target location. They were allowed to interact with the task to get comfortable with the use of the joystick. We collected the time series of sensor action pairs as well eyetracker data for the entire training period. We also videotaped the subject and recorded all their verbal utterances. In this paper, we focus on the time series of sensor action pairs to

<sup>1</sup>Five undergraduates at San Diego State University participated in this experiment. The data collection was performed by our collaborators Diana Gordon and Sandra Marshall.

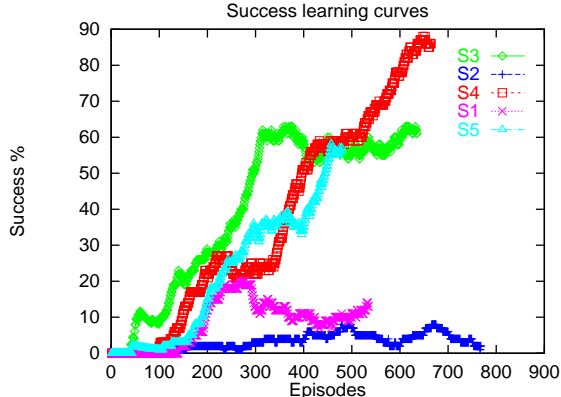

Figure 1: The evolution of success percentages on the Navigation task as a function of training for five subjects.

determine the strategy used by the subject.

In Figure 1 we show the learning curves of the five subjects. Note that the success learning curves are remarkably similar for the three subjects who eventually acquired the task. Subjects go through periods of relatively stable performance, punctuated by substantial improvements. The success curves for the subjects who fail to learn the task are also very similar. This raises hope for building a common computational model for all subjects, with a few parameters to account for individual variations.

The visuomotor performance data for the task is a time series in which each element is of the form: (*episode, timestep, range, bearing, s1, s2, s3, s4, s5, s6, s7, last\_turn, last\_speed turn, speed*). We have over thirty megabytes of visuomotor data for each subject. Extracting the policy used by the subject from this data is difficult for several reasons: (1) the high dimensionality of the data, and the need to find a small number of partitions in the sensor space that meaningfully cluster action choices, (2) noise in the motor data because of joystick hysteresis, (3) data is non-stationary, since the policy adopted by a subject changes with training.

### The approach: comparison against the optimal policy

The key to interpreting visuomotor data is a partitioning of the sensor space into a small number of equivalence classes, each of which is associated with an action choice policy. In this paper, we use the discretization of the sensor space adopted by a near-optimal policy to analyze the distribution of

1. *Part 1: Seek goal: (Sonar in direction of goal is clear)* Follow that sonar at half speed, unless it is the straight ahead sonar, then travel at full speed.
2. *Part 2: Avoid mine/gap finder: (Sonar not in direction of goal is clear)* Turn in place in the direction of the first clear sonar counted from the middle outward.
3. *Part 3: Avoid mine/gap finder: (No clear sonar)* If the last turn was nonzero, turn again in the same direction by that amount, else initiate a turn by summing the sonars to the left and right, and turning in the direction of the lower sum.

Table 1: The three-part near-optimal policy for the NRL Navigation Task. The italicised conditions for each part represent the equivalence class of sensor values that define the part.

actions chosen by our subjects. This approach allows us to determine the deviations of the subject’s strategy from that of the near-optimal policy, which can then be the basis of directed training. A potential disadvantage of the approach is that if there are other near-optimal policies that adopt very different discretizations, a subject using them would be misdiagnosed as making strategic errors<sup>2</sup>. We now describe the near-optimal policy that we discovered, and then present results of modeling the subject’s strategy viewed through its sensor space discretization.

### A near-optimal policy for the Navigation task

A near-optimal policy for the task is deterministic and is shown in Table 1. It must be emphasized that *discovering this solution was not easy!*. It took several months of work with a machine learning algorithm to arrive at this policy.

The near-optimal policy in Table 1 succeeds at least 99.7% of the time; its performance has not been matched by our best human subjects. There are three key properties of the near-optimal policy.

1. *task decomposition*: the policy decomposes the overall goal into the subgoals of avoid-mine and

<sup>2</sup>However, we were unable to determine other near-optimal policies for the NRL task after months of computation and investigation.

seek-goal, a decomposition which appears universal among our human subjects. However, the solutions to the sub-goals are tightly coupled and this is difficult for humans to learn.

2. *dependence between turn and speed choices*: Turning at zero (or close to zero) speeds is essential for success on this task. In addition, turning consistently in one direction while trying to find gaps in the minefield, is crucial.
3. *appropriate discretizations*: the near-optimal policy discretizes the sonar values that range from 0 to 220 into a binary distinction of clear/blocked with the threshold set at 50. The bearing sensor with 12 values is discretized into six, and the range sensor is ignored. The action space is discretized too: the turn action with 17 values is discretized into nine values, and speed with 9 values is discretized into three (zero, half speed, full speed).

The near-optimal policy partitions the state space into three mutually exclusive and collectively exhaustive components. The effective number of states considered by Parts 1 and 2 of the policy is  $2^7 * 6$  which is 768. This is because both parts consider the values of seven sonars, each of which is discretized into clear and blocked, and six values for bearing. The 768 states are really equivalence classes over  $\approx 10^{14}$  base states in the original sensor space. Part 3 examines the previous turn, and thus deals with an effective state space of size  $9 * 27$  which is 243.

### Model extraction algorithm

For ease of presentation, we first describe the model extraction method under the assumption that the visuo-motor sequence data represents a stationary process. This assumption will be relaxed at the end of this subsection. Using the discretizations and definitions of three parts of the near-optimal policy, we classify each sensor-action pair in the visuo-motor sequence as belonging to Part 1, Part 2 or Part 3 equivalence classes. For example, if the sonar in the direction of the goal is clear in the sensor vector, the sensor action pair is classified as a Part 1 pair.

Since the action decisions in Part 1 (resp. Part 2) of the near-optimal policy depend only on the current values of the discretized bearing, we estimate the conditional probability that the subject

chooses a particular discretized<sup>3</sup> action (turn and speed) given the value of the discretized bearing. For discretized action  $a$  in the set  $A$ , and discretized bearing  $b$  let  $n_{ab}$  be the number of times  $a$  is taken by the subject in a Part 1 sensor action pair with bearing  $b$ .

$$P(a|b) = \frac{n_{ab}}{\sum_{c \in A} n_{cb}}$$

The action selection scheme adopted by the near optimal policy for Part 3 sensor equivalence class is inherently sequential. Therefore, to fit Part 3 behavior, we use hidden Markov models (HMMs) (Rabiner, 1989). We identify sequences of sensor-action pairs that belong to Part 3 and train a three state left-to-right HMM on the data<sup>4</sup>.

The parametric hybrid model that we construct from the subject data is shown in Figure 2. Note that the model reflects the task structure. In particular, we use conditional action probability distributions to extract subject behavior on the seek-target subgoal of the task, and a combination of a conditional action probability distribution and an HMM to describe the solution of the coupled subgoal of avoid-mine. This model has few relatively few parameters and can be easily estimated online. It describes the subject’s policy viewed through the equivalence class filter imposed by the near-optimal policy. By comparing the subject’s model for the three parts against that of the near-optimal policy, we can read off strategic errors in the subject’s policy. Examples of such comparisons are offered in the next section.

To accommodate the non-stationary visuo-motor data sequence, we identify stationary subsequences from which the conditional probabilities are estimated and the HMMs are trained. We estimate conditional probability distributions for Part 1 and Part 2 and HMMs for Part 3 over small contiguous blocks<sup>5</sup> of episodes in the data sequence. We then use a standard measure of distance between

<sup>3</sup>The original action set has cardinality 153; the discretized set has nine turns and three speeds making a total of 27 actions.

<sup>4</sup>We experimented with a number of hidden states ranging from 2 to 10, and using log-likelihoods on a left-out test set, we determined that three was the best choice for number of hidden states.

<sup>5</sup>The size of the blocks is determined empirically, and we respect day boundaries in the construction of the blocks.

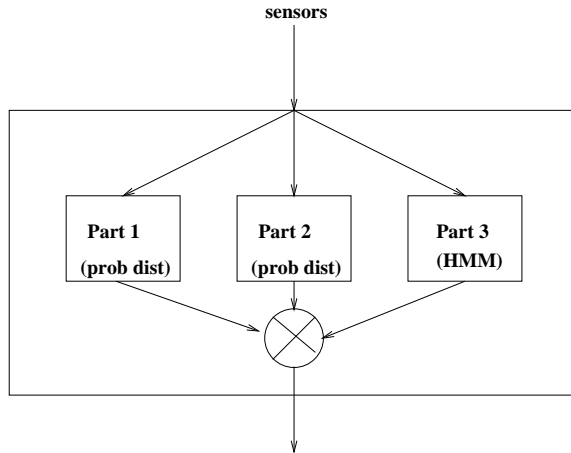

Figure 2: The structure of our hybrid model for the Navigation task.

distributions (KL-divergence<sup>6</sup>) to determine when a significant shift in the Part 1 and Part 2 distributions have occurred. For the HMMs for Part 3, we use KL divergence between both the transition probabilities and the output probabilities to determine when a significant shift has occurred. This procedure identifies points in the sequence that correspond to significant differences in the action selection distributions. These shift points are supported by verbal protocol data as well as eyetracker data. The sequences between shift points are taken as stationary, and the model extraction procedure described above is applied to them.

We now turn to the presentation of experimental results from the use of our model extraction technique on the visuo-motor data corpus for the NRL Navigation task.

## Modeling Results

Examination of the conditional probability distributions of part 1 and 2 and HMMs of part 3 from the three successful subjects reveals that they learn the following.

1. to follow the as-the-crow-flies strategy in the direction of the goal in states in Part 1.
2. to slow down significantly when turning in Parts 1, 2 and 3.
3. to turn minimally to avoid mines in states in Part 2.

<sup>6</sup> $KLdiv(p, q) = \sum_{s \in S} p * \log(p/q)$ , where  $p$  and  $q$  are discrete distributions defined over a set  $S$ .

action	day 1	day 2	day 3	day 4	day 5
$t = 0, s = 0$	0.334	0.370	0.192	0.090	0.078
$t < 0, s = 0$	0.104	0.083	0.106	0.052	0.031
$t > 0, s = 0$	0.083	0.075	0.081	0.021	0.035
$t = 0, s > 0$	0.408	0.454	0.552	0.695	0.646
$t < 0, s > 0$	0.042	0.005	0.015	0.052	0.081
$t > 0, s > 0$	0.028	0.014	0.053	0.090	0.129
KLdiv	3.528	4.220	2.894	2.369	2.011

Table 2: The evolution of the conditional action probability distribution for Subject 4 in Part 1 when bearing = 11 o'clock. The turn  $t$  and speed  $s$  choices are discretized into six categories for reading ease. Turns greater than zero are left turns, and turns less than zero are right turns. For a full explanation of this table, please see the text below.

- to turn in place consistently to find gaps in the minefield in Part 3.

We demonstrate the first point above with data from Part 1 for Subject 4. For this subject, shifts in Part 1 distributions correspond to day boundaries, so we present the evolution of his action selection policy for each day of training. Table 2 presents the conditional probability of Subject 4 taking an action  $a$ , given that the bearing (goal direction) is 11 o'clock. That is, the target lies slightly to the left of the current heading of the vehicle. The near-optimal policy dictates a mild turn to the left. The KL divergence between the subject's policy and the near-optimal policy is shown in the last row of the table. Note that the subject's policy initially diverges and then approaches the near-optimal policy between day 2 and day 3. Also note the rapid decline in the probability of pausing (turn and speed both equal to zero) as training proceeds, with the most dramatic reductions occurring between day 2 and day 3 and day 3 and day 4. The probability that the subject chooses a left turn goes down from day 1 to day 2, but then steadily increases from day 3 forward. All action probabilities except for straight ahead ( $t = 0, s > 0$ ) and left turn ( $t > 0, s > 0$ ) rapidly decay to zero, indicating that the subject is learning to follow bearing well in the Part 1 equivalence class.

It should be emphasized that while Part 1, Part 2 and Part 3 models for each subject co-evolve, they do not evolve at the same rate, and rarely do significant shifts in these probability models coincide. While Part 1 distributions evolve rather slowly and shifts in them occur aligned with day boundaries;

Figure 3: A hidden Markov model that generates and explains the behavior of Subject 5 in states where all sonars are blocked, day 2, episodes 45-67.

Part 3 HMMs evolve much more quickly. For example, for Subject 5, the Part 3 HMM we acquired on data from episodes 45-67 of day 2, differs significantly from the one learned from episodes 68-90 of day 2. These two HMMs are shown in Figures 3 and 4. The first HMM in Figure 3 is a mathematical description of the following strategy: pause (speed = 0 and turn = 0) for a while, and then make an average of two moves with non-zero speed and turn, and finally settle into oscillating back and forth between pauses, left and right turns at zero speed until time runs out. Note that the probability of left and right turns in the terminal hidden state 3 are about the same. In Figure 4, the HMM encodes the following very different strategy: pause for a while, make a left turn at zero speed, and then settle into an action pattern with a consistent preference for turning to the right at zero speed. That is, the subject no longer oscillates back and forth when hemmed in by mines, she sweeps them from left to right trying to find a gap between the mines. This behavior is fairly close to the near-optimal policy for Part 3. In fact, with practice we can get her to spend less time in the state labeled 1, completely eliminate state 2, and in state 3, we can zero out her tendency to pause and increase her probability to turn right. This analysis forms the basis for designing lessons to help the subject acquire greater competence at the task.

How good a fit to performance does the model in Figure 2 provide? The results on Subject 5 for day 2, for episodes 45-67 and episodes 68-90 are shown in Table 3. Note that although the magnitudes pro-

duced by the model only coarsely approximate those produced by the subject, the trends are captured. For example, both model and subject increase the number of timeouts and reduce the number of their explosions. To get better fits to the performance data, we are currently experimenting with distributions for Parts 1 and 2 conditioned additionally on the previous action.

## Conclusions and Related Work

Our work builds on several distinct pieces of work in the cognitive science as well as the machine learning community. The use of probabilistic models in generating hints for performance improvement is considered by (VanLehn, et. al., 1998). Our work uses a mixture of probabilistic models (conditional action distributions and HMMs) instead of Bayesian networks, and our models are automatically learned from visulmotor data. While the structure of the model is obtained from task analysis (Fredericksen and White, 1989), the parameters are learned by sampling the visulmotor data corpus. The idea of behavior cloning introduced by (Sammut et. al.,

1998) underlies our approach, however the specific techniques for partitioning and learning from non-stationary data are different and novel.

In sum, we have developed a new hybrid model for the NRL Navigation task and presented methods for automatically learning it from low level visulmotor data. The model succinctly represents the deviation of the subject’s policy from a near optimal policy, and allows directed design of new training instances. The model is expressive enough to capture individual differences in strategy. Our current work is to provide closer behavioral fits to the visulmotor data by using richer probabilistic representations.

## Abstract

A distinguishing feature of self-organizing models of cognitive structure is that they permit incompatible structures to coexist at least temporarily. Here we report on a connectionist model of natural language processing which appears to temporarily construct incoherent structures. We then describe two reading-time studies which reveal people exhibiting the same tendency. In particular, both networks and people show sensitivity to the irrelevant structural interpretations of the underlined phrases in (1) and (2).

(1) We did not think the company would fire truck drivers without consulting the union first.

(2) The manager watched the waiter served pea soup by the trainee.

This kind of sensitivity is absent in parsing models which treat grammatical constraints as absolute because such models lack a principled method of generating incoherent parses. Connectionist networks make the right predictions by using feedback and self-organization. Our results push in the direction of seeking a solution to the tractability problems of parsing by using dynamical mechanisms in a parallel architecture.

## Introduction

Current sentence-processing research tends to focus on ambiguity-related processing in sentences like (1) – (3):

(1) The mechanic maintained the truck was working beautifully.

(2) The cop arrested by the detective was chagrined.

(3) The cook stirred the soup with the tomatoes.

Each of these sentences has a structural ambiguity which is resolved on the basis of structural or pragmatic information when the underlined words arrive. Reading time and eye tracking studies show that when biases favor the wrong interpretation initially, readers tend to slow down and/or make regressions in the disambiguating region, which suggests that they either choose the wrong parse initially or are biased toward it (see Frazier, 1988; Tanenhaus & Trueswell, 1995).

Such phenomena accord well with a model of sentence processing which assumes people construct phrase-structure parses incrementally based on the input up to the current point in time. On this view, the slow-down in the disambiguating region is due either to extra time

Figure 1: The Zöllner illusion.

spent on revising an incorrect parse, or to extra time spent on revising the weighting assigned to different possible parses maintained in parallel.

Focusing for a moment on cognitive processes outside of sentence processing, there is a good deal of evidence that people are reliably vulnerable to certain adverse influences when interpreting complex stimuli. In the Zöllner illusion (Held, 1971—Figure 1), lines on a page appear to be nonparallel even though retinal and depth of field information indicate parallelism. Similarly, in the Stroop effect (Stroop, 1966), a decision is supposed to have been made ahead of time to interpret the stimulus along one particular dimension of contrast (e.g. color), and yet when the stimulus is presented, people are often led astray by irrelevant verbal information.

These cases are different from the classic sentence processing examples listed in (1) through (3) in that they show people temporarily failing to rule out an interpretation that could be ruled out absolutely, given the information at hand. What would be the analogous cases in sentence processing?

## Definition of Ungrammatical Influences

There is a class of sentences in which one parse of a word sequence can be completely ruled out on grammatical grounds and yet (we hypothesize) people are influenced by it anyway. The following are examples of such hypothesized “Ungrammatical Influences”:

- (4) a. They won’t fire truck drivers on Sunday.  
b. They won’t hire truck drivers on Sunday.

- (5) a. The manager watched the waiter served pea soup by the trainee.  
 b. The manager watched the waiter given pea soup by the trainee.

Each of the (a) examples has a familiar construction within it that is irrelevant to the only grammatical parse of the sentence. But by the time this distractor construction is encountered, it can be ruled out on grammatical grounds. Our hypothesis is that people are influenced by this “ruled out” parse nevertheless. Thus the (a) examples should be processed differently from the (b) examples which lack the distractors. In (4), the sequence of words “fire truck” forms a familiar compound in English, but coming on the heels of a modal verb, “would”, the word “fire” can only reasonably be interpreted as a verb, not a noun. Similarly, in (5a), the second verb “served” must be interpreted as a passive verb introducing a reduced relative clause which modifies the noun phrase, “the waiter”. But, taken in isolation, “the waiter served pea soup” makes a sensible transitive construction with an active verb.

Our hypothesis is that readers will be distracted by these pockets of coherent structure, even though the structures are incompatible with prior information.

## Models

We find that an often-studied connectionist network, the Simple Recurrent Network (or SRN), behaves in accordance with the hypothesis that Ungrammatical Influences exist. This prediction distinguishes it from most current models of sentence processing.

Elman (1991) showed that a recurrent connectionist network trained by and approximation of backpropagation through time (Rumelhart, Hinton, and Williams, 1986) on word prediction could extract much of the structure of a natural-language-like generating process from a corpus generated by the process.

We trained such a network on the output of Grammar 1 (see Table 1). The network was trained on the task of predicting next words in a constantly growing corpus of strings generated by Grammar 1. The sentences were presented to the network one word at a time. Each input unit corresponded to a possible current word and each output unit corresponded to a possible next word (Elman, 1990, 1991). The learning rate was set to 0.01 throughout and no momentum was used.

The network’s output layer had normalized exponential units. During training, error on a given word was thus defined as the Kullback-Leibler Divergence between the vector of network output activations and the output encoding of the next word that occurred in the corpus (Rumelhart, Durbin, & Chauvin, 1995). We stopped training when the network had successfully distinguished the underlying states of the grammar. At this point, it had seen on average about 500,000 words in sequence.

Since optimal training of such networks causes the output activations to converge on the expected value of the outputs given the inputs, we computed the Kullback-Leibler Divergence between the output activation pattern and grammar-derived probability distributions for

Table 1: A simple phrase structure grammar for generating Noun Noun compounds and Noun/Verb ambiguities.

0.50 S	→ SVP
0.50 S	→ SNP
0.17 SVP	→ to waste N[Obj] is unforgivable
0.17 SVP	→ to bear N[Obj] is necessary
0.17 SVP	→ to mail N[Obj] is costly
0.17 SVP	→ to place N[Obj] is challenging
0.16 SVP	→ to cart N[Obj] is toilsome
0.16 SVP	→ to fuel N[Obj] is ignoble
0.17 SNP	→ the waste baskets are large
0.17 SNP	→ the bear cubs are round
0.17 SNP	→ the mail men are persistent
0.17 SNP	→ the place mats are flat
0.17 SNP	→ the cart wheels are shaky
0.16 SNP	→ the fuel tanks are full
NObj	→ baskets, mats, cubs, wheels, tanks, men

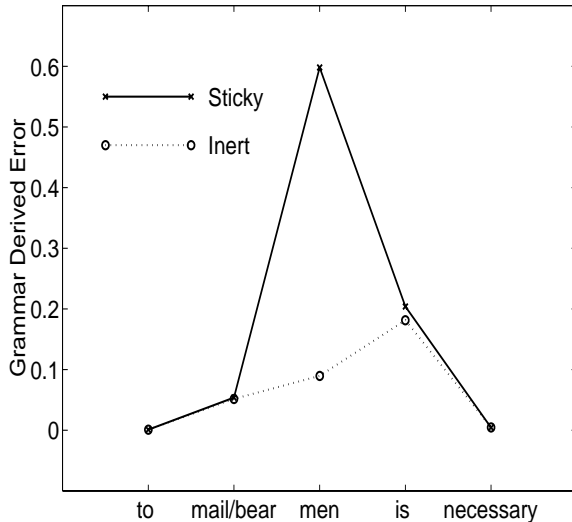

each string of interest. The average Divergences over the six test and control sentences of the form (4) from the grammar are shown in Figure 2.

We repeated the simulation on 10 networks that started learning with different random initial weights. The contrast between the Sticky and Inert conditions occurred in every case. In every case, if we had stopped training earlier (before the network sorted out the differences between states of the underlying grammar), the effect would have been even more pronounced: that is, the network was overwhelmed by the local coherence of the Sticky cases, initially failing to recognize when they occurred in the infinitive context. The effect was somewhat unstable if we trained the network longer on the same materials, and sometimes reversed itself. We suspect that this instability might be reduced if the distractor compounds were not such a prominent feature of the grammar. In real language corpora, coincidences of the Sticky type appear to be quite rare. There are no instances, in the million word Brown Corpus, of coincidental juxtaposition of the 20 sticky pairs used in Experiment 1.

Following Juliano & Tanenhaus (1994), we make an analogy between the network’s error scores and reading times in the self paced reading task (Just, Wooley, & Carpenter, 1982) that is often used to study human sentence processing. The network model thus predicts that readers can be distracted by irrelevant interpretations of pairs of words, and that this distraction will lead to higher reading times on the distracting items.

It appears that the Simple Recurrent Network is prone to be distracted by Ungrammatical Influences. By contrast, standard models of syntactic processing, which assume incremental construction of phrase-structure parses, do not predict such effects, for such models insist on global coherence of each parse they construct. There

Figure 2: Simulation 1: Divergence from grammar-derived expected values. Sticky sentences contain irrelevant Noun-Noun compounds immediately after the main verb. Inert sentences do not.

is one class of hybrid Connectionist-Symbolic models which may, with some modifications, predict Ungrammatical Influence effects: it is the class consisting of the Competitive Attachment Processor (“CAPERS”) of Stevenson (1994) and the Dynamical Unification-Space parser of Vosse and Kempen (1999). These parsers build phrase structure trees by positing variable-strength bonds between nodes in a phrase-marker, and allowing incompatible attachment possibilities to compete with each other under a set of constraints which favor globally coherent structures. Both of these frameworks currently assume that words are brought into the “Unification Space” one at a time, and that some resolution is reached before additional words are incorporated. Thus they do not permit local coherences between successive words to give rise to detached substructures. Nevertheless, it is natural to consider the possibility of allowing them to do so. If one were to permit arbitrary local bonding, then these dynamical structure-building models would probably (modulo the setting of some noise and decay parameters) predict Ungrammatical Influence effects.

What, then, is at stake when we ask the question if Ungrammatical Influences exist? Distinguishing properties of the SRN and the hybrid connectionist models are the use of dynamical (continuously adjusting) feedback and self-organization. These models contrast with chart parsers, pushdown automata and other incremental symbolic parsing systems which maximize the use of constraining information at each point in time. Research on incremental symbolic parsing has strained to grapple with tractability problems associated with the combinatorial growth of parse structures. It seems, at first blush, that opening the door to the inclusion of local coherences, as the Ungrammatical Influences hypothesis

suggests, will only make matters worse. But this impression may be misleading. The coincident emphasis on feedback mechanisms, which allow efficient elimination of incoherent parses through competition, may be just what is needed to permit a parallel processing solution to the tractability problem. Thus, the significance of finding empirical evidence for Ungrammatical Influences is that it would push us in the direction of seeking such a solution.

We turn, now, to empirical investigation of the hypothesis.

## Experiment 1

Tabor and Richardson (1999) compared examples like those in (4a-b) above.

### Method

#### Subjects

Thirty-two undergraduates from Cornell University participated in the experiment. All were native speakers of English. The subjects received course credit for their participation. The experiment lasted for about 30 minutes. The data from one subject was removed from the analysis because of a corrupted file problem.

#### Materials.

Sixteen target sentences and 16 controls were created. Each target sentence included a clause beginning with a syntactic pattern that strongly constrained the next word to be a verb (e.g., *Some people cannot...* (NP Aux: 7 stimuli), *We decided to...* (NP V[inf] to: 7 stimuli), *on a proposal to...* (P NP to: 1 stimulus), *need a truck to...* (V NP to: 1 stimulus)). This next word (labeled “Word 0” in Figure 3) was lexically ambiguous between a verb sense and a noun sense. In its verb sense, it fit naturally with the preceding and following sentential context, both syntactically and semantically. In its noun sense, this word formed a compound with the word after it (“Word 1”), but this compound did not fit the surrounding context either syntactically or semantically. In 15 of the 16 cases, the compound was a Noun-Noun compound. In one case (“fail safe”) the compound was an Noun-Adjective compound. The control sentences were exactly the same as the target sentences except that Word 0 did not form a familiar compound with Word 1. In 14 out of the 16 controls, Word 0 was ambiguous between a verb sense and a noun sense (the two exceptions were “attend” and “flunk”). This control ambiguity was important for ruling out the possibility that any contrast we might observe between target and control sentences might be due to contrasting ambiguity in Word 0.

#### Procedure.

The sentences were presented using the moving-window self-paced-reading method of Just, Carpenter, and Wooley (1982). Readers read sentences one word at a time, pushing a spacebar to see each successive word. Reading times are measured as intervals between spacebar presses.

The 20 targets and controls were sampled randomly and distributed among 80 filler items. The experiment was preceded by a sequence of six practice trials.

Figure 3: Graph of mean reading time versus position for Experiment 1.

**Results.** All subjects scored better than 80% on the comprehension questions.

We computed the base 10 logarithms of the raw reading times to normalize their distribution. We performed a linear regression with characters-per-word as independent variable and subjects as random factor. The analyses we report below were performed on the standardized residuals from this regression analysis (Trueswell, Tanenhaus, & Garnsey, 1994).

Figure 3 shows average self-paced reading times at word positions -2 through 5. For each region of interest, subject and item means were subjected to separate analyses of variance (ANOVAs), each with a single factor: Stickiness. The means were not significantly different across the two conditions at any word prior to Word 2 or beyond Word 4. The effect of stickiness was significant in both subject and item analyses in the region defined by Words 2, 3, and 4 together ( $F(1, 30) = 10.77, p < .005$ ;  $F(1, 15) = 4.79, p < .05$ ). The stickiness effect was also significant in the subject analysis at Word 2 alone ( $F(1, 30) = 5.82, p < .05$ ), at Word 3 alone ( $F(1, 30) = 8.78, p < 0.01$ ), and at Word 4 alone ( $F(1, 30) = 6.38, p < .05$ ). Stickiness was marginally significant in the item analysis at Word 3 alone ( $F(1, 15) = 4.35, p = .054$ ) and at Word 4 alone ( $F(1, 15) = 3.51, p = .08$ ).

#### Discussion.

These results support the claim that Ungrammatical Influences involving two word sequences exist.

But there is an alternative explanation of the outcome should be considered. An early indication of the existence of Ungrammatical Influences came from a priming experiment on the modularity of the lexicon. Tanenhaus, Leiman, & Seidenberg (1979) found that even the irrelevant meaning of a syntactically ambiguous word (e.g. “rose”) would cause priming for a short interval (< 200ms) after the word was read in a syntactically

constraining context (e.g., “They all rose.”). These results are naturally accounted for in a model that assumes that an activation based lexicon operates partially independently of a phrase-building parser. An ambiguous word activates nodes corresponding to all its senses in the lexicon, and irrelevant nodes are only clamped down when syntactic information is later brought to bear. The results of Experiment 1 may reflect such lexical “automaticity”, since the two-word locally coherent structures are Noun-Noun compounds, which are arguably lexical items (e.g., Mohanan, 1986). Perhaps the parser correctly chooses to treat these sequences as Noun-Verb collocations, but activation of the compound sense in the lexicon creates interference which slows reading down.

Thus Experiment 1 does not decisively demonstrate the existence of Ungrammatical Influences. The next experiment is designed to probe for the existence of Ungrammatical Influences in a case that does not conform to the lexical activation model’s predictions.

## Experiment 2: English clauses

### Experiment 2

The examples in (5a) contain a potentially distracting local coherence in the form of a clause. It is less convincing that clauses are stored as lexical units since they occur in so many combinations and their meanings can generally be computed compositionally.

#### Method.

##### Subjects.

47 subjects were recruited from classes and through advertisement on the campus of the University of Connecticut. All were native speakers of English. They received either money or course credit for their participation. The experiment lasted for about 30 minutes.

##### Materials.

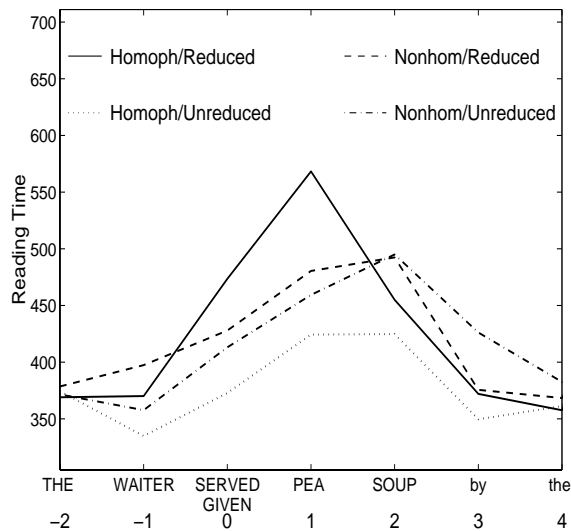

Eighteen experimental items were created. Each item involved four conditions as in (6):

(6) The	manager	watched	the	waiter...			
		0	1	2	3		
a.		served	pea	soup	by...	(R / H)	
b.	who	was	served	pea	soup	by...	(UR / H)
c.			given	pea	soup	by...	(R / NH)
b.	who	was	given	pea	soup	by...	(UR / NH)

Each item included a noun phrase in a non-subject position which was modified by a relative clause in passive voice. Two dimensions of contrast in the relative clause gave rise to four conditions for each item. The relative clause was either reduced (R) or unreduced (UR); its past participle verb was either homophonous and homographic (H) with the corresponding past tense form or distinct from it (NH). Relative clauses like these have been extensively studied in the case where they occur as modifiers of nouns in subject position in a finite clause as in (7) (e.g., Ferreira and Clifton, 1986; Trueswell, Tanenhaus, and Garnsey, 1994).

(7) The waiter served pea soup by the trainee ate ravenously.

Figure 4: Reading times in the four conditions of Experiment 2.

The evidence indicates that when it is semantically sensible to interpret the verb following the subject noun as the main verb of the clause, readers have a strong tendency to do so. Consequently, they become confused starting around the words “by the trainee ate” in a case like (7) because these words disambiguate in favor of the relative clause reading. In a case like (6a), however, the syntax of the words prior to the reduced relative clause precludes the possibility of a main verb reading of the relative clause verb (“served”). If readers were to compute such a reading, then, this would be a case of an Ungrammatical Influence.

We are looking for an effect of Reduction in the Homophonous case. If this effect obtains and the Unreduced cases are read faster than the Reduced cases, the Ungrammatical Influences hypothesis will not be contradicted. However, it would be premature to take such a result on its own as evidence for the existence of Ungrammatical Influences. Greater speed of processing is expected at the relative clause verb in (b) simply because the syntax is more constraining at this point in case (b) than case (a). That is, it is generally the case that processing speed is faster at grammatical events that are more expected (Jurafsky, 1996; Tabor, Juliano, and Tanenhaus, 1997). Thus, we expect a slowing effect of Reduction in the Nonhomophonous case as well ((d) vs. (c)). For this reason, we have employed the more complex 2 x 2 design. We expect that reduction will slow processing in both cases (a) and (c), but it will slow it more in (a) than in (c). If this interaction occurs, then we will have convincing evidence of the existence of Ungrammatical Influences.

#### Procedure

The procedure was the same as for Experiment 1.

**Results.** All subjects scored better than 80% correct on the comprehension questions and all the data were used in the analysis.

Figure 5: Interaction between Homophony and Reduction in Experiment 2 (Words 0 to 2).

For each region of interest, subject and item means were subjected to separate analyses of variance (ANOVAs), each with two factors: Homophony and Reduction. There was a main effect of Reduction in the region defined by Words 0 to 2 ( $F(1, 46) = 16.83, p < .001$ ;  $F(1, 17) = 7.71, p = .013$ ). There was a main effect of Homophony in the region defined by Words 2 to 3, that was significant in the subject analysis only ( $F(1, 46) = 21.10, p < .001$ ). In both subject and item analyses, there was a significant interaction between Homophony and Reduction over the region defined by words 0 to 2 ( $F(1, 1) = 26.83, p < .001$ ;  $F(1, 1) = 6.99, p = .018$ ). The interaction was also significant at Word 0 ( $F(1, 46) = 12.31, p = .001$ ;  $F(1, 17) = 11.66, p = .004$ ), and significant by subject at Word 1 ( $F(1, 46) = 6.03, p = .018$ ;  $F(1, 17) = 3.85, p = .069$ ) and Word 2 ( $F(1, 46) = 4.25, p = .045$ ). Figure 4 is a graph of reading times for Experiment 2. Figure 5 is graph of the interaction. As Figure 5 indicates, Reduction slowed reading times in both the Homophonous and the Nonhomophonous conditions, but the slowing was significantly greater in the homophonous case.

#### Discussion

The existence of the interaction, with Reduction slowing the Homophonous case more than the Nonhomophonous case, supports the Ungrammatical Influences hypothesis.

There is one aspect of the outcome for which we do not have a clear explanation. The distracting effect of the local structural ambiguity affects reading times earlier in Experiment 2 than in Experiment 1, relative to the locally ambiguous region. We speculate that this difference in timing stems from the fairly unusual syntax of the grammaticality correct interpretation of the Experiment 2 sentences. Reduced relative structures with ditransitive verbs are especially unusual, so readers may be working hard to interpret the sentences in the first place,

and an additional distraction from an Ungrammatical Influence may easily disrupt processing. By contrast, the syntactic structures of Experiment 1 are very common modal+Infinitive or “to”+Infinitive collocations, so readers may not detect the distracting influence until it has had more time to “sink in”. This interpretation again supports a dynamical treatment of information in parsing: some information takes longer to emerge than other information.

### Conclusion

We have focused on the hypothesized phenomenon of Ungrammatical Influences: the syntactic parser is expected to be influenced by local, phrasal coherences that are incompatible with the structure of preceding syntactic material. Two experiments supported the existence of Ungrammatical Influences in parsing. Such effects push the theory of parsing strongly in the direction of dynamical, self-organizing models: Ungrammatical Influences occur because the parser is letting all local coherences among words compete to combine into a maximally coherent structure, rather than deductively eliminating parses based on top-down well-formedness constraints.

Although the present experiments suggest treating Ungrammatical Influences as a kind of interference effect (consistent with the class of Limited Resource models of parsing). Ungrammatical Influences may not always get in the way of parsing. Galantucci, Flores D’Arcais, and Tabor (1999) found that when sentences required people to establish reference for a pronoun, and there was a natural candidate embedded in the internal structure of a compound word (e.g., *The killjoy<sub>i</sub> did not manage to kill it<sub>i</sub> after all.*), processing was facilitated, even though grammatically, the binding is disallowed. These results, combined with the results discussed in this paper suggest that the theory of grammar needs to take up in earnest the problem of incoherent structure representation.

### Acknowledgments

Daniel Richardson was a major contributor to the early stages of this work. Many thanks also to David Perkowski and Kate Finerty who helped with the design and running of the experiments. Helpful comments were provided by Ted Gibson, Neal Pearlmutter and the members of Pearlmutter’s lab group at Northeastern University as well as by the members of the University of Connecticut Linguistics/Psychology lunch talk group.

## Abstract

A number of language processing studies indicate that violations of syntactic constraints are processed differently from violations of semantic constraints (Brain imaging: e.g., Ainsworth-Darnell et al., 1998; Ni et al., in press; Speeded grammaticality judgment: McElree & Griffith, 1995; Eye-tracking: Ni et al., 1998). Although these results are often taken as support for the view that the processor employs two separate modules for enforcing the two classes of constraints, we find (in keeping with Rohde & Plaut, 1999, and Tabor & Tanenhaus, 1999) that a nonmodular connectionist network can learn a quantitative distinction between the two types of constraints. But prior connectionist studies have been inexplicit about why the distinction arises. We argue that it stems from the distinct distributional correlates of the different types of information: syntax involves gross distinctions; semantics involves subtle ones. We also describe the Bramble Net, an attractor network which derives grammatical categories and models an approximation of the syntax/semantics distinction in qualitative terms. These results support Elman's (1990) suggestion that grammatical structures may arise by self-organization, rather than by hardwiring. They also help clarify what the grammatical structures are in a self-organizing connectionist network, and emphasize the usefulness of dynamical systems theory in grammatical explanation.

## Introduction

### Definition of syntax vs. semantics

By the distinction between syntax and semantics we mean the fundamental one that Chomsky (1957) identified when he contrasted (1a) with (1b).

- (1) a. Colorless green ideas sleep furiously.  
b. Furiously sleep ideas green colorless.

The modificational relationships between the words in (1b) are not evident to a native English speaker, and one cannot identify any coherent phrasal hierarchy. We thus label (1b) as syntactically anomalous. By contrast, native speakers have no trouble deciding on a parse tree for (1a), but the meanings of the complex phrases are odd and seemingly contradictory. We thus call (1a) semantically anomalous.

By employing some of the basic apparatus of Generative Grammar, we can make a finer characterization of the two types. If we assume that phrases are organized

around grammatical heads which select the semantic attributes of their complements, then (1a) can be diagnosed as an amalgam of *selection violations*. *Subcategory errors* involve incorrect selection of an argument-structure constellation, typically of a verb, (e.g., in \*Ermin put the book). *Agreement errors* involve inconsistencies between elements that are required to share a common feature like number or gender (e.g., \*They eats.) We refer to other mistakes in the sequencing of categories (e.g. \*See dog dog) as *category errors*. The last three types are standardly considered syntactic errors.

### Evidence for the distinction

Drawing a fundamental distinction between syntax and semantics has several advantages.

First, it is only by factoring out the variation in sentence quality due to semantic contrast that it is possible to discern the simple approximation of the range of a language that its phrase structure rules provide (Chomsky, 1957). These rules receive independent justification from the observation that they permit a compositional treatment of meaning that largely accords with human judgment (Frege, 1892).

Second, several recent language processing studies indicate distinct processing responses to syntactic and semantic anomaly. McElree and Griffith (1995) used a speeded grammaticality judgment task to find out how quickly people could detect syntactic and semantic anomalies. They found that detection of syntactic anomaly (both subcategorization violation and category violation) rose above the level of chance about 100 ms. sooner than detection of semantic anomaly (selection violation). Ni et al. (1998) and Braze et al. (submitted) used an eye-tracker to monitor participants as they read sentences that were semantically (selection violation) and syntactically (agreement violation) anomalous. They found that readers slowed down at both kinds of anomalies, but for syntactic anomalies the distribution of their regressive eye movements spiked abruptly on the anomaly itself or shortly after, while for semantic anomalies it was strongly skewed toward the end of the sentence. Ainsworth-Darnell et al (1998), tied together many previous EEG studies by demonstrating independent responses to the two types of anomalies in individual participants. Ni et al. (in press) showed distinct regions of brain response to the two types using fMRI.

## Models

The distinction between syntactic and semantic anomaly seems to be well supported both theoretically and empirically. It is therefore desirable to have a good understanding of how it is instantiated in mental representations. The standard view, coming from Generative Linguistic Theory, assigns separate modules the jobs of checking the two types of anomaly. But this model leaves open the question of how a learner decides whether to attribute an observed distributional systematicity to a syntactic or semantic module. For example, why is “Dogs moo” classified as a semantic anomaly, while “Dogs barks” is a syntactic one?

Connectionist models have exhibited an ability to glean both syntactic and semantic information from text data. Elman (1990, 1991) trained a Simple Recurrent Network or “SRN” on the task of predicting each next word in a simple, English-like corpus. He found that a hierarchical cluster analysis of the trained-network’s hidden unit space contained clusters corresponding to both syntactic classes (Noun, Verb, and various transitivity classes of verbs) and semantic classes (Animate, Large, Edible, etc.). Rohde and Plaut (1999) studied a similar simulation and found that the inclusion of semantic-like lexical cooccurrence biases significantly enhanced the ability of the network to learn complex phrase structures. Moreover, the average lowest transition likelihoods in natural grammatical sentences were higher than the average lowest in grammatical but semantically odd (selection violation) sentences, which in turn were higher than the average lowest in ungrammatical sentences (including verb subcategorization, agreement, and other category sequencing violations). Allen & Seidenberg (in press) used a continuously settling recurrent network and included a bidirectional mapping from form to meaning. The resulting fixed point dynamics provided good generalization behavior.

These results indicate that connectionist networks can derive a distinction between syntactic and semantic structure, while encoding both in a common metric space. But the results raise many questions about what syntactic and semantic structure consist of in such self-organizing models. While, the resemblance of network cluster structures to linguistic categories is suggestive and the alignment of graded network properties with category levels (well-formed, semantically odd, ungrammatical) are encouraging, the findings do not provide much insight into why the resemblances hold or what general properties of the networks produce these results. We performed several additional simulations to better understand how connectionist networks represent syntactic and semantic structure.

### Simulation 1

Following Elman (1991) and Rohde and Plaut (1999), we employed a SRN with three hidden layers, and recurrent connections only in the middle hidden layer. The 30 input units were clamped on or off, one at a time, with each unit uniquely coding the appearance of a particular word. The hidden units (10 in layer 2, 20

in 3, 10 in 4) had fixed sigmoid activation functions. The target at each point in time was an activation of 1 on the output unit corresponding to the next word in the training sequence. We wanted the outputs to converge on probability distributions over next words, so the output units as a group had the softmax (normalized exponential) activation function. We thus employed the multinomial cost function (Rumelhart et al, 1995) and the delta rule was used to adjust the hidden-to-output weights. The remaining feedforward units were trained using additional backpropagation (Rumelhart, Hinton, & Williams, 1986), and the recurrent connections were trained on the approximation to backpropagation through time (BPTT) in which the gradient is estimated on the basis of only a single previous time step of the hidden units (see Pearlmutter, 1995).

We used probabilistic context free rewrite rules to construct a simple grammar similar to the one used by Elman 1990 for training a syntax network (Table 1). The grammar generated only nouns, verbs, and end-of-sentence markers (“periods”). The verbs were either transitive or intransitive. Both the nouns and verbs fell into a number of semantic classes (See Table 1). We defined a selectional violation to be a sentence in which a verb had the right transitivity, but the noun features were not consistent with the grammar (e.g., N[inanimate] V[eat] N[food]). We defined a subcategorization violation to be a sequence in which a strictly intransitive verb took an object, or a strictly transitive verb did not.

The grammar was used to generate strings of words at random. These were strung together end to end and presented to the network one word at a time. The network was trained with a learning rate of 0.01. Momentum was

Table 2: Means of the grammaticality measure. All within-language comparisons are significant ( $p < .001$ ).

not used.

The grammar was used to compute exact target distributions for every juncture between words in the training corpus (see Rohde & Plaut, 1999). The Kullback-Leibler divergence ( $E$ ) between the network’s output and the correct distribution was computed at each word in the training corpus ( $E_w = \sum_i t_i \ln t_i/o_i$  where  $t_i$  is the target for unit  $i$  and  $o_i$  is its output on word  $w$ ). Training was stopped when the cumulative divergence error over a large sample of patterns was consistently small enough that we could conclude that the network was not conflating any of the target distributions with one another (approximately 1 million word presentations).

Rohde & Plaut (1999) studied a measure of sentence goodness based on the network’s output predictions. They found that the mean goodness (log of the product of the two lowest output activation transitions) of normal grammatical sentences was higher than that of selection violation sentences, and the selection violation sentences, in turn, had a higher mean than syntactic violation sentences. Because our sentences were much shorter than theirs, we used a simplified version of their goodness measure (log of the single worst transition) and tested it on well-formed sentences, selection violations, and subcategorization violations. We also found a clear stratification (See the “SVO” rows in Table 2).

One of the consequences of defining syntactic category descriptions independently of semantic classifications is that category order is expected to be able to vary independently of the contrast between semantic and syntactic violation. Generative theory thus predicts that the distinction between selection and subcategorization will persevere across languages with different fundamental word orders. To see if the network made a similar separation, we tested it on the output of a grammar exactly like Grammar 1 except that the order of constituents was systematically Subject (Object) Verb (SOV) rather than Subject Verb (Object) (SVO). Indeed a similar relationship between goodness values obtained in the SOV case (Table 2).

A disadvantage of Rohde and Plaut’s goodness measure is that it does not explicitly characterize the effects on processing of making a low-probability transition. The experiments of Ni et al. (1998) and Braze et al. (submitted) indicate that people react to the anomaly of a sentence at or after the anomalous word or words (in Rohde and Plaut’s terms, after they have made a low-

probability transition). We studied the response of the network to anomalies by examining the hidden unit representations. To do this, we presented a long sequence (2000 words) of grammar-generated words to the network and recorded the hidden unit states associated with each word. Tabor et al. (1997) called this kind of sample a *Visitation Set*. We then tested the network on ill-formed sentences by finding the hidden unit location visited following the transition with the lowest output activation over the course of the sentence (the *low-point*). Table 3 shows the mean distance in hidden unit space between the low-point and the nearest point in the Visitation set for samples of selection violation sentences and subcategorization violation sentences. For comparison, a new random sample of grammatical sentences was also tested against the visitation set.

The minimum distance measure parallels Rohde and Plaut’s grammaticality measure, and points to a useful way of characterizing the effect of anomaly on the network: there is a subset of the hidden unit space that the network sticks to during grammatical processing. This subset is approximated by the Visitation Set. Selection violations throw the network off the track somewhat. Syntactic violations throw it off more substantially.

This geometrical contrast between the anomaly types has a simple explanation in terms of the distributional distinction between selection and subcategorization. Subcategorization refers to more abstract classes than selection. Thus more instances of training are involved in the development of subcategorization contrasts than in the development of selection contrasts, and subcategorization distinctions produce larger separations in hidden unit space. Violations are cases where the information provided by the current word clashes with the information provided by the preceding context. The network responds to such clashes by averaging the conflicting signals. In the case of selection violation, this averaging interpolates between nearby structures. In the case of syntactic violation, the averaging interpolates between widely separated, major clusters. As a result, syntactic violations tend to result in greater displacement from familiar territory. We hypothesize that the empirical results of McElree & Griffith (1995), Ni et al. (1998), and Braze et al. (1999), which found syntactic violations more readily detected than semantic, stem from this contrast: wildly divergent states are easier to distinguish from normal states than slightly divergent ones.

## Simulation 2

Samples of geometric relationships in the SRN’s hidden unit space do not make it clear what the network’s total generalization behavior is, nor whether its coverage of a language can match that of symbolic phrase structure rules. Nor do relative distance measures alone explain the eye-tracking and brain-imaging results indicating qualitatively distinct responses to semantic and syntactic anomaly. Our previous work on sentence processing (Tabor et al, 1997; Tabor & Tanenhaus, 1999) suggests that the study of dynamical settling networks can clarify the structural principles underlying connectionist sequence-learning. We designed the Bramble Network (BRN) to explore this hypothesis. The BRN is similar to the simple version of the SRN that has one input layer, one recurrently connected hidden layer, and one output layer. But the BRN has two sets of recurrent connections in the hidden layer. One set, the discrete weights, works like the recurrent connections in the SRN, changing the hidden activations discretely every time a new word is read. The other set, the continuous weights, undergoes continuous settling according to Equation (1).

$$\frac{dv_i}{dt} = net_i - v_i \quad (1)$$

where  $v_i$  = unit state,  $net_i = b_i + \sum_j w_{ij}\sigma(v_j)$ ,  $b_i$  = unit bias,  $w_{ij}$  = weight from  $j$  to  $i$ , and  $\sigma(x) = \tanh(x)$ .

In the BRN, the input and context units are updated first. Then the input-to-hidden weights and the discrete hidden-to-hidden weights are used to compute an initial state of the hidden units. Continuous settling is carried out via the continuous weights among the hidden units. Finally, the hidden-to-output weights map the final state of the hidden units to the output.

The discrete weights in the BRN are updated just as in the SRN. We also assume that settling only occurs for brief periods of time (1 cycle) before the discrete weights are updated. This makes it easier for the network to discover dependencies across words. The continuous weights are updated according to a principle of stability maximization. That is, for continuous weights, we define the error on unit  $i$  as  $E_i = (dv_i/dt)^2$  so that  $dE_i/dw_{ij} = 2\sigma(v_j)(net_i - v_i)$ . This equation says: change the weights in the direction that minimizes the magnitude of recent activation change. Continuous weight learning is applied only when the network has almost converged to a stable state. It thus moves the stable state in the direction of the initial state, causing bifurcations when widely separated initial states are associated with a single attractor. The overall effect is that the attractors of the continuous weights tend to track the centers of masses of clusters defined by the discrete weights (cf. Tabor, Juliano, & Tanenhaus, 1997). We found it most effective to train the network with a mixture of fast (1 cycle) discrete weight training and slow (approximating convergence) continuous weight training. A similar result was produced more quickly when we did all the discrete training first and then followed it with the continuous training. The simulation we report below used this batch technique.

Figure 1: Principal component projection of the visitation set for the Simulation 2 network.

As in Simulation 1, the network was trained on output from Grammar 1. In this case, we trained it directly on the output of the grammar for 200,000 words of discrete training (learning rate = 0.002, momentum = 0.9) and then 120,000 words of continuous training (learning rate = 0.05, no momentum). At this point, both discrete and continuous training had successfully distinguished the states of the grammar.

To gain insight into the organization of the trained BRN’s processing, we saved the trajectories associated with a random sample of 200 words in sequence from Grammar 1. We performed Principal Component Analysis (Jolliffe, 1986) on this set of points in order to make the structure visible. The trajectories are graphed in Figure 1. (The two principal components shown account for 87% of the variance). Note that there are regions corresponding the major lexical classes (Noun, Verb, and Period). There are also discernible subclusters within the lexical classes. These correspond to both syntactic (e.g. Subject versus Object, Transitive vs. Intransitive) and semantic (e.g. Big vs. Small, Edible vs. Inedible) classes as well as some clusters whose determinants have not yet ascertained.

We tested the network on the same sets of good and anomalous sentences that were used in Simulation 1. We defined convergence times for the network by using Euler integration to compute trajectories with  $\Delta t = 0.05$ , and stopping a trajectory when the distance between successive points on the trajectory passed below a threshold (0.005) or when a maximum of 200 steps was reached. The number of steps in the trajectory was taken as a model of reading difficulty. Table 4 shows mean convergence times for several string classes of interest.

When we designed this model, we expected convergence times to provide a good model of human reading times. This prediction is partially sustained in the contrast between normal sentences in their most familiar sequence (71.43) and selection violations (84.52), for much processing evidence supports the claim that readers slow

down when they encounter less familiar sequences (see Jurafsky, 1996). In a loose sense, the model's very high reading times for syntactic anomalies are also consistent with empirical evidence, for Ni et al. (1998) and Braze et al. (submitted) found readers making substantial regressive eye movements at syntactic anomalies, which implies that they take quite a long time to read past the anomalies. However, it is not clear whether the BRN can predict the McElree and Griffith results showing fast detection of syntactic anomalies. It needs to be able to tell quickly when it's not in a familiar attractor basin. We leave this as a question for future work.

Figures 2–4 show a sample of selection violations, subcategorization violations, and category violations (trajectories end on the x's) against the background of normal processing (end on the o's). The sample of anomalous events was generated by picking the longest trajectory in each sentence. These graphs reveal an interesting structure around which the computation is organized. There appears to be a stable connected manifold (con-

Figure 3: The trajectories the network follows upon processing subcategorization violations (solid lines).

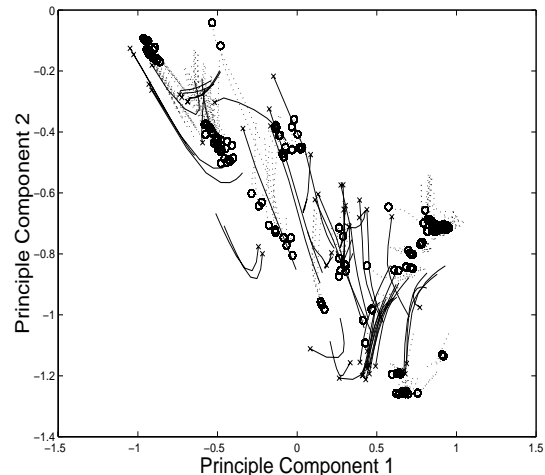

Figure 4: Figure 7. The trajectories the network follows upon processing category violations (solid lines).

tinuous structure that attracts nearby trajectories) running from the upper left of the figure to near the lower right.

There also appear to be pieces of connected manifolds extending to the various other regions where normal processing trajectories end. Perhaps the combination of these manifolds is the locus of grammatical processing. Even semantically anomalous transitions and subcategorization anomalies land by and large on this manifold, though the anomalous cases tend to land on different parts from the normal cases. By contrast, the category violations generally lead to attractors that are separate from the manifold. This suggests that the highly relativistic network model does make a qualitative distinction between types of sentences, and its distinction lines up approximately with current notions of syntactic vs. semantic structure. It is true that the dividing line seems to be different from that of standard linguistic theory, for it is between subcategorization and category error,

rather than between selection and subcategorization error. This difference may stem from a difference between our training grammar and natural language: in natural language, subcategorization constraints are generalizations over more populous classes of items than they are in Grammar 1.

### Conclusions

These graphical results suggest an interesting possibility: the skeleton of a language may be a connected manifold in a dynamical system. Such a finding would be appealing because a connected manifold contains an infinity of points, more than we could ever observe. Thus, identifying such a skeleton could be a way of characterizing one aspect of the unbounded nature of linguistic generalization. Such an insight would be similar to the sort of insight that Generative Theory strives for when it posits a phrase structure or transformational architecture. The trouble with current Generative models, however, is that the steps leading to their creation are very controversial (witness the plethora of current syntactic theories), the data themselves are controversial (note the disagreement about grammaticality judgments), and much of the decision-making that goes into building models of specific parses is not made explicit (note the paucity of implemented parsers that employ modern syntactic theory). The dynamical connectionist approach may be an effective alternative, for it is based on a relatively uncontroversial mathematical theory, it uses performance data rather than competence data and thus does not depend on grammaticality judgments, and the process of choosing a parse is explicit. Moreover, unlike the natural language parsers that have been implemented for practical application, the connectionist theory makes contact with fundamental questions about the principles that underlie linguistic representation.

## Abstract

We apply a computational theory of concept learning based on Bayesian inference (Tenenbaum, 1999) to the problem of learning words from examples. The theory provides a framework for understanding how people can generalize meaningfully from just one or a few positive examples of a novel word, without assuming that words are mutually exclusive or map only onto basic-level categories. We also describe experiments with adults and children designed to evaluate the model.

## Introduction

Learning even the simplest names for object categories presents a difficult inference problem (Quine, 1960). Given a typical example of the word “dog”, e.g. Rover, a black labrador, the possible inferences a learner might make about the extension of “dog” are endless: all (and only) dogs, all mammals, all animals, all labradors, all black labradors, all black things, all running things, this individual animal (Rover), all dogs plus the Lone Ranger’s horse, and so on. Yet, even children under five can often infer the approximate extension of words like “dog” given only a few relevant examples of how they can be used, and no systematic evidence of how words are not to be used (Carey, 1978; Markman, 1989; Regier, 1996). How do they do it?

One influential proposal has been that people come to the task of word learning equipped with strong prior knowledge about the kinds of viable word meanings (Carey, 1978; Clark, 1987; Markman, 1989), allowing them to rule out *a priori* the many logically possible but unnatural extensions of a word. For learning nouns, one of the most basic constraints is the *taxonomic assumption*, that new words refer to taxonomic classes, typically in a tree-structured hierarchy of natural kind categories (Markman, 1989). Given the one example of “dog” above, the taxonomic assumption would rule out the subsets of all black things, all running things, and all dogs plus the Lone Ranger’s horse, but would still leave a great deal of ambiguity as to the appropriate level of generalization in the taxonomic tree that includes labradors, dogs, mammals, animals, and so on. Other, stronger constraints try to reduce this ambiguity, at the cost of dramatically oversimplifying the possible meanings of words. Under the *mutual exclusivity* constraint, the learner assumes that there is only one word that applies to each object (Markman, 1989). This helps to circumvent the problem of learning without negative evidence, by allowing the inference that each positive example of one word is a negative example of every other

word. Having heard Sox called “cat” as well as Rover called “dog”, we can rule out any subset including both Rover and Sox (e.g. mammals, animals) as the extension of “dog”. But some uncertainty in how far to generalize always remains: does “dog” refer to all dogs, all labradors, all black labradors, or just Rover himself?

Inspired by the work of Rosch et al. (1976), Markman (1989) suggested the even stronger assumption that a new word maps not to just any level in a taxonomy, but to an intermediate or *basic* level. Basic-level categories are intermediate nodes in a taxonomic tree that maximize many different indices of category utility and are widely recognized throughout a culture (Rosch et al., 1976). Whether children really have a bias to map words onto basic-level kinds is controversial (Callanan et al., 1994), but it is certainly a plausible proposal. Moreover, the basic-level constraint, together with the taxonomic constraint and mutual exclusivity, actually solves the induction problem, because each object belongs to one and only one basic-level category. However, this solution only works for basic-level words like “dog”, and in fact is counterproductive for all the words that do *not* map to basic level categories. How do we learn all the other words we know at superordinate or subordinate levels? Some experimenters have found that seeing more than one labeled example of a word may help children learn superordinates (Callanan, 1989), but there have been no systematic theoretical explanations for these findings. Regier (1996) describes a neural network learning algorithm capable of learning overlapping words from positive evidence only, using a weakened form of mutual exclusivity that is gradually strengthened over thousands of learning trials. However, this model does not address the phenomenon of “fast mapping” (Carey, 1978) – the meaningful generalizations that people make from just one or a few examples of a novel word – that is arguably the most remarkable feat of human word learning.

To sum up the problem: taking the taxonomic, mutual exclusivity, and basic-level assumptions literally as hard-and-fast constraints would solve the problem of induction for one important class of words, but at the cost of making the rest of language unlearnable. Admitting some kind of softer combination of these constraints seems like a reasonable alternative, but no one has offered a precise account of how these biases should interact with each other and with the observed examples of a novel word, in order to support meaningful generalizations from just one or a few examples. This paper takes some first steps in that direction, by describing one possible learning theory that is up to the task of fast mapping

and applying it to model a simple experimental situation. Our experiments use real, everyday objects with an intuitively clear taxonomic organization, but they require subjects to learn multiple words at different levels of generality which violate the strict versions of mutual exclusivity and the basic-level constraint. Our theory is formulated in terms of Bayesian inference, which allows learners to combine probabilistic versions of *a priori* constraints with the statistical structure of the examples they observe, in order to acquire the sort of rich, multi-leveled vocabulary typical of natural languages.

The paper is organized as follows. Section 2 describes our basic word learning experiment and presents data from adult participants. Section 3 describes the Bayesian learning theory and its application to modeling the data in Section 2. Section 4 concludes and discusses some preliminary data from a parallel experiment with children.

## Experiments with adult learners

Our initial experiments were conducted with adult learners, although the studies have been designed to carry over to preschoolers with minimal modification. The experiment consists of two phases. In the *word learning* phase, participants are given one or more examples of words in a novel language and asked to pick out the other instances that each word applied to, from a large set of test objects. In the *similarity judgment* phase, participants judge the similarity of pairs of the same objects used in the first phase. The average similarity judgments are then submitted to a hierarchical clustering algorithm, in order to reconstruct a representation of the taxonomic hypothesis space that people were drawing on in the word learning phase.

**Participants.** Participants were 25 students from MIT and Stanford University, participating for pay or partial course credit. All participants carried out the word learning task and the first nine also participated in the similarity judgment phase that followed.

**Materials.** The stimulus set consisted of digital color photographs of 45 real objects. This set was structured hierarchically to mirror, in limited form, the structure of natural object taxonomies in the world. Objects were distributed across three different superordinate categories (animals, vegetables, vehicles) and within those, many different basic-level and subordinate categories. The 45 stimuli were divided into a test set of 24 stimuli and a training set of 21 stimuli.

The training stimuli were grouped into 12 *nondisjoint* sets of examples. The first three sets contained one example each: a dalmatian, a green pepper, or a yellow truck, representing the three main branches of the microworld’s taxonomy. The remaining nine sets contained three examples each: one of the three objects from the single-example sets (the dalmatian, green pepper, or yellow truck), along with two new objects that matched the first at either the subordinate, basic, or superordinate level of the taxonomy. For example, the dalmatian was paired with two other dalmatians, with two other dogs (a mutt and a terrier), and with two other animals (a pig and a toucan) to form three of these nine multiple-

example sets.

The test set consisted of objects matching the labeled examples at all levels: subordinate (e.g., other dalmatians), basic (non-dalmatian dogs), and superordinate (non-dog animals), as well as many non-matching objects (vegetables and vehicles). In particular, the test set always contained exactly 2 subordinate matches (e.g. 2 other dalmatians), 2 basic-level matches (labrador, hush-puppy), 4 superordinate matches (cat, bear, seal, bee), and 16 nonmatching objects.

**Procedure.** Stimuli were presented on a computer monitor at normal viewing distance. Participants were told that they were helping a puppet who speaks a different language to pick out the objects he needs. Following a brief familiarization in which participants saw all 24 of the test objects one at a time, the experiment began with the word learning phase. This phase consisted of 32 trials in which learners were shown pictures of one or more labeled examples of a novel monosyllabic word (e.g. “blick”) and were asked to pick out the other “blicks” from the test set of 24 objects by clicking on-screen with the mouse. On the first three trials, participants saw only one example of each new word, while on the next nine trials they saw three examples of each word.<sup>1</sup> Subject to these constraints, the 12 example sets appeared in a pseudo-random order that counterbalanced the order of example content (animal, vegetable, vehicle) and example specificity (subordinate, basic, superordinate) across participants. The frequencies with which each test objects was selected by participants when asked to “pick out the other blicks” were the primary data.

In the similarity judgment phase that followed these trials, participants were shown pairs of objects from the main study and asked to rate their similarity on a scale of 1 to 9. They were instructed to base their ratings on the same aspects of the objects that were important to them in making their choices during the main experiment. Similarity judgments were collected for all but six of the 45 objects used in the word learning experiment; these six were practically identical to six of the included objects and were omitted to save time. Each participant in this phase rated the similarity of all pairs of objects within the same superordinate class and one-third of all possible cross-superordinate pairs chosen pseudo-randomly, for a total of 403 judgments per participant (executed in random order). Similarity ratings for all nine participants were averaged together for analysis.

**Results and discussion.** The results of the word learning phase are depicted in Figure 1. Figure 1a presents data collapsed across all category types (animals, vehicles, and vegetables), while Figures 1b-d show the data for each category individually. The four plots in each row correspond to the four different kinds of example sets (one, three subordinate, three basic, three superordinate), and the four bars in each plot correspond to test objects matching the example(s) at each of four different levels of specificity (subordinate, basic, superordinate, nonmatching). Bar height (between 0 and 1)

<sup>1</sup>The last 20 trials used different stimulus combinations to explore a different question and will not be analyzed here.

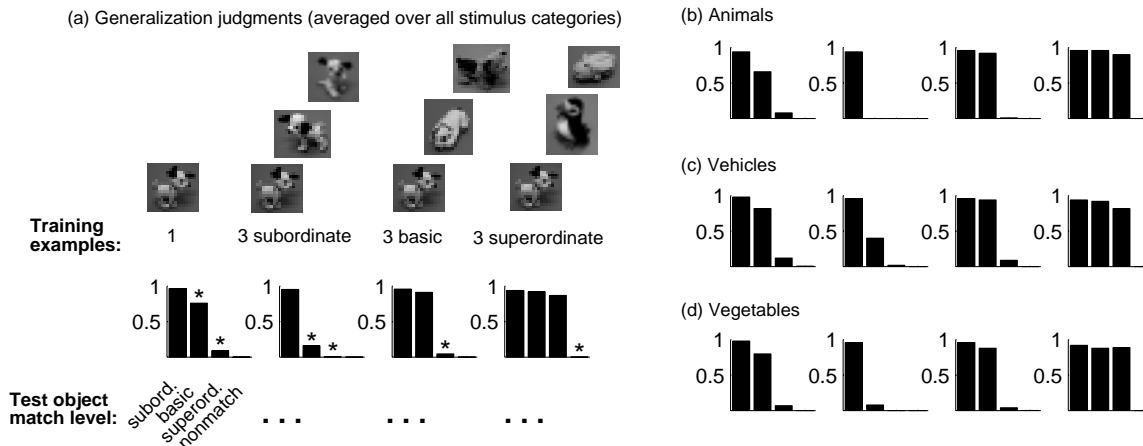

Figure 1: Generalization judgments averaged across categories (a) and broken down into individual categories (b-d).

represents the average probabilities with which participants chose to generalize to the corresponding kind of test object. In Figure 1a, asterisks denote probabilities that are significantly lower than the probabilities to the immediate left ( $p < .05$ , one-tailed paired t-tests ( $df = 24$ ) with Bonferonni correction for 12 comparisons), indicating significant gradients of generalization.

The first plots in each row represent trials in which only a single labeled example was provided. Across all three major categories, participants generalized almost always (97% of trials) to test objects matching the example at the subordinate level (e.g., other dalmatians), often but not always (76% of trials) to basic-level matches (e.g., non-dalmatian dogs), rarely (9% of trials) to superordinate matches (e.g., non-dog animals), and practically never ( $< 1\%$  of trials) to nonmatching test objects (e.g., vegetables or vehicles). Thus, generalization from one example appears to fall off according to a gradient of exemplar similarity, with a threshold located around the basic level.

A different pattern emerges in the last three plots of each row, representing trials on which three labeled examples were provided. Instead of a gradient of generalization decreasing with similarity to the example, there appears in most cases to be a sharp transition from near-perfect generalization to near-zero generalization. The cut-off occurs at the level of the most specific category containing all three labeled examples. That is, given three dalmatians as examples of “blicks”, participants generalized to all and only the other dalmatians; given three dogs, to all and only the dogs, and so on.

Two aspects of these results are consistent with the existing literature on word learning in children. First, we found what appears to be a basic-level bias in generalizing from one example. This interpretation is complicated by the fact that our participants already knew a very familiar word in English for each of the basic-level categories used in our study, “pepper”, “truck”, and “dog”. The tacit knowledge that objects are almost always named spontaneously at the basic level (Rosch et al., 1976) may have increased participants’ propensity to map words in a new language onto these basic-level

categories, and this bias could exist over and above any preference children or adults might have to map words for unfamiliar objects onto basic-level categories. Second, we found that giving participants more than one example had a dramatic effect on how they generalized to new objects, causing them to select all objects at the most specific taxonomic level spanned by the examples and no objects beyond that level. This finding is consistent with developmental studies in which children given two examples from different basic-level categories were significantly more likely to generalize to other objects of the same superordinate category, relative to children given only a single example (Callanan, 1989).

Our results also differ from the developmental literature in important ways. First, we found a qualitative difference in generalization from one labeled example versus several labeled examples. While generalization from a single example decreased according to a gradient of similarity to the test objects, generalization from three examples followed more of an all-or-none, threshold pattern. Second, we found that people could use multiple examples to infer how far to generalize a new word at any level of specificity in a multi-level taxonomy of object kinds, not just at the basic or superordinate levels.

Figure 2 shows the results of a hierarchical clustering (“average linkage”) analysis applied to participants’ similarity judgments from the second phase of the experiment. Each leaf of the tree corresponds to one object used in the word learning phase. (For clarity, only objects in the training set are shown.) Each internal node corresponds to a cluster of stimuli that are on average more similar to each other than to other, nearby stimuli. The height of each node represents the average pairwise dissimilarity of the objects in the corresponding cluster, with lower height indicating greater average similarity. The length of the branch above each node measures how much *more* similar on average are that cluster’s members to each other than to objects in the next nearest cluster, i.e., how distinctive that cluster is.

This cluster tree captures in an objective fashion much of people’s intuitive knowledge about this domain of objects. Each of the main classes underlying the choice of

Figure 2: Hierarchical clustering of similarity judgments yields a taxonomic hypothesis space for word learning.

stimuli (vegetable, vehicle, animal, pepper, truck, dog, green pepper, yellow truck, and dalmatian) corresponds to a node in the tree (marked by a circled number). Moreover, most of these clusters are highly distinctive, i.e., well-separated from other clusters by long branches, as one would expect for the targets of kind terms. Other naturally “nameable” nodes include cluster #23, containing the tractor, the bulldozer, and the crane, but no other vehicles, or cluster #33, containing all and only the mammals. Still other clusters reflect more subtle similarities. For example, cluster #18 includes all of the trucks and also the yellow schoolbus. While the schoolbus does not fall into the class of trucks, it intuitively comes much closer than any other non-truck object in the set. This intuitive taxonomy of objects will form the basis for the formal Bayesian model of fast mapping described next.

## A Bayesian model

We first describe the general approach, saving the details for below. We assume that the learner has access to a hypothesis space  $\mathcal{H}$  of possible concepts and a probabilistic model relating hypotheses  $h \in \mathcal{H}$  to data  $X$ . Let  $X = \{x^{(1)}, \dots, x^{(n)}\}$  denote a set of  $n$  observed examples of a novel word  $C$ . Each hypothesis  $h$  can be thought of as a pointer to some subset of objects in the world that is a candidate extension for  $C$ . The Bayesian learner evaluates these hypotheses by computing their *posterior* probabilities  $p(h|X)$ , proportional to a product of *prior* probabilities  $p(h)$  and *likelihoods*  $p(X|h)$ :

$$p(h|X) \propto p(X|h)p(h) \quad (1)$$

The prior, along with the structure of the hypothesis space, embodies the learner’s pre-existing (though not necessarily innate) biases, such as the taxonomic or basic-level assumptions. The likelihood captures the statistical information inherent in the examples. The poste-

rior reflects the learner’s degree of belief that  $h$  is in fact the true extension of  $C$ , given a rational combination of her observations  $X$  with her relevant prior knowledge about possible word meanings.

**The hypothesis space.** Tenenbaum (1999) introduced this Bayesian framework for learning simple concepts with hypotheses that could be represented as rectangular regions in a multidimensional continuous feature space. Here we adapt that framework to the task of word learning, assuming that the hypotheses can be represented as clusters in a tree-structured taxonomy (e.g., Figure 2). Such a hypothesis space is clearly not appropriate for learning all kinds of words, but it may be a good first approximation for learning common nouns under the taxonomic assumption. Assuming a tree-structured hypothesis space makes the model more tractable but is by no means a requirement of the Bayesian framework. In principle, any subset of objects could be a hypothesis under consideration.

**Priors and likelihoods.** Both priors and likelihoods can be defined in terms of the geometry of the cluster tree. The crucial geometrical feature is the height of node  $h$  in the tree, which is scaled to lie between 0 (for the lowest node) and 1 (for the highest node) and measures the average dissimilarity of objects within  $h$ .

We take the prior  $p(h)$  to be proportional to the branch length separating node  $h$  from its parent:

$$p(h) \propto \text{height}(\text{PARENT}(h)) - \text{height}(h). \quad (2)$$

This captures the intuition that more distinctive clusters are *a priori* more likely to have distinguishing names. For example, in Figure 2, the class containing all and only the dogs (#29) is highly distinctive, but the classes immediately under it (#27) or above it (#30) are not nearly as distinctive; accordingly, #29 receives a much higher prior than #27 (proportional to .181 vs. .028).

The likelihood function comes from assuming that

the observed positive examples are sampled at random (and independently) from the true concept to be learned. Imagine that each hypothesis consisted of a finite set of  $K$  objects. Then the likelihood of picking any one object at random from a set of size  $K$  would be  $1/K$ , and for  $n$  objects (sampled with replacement),  $1/K^n$ . Hence set size is crucial for defining likelihood. While we do not have access to the “true” size of the set of all dogs in the world, or all vegetables, we do have access to a psychologically plausible proxy, in the average within-cluster dissimilarity (as measured by cluster height in Figure 2). Moving up in the tree, the average dissimilarity within clusters increases as they become larger. Thus equating node height with approximate cluster size, we have for the likelihood

$$p(X|h) \propto \left[ \frac{1}{\text{height}(h) + \epsilon} \right]^n, \quad (3)$$

if  $x_i \in h$  for all  $i$ , and 0 otherwise. (We add a small constant  $\epsilon > 0$  to  $\text{height}(h)$  to keep the likelihood from going to infinity at the lowest nodes in the tree (with height 0). The exact value of  $\epsilon$  is not critical; we found best results with  $\epsilon = 0.05$ .) Equation 3 embodies the *size principle* for scoring hypotheses: smaller hypotheses assign greater likelihood than do larger hypotheses to the same data, and they assign exponentially greater likelihood as the number of consistent examples increases. This captures the intuition that given a dalmatian as the first example of “blick”, either all dalmatians or all dogs seem to be fairly plausible hypotheses for the word’s extension (with a likelihood ratio of  $14.08/3.50 \approx 4$  in favor of just the dalmatians). However, given three dalmatians as the first three examples of “blick”, the word seems much more likely to refer only to dalmatians than to all dogs (with a likelihood ratio now proportional to  $(14.08/3.50)^3 \approx 65$  in favor of just the dalmatians).

**Generalization.** Given these priors and likelihoods, the posterior  $p(h|X)$  follows directly from Bayes’ rule (Equation 1). Finally, the learner must use  $p(h|X)$  to decide how to generalize the word  $C$  to new, unlabeled objects.  $p(y \in C|X)$ , the probability that some new object  $y$  belongs to the extension of  $C$  given the observations  $X$ , can be computed by averaging the predictions of all hypotheses weighted by their posterior probabilities  $p(h|X)$ :

$$p(y \in C|X) = \sum_{h \in \mathcal{H}} p(y \in C|h)p(h|X). \quad (4)$$

To evaluate Equation 4, note that  $p(y \in C|h)$  is simply 1 if  $y \in h$ , and 0 otherwise.

**Model results.** Figure 3a compares  $p(y \in C|X)$  computed from the Bayesian model with the average generalization data from Figure 1a. The model achieves a reasonable quantitative fit ( $R^2 = .93$ ) and also captures the main qualitative features of the data: a similarity-like gradient of generalization given one example, and more all-or-none, rule-like generalization at the most specific consistent level, given three examples. The main errors seem to be too little generalization to basic-level matches given one example or three subordinate examples, and

too much generalization to superordinate matches given three basic-level examples. All of these errors would be explained if participants in the word learning task had an additional basic-level bias that is not captured in their similarity judgments. Figure 3b shows the fit of the Bayesian model after adding a bias to the prior that favors the three basic-level hypotheses. With this one free parameter, the model now provides an almost perfect fit to the average data ( $R^2 = .98$ ). Figures 3c and 3d illustrate respectively the complementary roles played by the size principle (Equation 3) and hypothesis averaging (Equation 4) in the Bayesian framework. If instead of the size principle we weight all hypotheses strictly by their prior, Bayes reduces to a similarity-like feature matching computation that is much more suited to the generalization gradients observed given one example than to the all-or-none patterns observed after three examples ( $R^2 = .74$  overall). If instead of averaging hypotheses we choose only the most likely one, Bayes essentially reduces to finding the most specific hypothesis consistent with the examples. Here, that is a reasonable strategy after several examples but far too conservative given just one example ( $R^2 = .78$  overall). Similarity-based models of category learning that incorporate selective attention to different stimulus attributes (Kruschke, 1992) could in principle accommodate these results, but not without major modification. These models typically rely on error-driven learning algorithms, which are not capable of learning from just one or a few positive examples and no negative examples, and low-dimensional spatial representations of stimuli, which are not well-suited to representing a broad taxonomy of object kinds.

## Conclusions and future directions

Research on word learning has often pitted rule-based accounts (Clark, 1973) against similarity-based accounts (Jones & Smith, 1993), or rationalist accounts (Bloom, 1998) versus empiricist accounts (Quine, 1960). In contrast, our work suggests both a need and a means to move beyond some of these classic dichotomies, in order to explain how people learn a hierarchical vocabulary of words for object kinds given only a few random positive examples of each word’s referents. Rather than finding signs of exclusively rule- or similarity-based learning, we found more of a transition, from graded generalization after only one example had been observed to all-or-none generalization after three examples had been observed. While special cases of the Bayesian framework corresponding to pure similarity or rule models could accommodate either extremes of this behavior, only the full Bayesian model is capable of modeling the transition from similarity-like to rule-like behavior observed on this task. The Bayesian framework also brings together theoretical constraints on possible word meanings, such as the taxonomic and basic-level biases, with statistical principles more typically associated with the empiricist tradition, such as the size principle and hypothesis averaging. No one of these factors works without the others. Constraints provide sufficient structure in the learner’s hypothesis space and prior probabilities to enable reasonable statistical inferences of word meaning from just

Examples: 1      3 subordinate      3 basic      3 superordinate

Figure 3: Predictions of the basic Bayesian model and three variants for the data in Figure 1.

a few random positive examples.

Still, the hardest questions of learning remain unsolved. Where does the hypothesis space come from? Are constraints on the hypothesis space learned or innate? In ongoing work, we are exploring how unsupervised learning algorithms might be used to bootstrap a hypothesis space for supervised concept learning. For example, can clustering algorithms like the one we used to construct our taxonomic hypothesis space still be successful when applied to more primitive perceptual representations of objects, instead of adult humans' similarity judgments? Generalizations of the Bayesian framework also hold some promise as bootstrapping mechanisms, in virtue of their ability to propagate probabilistic information from raw data up to increasingly higher levels of abstraction. Perhaps we begin life with a hypothesis space of hypothesis spaces – each embodying different possible constraints on word meanings – and grow into the most useful ones – those which consistently contain the best explanations of the word-to-world pairings we encounter – through the same mechanisms of Bayesian inference used to learn any one novel word.

Examples: 1      3 subordinate      3 basic      3 superordinate

Figure 4: Data from child word learners.

We are also working to extend this line of research to studies of child learners, and to studies of both adults and children learning words for novel objects. Figure 4 shows some promising pilot data from a study with 4-year-old children, using familiar objects in a design approximately parallel to the above adult study. Like the adults, children given three examples of a novel word adapt their generalizations to the appropriate level of specificity, although their superordinate generalizations are less consistent. When given just one example, children show a gradient of generalization much like the adults, but with significantly fewer responses at the basic level and above. If anything, children's overall patterns of responses look more like the Bayesian model's predictions *without* the added basic-level bias (Figure 3a) than *with* that added bias (Figure 3b). Consistent with Callanan et al. (1994), this suggests that a strong basic-level bias may not be a fundamental building block of

early word learning – at least, not as distinct from the more general bias in favor of labeling distinctive clusters that the Bayesian model assumes – but rather develops later as the child gains experience about how words are typically used. This issue is one aspect of a broader question: to what extent should differences between child and adult word learners be attributed to differences in their hypothesis spaces, probability models (e.g., priors), or learning algorithms? We hope to answer these questions as we conduct more extensive studies with child learners.

### Abstract

We investigate the comprehension of sentences where an aspectual incompatibility between a verbal predicate (*send a check*; completive reading) and a verbal modifier (*for years*; durative reading) is resolved through the operation of aspectual coercion. Aspectual coercion modifies the aspectual properties of the predicate in the direction required by the verbal modifier; here the result is an obligatory iterative interpretation for the combined string (*send a check for years*). We find that sentences where the iterative interpretation arises as a result of coercion (*Howard sent a large check to his daughter for years*) show a significant reading delay in the coercion and post-coercion regions as compared to sentences where an iterative interpretation is achieved by other means (*Howard sent large checks to his daughter for years*). Such delay does not occur with substitution of an aspectually neutral modifier (*last year*). We propose that the observed delay is a processing reflex of aspectual coercion deriving either from an initial misanalysis of the aspectual representation of the utterance, or from the need to postulate a null iterative operator in order to arrive at a coherent interpretation of the coerced sentence.

### Aspectual Coercion

This study investigates the processing correlates of aspectual coercion. Aspectual coercion has been proposed in the linguistic and computational literature (e.g. Moens & Steedman, 1988) as an operation that resolves a mismatch between the aspectual properties of the verbal predicate, on one hand, and a (temporal) sentential operator, on the other. In English, the operation of coercion does not have an overt morphological reflex. Therefore, it is generally considered to lack a structural counterpart in the syntax. Instead, the effects of coercion are purely semantic: The verbal predicate obligatorily receives a specific aspectual interpretation, which differs from its most natural (or default) aspectual reading. An inquiry into the processing correlates of aspectual coercion promises to provide valuable information

about the mechanisms of semantic processing in general, and details of computing the aspectual interpretation of an utterance, in particular. This study examines the effects of durative adverbial modifiers on the aspectual interpretation of the predicate. It is hypothesized that coercion triggered by such modifiers is associated with a specific processing cost.

### Aspect

The grammatical category of *aspect* relates to the internal temporal structure of an event. Aspectual distinctions are anchored around the presence or absence of logical boundaries in the denotation of events. For example, the eventuality denoted by the verb ‘find’ seems to contain a logical endpoint, namely the moment at which one becomes aware of the existence of some novel object. It is implausible that the act of finding extends beyond this endpoint; similarly, we cannot say that an event of finding has been instantiated unless this endpoint has been realized. By contrast, the state denoted by the verb ‘love’ can plausibly extend indefinitely in time. This does not mean that loving cannot reach a terminal point; rather, such a point is not a logically necessary component of the verb’s meaning. For the purposes of this paper, we will call those aspectual readings that contain a necessary and/or realized event boundary *telic*; aspectual readings that are open-ended (i.e. indeterminate with respect to an endpoint) will be called *atelic*.<sup>1</sup>

---

<sup>1</sup>Strictly speaking, the labels *telic* and *atelic* are usually applied to the lexical-conceptual structure of events; the properties of sentential utterances are described as *bounded* vs. *unbounded*; *perfective* vs. *imperfective*, etc. We keep only one set of labels for simplicity; however, it is worth pointing out that we consider *telic* at the sentential level interpretations where the logical endpoint of an event is understood to have been instantiated, i.e. roughly the idea described by the traditional notion of perfectivity.

While telicity is encoded in the conceptual structure of events, it can be modified by the larger context within which an event is embedded. Thus we have a distinction between *lexical* and *grammatical* aspect. Lexical aspect categorizes verbs into aspectual classes based on their meaning (Dowty, 1978; Vendler, 1967). The atelic lexical classes encompass *states* and *processes*:<sup>2</sup> Verbs such as *love* or *write* describe temporally unbounded eventualities, or, alternatively, eventualities with homogenous reference: A subpart (subinterval) of a state of loving is still a state of loving, and a subpart of an act of writing is still an act of writing. The telic lexical class is that of *events*: Verbs such as *find* denote eventualities that involve some change or transition between different states of affairs. The transition corresponds to the logical boundary of the event. Events have non-homogenous reference: it is hard to conceive of subparts of the event of finding an object, and if we imagine a situation where the object is found after an active search, then any subparts of this (larger) event are instantiations of searching, rather than finding.

The aspectual reading of a fully articulated utterance is not always transparently related to the lexical aspect of its main verb. Rather, the computation of sentential aspect is influenced by the presence of nominal arguments and temporal sentential modifiers. Within the verbal predicate, the presence of an object and its cardinality have important consequences for the resulting aspectual reading: Singular and/or definite (count) objects support telic interpretations, whereas bare plural and/or mass noun objects support atelic interpretations of the verbal predicate. To illustrate, by itself the verb *'write'* denotes an unbounded process; when combined with a singular object (*write a book*), it denotes a bounded event in the course of which some change/transition is effected (i.e., a new object - a book - comes into existence). This type of predicate is traditionally referred to as an *'accomplishment'*. However, if the same verb is combined with a bare plural object (*write books*), it receives an atelic aspectual reading: The predicate now denotes an iterative or habitual process of book-writing. Similarly, punctual eventive verbs, such as *'send'*, receive an iterative interpretation when combined with a bare plural or mass noun object: The predicate *'send letters'* denotes a process that can potentially repeat itself over an indefinitely long period. Since there is no special instance of iteration that is regarded as the terminal point of the iterative event, iterative interpretations are open-ended. The importance of the cardinality of the object for the aspectual reading of predicates leads some authors to propose that aspectual properties are computed over the verb-argument complex (Verkuyl, 1993).

To illustrate the effect of temporal operators, the English progressive operator alters the aspectual properties of its input into those of an ongoing process (i.e. an atelic eventuality). Consequently, even though the primitive predicate *'send a letter'* is associated with a telic reading, its progressive version, *'I'm sending a letter'*, is an atelic process that does not allow an inference to the completion of the ongoing event. The modification of the aspectual properties of a

verbal predicate by sentential operators is known as aspectual coercion. This paper focuses on the processing cost associated with one particular instance of coercion, which arises in the presence of adverbial material denoting temporal span.

### Adverbial Coercion

A long-standing observation in the aspect literature maintains that adverbs denoting extent in time are sensitive to the aspectual category of the predicate that they modify. Adverbs of duration, such as *'for X time'* or *'throughout'*, combine with atelic predicates: *John wrote letters for an hour*, whereas adverbs of completion, such as *'in X time'*, combine only with telic predicates: *John wrote a letter in one hour*.

However, this generalization is not entirely correct. Adverbs of duration can occur in combination with any aspectual type of predicate; the output of such combination, however, is necessarily interpreted as an atelic eventuality. Thus, even though the primitive *'write a letter'* is a telic accomplishment predicate, its modified counterpart *'write a letter for an hour'* is interpreted as an atelic process of letter-writing that lasted one hour. The absence of telicity in this expression is made evident by the fact that the sentence *'John wrote a letter for an hour'* does not entail that at the end of the hour the letter in question has actually been written. Similarly, the primitive punctual predicate *'send a letter'* can be modified with a durative expression *'for several years'*. In this case, the overall interpretation shifts to the eventuality denoted by the predicate repeating itself over and over (with some pragmatically plausible frequency) for the extent of several years. Thus, it is clearly the case that adverbs of duration act like coercing operators for some predicates. This behavior is not surprising if we assume that the denotation of durative adverbs picks out a temporal interval within which an event unfolds: Since an interval interpretation is necessarily atelic, all input to the durative adverbial must acquire atelic properties. The specific reinterpretation that occurs as a result of combination of a predicate with a durative modifier is still somewhat dependent on the basic properties of the input event. An accomplishment predicate (*write a letter*) contains a simple process within its denotation; therefore, reinterpretation usually amounts to *'stripping'* off its culmination phase and understanding the predicate as an instance of the underlying process that did not reach its endpoint (Moens & Steedman 1988). Punctual events, on the other hand, have neither internal structure nor internal temporal extent. The only way in which they could be forced into an interval interpretation is by introducing a process of repetition of the punctual event. This is what happens in an example such as *John sent a letter to the company for several years*.

To summarize, several factors can potentially contribute to the overall aspectual reading of an utterance: The aspectual class of the main verb, the cardinality of its object, and the input specifications of modifying adverbial material. This situation creates a certain degree of instability within the parsing system, since material encountered later in an utterance can conflict with properties of the semantic representation that have been built up on the basis of material encoded earlier in the utterance. For instance, if the parser is

<sup>2</sup>There exist various classifications of verbal lexical aspect; the one adopted here is due to Mourelatos (1981).

assumed to incrementally compute a telic representation for the *entire utterance* upon encountering a telic verb (or its combination with a singular object), subsequent modification with a durative adverbial should trigger (potentially observable) aspectual reanalysis immediately after the durative modifier is encoded. Alternatively, one might hypothesize that in the absence of overt aspectual markers, such as a progressive or a perfect operator, aspectual commitment is postponed until all relevant material has been encoded. On that view, sentential aspect is left underspecified for the duration of the sentence. Where no further material relating to aspect becomes available, the aspectual reading for the sentence is determined over the properties of the entities that make up the predicate. However, if additional salient entities, such as a temporal modifier, emerge, these are taken into consideration in the initial computation of sentential aspect. Coercion in this model would amount to nothing more than a selection of the appropriate aspectual value based on all the lexical information provided, though we might expect to observe increased sentence ‘wrap-up’ processing time as the correct aspectual properties of the utterance are calculated, especially when factors informing the computation of aspect are in conflict. Further complications can arise if issues of plausibility/frequency are taken into consideration. It could be, for example, that particular verb + object combinations (given the importance of the cardinality of the object) increase the probability that the overall interpretation of the utterance will be of a certain kind (telic or atelic), and lead to an early adoption of the respective aspectual interpretation. For some verbs, one aspectual usage may be more frequent than the other (for example, the eventuality denoted by the verb ‘break’ may be less likely to be represented as an (iterated) process than the eventuality denoted by the verb ‘kick’, especially when it is understood to affect the same unique object). The kinds of aspectual reinterpretations triggered by coercion may also involve varying degrees of reanalysis: reinterpreting an event as a sequence of iterations is representationally different from reinterpreting an event as incomplete. Clearly, we cannot begin to unravel all of these issues at the same time. The present paper concentrates on one specific question: Is there a processing cost associated with the coercion which occurs when verbs denoting punctual events are forced to assume a repetitive interpretation, and if so, how does this inform our understanding of the mechanisms underlying semantic parsing?

### The Psycholinguistics of Aspect

To date, very little research examining the psycholinguistic implications of the coercion process has been reported. In one important exception, Piñango, Zurif and Jackendoff (1999) examined processing costs associated with coercion using a cross-modal lexical decision task. They investigated the effect of interpreting a durative temporal adverbial following a punctual verb (*kick*) vs. a non-punctual verb (*examine*). When the presentation of a lexical decision target coincided with the disambiguation point of the underlined temporal adverbial in coercion contexts like *The man kicked the little bundle of fur for a long time to see if it was alive*, they observed slower responses in comparison to decisions made in the corresponding location for non-coercing contexts

(i.e., *The man examined the little bundle of fur for a long time to see...*). Piñango et al. attribute the longer decision times to the increased processing costs associated with the coercion operation.

Although these results are suggestive, one potential problem undermines their interpretation. The creation of minimal pairs by systematically alternating verbs introduces other interpretive differences to which the observed processing variation might be attributed: Sentences in the “coerced condition” entail an iterative interpretation, unlike most sentences in the “non-coerced condition”. This difficulty suggests that further, more rigorous examination of the on-line implications of the coercion process is indicated.

The experiment presented here expands on Piñango et al.’s strategy of contrasting coercion and non-coercion contexts. We examine the processing correlates of the specific type of semantic coercion which arises from the combination of punctual verbs (e.g. *send*) with a durative adverbial (*for X time*), culminating in an iterative reading of the entire utterance. Since it is unclear whether iterative interpretations are computationally more demanding than non-iterative ones, the critical alternation in the materials that we employ hinges on varying the cardinality of the direct object (as opposed to varying the verb) as the factor which controls the initial repetitive vs. non-repetitive aspectual status of the predicate. It should be recalled that bare plural direct objects impose an iterative reading (*send letters*), whereas singular direct objects impose a single-instance reading of the event denoted by the predicate (*send a letter*). In the case of the bare plurals, the repetitive event interpretation is signaled by the plural object prior to the introduction of the durative adverbial and that adverbial simply specifies the temporal span over which the repetitive event occurs. Thus, the interpretation of bare plurals modified by durative adverbials (*sent letters for many years*) is straightforward, since the (atelic/iterative) aspectual reading of the predicate is consistent with the aspectual input specifications of the modifier.

In contrast, the introduction of a durative adverbial modifier following a singular object (*send a letter for many years*) triggers aspectual conflict between the telic predicate and the durative adverbial. This incompatibility is hypothesized to be resolved via the coercion process, through which the predicate is reanalyzed as an iterative event spanning the specified interval. If the reanalysis process suggested as a correlate of aspectual coercion is computationally demanding, we should expect to observe increased processing load at or subsequent to the introduction of aspectual incompatibility (as seen in sentences containing iterative events over singular objects). Evidence of this cost should be observed when we compare parallel regions of the singular vs. bare plural items, just because the coercion operation is hypothesized to occur only over the predicates containing singular objects.

Further, since aspectual coercion is triggered by a specific type of temporal modifier, we would not expect to see evidence of coercion with adverbs that are indifferent to the aspectual properties of the predicates that they have scope over. This expectation is independent of the cardinality of the direct object of the predicate (*sent a letter last year* vs. *sent letters last year*). Although these sentences come to

mean different things (singular vs. multiple instances of letter-sending, corresponding to telic/perfective and atelic/imperfective aspect, respectively), in both cases the aspectual reading is determined solely on the basis of the properties of the verb + object complex, and depends specifically on the cardinality of the direct object. So, temporal adverbs which are indifferent to aspect are not hypothesized to contribute to the aspectual interpretation of the utterance and should combine easily with any type of aspectual input. Therefore, we would not predict any processing load variation to be observed at, or subsequent to, the introduction of such adverbials despite the diverging interpretations ultimately required by such sentences.

Thus, this experiment examines the processing cost associated with coercion toward an iterative interpretation of a telic verb + singular object predicate triggered by the presence of a durative temporal adverbial. Two separate non-coerced, control conditions are employed. First, processing load for the hypothesized coerced sentences is compared with processing load for sentences in which there is a telic verb + bare plural object predicate followed by a durative adverbial. In this control, the bare plural independently signals an iterative event reading so there is no aspectual conflict between the predicate and the temporal adverbial. Secondly, sentences containing durative adverbials are compared to parallel sentences containing non-durative temporal modifiers. This control should allow us to distinguish any potential effects of coercion, as we have described it here, from effects that might instead arise directly out of the singular vs. bare plural object contrast, independent of the coercion operation.

## Method

**Participants** Twenty-four right-handed, native English-speaking undergraduates with no history of language deficits enrolled at the Johns Hopkins University participated in the experiment for course credit or compensation.

**Materials** Thirty-six transitive aspectual achievement verbs were used to construct the experimental sentences. Each verb was used to create two VP predicates which varied on the cardinality of the direct object (singular indefinite vs. bare plural) so the resulting predicates differed only in iterativity. For each predicate, adverbial modifiers (durative vs. non-durative/aspectually neutral) were selected to allow equally (ultimately) plausible readings in all conditions. Thus, the experiment consists of a 2×2 design crossing **Cardinality** (*singular* vs. *plural*) and **Modifier Type** (*durative* vs. *non-durative*). As can be seen from the stimulus example from Table 1, with the exception of the cardinality of the direct object and the specific temporal adverbial, the lexical content of the sentences was identical across the four conditions.

Table 1: 2×2 experimental design crossing factors of Cardinality and Modifier Type.

	Durative modifier	Non-durative modifier
Singular object	Even though Howard sent <i>a large check</i> to his daughter <u>for many years</u> , she refused to accept his money <b>A</b>	Even though Howard sent <i>a large check</i> to his daughter <u>last year</u> , she refused to accept his money <b>C</b>
Plural object	Even though Howard sent <i>large checks</i> to his daughter <u>for many years</u> , she refused to accept his money <b>B</b>	Even though Howard sent <i>large checks</i> to his daughter <u>last year</u> , she refused to accept his money <b>D</b>

Condition A reflects the hypothesized coerced context: the aspectual properties of the predicate and the modifier are mismatched and we expect that any processing costs associated with the coercion operation should be observed in this condition. In contrast, no effects of coercion should be observed in the other conditions.

Experimental sentences were constructed on a bi-clausal frame, in which the critical adverbial phrase always occurred in the initial clause. Table 2 shows each sentence subdivided into presentation regions (roughly corresponding to phrases), with the temporal adverbial always occupying Region V. With the exception of the critical alternation, the lexical material within particular regions of a given item was identical. Thus, we expect that any processing costs associated with the coercion operation will be observed at or immediately downstream of region V.<sup>3</sup>

Table 2: Sentential frame for experimental sentences with type of material by region.

Region :	II	III	IV	V	VI-IX
I					
Although Because Even though	Subject + verb	Direct object	Preposi- tional phrase	Tem- poral ad- verb	2nd clause

Critical items were distributed into 4 lists such that each list included one token of each of the 36 critical items and nine items from each of the 4 treatment conditions. The 4 sets of experimental stimuli were each embedded into a list of 70 filler sentences. Filler items, which were also subdivided into roughly phrasal presentation regions, ranging from 5 to 9 regions in length, varied in syntactic structure as well as syntactic and semantic complexity. Since the experimental paradigm employed in this study allowed for the collection of sensibility judgment data, 30 of the filler items were designed not to make sense. Nonsense filler items were

<sup>3</sup>There is some evidence that processing of semantic information follows a slower time-course than syntactic processing (Boland 1997). This suggests that a coercion effect is likely to occur later than the actual presentation of coercing material, namely in region VI.

incongruous based on some grammatical violation (e.g., subject/verb agreement), conceptual/pragmatic constraints (e.g., implausible event), or both. Thus, the experiment consisted of 4 separate list conditions containing 106 items each. Individual lists were pseudorandomized for presentation order such that one or more filler items intervened between every pair of target items. Presentation lists orders were randomized independently to avoid item-ordering effects.

**Overview of Task & Procedure** This experiment employed a self-paced, makes-sense judgment task in which participants evaluated sentences presented region-by-region in the center of a computer screen. Participants were instructed to quickly read each region and indicate whether that text region “made sense” with respect to the previously presented material from that trial. Two types of data were recorded for each participant for each text region: reading/judgment times and regional rejection rates. The rate of text presentation was controlled by individual participants in that new text material replaced the previous material as soon as a participant indicated a judgment (via a button press). At the end of each trial, participants were asked to provide make-sense judgments for the entire sentence. Thus, the data collected in this task allows us to examine processing load effects via reading/judgment latencies for specific regions. In addition, by recording sensibility judgments we can examine by-region rejection rates to test our intuitions regarding the aspectual infelicity in the coerced condition. Furthermore, we can confirm that ultimately participants do arrive at a meaningful interpretation in all sentence conditions. Finally, the make-sense judgment task has the added advantage of discouraging fast readers from buffering text material or postponing their interpretations until sentence-final regions are reached. Although no judgment feedback was given on critical trials, participants were encouraged to actively engage in regional make-sense judgments by receiving negative feedback when their make-sense judgments conflicted with those of the experimenters on filler trials.

**Results**

In sentence-final judgments, participants rejected 19% of the sentences in Condition A (the coerced condition), but only 7% in Condition B (the non-coerced, bare plural condition):  $\chi^2 = 14.73$ ,  $df = 1$ ,  $p < .001$ . Rejection rates in Conditions C & D were 8% and 9%, respectively. Sentences which were judged to be nonsensical *overall* were excluded from further analysis. However, items for which participants indicated that one or more regions were nonsensical, but judged the sentence to be acceptable overall were included in the analysis.

**Reading time data** Analyses on the reading/judgment latencies were computed separately using subjects and items as random factors. Analyses of latencies for text regions preceding the temporal adverbial (I-IV) and in regions VII and VIII were not different across treatment conditions ( $F_s < 1$ ). Subsequent analyses focus on differences observed in Regions V (the adverbial modifier) and VI (immediately following the coercion region). In the full analysis evaluating Modifier Type and Cardinality, no main effect of Modifier

Type emerged (all  $p_s > .25$ ), although a main effect trend toward Cardinality emerged (Region V:  $F_1(1, 23) = 3.71$ ;  $p < 0.06$ ;  $F_2(1, 35) = 1.8$ ;  $p < 0.19$ .; Region VI:  $F_1(1, 23) = 4.97$ ;  $p < 0.05$ ;  $F_2(1, 35) = 2.88$ ;  $p < 0.09$ ). The interaction between these two variables was nearly significant at Region V ( $F_1(1, 23) = 5.40$ ;  $p < 0.02$ ;  $F_2(1, 35) = 2.60$ ;  $p < 0.11$ ) and significant at Region VI ( $F_1(1, 23) = 17.6$ ;  $p < 0.005$ ;  $F_2(1, 35) = 5.97$ ;  $p < 0.05$ ). This is not surprising since, here, the operation of coercion occurs only within certain factor combinations.

The crucial comparisons contrasted the effects of Cardinality within the Modifier Type alternation. As can be seen in Figure 1, response latencies for Regions V & VI in Condition A, the Singular+Durative, coerced iterative items, were significantly longer than those in Condition B, the Plural+Durative non-coerced, iterative items (Region V:  $F_1(1, 23) = 7.34$ ;  $p < 0.05$ ;  $F_2(1, 35) = 4.66$ ;  $p < 0.05$ ; Region VI:  $F_1(1, 23) = 24.51$ ;  $p < 0.0001$ ;  $F_2(1, 35) = 9.27$ ;  $p < 0.005$ ). In contrast, as is shown in Figure 2, no effects of Cardinality emerge in the critical text regions of sentences modified by Non-Durative adverbials (All  $F_s < 1$ ).

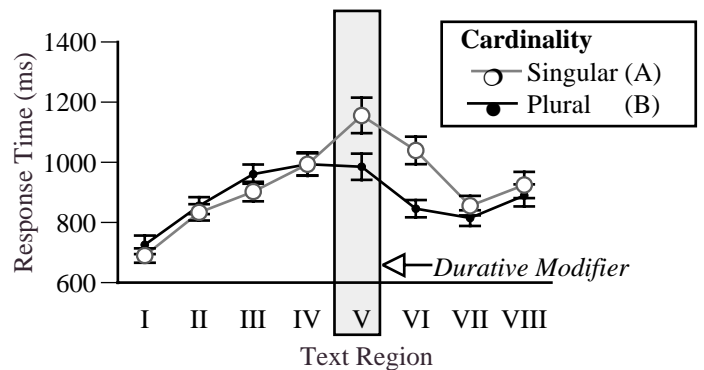

Figure 1: Response latency by text region for **Duratives** by Cardinality of Object

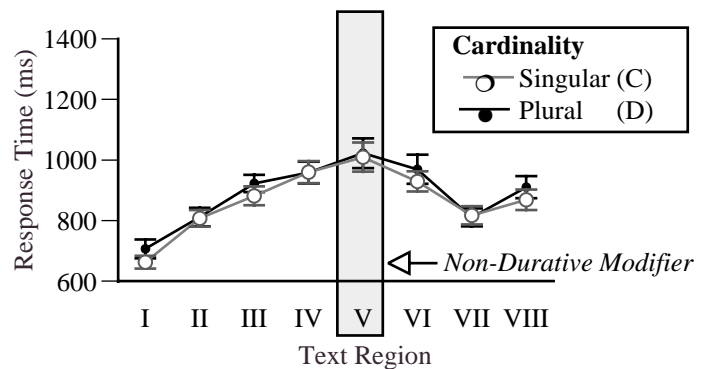

Figure 2: Response latency by text region for **Non-Duratives** by Cardinality of Object

**Make-sense judgment data** As can be seen in Figure 3, even in sentences which were ultimately judged to be acceptable, subjects indicated that the temporal adverbial Region V was difficult to integrate more frequently in the coerced singular durative condition than in the other treatment conditions. Chi-squared analysis reflects that this difference also holds for the Cardinality contrast within the Durative condition ( $\chi^2 = 9.40$  (df=1);  $p < .005$ ), but not between the non-durative conditions ( $\chi^2 = .07$ )

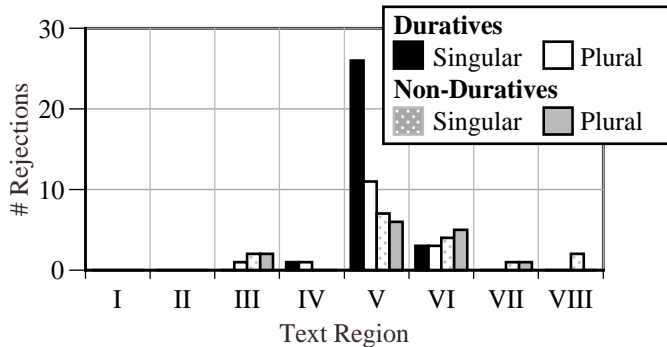

Figure 3: Regional make-sense judgments.

## General Discussion

This study investigated the comprehension of sentences where an aspectually incompatible predicate - modifier combination is interpreted with the aid of the semantic operation of aspectual coercion. Aspectual coercion operates by altering the aspectual specifications of the predicate in a direction matching the input specifications of the adverbial modifier. In the specific case studied here, the semantic consequence of coercion is an obligatory iterative (atelic) interpretation of predicates involving punctual eventive (telic) verbs when these predicates are modified with adverbs of duration. Iterativity arises in this particular situation as the only temporally unbounded analysis applicable to eventive verbs lacking a durational component in their conceptual structure. The goal of our study was to establish whether the coercion operation has any disruptive consequences for sentence comprehension.

We find that participants are significantly delayed when reading a durative adverbial modifier that follows an aspectually incompatible predicate (punctual verb + singular object), as compared to reading the same adverbial following an aspectually compatible modifier (punctual verb + bare plural object). No such difficulties arise when the same predicates are modified by aspectually neutral adverbials, which do not trigger coercion. We hypothesize that the observed latency is indicative of an increase in processing cost associated with the need to undergo coercion in order to form a coherent representation of the utterance. On the other hand, within the predicate, objects of specified vs. unspecified cardinality were read with a comparable degree of ease: this suggests that decisions about utterance aspectuality are made after both the verb and its arguments have been encountered.

While we take our results to indicate that coercion is, indeed, a costly operation, they are compatible with several hypotheses as to *why* this should be the case. On one hand,

it is possible that the difficulty in the comprehension of coerced sentences reflects a price associated with some reanalysis of the current representation of the utterance. That is, it could be that the combination of a telic verb and singular object leads to an early decision of a telic aspectual value for the utterance under construction; and subsequent modification of that value is undesirable (costly). If this is the case, we would expect to observe the same degree of processing difficulty to occur in sentences where iteration is introduced by means of an overt lexical item, e.g. *Howard sent a large check to his daughter every year*.

Alternatively, the difficulty in interpreting coerced iterative sentences may stem from the fact that the existing representation has to be updated through the mediation of an iterative operator that is not morpho-syntactically expressed. To make this point clearer: a durative adverbial must attach to input which has some atelic properties. When this input is a process (*write*) or contains a process-like subcomponent (*write a book*), combination with a durative modifier is unproblematic. However, if the input does not have a continuous interpretation (*send a check*), an attempt to combine it directly with a durative adverbial will lead to an incoherent conceptual representation. The strategy of introducing an iterative operator - which has the effect of creating a novel, atelic event as input to the modifier - can then be regarded as a form of repair. It is possible that the observed processing delay reflects an attempt at the combination of predicate and modifier without the mediation of an iterative operator with the concomitant failure to form a sensible interpretation of the whole. If this is the case, we would expect the coercion effect to disappear in cases where an overt iterative element makes the interpretation domain of the modifier explicit, e.g. again in *Howard sent a large check to his daughter every year*. We plan to address these issues in further research.

## Abstract

An empirical investigation was conducted on the characteristics of language use in graphics communication settings. Graphics communications, such as dialogues using maps, drawings, or pictures, provide people with two independent systems of representation, spoken language and graphics. Drawing on our dialogue data, we will show that the presence of a graphical representation significantly changes the way the spoken language is used, extending its expressive capacity in most cases. As two remarkable uses of language affected in this way, we will report the phenomena of *mediated reference* and *dual description*, illustrating them with actual examples from our data. Finally, a quantitative analysis of our data will show that these special uses of language are indeed as common as conventional uses of language in the presence of graphical representations.

## Introduction

Conversational exchanges that involve external graphical representations are quite common in our daily lives. People often give and ask directions by referring to maps, or they might draw a floor plan in discussing where to place furniture in a living room. Now, linguistic expressions denote objects and relations in the world. This denotation relation is governed by conventions inside the language. An utterance of a linguistic expression carries unique information about the world through these conventions. This is what the standard view of the semantics of language tells us. However, when we look at speech in conversational exchanges involving graphics, regardless of the language used, we will immediately notice utterances that do not conform to this standard picture.

This paper is a detailed examination of the impact of graphics on the use of language. Our data consist of actual two-party dialogues where participants draw or consult a map during verbal exchanges. We will focus on two remarkable uses of language, called “mediated reference” and “dual description,” that we found through an examination of our data. Both phenomena are clearly specific to dialogues involving some graphical representation, or at least, some external representation other than speech.

Briefly, *mediated reference* is a case where a linguistic expression reaches its “final” referent due to the fact that its “immediate” referent has a referential connection to this final one in the system of graphics. For example, our subjects often use the indexical “kore” (this) to refer to a building or some other landmark, although its immediate referent is clearly an icon on the map; the icon refers to the landmark in the system

of map, and this fact somehow enables the indexical expression to do so too. We will discuss more examples of mediated reference later, and introduce three more varieties of the phenomenon.

*Dual description* is a case where a declarative sentence is used to describe a fact that holds in the graphic as well as the corresponding fact in the situation represented by the graphic. Suppose, when asked about the number of stations between two particular stations, one counts the number of icons on a railroad map and says, “There are three stations in-between them.” Is this report concerned with the map itself, or with the mapped railroad? Is it reporting that the railroad map has three station icons between two particular station icons, or that the railroad system has three stations between the two stations? Whichever the answer may be, it seems clear that the speaker has managed to describe both facts with this sentence. Note that, on the semantics associated with the railroad map, the first fact means the second fact, and this semantic relation somehow underwrites the duplicative use of the sentence.

Both uses of language are so natural and common in a dialogue involving a graphical representation that people may not even be aware of the phenomena. In fact, their frequent occurrence in such settings suggests that they are not a deviant but rather a perfectly legitimate use of language. Yet the empirical research on the integration of linguistic and graphical representations has focused on the issue of how speech is used to disambiguate a graphic (Neilson and Lee 1994) or how a graphic is used to disambiguate speech (Lee and Zeevat 1990). The linguistic-graphic integration has been also studied from a logical point of view, but the focus has been on how a graphic expresses what cannot be easily expressed by a linguistic representation (Barwise and Etchemendy 1996, Shimojima 1999). For both views, the fundamental form of linguistic-graphic integration is a *parallel* one, where each mode of representation expresses information in its own way, but since one mode of representation expresses what the other form does not, they may work complementarily to each other. In contrast, the two phenomena that we are highlighting in this paper point to a rather different form of integration, where the presence of one mode of representation extends the expressive capacity of the other by affecting the way it is used. Our goal is to draw due attention to this *sequential* form of graphic-linguistic integration by demonstrating that the instances of that type of integration are commonly observed in actual human dialogues, as opposed to mere logical possibilities.

In the next section, we will describe the methods through

<sup>1</sup>Also with Kobe University.

which we collected our dialogue data. The two subsequent sections are, respectively, qualitative descriptions of the phenomena of mediated reference and dual description, where we illustrate each phenomenon with examples of language use drawn from our dialogue data. In these sections, the phenomenon of mediated reference is classified into four different types, and the mechanism underlying dual description is analyzed. The final section is devoted to a quantitative description of the two phenomena, where we use “content phrasal unit” to quantify the frequency of mediated reference and dual description in the dialogue process. As it turns out, these graphic-oriented uses of language occur as frequently as standard uses in our dialogue data, indicating that the speakers are quite ready to exploit the graphical representations at hand to extend the expressive capacity of their language.

## Data

The conversational data analyzed in this paper were gathered from a series of graphical communication experiments, which were conducted for a larger research project investigating the interactions between cognitive/communicative factors and graphical representations<sup>2</sup>. Our data consist of 19 task-oriented dialogues, with a total length of 116 minutes. Of these dialogues, 14 involve “a map sketching task” while the other 5 involve “a GRE task.”

**Map Sketching Task** In this task, two subjects were asked to work together as partners to draw a map showing four landmarks in Nara (a local town) as accurately as possible. The subjects were seated in separate, soundproof rooms and worked together using a shared virtual whiteboard and a full duplex audio connection. All inputs to the screen were by stylus, and any writing or erasing by one participant would appear simultaneously on their partner’s screen. The subjects were video-taped during the task.

**GRE Task** In this task, two subjects were asked to solve a logical reasoning problem from the Graduate Record Examination (GRE). The problem was on possible route selections in a hypothetical truck delivery area. The subjects were again required to work on the problem together and it was suggested that drawing a diagram on the screen might help them to answer the question. All pairs drew diagrams and eight pairs among the nine drew map-like ones. The communication environment of the subjects was the same as that in the map sketching task. The GRE task differed from the Map Drawing task in that the subjects had to not only draw an accurate map, but also use it for problem solving.

## Mediated Reference

Studies on the use of multimodal information in reasoning and communication have mostly focused on the complementary or parallel form of integration and have not closely examined the sequential form of integration of multiple modalities. Particularly, little is known about the directionality and the systematic nature of such integration. In our data, two directions were observed in referring to entities through the

sequential integration: mediated references via a representation system (a sketch map, a diagram, etc.) to the world and mediated references via the world to a representation system. We will call the former a *forward* mediated reference, and the latter a *backward* mediated reference. Further, mediated references can be observed between not only individuals but also relations. We will examine, in this section, the phenomena of mediated references observed in our graphical communication experiments. Figure 1 shows four possibilities of mediated references.

### Individual Mediated Reference

Consider the following utterances:

- (1) (From the map data, pointing to a part of the map with the stylus)

*de, koko-ni-ne, tasika Deiri-Sutoa-ga-ne,*  
and, here-DAT, probably, Daily Store-NOM,  
*kono kado-ni atta.*  
this corner-DAT was.  
“And I think there’s Daily Store on this corner.”

- (2) (From the GRE data, pointing to a path on the map with the stylus)

*kore-ga 100 desuka?*  
this-NOM 100 is  
“This is 100km, isn’t it?”

In (1), the speaker was pointing to a part of the map, and the linguistic expression “*koko* (here)” and “*kono kado* (this corner) literally denoted a part of the map. However, there was just a blank space on this part of the map and there were no symbols that could be regarded as an icon of a store. If we assume that the speaker was talking about the map, this utterance would be regarded as simply meaningless or at most false. In this task setting, it is unlikely that the speaker was talking nonsense or lying. Therefore, this utterance was a statement not based on the map but on the real world. Here, the linguistic expressions “*koko*” and “*kono kado*” referred to some place in the world via the place on the map. Similarly, no signs showing the distance could be seen on the diagram in the case of utterance (2), and no suitable properties for the referent of the expression “100” could be found on the diagram. Consequently, this utterance was also a description of some situation regarding the delivery route, not a part on the diagram. In these cases, the reliable correspondence between the spatial configuration of a map and a place in the world enabled *forward* mediated references: references to places in the world through places on the map.

We can also find examples of *backward* mediated references in the data. Some of them are as follows:

- (3) (From the map data, pointing to the icon of Nara Park on the map)

*ja, kore, moo-tyotto koen okkiku suru?*  
So this a-little-more park big make  
“So, shall we make this park a little bigger?”

- (4) (From the map data, after realizing that they made a mistake)

<sup>2</sup>These experiments were designed by Patrick G.T. Healey, Nik Swoboda, Ichiro Umata and Yasuhiro Katagiri.

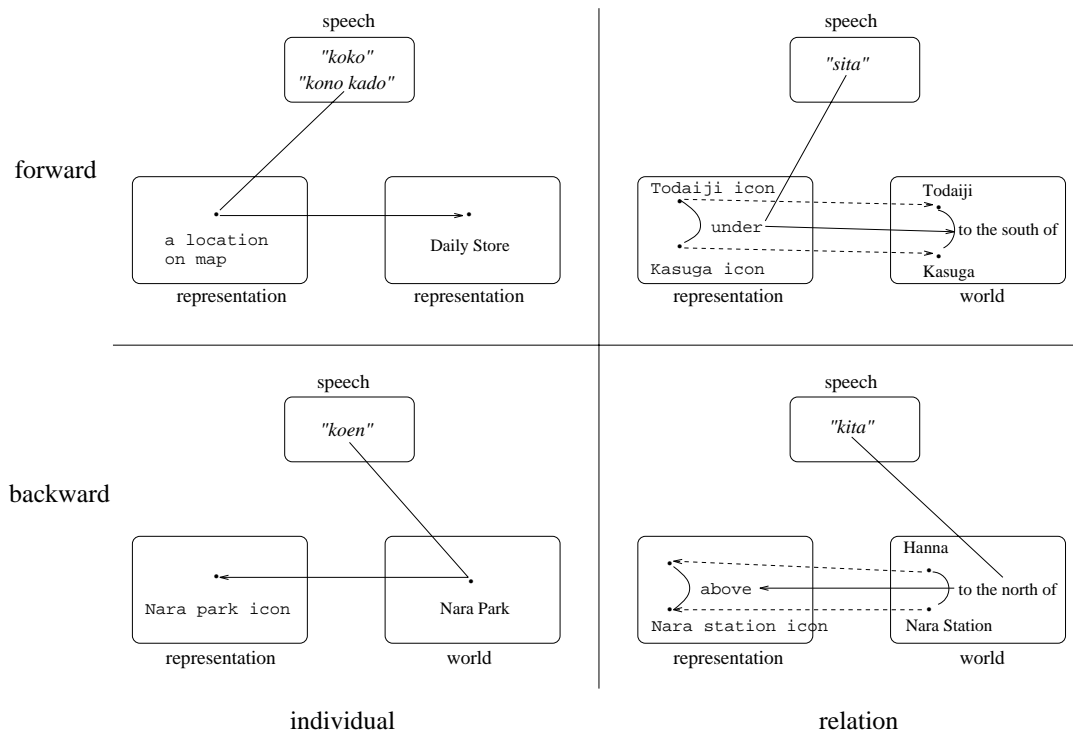

Figure 1: Four categories of mediated reference

*a jaa kesimasyoo Teramati Kita*  
 well so erase Teramati-town Kita-town  
 “Well, so, let’s erase the Teramati-Kita route.”

The linguistic expression “*koen* (park)” in utterance (3) literally denoted a real park. However, one cannot usually make a real park bigger, so this utterance cannot be regarded as a statement about the world. Rather, utterance (3) was a statement about some operation on the map, and “*koen*” referred not to the real Nara Park but rather to the icon on the map. Similarly, utterance (4) was a suggestion to erase the path on the diagram. They could not erase the delivery route itself because it was not assumed to be in the situation described by the GRE problem. In both statements, the objects in the world play an intermediate role, and the linguistic expressions refer indirectly to the icons on the map.

### Relation Mediated Reference

So far, we have concentrated on mediated references between individuals. However, there are also examples of mediated references between relations in our data. Consider the following examples:

- (5) (From the map data, pointing to a part of the map with the stylus)

*kokorahen-ni Toodaiji-ga aru*  
 around-here-DAT Todaiji-temple-NOM is  
*kara, kono sita-no hoo-kana?*  
 because this below-GEN direction-I wonder  
 “Because Todaiji is around here, it (Kasuga-shrine) is probably below this, isn’t it?”

- (6) (From the map data, looking at his partner’s drawing on the map)

*aa, soko zutto ue nobotteiku-to,*  
 Yes there straight up go  
*nyugakusiki-no toko dayo.*  
 entrance ceremony-GEN place is  
 “Yeah, if you go straight up there, you can find the place where we had the entrance ceremony.”

In dialogue (5), the speaker intended to show the listener where Kasuga-shrine was. However, since there were no Kasuga-shrine icons on the map, the subjects were talking about a real-world situation via the map. However, the linguistic expression “*sita*,” which roughly means *under* or *below*, cannot be regarded as referring directly to real world relations; in the real world, Kasuga shrine is not *under* Todaiji temple but *south* of it. Here, “*sita*” referred to the real world relation (i.e. *to-the-south-of*) indirectly via the relation on the map (*under*). This was based on the semantic correspondence established between the map and the world. Similarly, in the case of utterance (6), there were no icons for “*nyugakusiki-no toko*” (the place where we had the entrance ceremony) on the map. Therefore, this utterance was describing a state in the real world, and the expression “*ue*” referred to the spatial relation in the real world (i.e. *to the north*) via the relation on the map (i.e. *up*) in (6).

Excerpt (7) includes an example of a *backward* mediated reference to a relation, as well as examples of individual backward references.

- (7) (From the map data, revising the position of the Nara Station icon)

*Hanna Way-no yori kita-ni ittya*  
 Hanna Way-GEN than north-DAT go  
*akan?*  
 no good-Q

“So, we can’t draw it north of Hanna Way?”

Since one cannot change the place of the real train station, utterances in (7) were about the situation on the map. Thus, the linguistic expression “*Hanna Way*” in (7) referred backwardly to the icons on the map, not to a real world object. Similarly, the linguistic expression “*kita-ni*” (to the north of) makes a backward mediated reference to the relation of the places on the map (i.e. above) via the real world relation to the north of in this utterance<sup>3</sup>. Due to the preservation of the configurational constraints between the map system and the world, such mediated references to spatial relations are quite natural and are commonly found in conversations in which maps are used.

## Informational Duality

Thus, when a map accompanies a dialogue, speakers can make a wide variety of indirect references, either individual or relational, forward or backward, through the systematic semantic relations established between the map and the mapped area. From the speaker’s point of view, this means increased freedom of reference with a limited vocabulary, but from the listener’s point of view, this might mean an increased likelihood that an utterance will become ambiguous in regards to the map itself or the mapped region. For we cannot settle this issue simply by assessing the literal referents of the expressions used, due to the possibility of indirect reference. Purely semantic disambiguation of this sort is generally not applicable.

Fortunately, listeners can often rely on pragmatic cues to resolve such ambiguity, as we have seen in the cases of (1)–(7). Generally, listeners can reject an interpretation of a statement if, on that interpretation, an utterance is to perform a speech act that is not felicitous in that context, such as (i) describing or checking the current position of an object not on the map, or (ii) requesting or otherwise discussing an operation on the mapped region that is impossible to address. The examples (1), (2), (5), and (6) correspond to (i), and thus they were considered not to be about the map, while (3), (4), and (7) correspond to (ii), and they were considered not to be about the mapped region.

However, our data also contain a number of utterances *not* subject to even such disambiguations. In the following, we will consider some of those examples and analyze the informational and functional structures of such utterances.

### An Example

The following dialogue from our GRE data was conducted soon after the partners drew a graph-like map showing the routes connecting various towns, including Kawabata, Kitamati, and Hasimoto. The speakers are concerned with how many towns a truck driver can pass through in one day.

<sup>3</sup>The subjects erased the old icon and were just starting to draw a new one, so “*iku (itty)*” in this utterance expresses the movement of the icon on the map.

(8) A: *kazoemasukanee?*

(Shall we count?)

B: *soosuruto.*

(If we do so, then....)

A: *kazoeruto 3-tu kanaa. 4-tu-wa tyotto muridesuyonee.*  
(On my counting, it is three, I suppose. Four is not feasible, is it?)

B: *uun.*

(Hmm)

A: *Kawa toka dattara, kore moo sudeni 300 toka dakara, moo, Kita, kotti, Kita-ni*

(If this is Kawa or something, and if this is already 300 or so, well, Kita, here, to Kita [Mumbling indistinctively.]

*Kawa-kara Kita-ni itte Hasi-de, kore 3-tu desuyone.*

(Going from Kawa to Kita and then to Hasi, that’s three, isn’t it?)

The case in point is the last utterance of speaker A, which is underlined. On the one hand, one may well regard the names “*Kawa*,” “*Kita*,” and “*Hasi*” to denote the icons for Kawabata town, Kitamati town, and Hasimoto town. In this interpretation, the entire utterance concerns the map, and the speaker is reporting the following information:

(9) There are three town icons on the path: the Kawa icon, the Kita icon and the Hasi icon.

The icons for Kawabata town, Kitamati town, and Hasimoto town already exist on the map, connected by a particular path on the map. Thus, reporting the number of town icons on this path, such as reporting (9), is a speech act that the speaker may well perform at this point. In fact, the above excerpt shows that prior to this utterance, the subjects have explicitly agreed to do such counting. Thus, one cannot reject the interpretation of the utterance as concerned with the map for any obvious reason.

On the other hand, it is also natural to regard “*Kawa*,” “*Kita*,” and “*Hasi*” as indirectly denoting the real towns, and if so, the utterance conveys the following information about a traffic route in the mapped region:

(10) There are three towns on the route: Kawabata town, Kitamati town and Hasimoto town.

Recall that the present problem for the subjects is the maximum number of towns that a truck driver can pass through within one day. The reporting in (10) is directly relevant to the solution to this problem, and hence is a speech act quite likely to be performed at this point. Thus, the interpretation of this utterance as being about the mapped region cannot be rejected, either.

As we will see shortly, our data contain a number of examples of this type, where an utterance is as likely to be about the map as to be about the mapped region. Upon reflection, this type of utterance seems frequent in everyday dialogue involving some graphical representation—we do not always clearly explain this to listeners, or even to ourselves, whether our assertion or report is about the picture at hand or about the situation the picture depicts. So the question is: how can we understand such utterances? Are they *ambiguous* in the sense that: although such utterances are “really” concerned with either the map or the mapped region, they fail to provide sufficient cues to distinguish between them? If we frequently use such ambiguous utterances, how can we ever be successful in communication?

## Analysis

On these questions, we propose that such utterances are *not* concerned with either the picture or the depicted situation *exclusively*. Rather, they are concerned with *both*, and thus handle information about the picture as well as information about the pictured situation. Such utterances are therefore not ambiguous in the above sense. The problem of ambiguity occurs only when we assume that such an utterance is concerned with only one subject matter. Here we explicitly discard this assumption for the kind of utterances in question. For example, the subject matter of the underlined utterance in (8) is not single, but dual, and the utterance reports the number of the town icons on a particular path on the map, *as well as* the number of the towns on the corresponding route on the mapped region.

But how is it ever possible for a single utterance to have such dual informational contents? Briefly, this is possible because representation is a transitive relation. Due to this principle, whenever an utterance represents a picture having a property  $\alpha$ , and this property  $\alpha$  on the picture in turn represents the depicted object having property  $\beta$ , the original utterance will also represent this object having property  $\beta$ . In the present case, the underlined utterance in (8) represents the map having the structural property of (9), and due to the semantic convention associated with the maps, a map with the property (9) represents the mapped region as having the structural property (10). Thus, by transitivity, the utterance also represents the mapped region having the property of (10). This is how a single utterance carries two pieces of information: one about the map and the other about the mapped region.

This mechanism may be made clearer by using the analogy of a copy machine. Suppose you make a copy  $d'$  of a document  $d$ , and then make a copy  $d''$  of the copy  $d'$  that you just made. The copy  $d''$  being a copy of the copy  $d'$  accurately represents  $d'$  more or less, and carries information about  $d'$ . Notice that this copy  $d''$  also carries information about the original document  $d$ —we can look at the second copy  $d''$  and learn what the original document  $d$  is like. (In fact, this is usually the main use of the second copy: we look at it in order to get information about the original document, often forgetting that it also carries information about the first copy.) Thus, the second copy  $d''$  carries two pieces of information, one about the first copy, and the other about the original document. The second copy  $d''$  carries the latter *via* the first copy, thanks to the transitivity of representation.<sup>4</sup>

Our claim is that the same thing happens in the case of the utterance in (8), where the mapped region in the truck delivery area is the original document  $d$ , the map of it is the first copy  $d'$  of  $d$ , and the utterance is the copy  $d''$  of  $d'$ . The utterance in (8) carries information about the mapped region in the truck delivery area via the map, just as  $d''$  carries information about  $d$  via  $d'$ . The utterance carries depicted information (9) and (10) about the map and the mapped region, just as  $d''$  carries duplicated information about  $d'$  and  $d$ .

There are two major advantages to this claim. First, it avoids attributing ambiguity to utterances of this type that are

<sup>4</sup>The idea that the carrying of information is a transitive relation is called “the Xerox Principle” by Dretske (1981); this idea has been a focus of interest in situation theory (Barwise and Perry 1983) and was subsequently developed in qualitative information theory (Barwise and Seligman 1997).

found in spoken dialogues employing graphical representations. Therefore, such utterances are not particularly prone to misinterpretation, which is why these types of utterances can occur frequently without hindering smooth communications among speakers.

The second advantage of our analysis is that it gives us a way to capture a set of mechanisms provided by those “dual” utterances to facilitate problem solving processes involving the use of graphical representations. Recall, from our discussion on example (8), that a dual utterance occurs in a context where two different communicative acts are likely: one concerned with the picture and the other concerned with the depicted situation. In our reckoning, the speaker is considered to perform both acts with the utterance, without skipping or suppressing either act. A dual utterance effectively works as a bridge, and both the speaker and the hearer can engage in joint problem solving by matching and transferring information between the graphics domain and the problem domain. To clarify this point, let us suppose that utterance (8) was ambiguous and actually carried only one piece of information. If it was on the situation in the diagram, then the utterance itself would not convey the information about the world and would not directly lead to the answer to the question. If it was on the world situation, then it would show the answer but have no grounds for it. Under the assumption of dual information, the utterance provides both the answer and the basis for it at the same time: the information on the world based on the information on the graphics. Thus, in general, our proposal offers a more natural explanation of the use of such dual utterances in graphics communication, compared to theories that attribute a single informational content to it.

## Quantitative Analysis

We have demonstrated that a combination of graphical representation and linguistic representation in a graphical communication setting provides us with a novel sequential method for integrating of the linguistic and graphical modalities in the form of mediated and dual references. Our analysis so far has been concerned with classifications and functions of instances of these new types of references.

In order to further establish that the sequential integration actually provides us with a viable and effective mechanism for communication, we conducted a quantitative analysis on the relative frequencies of the “new” forms of references, both mediated and dual references; we performed comparison with “conventional” direct references within our data obtained in our Map and GRE experiment. Furthermore, the different characteristics of each task were expected to result in a different distribution of the final referents of linguistic phrases. The Map corpus was expected to have more instances referring solely to the object in the graphics domain, because the aim of the task was to complete a map. On the other hand, the GRE corpus was expected to include fewer of such instances, because the aim was to solve the problems of the world domain and the graphics simply assist in that purpose.

Our corpus consists of 14,011 words (9,179 for the Map and 4,832 for the GRE), and the number of content phrasal units<sup>5</sup> was 5,325 (3,394 for the Map and 1,931 for the GRE).

<sup>5</sup>A content phrasal unit is a minimum phrasal unit that has a con-

Figure 2: Relative usage frequencies of the direct, mediated and dual references)

Figure 3: Distributions of final target domains of references for the Map and GRE data

Of them, 4,667 units were the ones describing the situations of the graphics and/or the world domain (2,875 for the Map and 1,792 for the GRE). We classified these units into the three categories shown above: direct, mediated and dual references.

Figure 2 shows the relative usage frequencies of the three types of references: direct, mediated and dual. Of all the reference occurrences, 57% were instances of direct references and 43% were instances of either mediated or dual references. This clearly shows that mediated and dual references are not mere theoretical possibilities or exceptional phenomena, but rather are mundane mechanisms routinely employed in actual communication.

Task characteristics of the Map sketching task and the GRE task can also be captured in quantitative terms. Figure 3 shows the distribution of final target domains of reference for the two tasks. A direct reference to the world and a forward mediated reference through the graphics to the world share the world as their final target domain of reference. Similarly, a direct reference to the graphics and a backward mediated reference through the world to the graphics eventually refer to the graphics as their final target domain. A dual reference is indeterminate as to its final target domain. The final target domains exhibit significantly different distributions between the two tasks ( $\chi^2_{(4)} = 595.60, p < .001$ ). More concretely, (1) the Map data had more instances of graphic-only references, (adjusted residual: Map = 23.75, GRE = -23.75); (2) the GRE data had more instances of world-only references, (adjusted residual: Map = -6.27, GRE = 6.27); (3) the GRE data had more instances of dual references (adjusted residual: Map = -16.02, GRE = 16.02). Thus the assumption that the GRE data would have more world referents and fewer graphic referents than the Map data was supported. Furthermore, it is likely that dual references are strongly related to inferences on graphics, given the abundant instances of dual references in the GRE data.

tent word as its head.

## Conclusion

Based on the data of spontaneous spoken dialogues involving graphic representations, we have analyzed the impacts of the presence of a graphic on the use of spoken language. We found (1) a pre-established semantic relation between a graphic and the situation depicted by it provides the speaker with rich possibilities of mediated references, including forward individual, backward individual, forward relational, and backward relational references; (2) the same semantic relation also lets the speaker use a declarative sentence to express dual pieces of information; (3) mediated reference and dual description are not exceptional but rather mundane mechanisms routinely employed in actual communication; (4) the characteristics of communicative contexts affect the distributions of the final referents of linguistic phrases. We further suggested that the use of dual descriptions is strongly related to inferences on graphics.

These findings indicate that in spontaneous human communications, spoken language and a graphic representation may be used in the *sequential* composition, where the latter affects the usage of the former to extend its expressive capacity. This is in stark contrast to the common view of the interaction between linguistic and graphic modalities, where the integration is made only at the level of multiple pieces of information expressed by the two modalities in individual manners. A *parallel* composition of this type is not the only form of the graphic-linguistic integration, and probably, not even a dominant form.

## Abstract

This study addresses the dynamical nature of a ‘representation hungry’ cognitive task. Participants were asked to judge whether or not they thought they could reach a distant object with a hand-held rod. The dynamical effects observed in this study support a two-attractor model designed by Tuller, Case, Ding, & Kelso (1994). The results suggest that predictive judgments regarding the (im)possibility of an action may be better understood in terms of dynamically evolving basins of attraction rather than as depending on stable representational structures.

The ability to think about the outcome of a yet to be performed action seems to necessitate a representational explanation. How else to explain this ability except by assuming that the system constructs a model of the situation, represents the imagined action, and concludes on the basis of the ensuing representational structure whether the goal can be achieved by means of the action or not? In this paper we aim to question this representational presupposition by investigating the potential of dynamical systems theory (DST) to model simple prediction.

Within DST, the behavior of a system is analyzed as an emergent property of the interactions between its subsystems. During the last decade the tools of DST have proven to be valuable assets for understanding behavior emerging out of multiple interacting components (Beek, Peper, & Stegeman, 1995; Haken, Kelso, & Bunz, 1985; Schmidt, Carello, & Turvey, 1990; Vallacher & Nowak, 1994). However, most of the behavioral phenomena that are currently described with models developed in DST are not regarded as clear cases of *cognitive* behavior. DST has been challenged to try to deal with more ‘representation-hungry’ domains (Clark, 1997, p. 166-170; see also Clark & Toribio, 1994). One such domain, according to Clark, involves the class of cases that “include thoughts about temporally or spatially distant events and *thoughts about the potential outcome of imagined actions*” (Clark, 1997, p. 167; our emphasis). In the present paper we take a first, exploratory attempt towards answering this challenge by exploring whether participants’ verbal reports on the (im)possibility of an imagined action can be understood from within a DST framework. In our task participants have to indicate whether they think they can reach for an object on a distant table

with a rod. This task can be seen as a simple example of a situation in which one has to predict the possible outcome of an imagined action. By systematically manipulating rodlength we set out to study the dynamical aspects of this prediction behavior.

## Model description

Within the DST approach many different models have been developed to account for global patterns in behavior. Given that the task we studied involved discerning which rods enabled successful reaching and which did not, we used a dynamical model particularly designed to account for behavior with two attractor states. Tuller and colleagues (Tuller, Case, Ding, & Kelso, 1994; see also Case, Tuller, Ding, & Kelso, 1995) applied such a model to speech categorization phenomena. Following the example of Tuller et al. (1994) we use equation 1 to model our data.

$$V(x) = kx - \frac{1}{2}x^2 + \frac{1}{4}x^4 \quad (1)$$

$V(x)$  is a potential function with two minima which are assumed to correspond to two stable conceptual states, viz. ‘No’ (i.e., the participant indicates the belief or judgment that it is not possible to reach the object with the rod) and ‘Yes’ (the participant indicates the belief or judgment that it is possible to reach the object with the rod) respectively. The judgment regarding the imagined action is qualitatively denoted by  $x$  and  $k$  is the control parameter specifying the direction and the degree of tilt of the potential function (c.f. Tuller et al., 1994). As can be seen in Figure 1, for  $k = -1$  only one stable state exists in the system (i.e., ‘No’). Increasing  $k$  forces the function to tilt. Although the initial stable state persists, the attractor becomes more shallow. When the control parameter reaches the critical value  $-k_c$  an additional attractor appears (‘Yes’). From this point on, until  $k$  reaches the second critical value  $+k_c$ , the two stable states coexist (Both ‘No’ and ‘Yes’ are possible responses). At  $+k_c$ , however, the attractor corresponding to ‘No’ ceases to exist. Increasing  $k$  further only deepens the remaining attractor.

Figure 1 illustrates the tendency of dynamic systems to cling to the state they reside in. For each value of the control parameter the state in which the systems has settled is

Figure 1: Potential landscape defined by equation 1 for different values of  $k$  (after Tuller, Case, Ding, & Kelso, 1994)

indicated by the black dot. Ideally, the black dot will remain in the attractor it is in for as long as the attractor is relatively stable. This means that when multistability exists the location of the black dot on the potential function depends on whether the control parameter increased from  $-1$  to  $+1$  or decreased from  $+1$  to  $-1$ . As can be seen in Figure 1 this can lead to an observable effect classically associated with dynamical system's behavior, namely *hysteresis*. That is, the switch from 'No' to 'Yes' occurs at a higher value of the control parameter than the switch back from 'Yes' to 'No'.

As was said, this holds for the ideal case, in which the system is not perturbed in any way. Switches between states within the multistable region can occur, however, as a consequence of random disturbances. In a cognitive task like the one we studied, random disturbances may be assumed to correspond to psychological factors, such as fatigue, attention, boredom, and so on (c.f., Tuller et al., 1994).

To capture participants' behavior in our task the relationship between the control parameter  $k$  and the independent variable has to be specified. Following Tuller et al. (1994) we assume that this relationship is not a one-to-one correspondence. Instead  $k$  is a function of (1) rodlength, (2) the number of repetitions of the categorical judgments<sup>1</sup>, and (3) perceptual and cognitive characteristics of the participant. The relationship between the control parameter and rodlength can be symbolized by the following equation,<sup>2</sup>

$$k = \lambda + (N_{no} - N_{yes})S, \quad (2)$$

in which  $k$  specifies the value of the control parameter,  $\lambda$  is linearly proportional to the length of the rod,  $N_{no}$  and  $N_{yes}$  are growing functions of the number of accumulative repetitions of 'No' and 'Yes' respectively,  $S \geq 0$  and represents relevant characteristics of the participant that may fluctuate during the time course of the experiment. Given that  $S$  represents uncontrolled factors influencing task behavior, we cannot know the exact value of  $S$ . Therefore, we take a qualitative approach to the combined influences of  $(N_{no} - N_{yes})$  and  $S$  on the dynamics of the behavior of the participants. In equation 2 if  $(N_{no} - N_{yes})S = 0$  then  $k = \lambda$ . So

when either  $N_{no} = N_{yes}$  or  $S = 0$ , then there is a one-to-one correspondence between  $k$  and  $\lambda$ . However, for  $S > 0$ ,  $k$  will be larger than  $\lambda$  when  $N_{no} > N_{yes}$  and  $k$  will be smaller than  $\lambda$  when  $N_{no} < N_{yes}$ . The rationale of Equation 2 is illustrated by Figure 2 for a coupled sequential run, in which rodlength first systematically increases and subsequently decreases (abbreviated ID-run). For the sake of clarity we hold  $S$  constant and only look at the effect of the accumulative repetitions of a response.

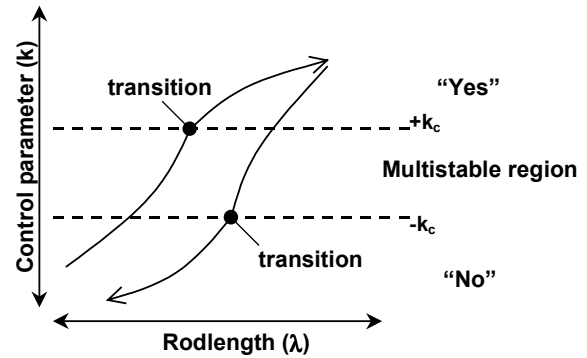

Figure 2: Illustration of the relationship between the control parameter and rodlength, for fixed  $S > 0$ , in a coupled sequential run in which rodlength first increases and subsequently decreases (see text for details).

In an ID-run the participant is presented at first with the smallest rod (bottom left in Figure 2). For short rods the participants start with no-responses and  $N_{no}$  will become increasingly larger than  $N_{yes}$  (which will remain zero) with every next trial. Due to the fact that  $N_{no}$  grows increasingly larger than  $N_{yes}$ ,  $k$  will increase faster than  $\lambda$  increases. When  $k$  reaches the value of  $+k_c$  a transition occurs and the participant switches to yes-responses. With every next trial  $N_{yes}$  will grow, whereas  $N_{no}$  will not. Hence the slope of the function  $k$  will decrease. Because the increase sequence is followed by a decrease sequence  $N_{yes}$  will start to outnumber  $N_{no}$ . This will cause  $k$  to decrease faster than  $\lambda$ . When  $-k_c$  is reached a transition occurs and the participant will switch to yo-responses. Figure 2 thus illustrates that for sufficiently large  $S$  the transition from 'Yes' to 'No' occurs at a larger rodlength than the transition from 'No' to 'Yes'. This is an example of the *enhanced contrast* effect. One can imagine that for a certain settings of the parameters one may find that the first and second transition occur at exactly the same rodlength, i.e. a *critical boundary*. However, the number of parameter settings that result in critical boundary

<sup>1</sup> See also Parducci's (1965; Parducci & Wedell, 1986) range-frequency theory and Helson's (1964) adaptation-level theory.

<sup>2</sup> See Tuller et al. (1994) for the original, more explicitly specified relationship between the control parameter  $k$  and the experimental variable  $\lambda$ . The simplification in the form of equation 2 is sufficient for our purposes.

is much smaller than the number of settings that result in either hysteresis or enhanced contrast.

The interrelationship between Equation 1 and 2 as described above leads to the following predictions for our experiment: (1) There is a tendency in the dynamic system to remain in the state it resides in. This means that participants will tend to give the same response as on preceding trials. (2) Accumulative repetitions of 'yes' will cause the multistable region to shift towards the upper end of the rodlength continuum. Conversely, accumulative repetitions of 'No' will cause the multistable region to shift towards the lower end of the rodlength continuum. (3) The higher the number of repetitions of 'Yes' in a run where rodlength increases and subsequently decreases the greater the chance of observing enhanced contrast and the smaller the chance of observing hysteresis. Conversely, the higher the number of repetitions of 'No' in a run where rodlength decreases and subsequently increases the greater the chance of observing enhanced contrast and the smaller the chance of observing hysteresis. Observations of critical boundary will overall be very limited. (4) Within the multistable region switches in perception can occur as a consequence of random disturbances. The narrower the multistable region (e.g., due to repetitions of a certain response – see figure 2) the smaller the chance of observing perceptual switches.

## Method

### Participants

Fourteen participants, 5 male and 9 female, participated in the experiment. All but two female participants were right-handed. The age of thirteen participants ranged from 22 to 28 years. One male participant was significantly older than the rest, viz. 56 years of age. The height of participants ranged from 1.56 to 1.88 meters, with an average of 1.76 meters. All participants, except one who volunteered, were paid for their participation or participated as a means to fulfilling a course requirement.

### Material

Rods with a diameter of 1.25 cm were used, ranging in length from 57.0 to 91.5 cm, in 1.5 cm increments.<sup>3</sup> The twenty-four rods were constructed from wood (density 0.67 g/cm<sup>3</sup>). Attached to each rod was a handle of identical material with the length of 11.5 cm and a diameter of 1.25 cm. A small disc divided the handle from the rod.

A PVC cylinder (diameter 5 cm, height 6 cm) was placed on a table (25x25 cm). The height of the table was adjusted

to the participant's wrist height with the arm at the side. The back of the cylinder was placed against a barrier of 12.5 cm height and the front of the cylinder was aligned with the front edge of the table.

### Procedure

A participant was asked to bend forward, with his/her preferred arm stretched as far as possible (i.e., bending forward while maintaining enough balance to stay flat on the feet). The distance between the feet and the hand in this position was measured. This measure was used to determine the distance to the table at which each participant was to be positioned during the experimental session (i.e., maximum distance reachable without rod + 75 cm<sup>4</sup>). Participants were subsequently asked to take this position and stayed there during the entire experiment. While standing at this distance it was explained to the participant that the goal was to displace the cylinder positioned on the table. The participant was subsequently handed a rod and was instructed to hold the rod so that it made an angle of approximately 45 degrees upwards with the horizontal. The participant stood upright with the rod in one hand and judged whether he was able to reach the cylinder with the rod from that position while keeping the two feet flat on the floor. After a participant had given his categorical judgment he returned the rod to the experimenter and was handed a new rod for which the participant again made a judgment. No feedback regarding accuracy was given.

### Design

Each participant performed this judgment under several conditions. There were three kinds of *sequences* in which rods were given to the participant, namely (1) increase sequences (I): rodlength increased from minimum to maximum in 1.5 cm increments; (2) decrease sequences (D): rodlength decreased from maximum to minimum in 1.5 cm increments; (3) random sequences (R): the rods ranging in length from the minimum to maximum were randomly assigned to the task. The two sequential condition I and D were always coupled, resulting in two kinds of coupled sequential runs: increase-decrease (ID) runs and decrease-increase (DI) runs. Coupled sequential runs were always followed by a random sequence, resulting in two possible blocks of runs, namely increase-decrease-random (IDR) blocks and decrease-increase-random (DIR) blocks. The random sequence served as a kind of buffer between the coupled sequential run preceding it and the coupled sequential run of the next block, and as a control condition in the analyses of the data.

Two different *ranges* were used in the experiment, namely range1 of 57.0 - 85.5 cm and range2 of 63.0 - 91.5 cm.

<sup>3</sup> Psychophysics studies (e.g. Morgan & Watt, 1989; Watt, 1984) suggest that the Weber fraction ( $\Delta I/I$ ) for length discrimination is approximately 0.05. In our experiment the fraction between the increment and rodlength ranged from 0.026 to 0.016. This means that in increase and decrease sequences the direction of change in rodlength is not perceivable for participants from one trial to another. On most occasions the fact that the hand-held rod is longer or shorter than a preceding rod does not become apparent within less than three or more trials.

<sup>4</sup> We added 75 cm to the personal maximum reaching distance, because in the range of rodlength used in this experiment 12 rods  $\leq$  75 cm and 12 rods  $>$  75 cm. Hence, for all participants exactly half of the rods used in the experiment would enable reaching, and half would not.

Thus, there were two possible minima and maxima for the three sequences described above. Within a given block the minimum and maximum for the three constitutive sequences (I, D and R) were the same. The four possible combinations of block and range in the experiment were thus, in shorthand, IDR-1, IDR-2, DIR-1 and DIR-2. Each of these combinations occurred twice in one experimental session, resulting in a total of 480 trials (2 ranges x 2 blocks x 3 sequences x 20 rods x 2 repeated measures) per participant. The block-range combinations were randomized within an experimental session, with the constraint that each block-range combination appeared as often in the first half of a session as in the second half.

## Results

Most participants showed a transition in judged possibility in all sequences (increase-, decrease- and random-sequences). Two of the fourteen participants, however, overestimated the distance reachable so much that the lower-end of the range (57.0 cm) was still too high to evoke a perceptual transition. For this reason these two participants were excluded from the analyses. Plotting the average response against rodlength for the remaining twelve participants for the three types of sequences resulted in the cumulative distributions as depicted in Figure 3.

Figure 3: Percentage of 'Yes' responses, averaged over subjects, per rodlength for increase, random and decrease sequences separately.

On average participants in this experiment tended to *overestimate* their reaching distance. Given the individually defined distance to table (personal maximum reaching distance without rod + 75 cm) the *expected* 50% category boundary would be about 75 cm for all participants. The *observed* 50% category boundaries as depicted in Figure 3 are all lower than this. The finding that participants tended to overestimate the distance reachable is in correspondence with findings in other experiments on judging reachability (Heft, 1993; Rochat, & Wraga, 1997).

To test the effect of sequence, suggested in Figure 3, a measure was required for the transition point in each sequence independently. Because in 36 sequences multiple transitions were observed across the rodlength continuum, the data of these sequences were transformed so that a single 'average' transition-point resulted<sup>5</sup>. For the other 192 sequences the real transition-point was simply used as average transition-point. On the average transition-points a 3 x 2 x 2 repeated-measures ANOVA was performed with Sequence (random-, increase- and decrease-run), Block (IDR, DIR), and Range (range1, range2). A main effect of Sequence was found,  $F(2, 22) = 14.68, p < .001$ . A difference contrast, comparing the average transition-points in increase- and decrease-sequences, revealed a contrastive effect, viz. the average transition-point was significantly lower in increase sequences (66.91 cm) than in the decrease sequences (70.73 cm),  $F(1, 11) = 17.19, p = .002$ . The average transition-point in random sequences was 69.23 cm. Further, the main effect of Range was significant,  $F(1, 11) = 12.39, p = .005$ . The average transition-point was smaller for range1 (68.20 cm) than for range2 (69.70 cm). None of the other effects was significant.

To see whether local contrastive or assimilative effects were present in random sequences the conditional probability of judging each rod as belonging to the same category as the preceding rod was investigated. We found that in random sequences participants tended to give the same response as given on the previous trial,  $\chi^2(1) = 58.54, p < .001$ .

Within the multistable region perturbing influences can make one percept change into the other and vice versa. Outside the multistable region only one perceptual form is possible. Taking these theoretical assumptions into consideration the boundary of the multistable region was estimated by the *last* transition-point<sup>6</sup> within a given sequence. Each coupled sequential run (ID-runs and DI-runs) was coded for the type of response pattern it showed, i.e. either hysteresis, critical boundary or enhanced contrast. In 66 of the 91 coupled sequential runs<sup>7</sup> (72.8%) an enhanced contrast effect occurred and in 20 runs (20.7%) a hysteresis effect. Critical boundary occurred in only 6 coupled sequential runs (6.5%), and no more than once per participant.

<sup>5</sup> This transformation involved re-ordering of the no- and yes-responses within a given sequence so that a single transition-point resulted. The total number of no-responses was projected onto the lower part of the rodlength continuum and the total number of yes-responses onto the upper part. The average transition-point was taken to be exactly between the rod receiving the last no-response and first yes-response in the transformed data.

<sup>6</sup> In an increase sequence this last transition-point was defined as being in between the longest rod receiving a no-response and its subsequent rod. Conversely, in a decrease sequence the last transition-point would be in between the shortest rod receiving a yes-response and its subsequent rod.

<sup>7</sup> Five coupled sequential runs were excluded from the analyses because no perceptual transition occurred.

Because participants overestimated the distance reachable the number of accumulative repetitions of ‘Yes’ in a ID-run were, on average, larger than the accumulative repetitions of ‘No’ in a DI-run. Hence, the dynamical model predicts that the chance of observing enhanced contrast is greater, and the chance of hysteresis is smaller, in ID-runs than in DI-runs. An analysis of the frequencies of the two response patterns confirmed this prediction. A Pearson Chi-Square test with SequenceCoupling (ID-, DI-runs), and ResponsePattern (enhanced contrast, hysteresis) indicated a significant association between SequenceCoupling and ResponsePattern,  $\chi^2(1) = 4.44, p = .035$ . Enhanced contrast occurred more frequently in ID-runs (37 times) than in DI-runs (29 times). Hysteresis on the other hand occurred more frequently in DI-runs (14 times) than in ID-runs (6 times). Critical boundary occurred as often in ID-runs (3 times) as in DI-runs (3 times).

Additional switches (i.e., alternating yes- and no-responses on successive trials preceding the last transition-point) occurred on 88 of the 3574 trials<sup>8</sup> in sequential runs. We found that more additional switches occurred in range1 (61 times) than in range2 (27 times;  $\chi^2=13.70, p < .001$ ). Interestingly, this effect of range was observable for both increase and decrease sequences (see Figure 4).

Figure 4: Number of additional switches observed in range 1 and range 2 for increase and decrease sequences separately.

The effect of range in decrease sequences can be understood as being due to the relatively large number of repetitions of ‘Yes’ in decrease sequences within range2 as compared to range1. The two-attractor model can also account for the effect of range in increase runs. As can be seen in Figure 3, even the shortest rods used in the experiment were occasionally judged to enable successful reaching. Further, the shortest rod in range2 (i.e., 63,0 cm) was judged as enabling successful reaching once by two participants, and as enabling successful reaching even 50% of the time by three participants. This means that the left boundary of the multistable region was not only on average

<sup>8</sup> This number indicates the total number of trials in the sequential runs of the experiment, i.e. (12 participants) x (40 trials) x (8 coupled sequential runs) = 3840, *minus* the first trial of each coupled sequential run and *minus* the trials in which a last transition-point was observed.

closer to the left end of the range of rodlengths, but even outside range2 for a considerable number of subjects. Thus, for these participants, the increase sequences in range2 started well within the multistable region. Consequently there were simply fewer opportunities for switching in increase sequences in range2 as compared to range1, which explains the low frequency of additional switches in range 2 for increase sequences.

## Discussion

Clark (1997) challenged DST to explain behavioral phenomena that are considered to be ‘representation hungry’ cases of cognition. We focused on the ability to predict the outcome of a to be performed action. Participants had to judge whether a rod afforded displacing an object from a certain distance. In our interpretation of Clark (1997) such behavior can be classified as ‘representation-hungry’, that is, the task seems to require a model of the situation, a representation of the imagined action, and computations based on those representations to determine whether the action will satisfy the goal.

In the present study we explored whether the judging behavior of our participants could be explained with a dynamical model. The results are in close agreement with the predictions derived from a two-attractor model (c.f., Case et al., 1995; Tuller et al., 1994). First, it was found that in random sequences participants tended to give the same categorical judgment as on preceding trials. This *assimilative* effect is in accordance with the notion that a dynamical system tends to cling to the state it resides in (*Prediction 1*).

Further, we observed that on average the transition from ‘No’ to ‘Yes’ in increase runs occurred at a shorter rodlength than the transition from ‘Yes’ to ‘No’ in decrease runs. Also we found that on average the transition occurred at a shorter rodlength in range 1 than in range2 (independent of the order of presentation of the rods). Both these effects can be interpreted as being due to the influence of accumulated repetitions of a certain response causing the multistable region to shift closer to one of the ends of the rodlength continuum (*Prediction 2*).

In coupled sequential runs (ID- and DI-runs) we observed all three effects that are predicted by the model, viz. hysteresis, critical boundary, and enhanced contrast. As expected critical boundary was the rarest of the three. Because participants overestimated their reaching distance to a large degree many more accumulative repetitions of ‘Yes’ responses occurred in coupled sequential runs in which rodlength first increased and subsequently decreased (ID-runs) than ‘No’ responses occurred in runs in which rodlength first decreased and then increased (DI-runs). As predicted, enhanced contrast occurred more often, and conversely hysteresis less often, in ID-runs as compared to DI-runs (*Prediction 3*).

Finally, more additional switches (alternating ‘No’ and ‘Yes’ responses) were observed when the multistable region

was expected to be relatively large, than when it was expected to be relatively small (*Prediction 4*).

Dynamic systems models typically describe behavior on the level of the whole system. On this account behavior is seen as a self-organized pattern, emerging from the interaction between subsystems. Such a pattern is called the collective variable or order parameter, which in turn can 'enslave' the behavior of the components (cf. Haken & Wunderlin, 1990, p. 7; Kelso, 1995, pp. 8-9). Despite the great complexity at the level of the interacting components the behavior of the system as a whole can be described and understood in terms of the lower-dimensional order parameter dynamics.

According to Clark (1997) an explanation of cognitive capacity in representational terms is valuable if the representations are distinguishable as entities serving a role as information-carriers for behavior. But what if, as DST would have it, a behavioral pattern is best understood as an emergent property of the overall activity of the system? Clark argues that in "such cases (if there are any), the overall system would rightly be said to represent its world—but it would not do so by trading in anything we could usefully treat as internal representations" (Clark, 1997, p. 168). We submit that the effects we observed can be fruitfully interpreted as a consequence of the inter-relationship between control parameter  $k$  and the collective variable  $V(x)$  governing the system. In all, these findings suggest that predictions regarding the possible outcome of an imagined reach are better understood in terms of dynamically evolving basins of attraction rather than as depending on stable representational structures.

## Abstract

Previous research has found that nonspecific goals (NSG) lead to better learning than a specific goal (SG). We studied this effect with a multimedia program in which participants had to learn about the outbreak of World War 1 either with the goal to find twenty dates (i.e., SG) or with the goal to explain the reasons for the war (i.e., NSG). As expected, the NSG-group better remembered facts about the text during the task and knew more at the end than the SG-group. The NSG-group may also better transfer what they had learnt to a new situation. To try to explain this effect, a number of process variables (strategy systematicity, motivation, number of pages read) were measured. SG- and NSG-group differed in terms of which variable best predicted learning: As expected, for the NSG-group challenge was the best predictor of performance, but probability of success was the best for the SG-group.

## Introduction

Effects of goal specificity on problem solving have been found in a number of recent studies (Geddes & Stevenson 1997; Miller, Lehman, & Koedinger, 1999; Sweller, 1988; Vollmeyer, Burns, & Holyoak, 1996). All these studies have found that giving problem solvers a specific goal state to reach led to poorer learning of the task than if they were given a nonspecific goal, such as to explore. However a difficulty has arisen when trying to form general conclusions about this work and its scope: different researchers have used very different tasks and have given different instantiations to the concept of goal specificity. Further the question arises of what relationship does the work on goal specificity in problem solving have to other goal specificity in organization psychology (see Locke & Latham, 1990), and possibly related research, such as that into explanation effects (Chi, Bassok, Lewis, Reimann, & Glaser, 1989).

To deal with this issue, in this paper we propose a conceptualization that generalizes what goal specificity is and applies that concept to the development of a new task for investigating goal specificity effects. This paper is a preliminary study that aimed to demonstrate goal specificity effects with a new task, and to show that this task has the potential to increase our knowledge of why such effects occur. We chose to use a multimedia learning program as

our task, both because of the explosion of interest in such programs (Issing & Klimsa, 1997) as cheap computer technology becomes widely available, and because it is very different to the problem solving tasks with which goal specificity effects have previously been found.

## Defining Goal Specificity

In Vollmeyer et al. (1996) we proposed that goal specificity effects could be explained in terms of dual-space theories of problem solving (Klahr & Dunbar, 1988; Simon & Lea, 1974). Specific goals (SG) could be seen as encouraging search of an instance or experiment space. Such a space corresponds to what is usually meant when we refer to problem solving as search; that is, we set specific subgoals that are part of that space and reach the goal via those subgoals. A specific goal is a state in such a problem space, which is why specific goals encourage a focus on this space. In contrast, a nonspecific goal (NSG) could be seen as encouraging search of rule or hypothesis space. Such a search space contains the possible rules or hypotheses that may govern the task, but testing such rules requires a coordinated search of instance and rule space.

If we assume that dual space theories provide an appropriate way to characterize specific and nonspecific goals, then it provides a definition of goal specificity. Specific goals are goals that promote reaching set states, nonspecific goals are those that encourage discovery of the nature of the task. By this definition, goal specificity qualitatively affects how people learn, not just how much.

**Self-explanation Theory.** Chi et al. (1989) found that students who explained math problems to themselves did better than students who only worked out examples. Although they do not use the term *goal specificity*, their characterization of explanations seems to fit to our definition of a nonspecific goal. Explaining math problems requires understanding the principles they are based on, whereas not requiring explanation allows problem solvers to focus on the solution alone.

However, self-explaining students took more time for the same task, thus, it could have been that time on task was a moderating variable. In several studies of the self-

explanation effect, Renkl (1997; for an overview, see Renkl, 1999) pointed out that time-on-task could be a moderator of performance. Self-explaining students take more time if given the opportunity, so in his experiments Renkl controlled for time and manipulated self-explanation in asking the self-explanation group to learn in a way they could explain the task to another person. Although both groups worked for the same amount of time, the self-explanation group had better learning outcomes than a group who only solved the problems. Therefore time-on-task appears to be important in these types of tasks.

**Goal Specificity in Organizational Psychology.** In organizational psychology, what has been known as goal specificity has been studied extensively in terms of goal setting (see Locke & Latham, 1990). In this literature specific goals are a form of target (e.g., “Make ten widgets”) whereas nonspecific goals are general admonitions to do well (e.g., “Make as many widgets as possible”). Tubbs’ meta-analysis (1986) showed that specific goals help performance ( $d = .82$ ), although some studies reported exactly the opposite. However these goals are specific and nonspecific in a different way to what has been meant in problem solving research. These goals are forms of targets, rather than states of the problem. Using our definition of goal specificity, we can see that the question of whether the two types of specificity are related depends on how these target goals might affect which space learners focus on. In this paper we will not address the possible connections between these two types of goal specificity.

**Goal Specificity in Multimedia.** In the literature on learning from multimedia texts, *open tasks* have been found to lead to better understanding than *closed tasks*. In their meta-analysis, Chen and Rada (1996) found consistently strong evidence that learners given an open task were more effective than learners given a closed task. However, there is a huge variety in what is subsumed under the closed or open manipulation. In general, closed tasks can be seen as those presenting learners with specific goals, for example to find a particular piece of information, whereas open tasks have very general goals, for example to learn for a test. Thus this distinction can be seen as roughly fitting to our definition of goal specificity: closed and open tasks are those with specific and nonspecific goals, respectively. Learning with multimedia is a particularly interesting domain for examining goal specificity as how people gather information can be explicitly coded by looking at the sequence of actions they perform on the computer. So it provides an opportunity for us to try to measure strategies.

**Goal Specificity and Motivation.** Kanfer and Ackerman (1989) proposed that goal specificity might affect motivation. To examine this issue we applied Vollmeyer and Rheinberg’s model (1998). They proposed a model that assumes that initial motivation affects learning through the mediating variables of motivational state during learning and strategies used for learning. The initial motivation contains four factors: (1) *probability of success*, which is the learners’ level of certainty about whether they will succeed

in performing the task; (2) *fear*, which is how anxious learners are about failing in the task; (3) *challenge*, which is the extent to which learners perceive this task as requiring competence; and, (4) *interest*, which is how much learners like the topic of the program.

Schiefele (1996) reported that in several experiments interest had a positive effect on text learning, especially on understanding texts as opposed to learning facts. Given that interest and challenge are highly correlated (Rheinberg & Vollmeyer, in press), we assumed that challenge would have the same effect. For facts, we assumed that good learning depends more on the learner’s expectancy of receiving a good result. Our nonspecific goal definition can be seen as equivalent to what Schiefele called *understanding-oriented learning*, whereas our specific goal definition corresponds to *fact learning*. Therefore we expected that in a nonspecific goal condition initial interest and challenge would predict learning but in the specific goal condition probability of success and fear (which are indicators of expectancy) should be better predictors.

### Study Aims

This paper reports our first exploration of a multimedia program we developed to study goal specificity. To develop this task we had to determine how to apply the concept of goal specificity in problem solving to a very different task.

**Multimedia Program.** The topic of the program was the outbreak of World War 1. The computer could present up to 51 different pages describing the events leading up to the start of the war. Each page had links to other pages and could have links to videos, sound files, or text boxes containing additional information. Most of the pages were arranged into five sequences, each describing the events occurring in one of the five critical countries (Austria-Hungary, England, France, Germany, and Russia). In addition, topics such as nationalism and imperialism were covered. As an event could concern two or three countries (e.g., declaration of war), learners sometimes saw the same page in the sequence for multiple countries. After every page learners could decide whether to continue reading pages about the same country or to switch to another country or topic. Thus the program provided us with a way to examine the learners’ strategies. In Vollmeyer et al. (1996) we found that strategy systematicity was critical to performance but the task was so different that we could not use this operationalization. Therefore in the multimedia program we operationalized systematicity as the extent to which learners followed sequences, instead of jumping from one topic to another.

To operationalize goal specificity, Chi et al.’s (1989) idea of explanation seemed most applicable to this task given our definition of goal specificity. So we had NSG learners go through the program with the goal of explaining the outbreak of World War 1 to someone else. However unlike Chi et al. we did not have participants give explanations during the task. To increase the contrast between NSG and SG learners, the SG-learners were given a list of 20 specific events and asked to fill in the dates for those events.

**Predictions.** We expected the NSG group to learn more than the SG group, and to be better able to transfer the lessons of the outbreak of World War 1 to another situation. We expected this greater learning to be a result of NSG learners being more systematic. As the NSG learners are more systematic, that is they put more effort into understanding the content of a page they should spend more time per page than SG participants.

We did not expect goal specificity effects on initial motivation. However, the motivational state during learning may change during the task in different ways for the two groups as they react to their perceived success or failure in attaining their goal. In particular we tested Schiefele's (1996) proposal that challenge and interest would relate more strongly to performance for NSG than for SG learners.

## Experiment

### Method

**Participants.** Forty-five students at the University of Potsdam participated in the study and received DM 10.00 (~US\$5) or course credit.

**Design.** There were two levels of goal specificity. The SG group consisted of 24 participants who received instructions to look for dates in the history multimedia program. The NSG group consisted of 21 participants who were told to understand the problem as if they would have to explain it to another person.

**Procedure.** Before the participants started working with the multimedia program they read that they would learn about the outbreak of World War 1. They were informed that they would work with the program for about 25 minutes and then answer a questionnaire. We set a fixed time span as we felt it was important to control for time in order to remove any possibility of time-on-task being used as a factor to explain goal effects. We also told participants that they would be interrupted at various times so that we could ask them what they thought about the task. These interruptions were necessary in order to measure participants' motivational states and to sample their knowledge. The instructions also contained the goal specificity manipulation. The NSG participants were asked to "...work with the program so that you could tell another person about the reasons for the outbreak of World War 1." The SG participants were asked to "... work with the program so that you can fill out correctly the following time-line." The time-line consisted of twenty events, such as the assassination in Sarajevo, for which the learners had to find the dates in the program.

After reading the instruction participants answered the QCM (*Questionnaire of Current Motivation*, by Vollmeyer & Rheinberg, 1998). This questionnaire measured their initial motivation on the four factors *probability of success* (example items: "I think I am up to the difficulty of the task", "I probably won't manage to do this task"), *fear* (example items: "It would be embarrassing to fail at this task", "I feel petrified by the demands of this task"), *interest* (example items: "After having read the instruction the task seems to be very interesting to me", "For tasks like this I

don't need a reward, they are lots of fun anyhow."), and *challenge* (example items: "This task is a real challenge for me", "If I can do this task, I will feel proud of myself").

When working with the multimedia program participants were interrupted every seven minutes for a total of three times. During each of the three interruptions they were asked to answer two types of questions: a motivational state questionnaire, and one factual question about each of the last three pages the participants had seen in the program.

**Process Variables.** Three process variables were measured while learning.

(1) *Motivational state.* Every seven minutes participants answered ten questions (example items: "The task is fun", "I'm sure I will find the correct solution") on a seven-point scale. A composite score was calculated to represent motivational state. Responses were averaged together.

(2) *Strategy systematicity.* Our aim was to find indicators for how systematically a learner works through the program. As this was our first use of this multimedia program, it was not clear what the best measure was. We chose to measure how often learners read a page that followed from the previous one, as opposed to jumping to a new topic. This variable was called sequence. For this we counted the pages that followed logically from the previous one. We then divided this count by the total number of pages participants looked at. An example of following a sequence would be if after the first page for Germany the second page for Germany was looked at. Switching to the first page of France would have been counted as not following the sequence.

(3) *Number of pages.* We counted the number of pages that participants looked at for more than five seconds. Pages looked at for 5s or less were probably mistakes, or arose because the learner realized they had already read the page. Given that each learner was given about the same amount of time to work with the program, we expected that looking at fewer pages would be an indicator of going into the contents of the pages in greater depth.

**Outcome Variables.** To measure knowledge we used a pilot study to develop a questionnaire. For every page that was part of a sequence for a country or side topic (34 in all), we formulated a multiple-choice question with five options. As we had the hypothesis that NSG-learners would read more carefully than SG-learners we formulated factual as well as inference questions, similar to the suggestion of Royer, Carlo, Dufresne and Mestre (1996). So 24 pages had factual questions, ten had inference questions, and one general question was asked.

There were three outcome variables, two were indicators of knowledge and one of transfer.

(1) *Sampled knowledge.* The relevant item from the questionnaire was asked about each of the last three pages learners had seen.

(2) *Accumulated knowledge.* After participants had worked with the multimedia program for approximately twenty-five minutes, they were given the whole questionnaire.

(3) *Transfer.* If NSG-participants understood the program on a deeper level then they should have an advantage in

understanding a similar situation. So we asked them to imagine a scenario in which four tribes were deciding whether to form alliances. Analogous to World War 1, between some tribes there were permanent conflicts over resources and between some there were no fundamental problems. Participants took the role of one tribe's leader and decided whether to form an alliance, then justified their answer. The arguments of participants agreeing to make an alliance were classified into two categories: *security* ("It's more secure to have partners."), and *nationalism* ("Having a partner gives my tribe more power."). Participants who disagreed with making an alliance had their arguments classified as either *war avoidance* ("My tribe has to help the partner in a conflict even if it is not our conflict."), or *egoism* ("I don't want to fight for others."). The participants' statements could be assigned to categories with an inter-rater reliability of Cohen's (1960)  $\kappa = .94$ . Nationalism and egoism explanations were considered less interesting as they were only seldom mentioned in an unpublished pilot study.

## Results

**Preliminary Analyses.** Our intention was to examine the process of learning by measuring the variables motivational state and sampled knowledge, so we interrupted learning three times. However, motivational state during learning stayed constant (motivational state at time point 1:  $M = 5.42$ ,  $SD = 0.76$ ; at time point 2:  $M = 5.49$ ,  $SD = 0.82$ ; at time point 3:  $M = 5.52$ ,  $SD = 0.90$ ;  $F[2, 86] = 0.84$ ,  $p = 0.44$ ) and at a high level (scale from 1 = low motivational state to 7 = high motivational state). There was no feedback given to participants, but this result suggests that learners did not experience success or failure while working with the program. If they had done so, then motivation would probably have increased or decreased, as Vollmeyer, Rheinberg, and Burns (1998) showed.

The second variable was sampled knowledge. As a consequence of the design this measure should not change over time as participants always received questions about the last three pages they saw. As the pages were not cumulative, answers to these questions cannot reflect accumulation of knowledge. Instead they sample how well the participants were learning as they worked through the program. For each set of three questions learners scored between 0 and 3. We also tested whether knowledge was constant during learning. Because we expected no difference between knowledge sampled at different points, we averaged the knowledge scores as well as the motivational states.

**Effects of Goal Specificity.** The first aim of our study was to test the hypothesis that learners with a specific goal acquired less knowledge than participants with a nonspecific goal. Achieving a worse outcome may be a result of poor strategies and/or motivation, which were measured as mediating variables.

The most important measures were knowledge during learning and accumulated knowledge, as these should demonstrate that giving participants specific goals decreased

their learning performance. For knowledge during learning, the possible range for correct answers was 0 to 9 (three times questions about three pages). As expected, the SG-group could not answer correctly as many questions as the NSG-group,  $t(43) = 3.34$ ,  $p = .002$ , as the means in Table 1 show. The same effect was found on the multiple-choice questions after learning with the program. The answers were adjusted in that answers were only analyzed to questions about pages participants had actually seen. Thus the means in Table 1 show the proportion of correct answers to pages seen. For the factual questions, the NSG-group answered 44%, compared to 29% for the SG-participants,  $t(43) = 4.18$ ,  $p < .001$ . NSG-participants were also better on inference questions,  $t(43) = 3.20$ ,  $p = .003$ . Even if we had not applied the adjustment, the effect for goal specificity on knowledge for facts holds (SG:  $M = 8.96$ ,  $SD = 3.62$ ; NSG:  $M = 12.67$ ,  $SD = 3.34$ ,  $t[43] = 3.56$ ,  $p = .001$ ) as well as for inferences (SG:  $M = 3.08$ ,  $SD = 1.21$ ; NSG:  $M = 4.52$ ,  $SD = 1.86$ ,  $t[43] = 3.11$ ,  $p = .003$ ).

Table 1: Descriptive statistics for the SG-group ( $n = 24$ ) and the NSG-group ( $n = 21$ ) on process and dependent variables.

	Groups	M	SD
sampled knowledge	SG	3.79	1.74
	NSG	5.52	1.72
knowledge (facts)	SG	0.29	0.12
	NSG	0.44	0.13
knowledge (inference)	SG	0.23	0.12
	NSG	0.37	0.16
number of pages	SG	46.58	13.72
	NSG	39.43	9.83
Interest	SG	4.93	1.32
	NSG	4.93	0.99
Challenge	SG	4.96	1.00
	NSG	4.58	0.89
probability of success	SG	5.47	0.85
	NSG	5.45	1.04
Fear	SG	2.68	1.10
	NSG	3.06	1.38
motivation during learning	SG	5.47	0.70
	NSG	5.49	0.86
sequence	SG	0.71	0.01
	NSG	0.73	0.01

We found a clear effect of goal specificity on learning outcomes, so we tested whether our goal specificity manipulation affected process variables. As Table 1 shows, SG-participants looked at more pages,  $t(43) = 1.98$ ,  $p = 0.054$ . Although this effect was not quite significant, we analyzed the process and dependent variables by relating them to the number of pages looked at.

We did not expect any effect of goal specificity on initial motivation. As the means in Table 1 indicate, none of the four factors of initial motivation (interest, challenge, probability of success, fear) differed,  $p$ 's  $< 0.15$ . As the items were answered on a scale from 1 to 7, the means

demonstrate that all participants regarded the task as easy (probability of success:  $M = 5.26$ ,  $SD = 0.93$ ), interesting (interest:  $M = 4.93$ ,  $SD = 1.17$ ), challenging (challenge:  $M = 4.78$ ,  $SD = 0.95$ ), and that it aroused few fears (fear:  $M = 2.85$ ,  $SD = 1.24$ ).

As process variables, motivational state and strategy systematicity were measured. The motivational state measure (averaged over three time points) did not differentiate the SG-group from the NSG-group,  $t(43) = 0.11$ ,  $p = 0.92$ . The indicator for how systematically learners work with the multimedia program was the proportion of pages that followed logically from the previous page. Although we had expected that the SG-group would jump around more in the program, we could not find a difference,  $t(43) = 0.83$ ,  $p = .41$ . Across both groups, participants chose the next logical page 73% of the time; that is, they followed the sequence for the country they were reading about.

We expected that NSG participants faced with our transfer task would be less likely to agree to an alliance that risked a wider war. Therefore, we tested whether the groups differed in who would agree to an alliance and what argument they would use. As Table 2 shows, there was a tendency for more SG-participants than NSG-participants to agree to an alliance,  $\chi^2(1) = 3.27$ ,  $p = .071$ .

Table 2: Number of participants in SG- and NSG-group agreeing to an alliance.

	agreement to alliance	
	alliance	no alliance
SG	12	12
NSG	5	16

When we categorized the arguments used to justify whether to enter an alliance, we dropped the categories of *nationalism* (one in each group) and *egoism* (7 in SG, 6 in NSG) from the analysis. These two categories are unlikely to be influenced by the program. Of the remaining two categories, we found that war avoidance (the theme our participants would be likely to use if they understood the program) was used as a justification more often by NSG participants than SG participants, who instead were more likely to use security as a justification,  $\chi^2(1) = 4.82$ ,  $p = .028$  (see Table 3). Thinking in terms of security might be a more surface reaction to the event described in the program.

Table 3: Distribution of the SG- and NSG-group which arguments were given for or against alliance.

	argument pro/con alliance	
	war avoidance	security
SG	5	11
NSG	10	4

**Cognitive-motivational Model.** The aim of the study was to explore whether the concept of goal specificity could be applied to a more realistic multimedia task. Previously we have looked at how motivation may affect the learning process in different ways depending on the goal (Vollmeyer,

et al., 1998). However, the sample size in this preliminary study is not large enough for the type of path analyses required to examine this issue. Therefore, a first step was to look for differences between groups in term of which variables affected accumulated knowledge. As knowledge for facts and inferences were correlated,  $r = 0.66$ ,  $p < 0.001$ , and there were fewer inference questions than fact questions, we will only report knowledge for facts. Number of pages also did not relate to motivation. Correlations of final knowledge with initial motivation and process variables are presented in Table 4.

Independent of the manipulation, sampled knowledge and strategy systematicity (i.e., *sequence*) should be positively correlated with accumulated knowledge. Whereas for sampled knowledge a relationship to accumulated knowledge was found, this was not the case for *sequence*. The latter result makes doubtful whether *sequence* is a valid indicator for strategy systematicity.

We examined Schiefele's (1996) proposal that interest and challenge could play a more important role for NSG learners. Table 4 shows that interest and challenge correlate with accumulated knowledge for the NSG-group but not for the SG-group. However, the difference in correlations is only significant for challenge ( $z = 2.59$ ,  $p = 0.014$ ).

To analyze which variable was the best predictor for accumulated knowledge, we calculated a regression on the four initial motivational factors, motivation during learning and sampled knowledge. As the correlations had shown different patterns in the experimental groups, they were analyzed separately. For the SG-group the best predictor for knowledge is probability of success,  $\beta = 0.46$ ,  $t = 2.56$ ,  $p = 0.018$ ,  $R^2 = .23$ , whereas for the NSG-group challenge,  $\beta = 0.61$ ,  $t = 3.42$ ,  $p = 0.003$ ,  $R^2 = .27$ , is the best.

Table 4: Correlations  $r(p)$  of accumulated knowledge with initial motivation and process variables separated in SG- ( $n = 24$ ) and NSG-groups ( $n = 21$ ).

	Correlations with accumulated knowledge	
	SG	NSG
sampled knowledge	<b>0.35</b> (0.10)	<b>0.46</b> (0.03)
interest	0.02 (0.92)	<b>0.51</b> (0.02)
challenge	-0.23 (0.28)	<b>0.51</b> (0.02)
probability of success	<b>0.48</b> (0.02)	0.31 (0.17)
fear	<b>-0.45</b> (0.03)	-0.31 (0.17)
motivation during learning	0.19 (0.37)	<b>0.39</b> (0.08)
sequence	-0.11 (0.62)	-0.14 (0.55)

## Discussion

The major result of our study was that we could demonstrate an effect of goal specificity on a more realistic task than those on which this type of research has previously been based. Switching from a problem-solving task to multimedia learning in the domain of history presented two difficulties: the first was that goal specificity had to be re-interpreted, the second was that the theoretical constructs needed new operationalizations.

**Goal Specificity.** With a new task and a different operationalization of goal specificity we could replicate the effect that an NSG group would learn more than a SG group, even when the task was to learn about the causes that led to the outbreak of World War 1. Therefore we met our aim of generalizing the concept of goal specificity from problem solving to multimedia learning.

**Goals and Motivation.** Compared to our research on problem solving, motivation during the task seemed to play a different role when working with a multimedia program. As our previous task was difficult to solve, motivation changed while working with that task. When working with this shorter and easier program no changes of motivation during learning were observed, but initial motivation was more predictive than was previously found. However, what motivational factors were most influential varied with goal specificity. For NSG interest and challenge were most important, but for SG fear and probability of success were. This provides further evidence that the way motivation affects performance varies with the type of goal.

**Operationalizations of Theoretical Constructs.** In a problem solving task every input can be categorized on a continuum of systematicity, but with a multimedia program it is not clear how to operationalize this variable. Even if learners can choose after every page what to see next, it is unclear whether choosing the next page in the sequence is a systematic strategy as we defined it. As our measure does not correlate with performance it is still open as to whether this is a valid measure. However, we have shown that this is a useful task for examining goal specificity, so it should be worthwhile in future research to try to develop and validate better measures of strategy.

## Abstract

The order effect, a phenomenon in which the final belief is significantly affected by the temporal order of information presentation, is a robust empirical finding in human belief revision. This paper investigates how order effects occur, on the basis that human belief has a coherence foundation and a probability/confidence distinction. Both the experimental results and the UEcho modeling suggest that confidence plays an important role in human belief revision. Order effects in human belief revision occur where confidence is low and disappear when confidence increases. UEcho provides a computational model of human belief revision and order effects

## Introduction

It is generally agreed that one constantly conducts *belief revision* – a process in which one revises one’s beliefs in the light of new information, with a goal to maintain a reasonably consistent and up-to-date belief system. It is of great philosophical and psychological interest to investigate whether one is able to achieve such a goal and what the underlying regularities are.

Psychological investigations of human belief revision have revealed an important finding – *the order effect* (e.g., Hogarth & Einhorn, 1992; Schlottmann & Anderson, 1995; Zhang, Johnson, & Wang, 1997). Generally speaking, the order effect refers to the phenomenon that the temporal order in which information is presented affects the final judgment of an event. Undoubtedly, the temporal order of incoming evidence often carries important information about the true meaning of an event. However, robust order effects have been found even in situations where the temporal order of incoming evidence seems not meaningful. It is these cases that make the order effect a very interesting phenomenon.

This paper aims to investigate how order effects occur in human belief revision, both empirically and computationally. It consists of four sections. In the first section, some previous studies on human belief and belief revision, uncertainty, and order effects are briefly reviewed. Then a psychological experiment and its UEcho modeling (see Wang, Johnson, Zhang; 1998; Wang, 1998) are reported in the next

two sections. The final section provides general discussions and conclusions.

## Human Belief Revision and Uncertainty

There are two main views regarding how an unconvinced belief could be justified (e.g., Gardenfors, 1990). According to the *foundations* approach, a rational individual derives beliefs from reasons for these beliefs. In other words, a belief is justified if and only if it possesses some satisfactory and “hard” underlying reasons. The *coherence* approach, in contrast, maintains that a belief may be held independent of its supporting reasons. An individual holds a belief as long as it logically coheres with the individual’s other beliefs. Therefore, coherent beliefs can mutually justify each other, and no belief is more fundamental than another.

How beliefs are justified has a direct implication on how beliefs should be revised when new information becomes available. Based on the foundations view, one should simply give up those beliefs that lose their underlying reasons and accept new beliefs that become well supported. An example is the *Truth Maintenance System* developed by Doyle (1979). In contrast, the coherence view emphasizes consistency and conservatism. Therefore, in belief revision one should retain as many of one’s beliefs as possible while accommodating any new evidence. In other words, as long as the coherence of the resulting state is maintained, a belief can survive without solid reasons. The so-called AGM theory of belief revision (Alchourron, Gardenfors and Makinson, 1985; Gardenfors, 1990) is one well-known example that adopts the coherence approach.

The coherence approach to human belief revision is generally preferred (see Gardenfors, 1990; Thagard, 1989). It has been argued that the foundational approach involves excessive computational cost. It is intellectually very costly to keep track of the reasons of beliefs. Moreover, it has been shown that the foundational approach conflicts with observed human behavior. For example, the *belief preservation effect* (e.g., Ross & Lepper, 1980) suggests that people are reluctant to give up some beliefs even when the original evidential bases of these beliefs are completely destroyed.

---

<sup>1</sup> Portions of this research were conducted when the authors were at The Ohio State University, Departments of Psychology (Drs. Wang and Zhang) and Pathology (Dr. Johnson).

Uncertainty is the ultimate reason for human belief and its revision. It is well agreed that there are two general types of uncertainty (see Walley, 1991). First, when the truth of a proposition is unknown but the average proportion of that proposition being true in the long run can be precisely specified, the indeterminacy involved in this case is called *uncertainty*. An example is tossing a fair coin. Second, in some cases, one can neither completely determine the truth of a proposition nor precisely specify the average proportion of that proposition being true in the long run. This type of uncertainty – the indeterminacy of the average behavior – is usually called *imprecision*.

The distinction between imprecision and uncertainty is so fundamental that it has caused a “holy war” in the field of uncertainty management. On the one hand, *probability theory* (along with Bayes’ Theorem for belief revision), the best-established formal method for uncertainty management, has long been criticized for its difficulty in handling imprecision. It has been suggested that while a probability number is sufficient to summarize the uncertainty dimension, a confidence measure is needed to handle the imprecision dimension, with a high confidence measure representing precise belief and a low confidence measure representing imprecise belief (see Almond, 1995). On the other hand, *fuzzy sets* and the *possibility theory* (see Zadeh, 1978) often deal with imprecision but not uncertainty. The *theory of belief functions* (see Shafer, 1976) deals with both imprecision and uncertainty. Along with Dempster’s rule for evidence combination, it thus provides a more complete picture of formal belief management.

### The Order Effect

A large number of empirical studies on human reasoning have demonstrated that people often systematically deviate from normative postulates. With the assumption that these normative postulates prescribe how a reasonable individual should behave, these systematic deviations are often labeled as *cognitive illusions, biases, or fallacies* (e.g., Kahneman, Slovic, & Tversky, 1982). Several well-known biases include *base rate fallacy, conjunction fallacy, and overconfidence* (see Kahneman & Tversky, 1996 for a review).

The order effect in human belief revision is yet another robust empirical finding (e.g., Hogarth & Einhorn, 1992). By a similar standard, the order effect should also be called a bias since the normative postulates, in particular Bayes’ Theorem, have no room for it – it simply violates commutativity. However, as many researchers have already pointed out, calling it a bias is nothing more than giving it a label, which provides no help to understand how and why the order effect occurs.

Miller and Campbell (1959) argue that order effects in belief revision represent order effects in memory. Specifically, due to memory decay, previous evidence items get weighted less as time goes by. Later studies showed that this view is problematic since direct comparisons suggest that beliefs are largely independent of recall of evidence items (e.g., Anderson & Hubert, 1963).

The serial integration model (e.g., Schlotzmann & Anderson, 1995), proposed in the framework of information integration theory (Anderson, 1981), claims that people pay less

attention to successive items of evidence due to attention decrement. Attention decrement results in different weights being assigned to different evidence items, which in turn results in order effects. Unfortunately, this model fails to specify what factors affect the attention decrement.

Hogarth and Einhorn (1992) proposed an anchoring and adjustment model to explain order effects. According to this model, belief revision is a sequential anchoring-and-adjustment process in which people adjust the current belief (the anchor) on the basis of how strongly new information confirms or disconfirms this belief. In addition, the adjustment weight is a function of both the anchor and the new evidence. More specifically, when the impact of the new evidence is smaller than the reference point, the adjustment weight is proportional to the anchor. And when the impact of the evidence is larger than the reference point, the adjustment weight is inversely proportional to the anchor. It is this kind of contrast effect that results in order effects. The model further adopts two parameters ( $\alpha$  and  $\beta$ ) to regulate this weight assignment process. It claims that the two parameters represent people’s sensitivity toward negative and positive evidence, respectively. In particular, the model argues that some individuals tend to view negative (or positive) evidence more seriously than others. Therefore, in terms of the underlying factors that regulate the weight assignment, the model actually points to unidentifiable individual differences.

### Summary

The above review reveals two important findings in the area of human belief and its revision. First, human belief has a coherence foundation. A belief can survive without solid foundational evidence. Beliefs hold each other as a coherent system. Second, human belief has a multi-component structure. The probability/confidence distinction suggests that a single probability number cannot capture all the important aspects of a belief. A confidence component is necessary.

Previous theories of order effects hardly take these findings into consideration. They often attempt to explain order effects by a weight assignment mechanism that weighs members of the evidence sequence differentially. However, they encounter great difficulties in fully explaining why weights have to be assigned in a particular way at a particular time. Consequently, in some cases, one or more task characteristics are particularly emphasized (e.g., memory decay, or attention decrement), which of course often only account for a fragment of the order effect. In some other cases, arbitrary parameters are adopted in the weight assignment to summarize unidentifiable sources.

The probability/confidence distinction suggests that the impact of the new evidence cannot be fully understood without the nature of the current beliefs being sufficiently appreciated. More specifically, the confidence component of a belief, mainly determined by the amount of previous experience, represents how easily this belief can be revised. A belief with no previous experience has very low confidence and is easiest to change. And a belief established by significant previous experience is committed with a high confidence level and thus is hard to change. In the context

of order effects, this analysis implies that the order effect pattern may change with different levels of experience. The rationale is as follows. As one keeps interacting with the environment, one gains more and more experience. As a result, beliefs are gradually tuned to the statistical structure of the environment (see Anderson, 1990). In addition, confidence increases as more experience is gained. Both factors will make one react to any new evidence more realistically rather than over-react or under-react. Since over-reacting and under-reacting are the fundamental causes of the order effect, then when one gains more and more experience about the environment, the order effect in belief revision should tend to diminish and disappear.

The experiment reported in the next section is designed to test this hypothesis.

## Experiment

### Design and Procedure

A modified version of the CIC (Combat Information Center, Towne, 1995; see also Wang, Johnson, & Zhang, 1998; Zhang, Johnson, & Wang, 1997) simulation was used as the task domain. In the CIC task used for this experiment, the goal of the participant, acting as a commanding officer of a naval ship, was to collect two pieces of information sequentially about an aircraft in the radar area and accurately identify its intention.

One piece of information was about the route (R), which indicates the target is either on or off a commercial air route. The other piece of information was self-identification (SelfID), which indicates the target's response after being warned. In a typical trial, the participant was shown a target and had to report the degree of belief (on a 0-100 scale) that the target is friendly before any evidence (i.e., initial belief) and after each piece of evidence (i.e., sequential belief revision). Finally, the participant was forced to make a two-alternative (i.e., friendly or hostile) judgment about the identity of the target. After the decision was made, the participant could request the true identity of the target if available. Whether this true identity information is available or not depends on the type of the trial, as explained later.

The experiment adopted a 3x(4) factorial design. The between-subject independent variable was the ratio of total friendly targets to total hostile targets in the training samples. The ratio was 1:1 (equal number of friendly and hostile targets), 3:1 (friendly targets are three times as frequent as hostile targets), or 1:3 (hostile targets are three times as frequent as friendly targets). The purpose of this factor was to create environments with different statistical structures and test if participants could gradually tune their beliefs to capture these structures.

The experiment attempted to investigate how the patterns of order effects changed with training. The training was organized in four blocks, which is the within-subject variable (see Figure 1). Five evaluation blocks were inserted in the process to provide a way to easily evaluate the pattern changes of order effects. The major difference between training trials and evaluation trials is that no true identity feedback was provided at the end of each evaluation trial.

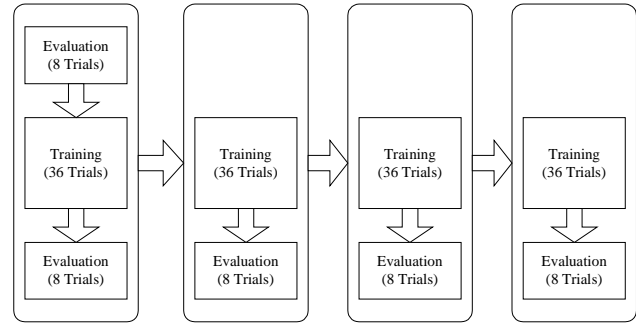

Figure 1. The experimental design

Each evaluation block had eight evaluation trials in it. The eight evaluation trials were constructed in the following way. There were two pieces of evidence (Route and SelfID), each of which had two possible values (“on” and “off” for Route, and “friendly response” and “no response” for SelfID), so there were 4 kinds of trials. Since each piece of evidence could be collected before the other, we had a total of eight different evaluation trials. Participants were instructed to summarize their training experience in order to perform these evaluation trials.

Each training block consisted of 36 trials. The trial distribution is dependent on the friendly-hostile ratio and is shown in Table 1. Since a value of “on” for Route and a value of “friendly response” for SelfID are regarded as positive evidence for a friendly target, they are represented by “+”s in Table 1. Similarly the opposite values are represented by “-”s.

Table 1. The trial distribution

Route	SelfID	1:1		3:1		1:3	
		F	H	F	H	F	H
+	+	8	2	12	1	4	3
+	-	4	4	6	2	2	6
-	+	4	4	6	2	2	6

140 undergraduate students participated in the experiment. They were randomly assigned to the three friendly-hostile-ratio treatment groups. The trials in each block were completely randomized for each participant.

### Results

The five evaluation blocks, distributed in the critical positions in the training, are the focus of our analysis. In addition, for the purpose of easily examining order effects, only the data from the two critical evidence sequences (“+-“ and “-+”) are reported. The results are shown in Figure 2.

Three major findings are identified. First, the effect of the friendly-to-hostile ratio is evident. While the average initial belief judgment (i.e., before any evidence) tends to increase with training in the 3:1 group (56.7, 59.0, 67.1, 68.6, from block1 to block4, respectively), it tends to decrease with training in the 1:3 group (47.8, 43.0, 41.3, 40.2,

from block1 to block4, respectively). Note that it is largely unchanged with training in the 1:1 group (50.0, 50.0, 49.5, 53.3, from block1 to block4, respectively). This pattern of result suggests that the initial belief judgments were gradually tuned to more closely reflect the built-in friendly-to-hostile ratios.

**Figure 2.** The belief revision patterns in all three friendly-to-hostile ratio conditions. The initial evaluation block before any training is labeled as block0, which also combines data from all three ratio groups. The evaluation blocks after each training block are labeled as block1 to block4, respectively. In each block, belief evaluation (from 0 to 100) is plotted against the evidence sequence, from init (before any evidence is presented) to e1 (the first piece of evidence is presented) to e2 (the second piece of evidence is presented). Because in general positive evidence raises belief ratings and negative evidence lowers belief ratings, plotting opposite evidence sequences (“+−” and “−+”) together results in a diamond shape (e.g., block4). Importantly, when the final belief ratings after both pieces of evidence are different, the diamond shape becomes the fish-like shape (e.g., block0), which indicates a recency order effect.

Second, the belief revision patterns change significantly across the whole training session. A recency effect is evident in block0 (the final belief judgment is 41.9 for the “+−” sequence vs 50.8 for the “−+” sequence), and this recency effect tends to disappear in the later blocks. More specifically, recency effects appear in block1 and disappear in block3 and block4 in all three ratio groups. This pattern is consistent with our prediction that order effects diminish and disappear with training.

Finally, it is interesting to note that the areas inside the diamond-like order effect patterns tend to become systematically smaller as the training progresses. Since the pattern is approximately symmetric vertically, we could use the height of the diamond as a rough estimation of the size of the area. The result shows that the area size decrement is statistically significant in the 1:1 and 3:1 groups, though not in the 1:3 group. This pattern of area decrement indicates

that participants fluctuated less in their belief judgments as more experience was gained, which further suggests that participants tended to be less sensitive to new evidence as confidence goes up.

In summary, the experiment results reveal that the recency effect disappeared as more training trials were performed. The disappearance of the recency effect suggests that instead of over-reacting in the light of new evidence, participants made more proper and more realistic reactions. As suggested previously, as more experience was acquired during training, the statistical tuning led participants to make more confident belief judgments, which eliminated over-reaction.

UEcho, first proposed in Wang, Johnson, and Zhang (1998) as a model of belief evaluation in abduction, is further developed to model the experiment results.

### A UEcho Model

UEcho is based on Echo, which is a connectionist implementation of the Theory of Explanatory Coherence (TEC), proposed by Thagard (1989, 1992) as a model of human abductive reason. Different from other theories of belief revision such as Hogarth & Einhorn’s anchoring and adjustment model, Echo takes a coherence view of belief evaluation as its foundation. According to Echo, a belief should be accepted if it is coherent with other beliefs, and rejected if it is incoherent with other beliefs. By quantitatively defining (explanatory) coherence, an Echo system pursues highest coherence by considering all related beliefs in a holistic manner. When the system converges, the most believable hypothesis set will defeat any competitors and pop out.

Although Echo has gained much empirical support, they have serious limitations (e.g., Wang, Johnson, & Zhang 1998): (1) Echo does not handle sequential belief revision; (2) Echo does not learn from experience; and (3) Echo does not distinguish confidence and probability. All these limitations cast doubt on Echo as a general model of human belief revision.

Wang, Johnson, and Zhang (1998) proposed UEcho (“U” for Uncertainty) as an extension of Echo to address the first two problems. They have shown that UEcho is able to model order effects. UEcho is further extended here to embed the probability/confidence distinction. By doing so, we expect that UEcho, as a coherence-based model of belief evaluation, provides an alternative model of human belief revision that is more plausible than the traditional weight-assignment-based integration models.

UEcho maintains that the activation of a node determines acceptability, thus representing the probability component of a belief. UEcho adopts three mechanisms to add a confidence dimension to the system.

All three mechanisms try to tune critical parameters based on previous experience. The first parameter is the parameter of skepticism  $\theta$ . In Echo,  $\theta$  represents the decay rate in the activation updating. The higher  $\theta$  is, the faster does the node activation decay. Confidence cures skepticism. Gradually tuning down  $\theta$ , based on experience, is a natural way to represent confidence. The second mechanism has to do with the parameter  $\alpha$  and  $\beta$  in the anchoring and adjustment model. As mentioned earlier,  $\alpha$  and  $\beta$  represents one’s

sensitivity toward negative and positive evidence, respectively. Although the anchoring and adjustment model attributes the sensitivity to some unidentifiable factors of personality, the two parameters are functionally closely related to confidence in the sense that as confidence goes up, the sensitivity to new evidence goes down. Incorporating and gradually tuning  $\alpha$  and  $\beta$  represents another aspect of confidence management in UEcho. Finally, UEcho extends Echo's parameter of *data excitation*. In Echo, data excitation is used to represent the assumption that observed data nodes have independent support of their own. The hypothesis nodes have no associated data excitation. By generalizing this parameter to hypothesis nodes, UEcho enables hypothesis nodes to learn and remember their activation values, thus to gradually gain self-support (or dis-support) of their own, based on past experience. For a detailed description of these tuning mechanisms, please see Wang (1998).

The exact same design and procedure was used to train a UEcho network, and the corresponding simulation results are shown in Figure 3.

**Figure 3.** The belief revision patterns in all three friendly-to-hostile ratio conditions, based on the UEcho simulation.

The modeling results match the experiment results remarkably well. First, the gradual separation of the curves of the three ratio groups nicely reflects the statistical tuning toward the built-in environmental friendly-to-hostile ratios. From block1 to block4, the average initial belief judgment is 50.0, 50.0, 50.0, 50.0 for the 1:1 group, 58.8, 63.9, 67.2, 69.0 for the 3:1 group, and 41.4, 36.7, 33.6, 32.7 for the 1:3 group, respectively. Second, the order effect pattern change is evident. A recency effect is significant in block0 (23.3 for “+−” vs 76.7 for “−+”). The magnitude of the recency effect, measured as the difference between the final judgment in “+−” and the final judgment in “−+”, decreases significantly from block1 to block4. More specifically, they are 8.4, 3.6, 2.0, 0.8 for the 1:1 condition, 9.1, 3.5, 1.6, 1.3 for the 3:1 condition, and 11.1, 6.1, 3.6, 2.5 for the 1:3 condition, respectively. Finally, the areas inside the diamond

shapes become systematically smaller with training as well, indicating the fluctuation in belief revision tends to be smaller as the training progresses.

In summary, by embedding the probability/confidence distinction, UEcho is capable of capturing the changes of order effect patterns at different experience levels. The close match between the simulation results and the experimental results in the decrement and disappearance of order effects with the increase of experience supports UEcho as a model of coherence-based and complex human belief revision.

## Discussions and Conclusions

Human belief and human belief revision are ubiquitous in everyday life and scientific discovery. The order effect, a phenomenon in which the final belief is significantly affected by the temporal order of evidence is a robust empirical finding in human belief revision. The order effect is generally regarded as a manifestation of human biases and an indication of human irrationality. It is the goal of this paper to study how the order effect occurs.

Previous research leads to the conclusion that human belief has a coherence foundation and consists of multiple components. Such a conclusion motivates and guides both the experimental study and the computational modeling work described in the paper. Both the experimental results and the UEcho modeling results show that order effects in belief revision exist at the early stage of training when the confidence level is low and they tend to diminish and disappear later when the confidence increases.

It is interesting to further speculate how the UEcho modeling results could tell us the possible rational basis of order effects. First of all, the fact that UEcho, which is based on rational postulates and intended to prescribe what people should do, naturally shows order effects (when the confidence level is low) convincingly “debiases” order effects. Second, the existence of order effects has ecological implications. UEcho reveals that order effects appear when the relevant experience is scarce, and order effects disappear when the relevant experience becomes rich. When the relevant experience is rich, one has confident expectations, which eliminate the need to over-react. When the relevant experience is scarce, one has to sufficiently appreciate every single piece of information since its relevance cannot be easily and accurately determined in the first place. In this sense, both the existence and the disappearance of the order effect are rational.

It should be noted that this study involves only the recency effect. It would be of great importance to explore how it can be tuned or extended to model the primacy effect. Whether it can model the full range of order effects using the same mechanism is a strong test for UEcho as a general model of human belief revision.

What does the current study say about human rationality in general? For a long time, the order effect, along with various other heuristics and biases (Tversky & Kahneman, 1974), has been taken as a demonstration that people systematically deviate from rationality. This view has been greatly challenged recently. Beyond philosophical debates, systematic investigations have been carried out to determine

the conditions under which the biases appear or disappear. For example, Gigerenzer (1991, 1994, 1996), among others, has shown that while people perform poorly in assessing subjective probability they assess relative frequencies reasonably well. Since using/reporting subjective probability is not something people are equipped with, “biases are not biases” (Gigerenzer, 1991, page 86), and heuristics are meant to explain something that does not exist. It has been demonstrated that all the biases, including the base rate fallacy, conjunction fallacy, and overconfidence, disappear or are significantly reduced when information is presented to participants in frequency format (e.g., 10 out of 100) instead of single-event subjective probability format (e.g., 10%) (Gigerenzer & Hoffrage, 1995). Noting that normative postulates often assume a stationary and discrete environment, many researchers have argued that the environment is neither stationary nor discrete. People may appear biased or deficient according to those normative postulates, but they are in fact very functional and optimal when a continuous and dynamically changing environment is assumed (e.g., Jungermann, 1983). The current study provides another example to show that this might be the case.

## Abstract

In this paper we present a methodology for situating GOMS models in complex sociotechnical work domains. The methodology is presented within a larger theoretical framework that relates GOMS modeling to other modeling systems according to principled and systematic guidelines.

Increasingly, computers play critical roles in the running of complex systems such as telecommunications networks and nuclear power plants. However, the role of human agents in these systems is also critical. As computer and software technology improve we see a decrease in the number of technical errors caused by computers, but there is also evidence of a corresponding rise in errors attributable to humans (e.g., Bennett, 1998). No doubt, this is due to the increasing complexity of computers and network systems.

In this paper, we consider the role of GOMS (Card, Moran, & Newell, 1983) in designing systems situated within complex, sociotechnical systems, that is, systems with multiple humans and multiple computers all interacting (see Vicente, 1999 for a more complete definition). GOMS is a method for modeling tasks according to a human agent's goals, operators, methods and selection rules (John, 1995). But in complex sociotechnical systems the task is often a small part of a larger, distributed task. The design problem is analogous to designing a complex operating system. Individual programmers design different components of the system, but each time a new component is added it is unclear if it will create a conflict in the system. Similarly, changing the way an individual performs a task within a complex sociotechnical system can have unforeseen consequences (for a discussion of this point and some interesting examples, see Hutchins, 1995). To deal with this problem operating systems are beta tested. Unfortunately, changes in a sociotechnical system cannot be beta tested and then fixed the next day. In fact, such changes are usually costly and time consuming, especially if people need training. Thus, we need a means to evaluate changes before they are implemented.

## Task Analysis

A task analysis is important for understanding the sort of knowledge driven tasks common in technical areas and large organizations. By knowledge driven we mean that the agent knows, implicitly and/or explicitly, the steps that must be completed. The need for a task analysis presupposes that the

process for completing the task quickly and without error is not common knowledge. Many studies have found that experts often have specialized knowledge that is not expressed in any manual, but is nevertheless crucial for completing the task in an acceptable manner (Mayer, 1997). This is particularly true of tasks situated in sociotechnical environments, which often involve a considerable amount of undocumented knowledge concerning how the various agents, computers, and artifacts involved are coordinated to complete the task.

The result of a task analysis is a model, which is then used to simulate changes in the system. The level of detail of the model will depend on the modeler's goals, and the representation of the model can range from a mental representation, to a paper and pencil representation, to a computerized representation. Furthermore, the goal may be to represent the whole task or only the major components, relationships, and/or functions that characterize the task. The important point is that this process allows some level of foresight into the effect of the proposed changes.

In this paper, we will be concerned with "*modeling systems*". This term is further defined below but for now we can say that a modeling system tells the researcher what types of behaviors to observe and how to organize the data into a functioning model. Thus, a modeling system both guides the task analysis and produces the model. A modeling system could be quite formal (e.g., NGOMSL, Kieras, 1988) or very informal, based on common sense notions about what is important in the task (in this case the researcher may be unaware they are using a modeling system). However, both our formal and informal modeling systems have difficulty coping with complex, distributed systems. One reason for this is that it is easier to think in terms of tasks performed by single agents than tasks distributed across multiple agents, especially when the distributed system is not under some sort of centralized control. When agents act locally and organize themselves, multiple different ways of completing the task can emerge. This results in several different levels of analysis, including the following: (1) the knowledge level, the steps that must be taken to complete the task, (2) variations on a theme, the different ways the task can be done given the constraints of the knowledge level, and (3) the different ways that agents can organize themselves to accomplish different steps of the task. To cope with this, a modeling system must be able to represent the

task at different levels and also be capable of integrating factors involved in completing the task with the factors involved with organizing and sustaining cooperation between the agents. In this paper, we describe how GOMS can be used to cope with this type of system, and the relative advantages of using GOMS under these conditions.

## GOMS

GOMS is a family of relatively formal modeling systems, but we would argue that it has a special status amongst modeling systems. In this regard, it is useful to consider Anderson's (1993) distinction between frameworks, theories and models of human cognition. According to this scheme, frameworks are "bold, general claims about cognition," (p. 2). Theories are created by adding specific assumptions as to how frameworks could be applied to the relevant class of behaviors, and models are created by adding assumptions as to how a theory could be applied to a specific situation or task. The idea that cognition can be understood in terms of production rules (i.e., if..then statements) is therefore a framework, and systems embodying assumptions as to how to use production rules are theories. However, rather than theory, we will use the term *modeling system*, because we are focusing on the process of model building, rather than on testing theories. So, to be clear, we will define a modeling system as a system that allows us to create a model within a specified framework.

The general idea behind GOMS is that well learned human behavior can be modeled using goals, operators, methods, and selection rules (e.g., John, 1995). This claim places GOMS clearly within the production rule framework. Using selection rules to choose between different methods for accomplishing a task essentially embodies the idea of the production rule (i.e., if this, then use this method). Also, operators are necessary for any production system to specify how the system retrieves information from the world and generates behaviors in the world (although operators are sometimes not explicitly represented in production system models of cognition, they are always assumed to exist). The idea that people have goals, or more specifically the idea that people create sub goals to bring them closer to their end goals, is the only element of GOMS that is not directly tied to implementing production systems. For example, the first attempts at implementing production systems (e.g., SOAR, ACT) did not contain any mechanisms for managing goals (Anderson & Lebiere, 1998). However, as Anderson and Lebiere (1998) point out, all of the current production system architectures have a structure for keeping track of goals. Thus, the idea that we use goals to organize cognition can be considered another framework (i.e., it is a bold, general claim about cognition). Therefore, GOMS can be interpreted as asserting that well learned behaviors can be captured using the combined frameworks of production rules and goal structures. At this level, GOMS itself is a general claim about a class of behaviors and remains at the framework level (it is also not possible to falsify this claim without adding further assumptions, another hallmark of the framework level, see Anderson, 1993).

Cognitive architectures can be considered as relatively complete modeling systems (Anderson, 1993). Unlike these

systems, GOMS has no mechanisms for constructing or searching the problem space, it presupposes that the agent has already learned how to get to the end goal. *The key insight, on which GOMS was founded, is that once a path through the problem space has been learned, the complexity of the modeling task is hugely reduced.* This makes moving from the framework level to the modeling system level easier. In fact, the simplest possible GOMS modeling system can be created by merely assuming the appropriate operators exist and structuring goals by connecting them serially, essentially creating a flow chart of goals with branching paths gated by production rules. This type of GOMS modeling system is frequently used, often to sketch out the task structure before creating a more fully functional model. Since this system has no name we will refer to it as Minimal-GOMS.

Other, specific GOMS modeling systems, such as NGOMSL (Kieras, 1988) and CPM-GOMS (Gray, John, & Atwood, 1993), have more detailed assumptions that are contained in the human information-processor (Card, et al., 1983). In this sense, GOMS can be considered a general outline for moving from the dual production rule/goal framework to a specific modeling system by adding assumptions concerning the human information-processor. Following from this, any model that (1) is explicitly or implicitly based on the dual production rule/goal framework, (2) refers only to knowledge driven behaviors (i.e., no learning or problem solving), and (3) makes assumptions concerning the behavior of the human agents involved, can be interpreted as a type of GOMS model. For lack of a better term, we will refer to models that fall into this category, but have not been explicitly created and labeled as GOMS models, as GOMS-like.

Since we are currently interested in modeling errors within complex sociotechnical systems, we searched the literature for error modeling systems and found over 50. However, comparing GOMS to these modeling systems it is clear that they are not on the same conceptual level. In fact, the product of many of the modeling systems we reviewed would be a GOMS-like model. This issue is often the source of confusion and contention between designers that favor GOMS and designers that do not. It is not uncommon to hear people say that modeling system X is a better approach than GOMS, when in actuality modeling system X is a system that produces GOMS-like models.

Part of the problem seems to have arisen from the association of GOMS with models of how long it takes to perform isolated tasks described at the level of individual mouse clicks and button presses. GOMS is particularly good at describing low level activities because the operators are relatively simple and can be described with a reasonable accuracy in the human information-processor (Card, et al., 1983). Since a lot of research, explicitly represented as GOMS research, was done at this level, there is a strong tendency for people to view GOMS as synonymous with the use of low level operators. In actuality, the grain size of the operators should depend on the goals of the researcher (West, Wong, and Vera, 1998).

In terms of complex sociotechnical systems, it is unlikely that GOMS could produce very accurate time estimates as it

is often not possible to assign very precise times to high level social operators (e.g. how long does it take arrange a lunch meeting with a colleague), although, it should still be possible to get good time estimates for well-defined sub tasks. However, the value of GOMS in a multi-agent system is that it allows us to examine the goals and methods of individual agents, and how these relate to the overall task. For example, multi-agent tasks are often described using a critical path analysis. In the case of a centrally controlled task the critical path represents the plan of the central controller. However, when the task is not centrally controlled (i.e., a complex system) the critical path is an emergent property of the interactions between the agents. A multi-agent GOMS model can allow us to examine these interactions for inefficiencies, goal conflicts, and sources of error.

### Complex Sociotechnical Systems

One of the most influential modeling systems in terms of modeling complex systems has been Rasmussen's decision ladder model (1980). As Vicente (1999) points out, the step ladder model is not really a model, but rather a *template* for creating models. Essentially, it is a generic model of information processing that can guide the modeler in terms of the general form a model should take (Vicente, 1999). We believe that the template approach is important for modeling complex, sociotechnical systems, and, more specifically, that it can be used to effectively situate GOMS models within such systems. As Vicente (1999) points out, work within a sociotechnical system cannot be fully captured by GOMS or GOMS-like models because this type of work involves ongoing learning and problem solving, which these models cannot handle. However, as John (1995) points out, GOMS can be very useful for elucidating the components of a task that are amenable to GOMS modeling. In other words, GOMS doesn't have to be the whole solution, but can be part of the solution.

Another important aspect of sociotechnical modeling systems is that they need to be multifaceted in focus. For example, Vicente's modeling system is actually a collection of modeling systems for examining various aspects of the sociotechnical environment, including: the work domain, control tasks, strategies, social organization and cooperation, and worker competencies. Likewise, a modeling system advocated by a well known consulting firm in this area involves a work flow model, a cultural work model, a sequence work model, an artifact model, and a physical environment model (this system is adopted from Beyer & Holzblatt, 1997). What GOMS adds is the potential to integrate knowledge gained in these different domains into a unified model of the knowledge driven portions of the process. Our approach to this is to use a template that (1) allows the task to be described at different levels of complexity and (2) describes how people situate knowledge driven tasks within a complex environment involving ongoing learning and problem solving.

### The Basic Model

Our modeling system is closely related to Norman's (1986) seven-stage model of user activities. However, similar to Rasmussen's decision ladder model, we intend our model to be a generic template for information processing in general, rather than a specific model of human cognition. The framework, which is described in Figure 1, revolves around the goal, *create-plan*. This goal is meant to deal with learning and problem solving, so overall it lies outside the reach of GOMS. One approach to modeling this component would be to use a production/goal based cognitive architecture (e.g., ACT-R, SOAR). This would tie in nicely with the GOMS aspects of the model since they share a common framework, however, any approach can be used, including treating *create-plan* as a black box.

In our current work on telecommunications network maintenance and management we are using Vicente's (1999) work domain analysis to provide the underpinnings for the create-plan component. This involves understanding the constraints imposed by the sociotechnical system and, rather than specifying what a worker should do, specifying what a worker should not do. For example, the main constraint that we have identified is that of the working path (the path through the network carrying live traffic) and the protection path (a path to which the traffic could be shifted). This constraint is critical because whenever work needs to be done or a problem occurs the traffic must be rerouted along a protection path. We are also using Hutchins' (1995) concept of organizational learning to look at how workers pick up on this constraint. GOMS modeling, based on the Figure 1 template, provides the means for describing and evaluating how knowledge driven, procedural tasks fit into the picture. The use of GOMS is very important since this type of sociotechnical system involves many knowledge driven components.

From the perspective of the rest of the model, the function of the create-plan component is to output a knowledge driven plan. The plan may be complete and well thought out but in many cases this will not be the case. Essentially, the cycle embodied by the template is to continue with a plan until it is evaluated as inappropriate or is completed. To further structure this process we need to invoke another GOMS concept, the *unit task* (see Card, et al., 1983). In theory, a plan could be of any size, but we conceptualize plans as unit tasks in the sense that they should correspond to actions that the agent believes can be accomplished without a terminal interruption. Thus, the size of the plan is determined by the nature of the task. For example, the results of Kvan, West, and Vera (1998) indicate that architects in the process of collaborating over a shared whiteboard use very short plans, whereas maintenance procedures on network hardware can involve lengthy procedures that must be completed once started.

Another important function of the create-plan component is to integrate technical, environmental, and social aspects of the task. Thus, in addition to technical procedures a plan should include how to deal with issues arising from the physical environment the task is situated in, as well as the social issues involved in getting cooperation from other agents. As West, et al. (1998) argued, in many cases there are routine ways of dealing with these issues if they

represent routine occurrences. However, in other cases these issues may be dealt with in unique, creative ways. Either way, the model is capturing valuable information (i.e., routine solutions or different case based solutions). Note, though that we are not saying that plans are always complete in this sense. In many cases, plans fail because they do not include ways to deal with problems arising from the physical or social environment. In this case, the system returns to the create-plan process to fix the plan or come up with another.

The other components of the template are described below:

1. Retrieve-next-action – This is meant to reflect the fact that the representation of the plan may be distributed. It is often the case that workers do not have all the knowledge necessary for the task, but they know where to get it (e.g., memory, personal notes, manuals, colleagues).
2. Execute-action – This step refers to firing of operators. As is normally the case in GOMS models, operators can be either physical (e.g., move the mouse), perceptual (e.g., search the screen), or cognitive (e.g., add two numbers). Operators can also vary in grain size and represent complex tasks. For example, an architect might use an operator, *make-aesthetic-judgement*. Such an operator could be represented in terms of the % chance that such a judgement will be positive, or may merely represent the fact that the judgement takes place at a certain point in the model. The grain size and function of the operators will depend on the modeler's goals (see West, et al., 1998 for a discussion about high level operators). This step is also where communication is initiated between agents by using an operator to place messages in the environment (e.g., voice, email, etc.).
3. Update-situation-knowledge – After having acted in some way this section refers to updating the task knowledge to reflect these changes and any other relevant changes that may have occurred during that time (including messages from other agents). For isolated, low level actions this step could be assumed to occur as the actions are being executed. For complex, interactive actions the process of checking may be quite extensive, and may also involve retrieving knowledge from various sources. In this case adding a box above it entitled, *retrieve-data*, might be a good idea.
4. Evaluate – Like create-plan, this box may involve actions that step outside of GOMS. If the situation has changed in an unexpected way there must be a judgement as to whether or not the plan is still appropriate. By definition, unexpected changes will not be part of the plan (Vicente, 1999), so there is a need to step outside of the plan into problem solving or creative thinking to make this judgement. However, it is possible to handle expected or common problems within a plan. Another issue that is important here is the agent's evaluation of risk. Human agents will often engage in risky behaviors, especially if they are under time pressure. Often workers will have heuristics for evaluating risk that can be captured by GOMS.

5. Execute-Patch – if there is a known and immediate fix for a problem the agent goes to execute-patch where the patch with highest probability of success is executed. These known patches can be considered to be implicitly part of the plan. If there is no immediate fix the agent goes to create-plan where a known fix is inserted into the plan to be executed later, or the plan is recreated to cope with the problem.
6. Parallel External Monitoring (PEM) – This module operates in parallel, monitoring the environment for alarms. Creating the model for PEM involves understanding the extent to which the agent can pay attention to the task and also to the general environment. For example, an alarm siren could be assumed to be always picked up, whereas an alarm on a screen could only be picked up when the agent is looking at the screen. The other aspect of the PEM model is that it contains rules for when to interrupt the system and go directly to update-situation-knowledge, and when to store the information in memory until the update-situation-knowledge process comes up. The goal of this model is to capture expert knowledge about monitoring and interruptions.

Figure 1. A generic Minimal-GOMS template

### Multiple Agents

So far we have dealt only with modeling an individual. In fact, the original version of this template was developed in an attempt to make sense of data gathered from pairs of architects working collaboratively over a shared whiteboard. As reported in Kvan, West, and Vera (1998), the architects never developed a plan for the collaboration, instead they

dealt with issues and organized themselves as they went along. This resulted in very different organizational structures, all of which were difficult to model. To simplify things a version of the Figure 1 template was developed to first understand the behavior of the individual architects. To create a model of two agents working together you just simply add another template. No lines of communication need to be drawn between the two templates. Instead what is needed is a simple model of the environment that the agents can act on by altering the physical components of the task and by creating messages (e.g., voice, notes, email, etc.). Since the agents are modular they can be added or deleted without too much trouble, so it is possible to have more than two agents.

Using this approach, it was obvious that architects generate very small plans with regard to the task (e.g., draw box at location X) that serve a constantly evolving creative vision. Thus, low level GOMS models of the task components, as defined by the plan size, would be appropriate. However, in addition to creating objects the architects also needed to understand the objects that their partner was creating. This caused a problem in one condition of the experiment in which the architects used a chat line to communicate. To attach a message to an object (e.g., "what is that?") they would either have to describe the object in the message or tell the other person to watch the their whiteboard pointer while they pointed (the white board could get quite complex in terms of the number of objects on it). A solution that would involve fewer steps would be to attach a text box to the pointer to combine the activities of message passing and pointing. This particular solution is not complex, but recognizing the need for it was facilitated by integrating the collaborative elements of the task into the model. Also, notice that although the pointing/messaging solutions the architects came up with were the result of online problem solving, once created they could be treated and evaluated as GOMS type methods.

### Distributed Agents

Although the template is useful for organizing models in which individuals interact, only a relatively small number of agents can be included before the model gets unwieldy. In contrast, complex sociotechnical systems often involve a considerable number of agents. However, we have found that the template is scalable to what we call *distributed agents*. The central premise of distributed cognition is that cognitive agents can organize themselves to form larger, distributed cognitive systems (Hutchins, 1995). Our approach is to treat these distributed cognitive systems as individual agents and apply the same template. This is not to say that there are no differences between brain based cognition, distributed cognition occurring across small groups, or distributed cognition occurring across large groups. There are important differences between these types of structures. However, our argument is that the template captures something basic about the way cognitive systems, in general, deal with interactive, knowledge driven tasks.

We tried this approach at Oxfam, Hong Kong, for modeling the process of deciding how to deliver aid to flood victims in China and found that it simplified the process

considerably (West & Yeun, 1999). It also brought to our attention the distinction between distributed agents and official groups defined within the management structure (i.e., specific departments and their subdivisions). There is a strong tendency for organizations to understand themselves in terms of their official subdivisions, and this information should be part of a complex systems task analysis. However, the goal of GOMS is to build task models, not organizational models. Therefore, a distributed agent is meant to map onto agents that function together to complete a particular task, and will not necessarily map onto a particular department or section. This also means that a person may be a part of different distributed agents depending on the task they are working on. One benefit of this type of analysis is that it can provide insight into the relationship between the task and the management structure.

Following this approach, it is possible to create a higher level model describing the interaction between distributed agents. As with individual human agents, the approach is to represent each distributed agent using the template structure, with communication occurring by placing messages in the environment. Also note that it is possible to combine distributed agents into higher level distributed agents or to break them up into lower level distributed agents, depending on the level of the analysis. It is also possible to mix agents representing individuals with distributed agents. This allows the model to focus in on an individual without representing every other individual connected to the task.

Currently, we are using this modeling system to model tasks involved in telecommunications network maintenance and management. We have found that using this system greatly simplifies the modeling process and also allows the flexibility to address a wide variety of questions.

# Motivation in Insight versus Incremental Problem Solving

Mareike Wieth (wiethmar@msu.edu)

Bruce D. Burns (burnsbr@msu.edu)

Department of Psychology; Michigan State University  
East Lansing, MI 48824-1117 USA

## Abstract

Previous studies have shown a correlation between initial motivation and subsequent performance (e.g. Vollmeyer, Rheinberg, & Burns, 1998). However, it is possible that this relationship is due to a third factor such as general ability. To address this issue, our participants completed insight as well as incremental problems. These two types of problems have been shown to differ both theoretically and empirically due to differential underlying processes (e.g., Metcalfe & Wiebe, 1987). Results showed that motivation (in particular, *interest*) correlated with incremental problem solving but not with insight problem solving. The results were replicated with two different sets of problems solved by different groups of participants. Motivation was measured before solving the problems, so the difference between these two types of problems provides us with evidence that motivation is causal in producing better problem solving performance. Further, it suggests that when processes differ, motivational effect on performance will differ.

## Introduction

It has been difficult to demonstrate conclusively an effect of motivation on problem solving. This is partly because the difficulty of manipulating motivation reliably has forced research designed to examine this issue to rely on correlational studies. Studies such as Vollmeyer and Rheinberg (1998) and Vollmeyer, Rheinberg, & Burns, (1998) have shown a correlation between initial motivation and performance in a complex problem solving task. Although motivation is predictive of performance in these studies, it could still be argued that the correlation is due to a third factor. It is plausible that people with higher general ability at problem solving may not only be better at this task, but also be more highly motivated when faced with such a task. So motivation may not be a causal factor.

In order to learn more from correlational studies of motivation, a slightly different methodology is required. If we give problem solvers qualitatively different problems to solve and find that motivation has a different relationship to performance on these different types of problems, then we would have good evidence that it is not a general ability factor that accounts for any relationship found between motivation and problem solving performance. Two types of

problems that can have a similar form, but have been shown to be qualitatively different, are insight and incremental problems (e.g., Metcalfe & Wiebe, 1987). This makes them good candidates for a methodology looking for qualitatively different motivational influences on problem solving. So in this study we compared the effect of motivation on insight and incremental problem solving.

## Motivation and Problem Solving

It has long been acknowledged that motivation is important, for example, Simon (1967) emphasized the importance of motivational and emotional influence on cognition. However, for the most part motivation and its relationship to cognitive processes has been largely ignored by cognitive scientists. Investigating this influence has been seen as unnecessary because differences in motivation have been treated as background noise that that can be ignored when investigating specific cognitive processes. Even though the operation of Anderson's (1993) ACT-R depends crucially on the goal of the actor and how likely they think an action will be successful, he specifically rules out having to consider the more general goals of the actor. Although Anderson acknowledges the importance of wider goals, he takes the stance that once the actor is committed to doing something in a situation, the actor's more general motivation is irrelevant.

Whether it is sustainable to routinely ignore motivation and emotion when studying cognition is something that has come into question. For example, Kuhl and Kazén (1999) have shown that one of the most well-known of cognitive phenomena – the Stroop effect – can be wiped out by manipulating emotion. Recent research has also started to address the relationship between motivation and cognition (e.g., Kanfer & Ackerman, 1989; Lord & Levy, 1994; Pokay & Blumenfeld, 1990; Vollmeyer & Rheinberg, 1998; Vollmeyer, et al., 1998). With respect to problem solving, Vollmeyer and Rheinberg (1998) fitted their cognitive-motivational process model to a complex problem solving task called *Biology-lab*. The cognitive-motivational process model proposes an interaction between motivation and cognition such that initial motivation affects the motivational state during learning which in turn influences strategy use and acquisition of knowledge. In *Biology-lab* participants have to learn how to manipulate a complex learning environment by controlling several inputs and output variables. In particular, Vollmeyer & Rheinberg have shown that participants with higher motivation were

more likely to use a systematic strategy for acquiring knowledge and therefore performed better during the knowledge application phase. The results of this study and similar studies by Vollmeyer and colleagues using the *Biology-lab* simulation indicate that motivation can influence cognitive processes, such as strategy systematicity, and therefore lead to differential knowledge acquisition and performance.

Similarly, Pokay and Blumenfeld (1990) investigated the effect of motivation on learning strategies and performance on geometry proofs. In this study questionnaires assessing motivation and learning strategies were given to high school students in geometry classes at various points in the semester. The results of this study indicated that various motivational factors predicted strategy use, which in turn influenced performance on geometry tests (especially proofs) throughout the semester. This study provides further evidence for an interaction between motivation and cognition. These conclusions are consistent with other researchers such as Locke and Latham (1990) that have also argued that motivation affects performance via the processes used in a particular task.

### **Insight versus Incremental Problems**

Incremental problems require the solver to take a number of incremental steps in order to solve the problem. Incremental problems have also been referred to as *analytic* (Schooler & Melcher, 1995) or “grind-out-the-solution” problems since people can often solve these types of problems by persisting at the task. It might take time to reach the solution, but the solver has a good idea of how to get there. In contrast, insight problems are those in which the solver has a high probability of meeting an impasse, at which point the solver does not know what to do next (Schooler & Melcher, 1995). Insight problems are usually solved by a “flash of illuminance” (Metcalf & Wiebe, 1987), or by what has been referred to as an “Aha” experience where the solution is suddenly obtained (Schooler & Melcher, 1995).

Differences between these two types of problems have been demonstrated empirically by studies comparing performance on the two types. In a study by Metcalfe & Wiebe (1987) participants were asked to rate how close they thought they were to the solution every 15 seconds while solving incremental and insight problems. The rating results showed that problem solvers had a good idea when they were close to the solution for incremental problems, but were unable to perceive when they were close to a solution for insight problems. Solutions for insight problems came suddenly and with little awareness that the solution was about to be found. Additionally, it was discovered that participants were more successful at predicting which incremental problems they could solve than which insight problems they could solve. These results indicate that there are distinct difference between incremental and insight problems, which could be caused by qualitative differences in underlying processes used to solve these two problems (Metcalf & Wiebe, 1987). Weisberg (1992) has argued that the procedures used in the experiments by Metcalfe & Wiebe (1987) are questionable.

However, it appears that he agrees with the notion that there are different processes involved in solving insight and incremental problems (Weisberg, 1995). Further evidence that there are differences in the processes used to solve these two types of problems has been provided by studies that have had participants give verbal protocols while solving both incremental and insight problems (Schooler & Melcher, 1995; Schooler, Ohlsson, & Brooks, 1993). Schooler et al. found that participants asked to verbalize their problem solving strategies showed significantly impaired performance on insight problems but not on incremental problems. Additionally, it was found that participants paused more and tended to have a harder time articulating their thoughts while solving insight problems compared to incremental problems. Furthermore, the nature of the protocols also differed in that incremental problem protocols contained more logic or means-ends analysis statements than insight problems (Schooler & Melcher, 1995). These findings have been attributed to differences in the processes used to solve these two types of problems. Specifically, Schooler & Melcher and Schooler, et al. argued that the impairments during insight problem solving while verbalizing are due to the disruption of nonreportable processes that are critical to solving insight problems but are not necessary for solving incremental problems.

In an effort to better understand what these nonreportable processes might be, Schooler and Melcher (1995) cite unpublished data by Schooler, McCleod, Brooks, & Melcher (1993) that examined the correlation between a variety of ability measures (e.g., recognizing out of focus pictures, finding remote associates) and success at solving both incremental and insight problems. It was found that the measures predicting performance on the two types of problems were generally different. Anagrams and categorization tasks correlated with incremental problem solving, whereas the embedded figures and out of focus pictures tasks correlated with insight problem solving. These differential patterns of findings lend further support that the two problems draw on qualitatively different processes (Schooler et al.).

It has been suggested that these underlying differences arise from the way we solve insight and incremental problems. Insight problems require searching for an appropriate way to represent the problem and are often easily solved once the correct representation has been found. On the other hand, representation is not the focus for incremental problem solving, instead figuring out what steps to take to reach the solution is often the focus (Kaplan & Simon, 1990; Ohlsson 1984).

These empirical and theoretical differences in incremental and insight problems lend themselves very well to our aim: finding a differential influence of motivation on incremental and insight problems.

### **Motivation Effects on Both Problem Types**

How to get to the solution may be clear when solving incremental problems, but following the required strategy may require some effort and persistence. Vollmeyer and Rheinberg (1998) found that motivation influenced

performance via the use of a good strategy. They suggested that motivation keeps people persisting with the good strategy instead of trying to find some less effortful shortcut. Similarly Sweller (1988) has explained poor problem solving performance as due to the cognitive load imposed by effortful strategies such as means-ends analysis. Based on this we predicted that motivation would influence incremental problem solving. However, not all aspects of motivation may equally relate to performance. Schiefele (1996) argues that interest in the task should be particularly highly related to performance. Therefore, we focused particularly on this aspect of motivation.

In order to argue that any relationship that we may find between problem solving and motivation is not due to some third factor, we wanted to show that motivation does not just correlate with everything. From the above discussion, it appears that insight problems should provide this contrast. As mentioned before, the process of solving insight problems differs from that for incremental problem solving. It is process that Vollmeyer and Rheinberg (1998) and Locke and Latham (1990) focus on. In particular, Vollmeyer and Rheinberg believe motivation influences performance by encouraging participants to persist with a good strategy, yet for insight problems there is no good strategy to follow or to fail to persist with. Persistence may even be detrimental due to the creation of Einstellung effects (Luchins, 1942). Incubation, instead, has been found to be effective for solving insight problems. (Silveira, 1971). (Experienced problem solvers may learn heuristic strategies for insight problem solving, but our participants were not such experts.) The work reviewed above on insight problem solving suggests there is no conscious strategy to be followed in insight problem solving, so we predicted that there would be no relationship between motivation and insight problem solving.

The discovery of such a contrast between insight and incremental problem solving would argue that motivation plays a causal role in how well people solve problems, especially if motivation was measured before the task began. Evidence for this contrast would be finding a higher correlation between motivation and incremental problem solving than between motivation and insight problem solving. However neither of these correlations would be expected to be high given that ability rather than motivation should be the best predictor of problem solving performance.

## A Study

### Method

**Participants.** Two hundred and ninety-two Michigan State University students participated in this experiment for course credit.

**Materials.** Participant's initial motivation was assessed using the Questionnaire of Current Motivation (QCM, Vollmeyer & Rheinberg, 1998). This motivation questionnaire consists of 37 items which have been shown to measure four independent factors of motivation:

Challenge ("This task is a real challenge for me"), confidence in Success ("I think I am up to the difficulty of the task"), Fear of failure ("I am a little bit worried"), and Interest ("I would work on this task even in my free time"). The QCM is designed to measure motivation for a specific task (originally the *Biology-lab* task of Vollmeyer, Burns, & Holyoak, 1996), so some items had to be modified to fit this problem solving task. However, none of the items used to measure the four factors had to be modified and a check of the psychometric qualities of the questionnaire found the same factor structure (see Rheinberg, Vollmeyer, & Burns, under review).

Two separate sets of problems were created, each consisting of one insight problem and two incremental problems. The problems were randomly selected from problems previously studied by Metcalfe & Wiebe (1987) and Schooler, et al. (1993). The actual problems used in the two sets are presented in the Appendix.

Each problem also included a state motivation questionnaire consisting of five questions (see Vollmeyer & Rheinberg, 1998) in order to assess participants motivation towards solving each given problem.

**Procedure.** Participants solved their set of problems in the middle of a 45-50 minute group testing session composed of short unrelated tasks. Group size ranged from five to ten individuals. At the beginning of the session participants were asked to complete the QCM, which was then followed by one of the two sets of three problems (two incremental and one insight). Within each set, the three problems were given in a random order. When solving the set of problems participants were asked to first read the problem, then answer the five questions pertaining to the problem (which measured state motivation), re-read the problem, and then solve it. We did not restrict the time that participants were given to solve each problem, but they were aware that they would be given more tasks. Upon completion of the problem set participants went on to complete a series of unrelated tasks.

### Results

**Overall performance.** The incremental and insight problems were scored on a dichotomous right or wrong scale. To derive a subject's incremental score, the result for the two incremental problems was averaged together. Participants did more poorly than we expected on some of the six problems. For Problem Set One participants on average solved 1.52 of the 2 incremental problems correctly but only 16 percent solved the insight problem. For Problem Set Two participants on average solved 0.70 of the 2 incremental problems and 16 percent solved the insight problem. Note that unlike some other studies of insight problem solving (e.g., Schooler, et al., 1993) participants were not given another chance to attempt the problem if they handed in an incorrect solution.

We tested for any order effects on the problems as each set of three problems was presented in one of six possible orders. We found no evidence in either problem set that the order in which participants solved the problems affected

their performance: Problem Set One  $F(5, 146) = 1.35, p = .25$ ; Problem Set Two  $F(5, 133) = 0.98, p = .43$ .

Table 1: Correlations of the motivation factors with incremental and insight problem scores, and z-score test of the difference between the two correlations.

Problem Set One (n=152)	Incremental	Insight	z-score
Interest	.255 **	.000	2.16 $p = .030$
Challenge	.143 *	-.006	1.23 $p = .22$
Fear of Failure	.061	-.026	.076 $p = .96$
Success	.097	-.011	.89 $p = .37$
Problem Set Two (N=141)	Incremental	Insight	z-score
Interest	.240 **	-.011	2.26 $p = .024$
Challenge	.204 *	-.003	1.85 $p = .064$
Fear of Failure	-.039	.060	-.87 $p = .38$
Success	.169*	-.092	2.33 $p = .020$

\* $p < .05$  \*\* $p < .01$

**Initial Motivation.** As measured by the QCM, participants in both problem sets had reasonably high motivation. The means for the four motivation factors for participants in Problem Set One were as follows: Interest  $M = 4.02$  ( $SD = 1.07$ ), Challenge  $M = 4.41$  ( $SD = 0.88$ ), Success  $M = 5.19$  ( $SD = 0.92$ ), and Fear of failure  $M = 2.66$  ( $SD = 0.88$ ). For Problem Set Two the means were: Interest  $M = 4.02$  ( $SD = 1.05$ ), Challenge  $M = 4.36$  ( $SD = 0.93$ ), Success  $M = 5.36$  ( $SD = 0.83$ ), Fear of failure  $M = 2.65$  ( $SD = 1.02$ ). The two groups did not differ on any of these motivation scales (all  $p > .10$ ). Both groups thought the task moderately interesting and challenging, did not fear failure, and thought they would succeed.

The incremental problem solving scores and the insight problem solving scores were correlated with the four motivational factors of the QCM (Fear of failure, Challenge, Interest, and Success). These correlations are presented in Table 1. For both sets of problems it was found that both Interest and Challenge correlated significantly with incremental problem solving but not with insight problem solving. For each motivation factor we used a z-score conversion (see Olkin, 1967) to test the difference between the correlations of that factor with incremental and insight scores. Only for Interest was the correlation with incremental scores significantly higher than the correlation with insight scores, in both sets. Success correlated significantly with incremental problem solving only for set two, this finding was not replicated with set one. Fear of

failure did not significantly correlate with either incremental or insight problem solving for either set of problems. The difference between correlations for Success was significant for Problem Set Two, but we did not replicate this result with the other set. These findings show that motivation, in particular interest, consistently correlated with incremental problem solving but not insight problem solving.

**State Motivation.** In order to assess if participant's state motivation for each problem influenced problem solving, the three critical motivation questions presented on each of the problem sheets were averaged to create a state motivational score (see Vollmeyer & Rheinberg, 1998). The three critical items were: "This task will be fun", "I'm sure I will find the correct solution", and "It is clear to me how to proceed". Participants' motivation during the task was moderate (see Table 2). Each state motivation score was correlated with its corresponding problem. As Table 2 shows, only one correlation was found to be significant. In Problem Set One, one incremental problem correlated significantly with its state motivation,  $r(141) = .263, p < .01$ . All other correlations were found not to be significantly different from zero. Overall these findings indicate that motivation for each problem was not correlated with performance, regardless of problem type.

Table 2: Correlations of state motivation with each specific problem, together with the percent of subject correctly answering that problem and its mean state motivation (standard deviation in parenthesis).

Problem Set One	Percent correct	Mean (SD) of state motivation	State motivation correlation
Incremental Problem 1	63%	4.55 (1.23)	.263 **
Incremental Problem 2	89%	4.85 (1.18)	.098
Insight Problem	16%	4.15 (1.01)	.060
Problem Set Two	Percent correct	Mean (SD) of state motivation	State motivation correlation
Incremental Problem 1	14%	4.33 (1.23)	.057
Incremental Problem 2	55%	4.11 (1.37)	.058
Insight Problem	16%	4.00 (1.11)	.100

\*\* $p < .01$

## Conclusions

This study achieved our aim of demonstrating a differential relationship between motivation and different types of problems. We not only showed that motivation correlates with one type of problem solving, but that it does *not* correlate with another type. Thus we supported the claim that motivation affects problem solving, and made it hard to argue that such correlations are simply due to some general ability factor. Consistent with the suggestion of Vollmeyer and Rheinberg (1998) and Locke and Latham (1990), motivation only affected problems for which there was a process to be helped or to be disrupted.

The critical motivation factor was Interest, as predicted by previous research (Schiefele, 1996). Interest correlated significantly with incremental problem solving scores. This correlation was significantly higher than the correlation between motivation and insight problem solving scores. Note that although we only report a single study here, in effect the two groups represent a replication of this result. Given that the two groups of participants did different problems sets with differing degrees of success, there appears to be some generality to our findings.

Although the amount of variance in performance explained by motivation is statistically significant, it is small. This does not equate to saying that the influence of motivation on cognition must be correspondingly small. The measures we used were inherently noisy. The QCM is only a pencil-and-paper test of motivation and whether someone solves a particular problem on a particular day is a product of many factors. Further it should be noted that these sorts of problems are often considered to be stable tests of intelligence, so to find motivation influences on even these types of problems is particularly interesting. In future work we will measure ability so as to determine how much of the remaining variance in performance is accounted for by motivation once the variance due to ability has been removed.

We also measured participant's state motivation for each problem they solved. Out of the two problem sets we found only one problem, an incremental problem to be significantly correlated with its state motivation. Whereas this accords with our findings for initial motivation, it was not found consistently; therefore we cannot draw any conclusions. It is possible that the five-question state motivation measure was not sensitive enough or was just not appropriate for this type of task. The state motivation measure is also hard to interpret because it may not only anticipate the problem about to be solved, but also be a reaction to performance on the previous problems. Unlike initial motivation, which is measured before participants solve any of the problems, the direction of any causal arrow would be harder to determine for the state motivation questionnaire.

The main aim of this study was to find a differential effect of motivation on different types of problems, but as well as this we found a much more specific effect (on Interest) as we predicted we would. However, consistent with the idea that motivation affects performance via the mediating processes, we would have to concede that under appropriate conditions motivation may help insight

problem solving. Our conditions may have been particularly conducive to producing a motivation effect on incremental problem solving, but not insight problem solving. By not restricting time, we provided a way in which persistence could help incremental problem solving as the participant did not have to worry about how long it took to get to the solution. Not giving a time limit may have reduced the opportunity for persistence (due to motivation) to affect insight problem solving, as the participant could simply decide that there was no chance to get any further with the problem and just hand it to the experimenter. It is plausible, however, that giving a specific time period for solving problems might actually encourage motivated participants to persist with looking for a solution to insight problems. Therefore, in a situation such as this, motivation might correlate with insight problem solving and not necessarily with incremental problem solving. Note that this in no way weakens our primary aim, demonstrating a motivational effect on problem solving, as these arguments are predicated on the assumption that motivation affects the process of solving problems. The exact patterns of effects on problems solving under different conditions, is a matter for future research.

This was a preliminary study, so further research will be necessary to determine the exact nature of the different effects of motivation on insight and incremental problems. One potential problem with this study was that the insight problems used had a low rate of solution, therefore it would be useful to conduct future research on easier problems. Future research will also need to test our assumption that intellectual ability helps both insight and incremental problem solving. In this study, we assumed that ability affects insight and incremental problem solving equally. This assumption was critical to our argument that motivation helped problem solving rather than any relationship being due to a third-factor, such as ability.

**Implications.** The findings of this study, although somewhat preliminary, have several implications. They show that motivation can influence problem solving, and by extension other cognitive tasks. A practical implication of this is that cognitive scientists should be aware that different tasks might be influenced by motivation in different ways. These possible influences of motivation need, therefore, to be taken into account when designing studies and experiments, otherwise effects may be found simply due to influences of motivation. Most importantly the finding that insight and incremental problems are influenced differently by motivation can be used as a stepping stone to further disentangle motivation and its relationship to cognition.

### Appendix

<b>Problem Set One</b> (order was random)
<i>Incremental Problem 1:</i> Three cards from an ordinary deck are lying on a table, face down. The following information is known about those three cards (all the information refers to the same three cards):  To the left of the Queen, there is a Jack. To the left of a Spade, there is a Diamond. To the right of a Heart, there is a King. To the right of a King, there is a Spade. <b>Can you assign the proper suit to each picture card?</b>
<i>Incremental Problem 2:</i> Next week I am going to have lunch with my friend, visit the new art gallery, go to the Social Security office, and have my teeth checked at the dentist. My friend cannot meet me on Wednesday; the Social Security office is closed weekends; the dentist has office hours only on Tuesday, Friday, and Saturday; the art gallery is closed Tuesday, Thursday, and weekends. On which day can I do everything I have planned?
<i>Insight Problem:</i> A woman has 4 pieces of chain. Each piece is made up of 3 links. She wants to join the pieces into a single closed loop of chain. To open a link costs 2 cents and to close a link costs 3 cents. She only has 15 cents. How does she do it?
<b>Problem Set Two</b> (order was random)
<i>Incremental Problem 1:</i> The police were convinced that Alan, Ben, Chris, or Dan had committed a crime. Each of the suspects made a statement, but only one of the statements was true:  Alan said, "I didn't do it." Ben said, "Alan is lying." Chris said, "Ben is lying." Dan said, "Ben did it." <b>Who is telling the truth? Who committed the crime?</b>
<i>Incremental Problem 2:</i> If the puzzle you solved before you solved this one was harder than the puzzle you solved after you solved the puzzle you solved before you solved this one, was the puzzle you solved before you solved this one harder than this one?
<i>Insight Problem:</i> A dealer in antique coins got an offer to buy a beautiful bronze coin. The coin had an emperor's head on one side and the date 544 B.C. stamped on the other. The dealer examined the coin, but instead of buying it, he called the police. Why?

# Making Inferences and Classifications Using Categories That Are Not Linearly Separable

## Abstract

Previous research suggests that categories learned through classification focus on exemplar information, while categories learned by making predictive inferences focus on summary (i.e., prototype) information. To test this idea further, we demonstrated that it is more difficult to learn nonlinearly separable categories by making inferences than by classifying. This research also supports previous studies by indicating that different processes are likely to mediate inference and classification

In this paper, we examine the type of categorical information people assess in the process of obtaining inductive knowledge. Specifically, we investigate the extent to which abstract summary information about a category and specific information about individual exemplars of a category are used to make feature inferences.

Categories license inference in at least two ways. First, categories provide a summary representation of their members (e.g., a prototype). Given an unknown feature of a bird, for example, people may predict the value of that feature by referring to the bird prototype (Rips, 1975; Tversky & Kahneman, 1974; Yamauchi & Markman, 2000, in press). Another source of category-based induction comes from individual exemplars of a category. Many studies have shown that people classify items by retrieving information about specific exemplars from memory (Kruschke, 1992; Medin & Schaffer, 1978; Nosofsky, 1986). A similar process may be used to make feature inferences. In predicting an unknown feature of an item, people may predict characteristics of the new item based on exemplars stored in memory.

Studies investigating classification have shown that exemplar information plays a crucial role in making classification judgments. Research on inductive inference, however, reveals that category-level abstract feature information (e.g., prototypes) is crucial for inference. For example, Anderson and Fincham (1996) demonstrated that people are capable of predicting the value for one feature given the value of another, based on the overall correlation between the features in the study phase of the experiment, rather than on the basis of seeing those specific values during the study phase. Yamauchi and Markman (2000) further showed that varying the appearance of exemplars during learning disrupts classification, but not inference.

These findings suggest that, while classification and inference may be formally equivalent, they make use of

different kinds of information in practice (Yamauchi & Markman, 1998). In this paper, we extend this hypothesis and examine the idea that category-level summary information provides a basis for inference (e.g., prototypes), while exemplar information plays a major role in classification. In the following sections, we describe the inference and classification tasks that were employed in our experiments. Then, we examine the role of exemplar and prototype information in two experiments.

## Classification and Inference

In our experiments, classification is defined as a practice in which an item is placed into one of two groups based on its attributes. Inference is defined as a practice in which an attribute of an item is predicted given the category label of the item as well as information about its other attributes. For example, classification as we define it is akin to the prediction of a category to which a person belongs (e.g., Democrat) having observed his attributes (e.g., supports affirmative action and favors reduced defense spending). Inference is akin to predicting an attribute of a person (e.g., supports affirmative action) given a category to which he belongs, and other known attributes (e.g., is a Democrat and favors reducing defense spending). We further define the term *category label* as a symbol that represents category membership by denoting a particular group of exemplars, and the term *category feature* as a symbol that denotes a characteristic of an exemplar. Classification requires the prediction of the category label based on the features of the item; inference requires the prediction of a category feature based on the information about other features and the category label.

In our experiments, subjects learn two categories (Table 1a) through a classification task or an inference task. On a classification trial, subjects are presented with a stimulus depicting the values of the form, size, color and position of the geometric figure, and they predict the category label of that stimulus (see Figure 1a). On an inference trial, subjects are presented with the values of the size, shape and position of the geometric figure along with the category label to which the stimulus belongs (e.g., Set A), and they predict the value of the missing feature (e.g., the color) (Figure 1b). On different trials, subjects predict different features. In this manner, classification and inference are formally equivalent if a category label is regarded as simply another feature (Anderson, 1990; but see Yamauchi & Markman, 1998, in press, for further discussion).

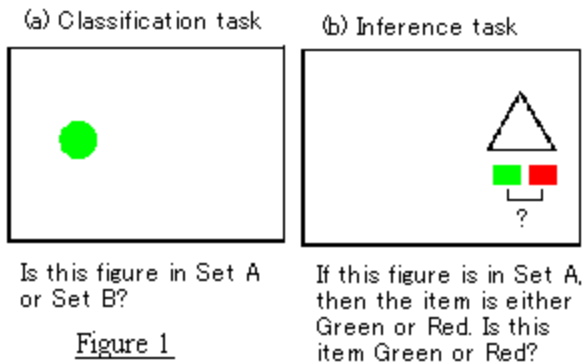

Table 1a The category structure Experiment 1

Learning	Category A					Category B

					B 7	0	0	1	1
					B 8	1	1	0	0

Table 1b Linearly Separable Categories

A 1	1	1	1	0	B 1	0	0	0	1
A 2	1	1	0	1	B 2	0	0	1	0
A 3	1	0	1	1	B 3	0	1	0	0
A 4	0	1	1	1	B 4	1	0	0	0
A 0	1	1	1	1	B 0	0	0	0	0

Figure 1a

In our previous studies (Yamauchi & Markman, 1998, 2000), we used linearly separable categories (see Table 1b) and found that these categories are easier to learn given an inference learning task than given a classification learning task. We reasoned that this result was obtained because inference relies on summary information about category members. The linearly separable categories have prototypes that summarize the feature values of the individual exemplars, although the prototype differs from all of the exemplars by a feature (e.g., A0&B0 in Table 1b). In this structure, additive combinations of feature values divide the two categories nicely; therefore, extracting prototypes from the two categories facilitates learning these categories.

Categories that are not linearly separable have a very different structure, and hence we expect a different pattern of performance on inference and classification tasks. A sample set of nonlinearly separable categories is shown in Table 1a. For these stimuli, subjects may find prototypes in the two categories (Category A=(1, 1, 1, 1) and Category B=(0, 0, 0, 0)). Nonetheless, this information is not useful for integrating category members in each category as no additive combination of feature values can predict category

coherence (Medin & Schaffer, 1978; Wattenmaker, Dewey, Murphy, & Medin, 1986). For example, the stimulus B2 differs minimally from the prototype in Category A but is included in Category B. In order to learn these categories, subjects need to remember the specific exemplars (see Medin & Schaffer, 1978). Because there are only 6 exemplars in the two categories, it is not difficult for subjects to store these exemplars in memory. It is difficult to learn to make feature inferences, however, because there is no abstract summary information that provides a good description of the categories. Thus, for nonlinearly separable categories, we expect a reversal in the ease of inference and classification relative to linearly separable categories, with the categories being difficult to learn and process through inference than through classification. We test this idea in Experiment 1.

## Experiment 1

We used geometric figures as stimuli. All the stimuli varied along four binary feature dimensions: size (large, small), form (circle, triangle), position (left, right) and color (red, green). This structure is shown in Table 1a. These stimuli and the categories are equivalent to those employed by Medin and Schaffer (1978).

In Experiment 1, the subjects learn these two categories in one of two conditions: (1) Classification or (2) Inference.<sup>1</sup> In the Classification Learning condition, the subjects respond to classification questions. In the Inference Learning condition, the subjects respond to inference questions. Initially, no information about the categories is given to subjects in our studies, so that they have to learn the two categories incrementally by trial and error, based on the feedback that they receive after their response. The learning phase continues until subjects reach a criterion of 90% accuracy in three consecutive blocks (18 trials) or until they complete 30 blocks (180 trials).

Following the learning phase, we test the nature of this category representation using transfer trials, which consist of classifications and inferences of old stimuli that appeared during learning and new stimuli that did not appear during learning. In the transfer phase, all the subjects receive the same trials. Transfer stimuli were designed to explore the distinction between inference and classification. For example, the transfer stimuli, A4-A6 and B4-B6, deviate equally from the prototype of each category. Thus, subjects in Inference Learning should be able to classify these stimuli equally well after learning. These stimuli differ in the extent to which they share features with individual exemplars. The stimuli B4-B6 are highly similar to one exemplar in Category A and one exemplar in Category B. In contrast, the stimuli

<sup>1</sup> In our original experiment, we also included a Mixed condition, in which half trials consisted of classification questions and the remaining half were inference questions. Most scores obtained from the Mixed condition fell approximately midway between the Classification condition and the Inference condition. In order to focus on the distinction between inference and classification, we will not report the results from the Mixed condition in this paper.

A4-A6 are highly similar to two exemplars in Category A, but are not similar to any of the exemplars in Category B (Medin & Schaffer, 1978, p. 218). Thus, subjects in Classification Learning (in contrast to those in Inference Learning) should classify the stimuli A4-A6 more accurately than the stimuli B4-B6. A similar prediction holds for the stimuli B7 (0, 0, 1, 1) and B8 (1, 1, 0, 0). These two stimuli are neutral with respect to the two prototypes. Both stimuli have two feature values consistent with Category A and two feature values consistent with Category B. However, they are highly similar to at least one of three exemplars of Category B (B7 is similar to B2, and B8 is similar to B3), but they are not similar to any of the exemplars of Category A. As a consequence, the stimuli B7 and B8 should be accurately classified into Category B as a function of exemplar storage during learning. Finally, because categories that are not linearly separable do not provide an accurate summary of category members, subjects in the two conditions should have difficulty making transfer inferences to new stimuli.

**Participants and Materials.** 49 subjects participated in this study. The data from 1 subject were lost due to an error in recording. In total, the data from 48 subjects (24 in each condition) were analyzed. Each category consisted of three exemplars that were shown during learning and transfer trials. In addition, there were eight new stimuli that were given only in the transfer phase. Two versions of the feature assignment were introduced in this experiment. In one version, the value of 0 was triangle and the value of 1 was circle. For color, the value of 0 was green and the value of 1 was red. For size, the value of 0 was small and the value of 1 was large. For position, the value of 0 was right and the value of 1 was left. In the other version, the values of form and size were reversed. Each stimulus was bounded by a 20.3 x 17.4 cm rectangular frame drawn with a solid black line on the computer screen.

**Procedure.** The experiment involved three phases — a learning phase, a filler phase and a transfer phase. In the learning phase, subjects were randomly assigned to one of two conditions — Classification and Inference. In the two conditions, subjects continued in the learning phase until they performed three consecutive blocks with a combined accuracy of 90% or until they completed 30 blocks (180 trials). A classification block consisted of presentations of six exemplars. One inference block consisted of one inference (along one of the four dimensions) for each of the six stimuli. In the two conditions, every exemplar appeared once in the feedback of each block. The order of stimulus presentation was determined randomly.

In Classification Learning, subjects saw one of the six stimuli and indicated the category to which it belonged by clicking a button with the mouse (Figure 1a). In Inference Learning, subjects inferred a value for one of the four feature dimensions while its category label and the remaining three feature values were depicted in the stimulus frame (Figure 1b). Different dimensions were predicted on different trials. Subjects responded by clicking one of two labeled buttons

with the mouse. For each stimulus, the location of the correct choice was randomly determined. Following each response, feedback and the correct stimulus were presented on the screen for three seconds. The stimuli presented during feedback were identical in both the classification and inference tasks.<sup>2</sup>

After the learning trials, there was a brief filler task, and then all subjects carried out the same transfer tasks. In the transfer phase, subjects were first given classification transfer followed by inference transfer. The transfer stimuli consisted of 6 old stimuli and 8 new stimuli (Table 1a). All of which were shown both in the classification transfer task and in the inference transfer task. The order of stimulus presentation for each task was determined randomly. All the feature inferences were given in Inference learning. No feedback was given during transfer.

## Results and Discussion

Overall, the basic results of Experiment 1 are consistent with our hypothesis (Table 2). With nonlinearly separable categories, inference was much more difficult than classification. This finding contrasts with previous research with linearly separable categories, where inference was easier than classification (Yamauchi & Markman, 1998).

In all, 17 subjects reached the learning criterion in the Inference Learning condition, and 22 subjects reached the criterion in the Classification Learning condition. Considering only those who reached the learning criterion, subjects in the Inference Learning condition ( $\bar{m}=15.8$ ) required significantly more blocks during the learning phase than did subjects in the Classification Learning condition ( $\bar{m}=10.5$ ),  $t(37)=3.32$ ,  $p<0.01$ , (Table 2).

For the classification transfer of old stimuli, subjects given Classification Learning ( $\bar{m}=0.92$ ) were significantly more accurate than subjects given Inference Learning ( $\bar{m}=0.69$ );  $t(37)=5.28$ ,  $p<0.01$ . As predicted classification, but not inference, involves comparisons to exemplars. Subjects given Classification Learning classified the stimuli A4-A6 ( $\bar{m}=0.76$ ) more accurately than the stimuli B4-B6 ( $\bar{m}=0.45$ ), although the two sets of stimuli deviate equally from the prototype of each category;  $t(42)=3.73$ ,  $p<0.01$ . In contrast, there was no statistical difference in classification accuracy for the stimuli A4-A6 ( $\bar{m}=0.63$ ) and the stimuli B4-B6 ( $\bar{m}=0.55$ ) in subjects given Inference Learning;  $t(32)=0.77$ ,  $p>0.1$ . Also as predicted, for the neutral stimuli B7 and B8, subjects in Classification Learning were more likely to classify these stimuli into Category B ( $\bar{m}=0.61$ ) than were subjects in

<sup>2</sup>The inference for the size of the stimuli B1 and B3 has two right answers. Given the inference question (0, ?, 0, 0), the response of the feature value 1 corresponds to the stimulus B3 and the response of the feature value 0 corresponds to the stimulus B1. We gave subjects a correct feedback irrespective of their responses for this question. This treatment should make inference learning faster, and thus functions against our hypothesis that inference learning requires more trials than classification learning for this category structure.

Inference Learning ( $\bar{m}=0.50$ ), but this difference was not statistically significant;  $t(40)=1.04$ ,  $p>0.10$ .

Table 2 The main results from Experiment 1

Classification Transfer					
	Old		New		Neutral
		Average	A4-A6	B4-B6	B7&B8
IL	0.69	0.59	0.63	0.55	0.44
CL	0.92	0.61	0.76	0.45	0.61
Inference Transfer					
	Old		New		Neutral
		Average	A4-A6	B4-B6	B7&B8
IL	0.79	0.46	0.40	0.51	0.36
CL	0.75	0.50	0.50	0.50	0.50

IL: Inference Learning, CL: Classification Learning

For the neutral stimuli B7&B8, we measured the proportion that subjects classified the two stimuli into Category B.

For the inference transfer, subjects in the two conditions were about equally accurate in making feature inferences for old stimuli; Inference Learning,  $\bar{m}=0.79$ , and Classification Learning,  $\bar{m}=0.75$ . Their performance declined sharply given the inference transfer of new stimuli; Inference Learning,  $\bar{m}=0.46$ , Classification Learning,  $\bar{m}=0.50$ . The performance exhibited by subjects in Classification Learning was no better than a chance level;  $t(21)=0.11$ ,  $p>0.1$  (one-tail). The performance exhibited by subjects in Inference Learning was actually significantly below chance;  $t(16)=-2.36$ ,  $p<0.05$  (one-tail). This poor performance contrasts with what we observed in classification transfer, where performance on new items was significantly above chance in both learning conditions. These results are consistent with the view that categories that are not linearly separable provide little support for predictive inference.

The results of Experiment 1 support our view that it is difficult to make inferences for nonlinearly separable categories. Furthermore, the results indicate that inference and classification, two of the main functions of categories, differ significantly in the category information they utilize. In Experiment 2, we investigate this hypothesis further by examining a factor that distinguishes inference and classification.

## Experiment 2

We have proposed that inference focuses on summary information about the category. In contrast, there is evidence that people who are trying to classify a set of items tend to focus on diagnostic information that reliably distinguishes between categories (Nosofsky, Palmeri, & Mckinley, 1994). For example, in sorting tasks people tend to divide the stimuli into groups on the basis of a single dimension, even when there is a clear family resemblance structure among the exemplars (Ahn & Medin, 1992; Medin, Wattenmaker, & Hampson, 1987). The hypothesis that classification tends to focus on diagnostic features and

inference tends to focus on summary information received indirect support in our previous studies (Yamauchi & Markman, 1998, 2000, in press). In Experiment 2, we will test this idea more directly and scrutinize the distinction between inference and classification.

Table 4 shows the structure of the two categories used in Experiment 2. The categories consist of 3 exemplars each. The stimulus configuration A0(1, 1, 1, 1) summarizes Category A, and the stimulus configuration B0(1, 1, 0, 0) summarizes Category B because these feature values are dominant in each feature dimension of the two categories. In this category structure, the first two dimensions (form and size in Table 4) of the two prototypes are the same, so that they are not useful for distinguishing between the two categories. In contrast, the last two dimensions (color and position in Table 4) are more informative for distinguishing between the categories. Thus, if classification promotes attention to the features that differentiate the two categories, subjects in Classification Learning should attend more to feature information about color and position than to information about form and size. In contrast, because inference is assumed to focus on relations among features within a category, subjects given inference learning should be equally sensitive to the four feature dimensions.

This category structure is also useful for distinguishing the extent to which subjects assess a summary of the category as opposed to individual exemplars. In particular, subjects in Inference Learning should have difficulty acquiring these two categories because the stimulus A2 is the prototype of Category B, but is actually a member of Category A. Subjects in Inference Learning should also have trouble inferring features that do not correspond to the prototype stimuli of the two categories (which we call *category-discordant features*). For example, subjects in Inference Learning should exhibit less accurate performance for feature values that do not correspond to the prototype (the value 0 of Category A, and the value 0 of form and size in Category B and the value 1 of color and position of Category B). These factors, however, should not influence subjects in Classification Learning, because this task should focus people selectively on diagnostic features and individual exemplars.

**Participants and Materials.** Subjects were 48 members of the Columbia University community. The materials used for this experiment were the same kind of four-dimensional stimuli used for Experiment 1, but they were organized into a different category structure (Table 4). Each exemplar of a given category had two feature values in common and one feature value different from the rest of the members of that category. The prototype of Set A was (1, 1, 1, 1), which was also a member of the category (exemplar A1 in Table 4). The prototype of Set B was (1, 1, 0, 0), which was actually a member of category A (exemplar A2 in Table 4). The six exemplars from Table 4 were used for Classification Learning and classification transfer. Inference Learning and inference

transfer consisted of inferences of all the feature dimensions of the six exemplars (in total 24 different questions).

Table 3 The category structure used in Experiment 2

	F	S	C	P		F	S	C	P

of category B. F=Form, S=Size, C=Color, P=Position

**Procedure.** The basic procedure of this experiment was identical to that described in Experiment 1.

## Results and Discussion

As predicted, learning these categories was particularly difficult for subjects given Inference Learning. All subjects (24) in Classification Learning, but only 8 subjects in Inference Learning reached the learning criterion. On average, subjects in Classification Learning spent 10.4 blocks, and subjects in Inference Learning spent 27.4 blocks in learning;  $t(46) > 10.0$ ,  $p < 0.01$ . Because the number of subjects who reached the criterion differed considerably between Classification Learning and Inference Learning, we analyzed the transfer data from each learning condition separately.

In Classification Learning, subjects exhibited accurate performance for classification transfer ( $\underline{m}=0.94$ ). Subjects' classification performance was generally high for all six stimuli. For the six transfer stimuli, the accuracy ranged from 88% to 96%. Subjects were also accurate in the classification of the stimulus A1 ( $\underline{m}=0.88$ ), which is the prototype of category A (and a member of category A) as well as stimulus A2 ( $\underline{m}=0.92$ ), which is the prototype of category B, but is actually a member of category A. During the transfer phase, subjects classified the stimulus A1 and the stimulus A2 equally well;  $Z=-0.02$ ,  $p > 0.1$  (Table 4).

Subjects in Classification Learning were also accurate in inference transfer ( $\underline{m}=0.83$ ). Consistent with our prediction, Classification Learning clearly led subjects to focus on the features that were useful for distinguishing between categories. Subjects in Classification Learning performed significantly better for the feature inferences of color and position ( $\underline{m}=0.86$ ) than for form and size ( $\underline{m}=0.80$ );  $t(23)=1.83$ ,  $p < 0.05$  (one-tailed).

In Inference Learning, we analyzed the data from all subjects, because only 8/24 subjects reached the learning criterion. First, the average performance for classification transfer by subjects in Inference Learning was  $\underline{m}=0.70$ . Unlike in Classification Learning, in Inference Learning there is a wide disparity between accuracy in classifying the stimulus A1 and the accuracy in classifying the stimulus A2. Subjects in Inference Learning accurately classified the prototype stimulus of Category A — A1(1, 1, 1, 1),  $\underline{m}=0.83$  —

but not the prototype stimulus of Category B — A2(1, 1, 0, 0),  $\underline{m}=0.46$ ;  $Z=2.41$ ,  $p < 0.01$ . This result suggests that subjects were focusing on information that summarized the categories rather than on information about specific exemplars.

Table 4 The main results of Experiment 2

	Classification Transfer			
	A1	A2	All exemplars	
IL	0.83	0.46	0.70	
CL	0.88	0.92	0.94	
	Inference Transfer			
	F	S	C	P
IL	0.72	0.68	0.73	0.68
CL	0.81	0.80	0.88	0.85

F=form, S=size, C=color, P=position

Consistent with our prediction, subjects in Inference Learning did not differ in the feature inferences of form and size, as compared to the feature inferences of color and position (form & size,  $\underline{m}=0.70$ , color & position,  $\underline{m}=0.70$ ). This result, combined with the results from Classification Learning, clearly indicates that inference and classification make use of different types of feature information.

Subjects in Inference Learning were not different in the inference transfer of Category-accordant features ( $\underline{m}=0.71$ ) (i.e., prediction of feature values that are the same as the value for the prototype of that category) and Category-discordant features ( $\underline{m}=0.69$ ) (i.e., prediction of features that have a different value than the prototype of the category);  $t(22)=0.62$ ,  $p > 0.10$ . A similar tendency appeared for subjects in Classification Learning; Category-accordance features ( $\underline{m}=0.84$ ) and Category-discordant features ( $\underline{m}=0.82$ );  $t(22)=0.69$ ,  $p > 0.1$ . We applied the same analysis to the learning performance of subjects in Inference Learning. The results revealed that subjects' learning performance was significantly more accurate for Category-accordant features ( $\underline{m}=0.63$ ) than for Category-discordant features ( $\underline{m}=0.56$ );  $t(22)=3.46$ ,  $p < 0.01$ . This analysis indicates that people find it difficult to make correct inferences for features that do not correspond to the category prototype during learning.

Taken together, The results of these studies support the hypothesis that nonlinearly separable categories are difficult to learn through inference. Our results also suggest that inference and classification promote a focus on different types of category information: The Classification Learning task guides subjects to focus on features that distinguish between categories; the Inference Learning task directs subjects to attend to the features that integrate the members within a category.

## General Discussion

These studies demonstrate that it is easier to learn categories through classification than through inference when the categories are not linearly separable. This finding

contrasts with earlier research with linearly separable categories, which found that inference learning was easier than classification learning. This finding reflects that summary category information is more important for inference than for classification. Our experiments, combined with the results from previous studies (Yamauchi & Markman, 1998, 2000, in press), suggest that the structure of a category is one of the major constraints on inductive inference. Unlike classification, inference requires feature information that relates the members of a category. Although some researchers argue that inference and classification are the same thing (e.g., Anderson, 1990), our results reveal that people exercise different strategies for the two tasks.

Why do people look for abstract summary information for inference, while they seek information about specific exemplars or diagnostic features for classification, even when they are given the same categories? This difference may follow from an intricate link between category representation and category functions. Classification is related to object identification and recognition (Nosofsky, 1986). Thus, it requires finding relationships between an individual exemplar and its category label. Once an object is identified, its overall feature information may become irrelevant except some features that are useful to distinguish between categories. In contrast, inference involves the prediction of missing feature values, and thus requires finding relationships between the category label and the features of the category (Gelman, 1986). In this case, the category identity of the object is known, and so information about the category features is needed to predict the value of missing features. Thus, differences in what is demanded in each task lead people to look for distinctions between groups given a classification task, and to seek commonalities within a group given an inference task.

## Abstract

In modelling analogy the Structure Mapping Engine (Gentner, 1983; Falkenhainer, Forbus and Gentner, 1989) can only map successfully on representations in a canonical form because it only permits mappings between relations with lexically-identical functors. We examine whether co-occurrence statistics can remedy this by providing an appropriate basis for modelling lexico-semantic relations. Using a co-occurrence model we reimplement SME to allow it to map between relations with functors that are lexically-distinct. Computational experiments are then reported which show that the resulting model, M-SME, maps successfully on representations which faithfully encode lexical properties, indicating that semantic constraints should only play a minimal role in the mapping process.

## The Structure-Mapping Theory

The structure-mapping theory was originally proposed as a set of constraints defining permissible mappings between a base and target domain in analogy (Gentner, 1983), and implemented in the Structure-Mapping Engine (Falkenhainer, Forbus and Gentner, 1989). Structure-mapping theory constructs analogical mappings between discrete domains (called ‘Dgroups’) of propositional statements, with the main focus being on mapping interconnected *relational* structure.

### The Lexical-Identicality Constraint

In detecting shared relational structure the structure-mapping theory only permits mappings to be made between relations if, and only if, they have lexically-identical functors and the same number of arguments. Thus there are two constraints on the formation of an initial *match hypothesis*. We call the first constraint on match hypothesis formation the *lexical-identicality constraint*, and it is important to observe that it carries a commitment to a canonical theory of representation because it requires that mappable relations are represented with identical names. For example, structure-mapping theory would not permit an alignment between the following two relations, even though it might be appropriate in a wider context:

(ORBITS PLANET SUN)

(REVOLVES\_AROUND ELECTRON ATOM)

The fact that ORBITS is not lexically-identical to REVOLVES\_AROUND also means that the corresponding

analogical mappings between the arguments of the relations (PLANET with ELECTRON, and SUN with ATOM) are not made. Holyoak and Thagard (1995) have argued that this constitutes a significant weakness in structure-mapping theory: “with its emphasis on structure to the exclusion of all other constraints, SME does not simply discourage mappings between non-identical but semantically similar items; it does not even permit them.”

Both the ACME (Holyoak and Thagard, 1989) and LISA (Hummel and Holyoak, 1997) models of analogy avoid this objection by postulating semantic links that hold between the names of relations. These links are hand-coded into the propositional representations on which the analogical mappings are generated. If a sufficiently strong semantic link is coded between two relations then a mapping can be countenanced between them. Thus, in the example above, ACME’s or LISA’s representations could incorporate a sufficiently strong semantic link between ORBITS and REVOLVES\_AROUND to enable a mapping to be generated from one relation to the other.

## The Canonical Representation Theory

Holyoak and Thagard’s criticism of the structure-mapping theory is not entirely fair, however, as it ignores SME’s commitment to a *canonical representation* (CR) theory. The CR theory claims that relations that are sufficiently similar in ‘meaning’ to facilitate mappings (e.g. ‘orbits’ and ‘revolves around’) are coded with identical tokens (in this case both might be coded as ‘orbits’). This extra assumption of the structure-mapping theory would allow the intuitively correct mapping to be made in the above case. However, since the postulation of semantic links and the CR theory rely on human-based coding decisions – and neither subscribe to a worked out model of semantics – both are ultimately equivalent in terms of their explanatory power.

The CR commitment of structure-mapping theory allows a *modular* approach to be taken to the cognitive modelling of analogy. By mapping across canonical representations questions of semantics are left outwith the scope of structure-mapping theory – SME thus remains noncommittal with respect to a theory of lexical semantics. In the experiments that follow we exploit SME’s modular approach to modelling by using the information provided by a co-occurrence model of lexical semantics to see if this allows SME to map successfully on non-canonical representations, and avoid the underspecifica-

tion inherent in the CR theory.

## Experimental Materials

**The ‘Karla the Hawk’ stories.** The Karla the Hawk materials were chosen as the test domain in this study (Gentner, Ratterman and Forbus, 1993). The materials consist of twenty sets of stories written in natural language. Each set consists of a base story, and four systematic variations of that story. Two factors are crossed over the four variant stories, as shown below.

	+ST	-ST
+SF	Literal Similarity	Surface Similarity
-SF	Analogical	First-Order Relations

Table 1: The commonalities each variant category shares with the corresponding base it is derived from.

The four story categories systematically vary the commonalities that are shared with the base-story from which they are derived. Each variant can either share or not share surface ( $\pm SF$ ) and structural ( $\pm ST$ ) commonalities with the corresponding base-story. Because analogy consists in two domains possessing a shared structure, this  $2 \times 2$  materials design allows for the controlled examination of SME’s performance. If SME is performing appropriately then we would expect a better mapping performance when mapping the base representations on to the LS and AN category materials, as they share structural commonalities.

**The Faithful Dgroups.** The standard representations that SME operates on, the *Original Dgroups*, encode relation names in canonical form in accordance with the CR theory. In order to test the performance of SME on representations that do not embody a commitment to the CR theory we developed our own representations that faithfully encode the relation names as used in the original natural language Karla stories. We call this set of representations the *Faithful Dgroups*, and they were produced by transferring the lexemes used to express relations in the original natural language Karla materials directly into the propositional form required by SME.

### Experiment 1A

This first experiment was conducted to test the performance of SME on the Original Dgroups, which are the original encodings of nine of the twenty Karla the Hawk story-sets (Forbus, Gentner and Law, 1994). This was in order to provide a base measure of SME’s performance.

**Method.** For each of the nine sets of Original Dgroups SME was used to map the base Dgroup onto its four variants. The Structural Evaluation Score (SES)<sup>1</sup> and number of match hypotheses formed for each mapping were then recorded.

<sup>1</sup>SES scores are automatically calculated by SME and provide a measure of the *quantity* of structure that has been mapped between two domains.

**Results.** The data for Experiment 1A can be seen in Table 2. The results of two-factor repeated-measure ANOVA testing are given below.

*SES scores:* the only significant effect was for  $\pm ST$  ( $F(1, 8) = 5.43, p < 0.05$ ). Both the  $\pm SF$  ( $F(1, 8) < 1$ ) and interaction ( $F(1, 8) = 1.24, p > 0.05$ ) factors produced nonsignificant effects.

*Match hypothesis formation:* the only significant effect was for  $\pm SF$  ( $F(1, 8) = 51.44, p < 0.01$ ). Both the  $\pm ST$  ( $F(1, 8) = 1.12, p > 0.05$ ) and interaction ( $F(1, 8) = 1.29, p > 0.05$ ) factors produced nonsignificant effects.

	LS	SS	AN	FOR
SES Category Mean	21.51	17.14	21.16	16.23
MH Category Mean	240.5	239.0	214.3	205.4

Table 2: The SES scores and number of match hypotheses formed with the SME model on the nine Original Dgroups.

**Discussion.** As expected, SME exhibits the required sensitivity to the structural commonalities of the Original Dgroups (witness the higher SES scores for the LS and AN mapping tasks). This is demonstrated by the fact that the only significant factor in the analysis of the SES scores was  $\pm ST$ . Interestingly, the number of match hypotheses formed for each category of match is sensitive to  $\pm SF$ . This reflects the fact that lexically-identical functors are more likely to occur in the Original Dgroups when there are shared surface features, and SME can only form match hypotheses between relations with lexically-identical functors.

### Experiment 1B

**Method.** The format of this experiment is the same as the previous one, except that this time SME was required to map across the Faithful Dgroups that faithfully encode the lexical properties of the original Karla representations.

**Results.** The results for Experiment 1B can be seen in Table 3. The details of repeated-measure ANOVA testing for two factors are given below.

*SES scores:* All three factors produced nonsignificant effects:  $\pm ST$  ( $F(1, 8) < 1$ );  $\pm SF$  ( $F(1, 8) = 4.72, p > 0.05$ ); and interaction effects ( $F(1, 8) < 1$ ).

*Match hypothesis formation:* Again, all three factors produced nonsignificant effects:  $\pm ST$  ( $F(1, 8) < 1$ );  $\pm SF$  ( $F(1, 8) = 3.21, p > 0.05$ ); and interaction effects ( $F(1, 8) < 1$ ).

Testing on both the SES scores ( $t = 11.37, df = 35, p < 0.01$ ) and the number of match hypotheses ( $t = 8.38, df = 35, p < 0.01$ ) revealed that there was a significant decrease in the the means of both from mapping on the Original Dgroups.

**Discussion.** As expected, SME does not exhibit the required sensitivity to  $\pm ST$  on the Faithful Dgroups, and the greatly reduced SES scores from its performance on the Original Dgroups show that it fails to map signifi-

	LS	SS	AN	FOR
SES Category Mean	1.62	1.21	1.47	0.94
MH Category Mean	92.1	84.7	93.1	78.6

Table 3: The SES scores and number of match hypotheses formed with the SME model on the Faithful Dgroups.

cant quantities of structure from one domain to another. Furthermore, the greatly reduced number of match hypotheses formed for each category of mapping (reduced from an overall mean of 224.8 in Experiment 1A to 87.13 in 1B) suggests a possible explanation of this failure: the constraints on the formation of match hypotheses are too strict to allow the appropriate local alignments to be made on the Faithful Dgroups (because there are an insufficient number of lexically-identical relations between different domains). This means that the raw material is not there for SME to combine to form the appropriate global mappings, and suggests that the process of match hypothesis formation needs to be altered if SME is to perform successfully on the Faithful Dgroups.

As noted above, the only point at which SME is committed to the CR theory is during the formation of match hypotheses. Therefore, if we are to remove SME’s commitment to the CR theory we need to do so by changing the constraints on the formation of match hypotheses to allow them to be formed between relations that are *sufficiently similar* instead of identical. This begs the question of what ‘sufficiently similar’ means.

### Co-occurrence Statistics

There is a growing body of evidence that the frequency with which different lexemes co-occur with one another (that is, are used together within a particular context, such as a paragraph or moving-window) can provide useful information about the semantic properties of those lexemes. For example, Landauer and Dumais (1997) report that the LSA model can pass a multiple-choice TOEFL synonym test. Lund, Burgess and Atchley (1995) present evidence that co-occurrence data can act as a good predictor of priming effects. Burgess and Lund (1997) demonstrate that the HAL model can produce clustering in its high-dimensional space according to the grammatical category of different lexemes.

We therefore decided to investigate the possibility of using the *Latent Semantic Analysis* (LSA) model (Landauer and Dumais, 1997; Landauer, Foltz and Laham, 1998) to see if it could provide SME with the sort of lexico-semantic information required for it to map successfully on the Faithful Dgroups (Note that although we use the LSA model, this does not indicate a particular commitment to that model alone, but rather we use it as an exemplar of the more general approach).

### Relaxing the Lexical-Identicality Constraint

Since the only commitment SME makes to the CR theory is during the formation of match hypotheses, where

it requires that relations have lexically-identical functors and the same number of arguments if they are to support a match hypothesis, SME’s code was altered so that it enforced different constraints on the formation of match hypotheses. In the modified version of SME (M-SME) two relations still have to have the same number of arguments to warrant a match hypothesis, but the *lexical-identity constraint* is relaxed. Instead of the two relations also having to have identical functors, the functors are compared with one another using the LSA model<sup>2</sup>. Only if they are assigned a score greater than a threshold value (called the *reconciliation-threshold*) is a match hypothesis formed. In this way, the relations with functors REVOLVES\_AROUND and ORBITS might be combined in a match hypothesis because the LSA model assigns them a score of 0.48.

The possibility of assigning different values (between 0 and 1) to the reconciliation-threshold generalises the original constraints that SME places on match hypothesis formation. When the threshold is set to 1 the reimplemented model performs just like the original SME because LSA only assigns lexically-identical functors a score of 1. When the threshold is set to 0 any two functors will be assigned an LSA score greater than or equal to the threshold, and so the only constraint on match hypothesis formation is that the relations in question have the same number of arguments<sup>3</sup>. It is clear that the reconciliation-threshold needs to be assigned a value that maximises the performance of M-SME.

### Setting the Reconciliation-Threshold

In order to determine a value for the reconciliation-threshold it is necessary to establish some criterion by which the *quality* of mappings can be assessed. The following experiments investigate whether such a measure can be derived from the number of match hypotheses and the SES scores of M-SME on a variety of mapping tasks.

### Experiment 2A

This experiment investigates the effect that varying the reconciliation-threshold has on the number of match hypotheses formed for each category of mapping (LS, SS, etc.). We predict that the number of match hypotheses formed for each match will decrease as the reconciliation-threshold increases because the semantic constraints on match hypothesis formation become stricter. This result will indicate that M-SME is functioning as expected. Furthermore, if the reconciliation-threshold can be used to reduce the number of match hypotheses formed then this could be used to limit the computational complexity of the mapping process.

**Method.** M-SME was used to map between the base domain and its four variants on the nine sets of Faith-

<sup>2</sup>The LSA model assigns two functors a score between 0 and 1, depending on their location in the highdimensional space defined by taking each lexeme sampled as a dimension.

<sup>3</sup>Note that the introduction of a reconciliation-threshold only affects the *formation* of mappings; the *evaluation* of mappings remains unaffected: M-SME calculates SES scores in exactly the same way as SME.

ful Dgroups, as the reconciliation-threshold was adjusted between 0 and 1.

**Results.** The results of Experiment 2A can be seen in Figure 1. The reconciliation-threshold is plotted against the number of match hypotheses formed for each category of the mapping task. This shows that the number of match hypotheses formed for each category of the mapping task decreases in a regular nonlinear fashion as the reconciliation-threshold is increased from 0 to 1.

Figure 1: A plot of the number of match hypotheses that M-SME produces in matching the base stories with their four variants as the reconciliation-threshold is adjusted.

**Discussion.** The regular decrease in the number of match hypotheses formed offers preliminary evidence that M-SME is performing as expected, and that the computational complexity of the mapping process can be limited by increasing the reconciliation-threshold. However, it is possible that in doing this the semantic constraints on mappings become too strict to allow the appropriate analogical mappings to be constructed. This clearly requires further investigation.

## Experiment 2B

This experiment investigates the effect of the reconciliation threshold on the SES scores produced for each category in the standard mapping task on the Faithful Dgroups.

**Method.** M-SME was used to perform the same mapping task as in Experiment 2A, but this time the SES scores for each category were recorded as the reconciliation-threshold was adjusted from 0 to 1. We predicted that there would be a consistent separation in SES scores between those materials exhibiting  $+ST$  and  $-ST$  as the reconciliation-threshold was varied, indicating that M-SME is sensitive to the structural aspects of the Faithful Dgroups.

**Results.** The results of this experiment are shown in Figures 2-3. Figure 2 shows the SES category scores against the reconciliation-threshold. Figure 3 shows the

same data, but this time with the mapping categories split in to those which share structural commonalities with the base stories, and those which do not.

Figure 2: A plot of M-SME’s SES scores on the standard mapping task with Faithful Dgroups against the reconciliation-threshold.

Figure 3: A plot of M-SME’s SES scores on the standard mapping task with Faithful Dgroups against the reconciliation-threshold (Dgroups are split into those exhibiting  $+ST$  and those exhibiting  $-ST$ ).

**Discussion.** Figure 3 offers preliminary evidence that M-SME is sensitive to the  $\pm ST$  factor on the Faithful Dgroups, as predicted. This represents a large improvement over SME’s performance on these materials. However, SES scores are a measure only of the *quantity* of structure that is mapped between two domains. Basing our evaluation of M-SME on SES scores alone is insufficient evidence of its success, because we need to ensure that it is sensitive to genuine analogies between domains and is not mapping inappropriate structure. So, a measure sensitive to the *quality* instead of just the *quantity*

of mapped structure is required.

### Experiment 3

To gain a useful measure pertaining to the quality of mappings made by M-SME, each of the individual alignments made in the successful global mappings were examined and rated for correctness.

**Method.** Each of the individual alignments produced by M-SME on the standard mapping task on the Faithful Dgroups were inspected and assessed for correctness (i.e. whether or not they represented genuine *analogical* alignments). The LSA score that sanctioned each alignment was also recorded, to see if the reconciliation-threshold could be set so as to prevent incorrect alignments from being made whilst still permitting correct alignments to be made.

Alignments made between the base and the SS and FOR categories were rejected, because it was unclear what would constitute a correct or incorrect alignment in these cases, as the materials were designed to share little or no structure with the corresponding base representation. The matches were performed with the reconciliation-threshold set to 0 to make the alignments generated as inclusive as possible. This was in order to collect the largest possible set of match hypotheses to see what the LSA scores were for each alignment.

Note that not *all* of the match hypotheses formed for each match were inspected, but only the ones that were included in the highest scoring global mapping for each attempted match. Although it would have been informative to consider all these hypotheses, there would have been approximately 16,200 of them<sup>4</sup>, which is too many to inspect by hand! This evaluation procedure imposes limitations on the information available. No conclusion can be drawn using this method about (i) the number of correct alignments that should have been, but are not, included within the best global mapping, and (ii) the number of incorrect alignments that are not included in the best global mapping.

**Results.** 85.99% of the alignments inspected were designated ‘correct’, whilst the remaining 14.01% were designated as ‘incorrect’. The mean LSA score between the two functors featuring in correct alignments was 0.731; the same score for incorrect alignments was 0.294. Statistical analysis showed this difference to be significant ( $t = 8.35$ ,  $df = 255$ ,  $p < 0.01$ ).

**Discussion.** The large proportion of alignments that are correct indicates that M-SME is mapping with great success on the Faithful Dgroups. The evidence of a significant separation between the LSA scores warranting the correct and incorrect alignments supports a naïve hypothesis that all match hypotheses a fixed number of standard deviations from the mean LSA score of the correct alignments could be rejected on the grounds that they are unlikely to be correct alignments. We feel that

---

<sup>4</sup>Given that there are a mean of approximately 900 match hypotheses formed (see Figure 1) for each of the 18 matches inspected (18 remain once the SS and FOR categories are discarded).

this is a bad hypothesis for the following reason:

Many functors that appear in the Faithful Dgroups are lexically-identical because they represent higher-order or structural relations that are not explicitly mentioned in the original natural language stories. For example, causal sequences and relations of temporal succession are rarely flagged explicitly in narratives, but instead have to be *inferred*. However, such relations are essential to producing the structured representations that SME and M-SME operate on. Therefore, because their lexical form is not given explicitly in the original materials they have to be assigned a canonical form (in the case of the Original Dgroups CAUSE and FOLLOWS were used chiefly). The great frequency of such functors in the Dgroups, which were generally aligned correctly, increases the mean of the LSA scores supporting correct alignments because identical functors receive an LSA score of 1. This makes the actual separation between the scores of the correct and the incorrect alignments smaller than the mean statistic indicates.

A consequence of this is that there is no one optimal value for the reconciliation-threshold that will effectively separate the correct from the incorrect alignments (because of the lack of a sufficiently distinct boundary between the two populations). Furthermore, a closer inspection of the LSA scores sanctioning correct alignments revealed that they were subject to a fairly wide distribution. If LSA is taken as a reasonable model of lexico-semantic information then this offers evidence that the relations that should be analogically aligned need not be semantically similar in a fixed way.

In this light, the nature of the structure-mapping algorithm urges caution in enforcing a prohibitively high value to the reconciliation-threshold. The structure-mapping algorithm makes match hypotheses, and combines them in an appropriate fashion to form global mappings. However, if the reconciliation-threshold is set at too high a value certain match hypotheses will not be formed. This can, in turn, inhibit further structural alignments (because match hypotheses can sanction other alignments under the *parallel-connectivity constraint*), resulting in the poor mapping performance that SME exhibits in Experiment 1B. It is sensible, therefore, to take the line of caution when it comes to setting the value of the reconciliation-threshold, and aim for a lower value that is more permissive.

The results here suggest that a suitable value for the reconciliation-threshold would be in the range 0.0-0.3. This should reduce the number of match hypotheses formed considerably (there are around 900 on average when the threshold is 0, and about 450 on average when it is 0.3; c.f. Figure 1), and thus decrease the computation required to combine the match hypotheses into global mappings, whilst preserving SES scores at a reasonable level and ensuring that a minimal number of correct alignments are prevented from being formed.

### Experiment 4

This final experiment is designed to conclusively test the mapping performance of M-SME on the Faithful Dgroups, with a fixed reconciliation-threshold.

**Method.** M-SME was used to perform the standard inter-set mapping task of Experiments 1A-B, with its reconciliation-threshold fixed to 0. The SES scores and number of match hypotheses formed were recorded for each category of match.

**Results.** The results of Experiment 4 are shown in Table 4. The results of the two-factor repeated-measure ANOVA analysis are as below.

*SES scores:* The only factor that produced a significant effect was  $\pm ST$  ( $F(1, 8) = 19.00, p = 0.02$ ). Both  $\pm SF$  ( $F(1, 8) < 1$ ) and interaction ( $F(1, 8) < 1$ ) effects were nonsignificant.

*Match hypothesis formation:* All three factors produced nonsignificant effects:  $\pm ST$  ( $F(1, 8) = 2.09, p > 0.05$ );  $\pm SF$  ( $F(1, 8) < 1$ ); and interaction effects ( $F(1, 8) = 1.40, p > 0.05$ ).

	LS	SS	AN	FOR
SES Category Mean	21.67	15.67	21.83	14.44
MH Category Mean	903.3	874.6	931.8	853.2

Table 4: The SES scores and number of match hypotheses formed with M-SME mapping on the Faithful Dgroups. The reconciliation-threshold is set to 0.

**Discussion.** The SES scores demonstrate the appropriate sensitivity to the  $\pm ST$  factor on the Faithful Dgroups, thus indicating that M-SME successfully generates analogical mappings on Dgroups that faithfully encode the lexical properties of the materials they are derived from. The number of match hypotheses is insensitive to  $\pm SF$  indicating that surface features are irrelevant to the formation of match hypotheses; this is a marked difference from the performance of SME in Experiment 1A.

## Conclusion

We have shown that SME’s commitment to the CR theory prevents it from generating analogical mappings on representations that faithfully encode lexical information (Experiments 1A-B). We then used the information provided by a co-occurrence model of semantics to produce an alternative model of analogical mapping, M-SME. Experiments 2A-B showed that M-SME functions as expected, but that there is no convenient measure of the *quality* of analogical mappings. In Experiment 3 the quality of alignments made by M-SME were inspected and rated for correctness. A detailed analysis of this data supported the idea that to maximise the quality of analogical mappings it is necessary to minimise the role that semantic constraints play during mapping. This result supports Gentner’s (1983) original insight that it is primarily *structural* constraints that determine analogical *mappings* (indeed, in Experiment 4 semantic constraints are effectively redundant in the mapping process). In the final experiment evidence was presented that M-SME is sensitive only to the structural properties of representations that faithfully encode lexical properties. Because a commitment to semantic links or the CR theory allows

coding decisions to reduce the search space that analogical mappers face, it is significant that M-SME can still produce mappings when presented with problems of this greater complexity. Whilst M-SME is a more expensive mapper overall, we think that a similarly improved model of the *retrieval* of analogies may enable the use of *contextual* information to reduce the search space in the mapping phase.

## Abstract

We study a computational model of the evolution of language in groups of agents to evaluate under which circumstances syntax emerges. The fitness in the model depends on the composition of the population. We find that this fact significantly alters the evolutionary dynamics. If scores are attributed to both speaker and hearer, expressive syntax is hard to obtain. If scores are attributed only to the hearer, syntax develops, but agents lose the willingness to speak. Implications and a possible solution of this paradox are discussed.

## Introduction

Among the many differences between human language and other animal communication systems, syntax is widely acknowledged to be particularly important. Syntax allows us to combine a finite set of meaningful units into an unbounded set of combinations. It allows us to speak about events happening at other times and places. It allows us to communicate about causal relations, to phrase questions or imperatives, and to share in detail previous experiences. The emergence of syntactic language is therefore considered to be one of the major transitions in evolution (Szathmáry & Maynard-Smith, 1995).

In the traditional view, syntax reconciles the need for high expressiveness with some of the natural boundary conditions on communication such as memory limitations, errors in distinguishing sounds, or bottlenecks in the transmission of language knowledge. However, present-day language fulfills many more functions than exchanging information, including facilitating social relations, individual expression, increase of status, esthetic experience and perhaps internalizing our knowledge of the world. It is unclear in what way such functions are recent side-effects, or play an important role in explaining the origins of language.

Discussions of such issues tend to be very unsatisfactory, because they seem hardly restricted by empirical or theoretical bounds. *Computational modeling* offers a

novel approach to these issues, because such models are at least restricted by whether or not the *combination* of assumptions implemented in the model yield the hypothesized outcome: syntactic language. This paper discusses a simple computational model of an evolving group of communicating individuals and studies under which selection pressures expressive, syntactic language arises. Before describing the model architecture and results, we will first briefly discuss the theoretical background and some related work.

## Evolution of language

Probably the most well-known speculation on the origins of human language is the paper of Pinker & Bloom (1990). Pinker & Bloom argue that syntax must originate in a process of evolutionary optimization, because “natural selection” is the only explanation for the origins of complex design in nature. The paper brings together a valuable collection of findings, but from a theoretical perspective it is problematic, because it lacks precision and formalization. In its weakest interpretation the central claim is trivial (there is no doubt that only members of the human species can acquire fluency in a human language) and in its strongest interpretation (“evolution has led to genes that explicitly specify a universal rule system for language”) the claim is untenable. However, the lack of a more precise aspect to Pinker & Bloom’s work, makes it hard to position their ideas between these extremes.

Moreover, Pinker & Bloom’s paper is symptomatic for the popular fallacy in linguistics that one can only choose between two explanations: (i) language originates in a genetic evolution, or (ii) language arises as the spontaneous result of general cognitive skills and social structure. We believe that putting these two explanations in opposition, excludes the most interesting part of the story. Spontaneous pattern formation (“self-structuring”) needs a mechanism to set the right parameters, and evolution needs a plausible substrate to operate on. Viewing self-structuring as a substrate for evolution (Boerlijst & Hogeweg, 1991a) offers a fresh perspective that allows one to study how evolution, genetic information, learning, development, embodiment and social structures all interact to shape

---

\*Present address: Sony CSL, 6, Rue Amyot, 75005, Paris, France; webpage: [www-binf.bio.uu.nl/~jelle](http://www-binf.bio.uu.nl/~jelle)

human language. Note that such an interactionist account differs fundamentally from a naive “some parts of language are innate, some are learned” view.

## Computational modeling

Recent work that studied such interactions in computational models has produced a wealth of new hypotheses and insights (Hurford, 1989; Hashimoto & Ikegami, 1996; Batali, 1997; Steels, 1997; De Boer, 1999; Kirby, 2000; Nowak & Krakauer, 1999; Hurford, 2000). Such models are *relatively precise* implementations of the underlying set of assumptions, and allow one to evaluate the internal coherence of such a set. Moreover, they are *productive*, in the sense that they often show unexpected behaviors that help to generate new hypotheses and concepts. And although they are necessarily simplified representations, the fact that their behavior can be experimentally evaluated makes it possible to study more complex phenomena than with analytical methods alone. Computational models therefore pre-eminently can make tractable systems with many variables and interactions.

On the issue of the origins of syntax, a number of intriguing mechanisms have been identified using computational modeling techniques. Although very diverse, they all emphasize the fact that syntax greatly increases the number of possible forms in a language. For instance, Batali (1997), Kirby (2000) and Hurford (2000) studied how *cultural evolution* can account for the emergence of syntax. Although they use several different formalisms, the common idea in this work is that the internal knowledge of language (the infinite “I-language”) is transmitted culturally (via a finite “E-language”) from one agent to another. This “transmission bottleneck” works as a filter, in which syntactic elements of language typically out-compete non-syntactic elements, because the former are inherently used more often.

Nowak & Krakauer (1999) studied a game-theoretic model of language evolution and identify a different mechanism that can account for the emergence of syntax. Using the matrix representations of Hurford (1989), they infer a “linguistic error limit”. Given that an individual makes mistakes in distinguishing sounds with a probability that depends on the similarity between those sounds, Nowak & Krakauer calculate a limit on the number of messages an individual can convey. They show mathematically that *word formation* and *syntax* can help overcome such a limit. Moreover, they show that both non-syntactic and syntactic strategies are *evolutionary stable strategies* (i.e. cannot be invaded by other strategies). However, every mixed strategy can be invaded by every mixed strategy that uses *more* syntactic sentences. Thus, the evolutionary process should lead towards grammar.

Hashimoto & Ikegami (1996) showed that syntax can emerge in an *evolving group* of communicating agents.

The agents in their model have an internal rewriting grammar, that generates a formal language using lexical or syntactic strategies. Because there is no limit on the number of rules, both strategies could in principle generate all possible strings in the finite domain that was used. However, at the start of the simulations agents are initialized with just one rule in their grammar. Because mutations add rules one at a time, and expressiveness grows much faster with grammar size using a syntactic strategy, syntactic agents out-compete non-syntactic ones.

An important aspect of Hashimoto & Ikegami’s model is that fitness is not a fixed measure, but depends on the kind of grammars that are present in the population. This leads to some counterintuitive results. For instance, they find that the most expressive agents are not necessarily the most successful and that a score for *not being recognized* accelerates the evolution of syntax. These observations are the starting point for the model study reported in this paper.

## The model

The model reported in this paper is a variant of the model of Hashimoto & Ikegami (1996). Of the many aspects that might be relevant, we study only one particular type of interaction: between evolutionary dynamics and group structure. We therefore ignore all aspects of grammar, except for the fundamental properties of compositionality and recursion. We ignore semantics, by just attributing scores for successful parsing. And we ignore learning, by assuming that agents end up with the same internal grammar, except from some changes that result from mutations in the innate component of language.

In this simplified model we will show that evolution shapes the linguistic environment of agents, but, conversely, that the group structure also shapes the evolutionary process. This interaction guides evolution in unexpected directions, and, depending on the implemented function of language, can both facilitate and hinder the development of syntax.

The model consists of a population of agents with an internal rewriting grammar, which they inherit with some mutations from their parent. The grammars are context free grammars, with nonterminal and terminal symbols from the small alphabets  $V_{nt} = \{S, A, B\}$  and  $V_{te} = \{0, 1\}$  respectively. As an extra restriction, we don’t allow the “S” at the right-hand sides of rules. At the start of most simulations, agents are initialized with a grammar with just one rule: randomly  $S \mapsto 0$  or  $S \mapsto 1$ . Agents have the ability to derive (“speak”) and parse (“understand”) strings of 0’s and 1’s of maximum length 6, using the rules from the grammar. Within these constraints the maximum expressiveness is 126. We define compositionality as using the non-terminals A and B, and recursion as using rules that were used before in the same branch of the rewriting tree.

Agents interact in a set-up of “language games”. In every game all agents can speak one string and try to recognize the strings produced by other agents. Every generation a number of games is played and scores are attributed for successful communication. In most simulations, we use an explicit “innovation pressure”. This pressure is implemented by discounting scores with the number of times a string is already heard before, and corresponds to a semantic need for a rich repertoire of forms. We designed several scoring schemes that reflect hypotheses on the function of language. The most important schemes are labeled “communication” and “perception”:

**communication** corresponds to a selection pressure to optimize the total of exchanged information, such that both the speaker and the hearer benefit from successful communication. This pressure is implemented by a score for recognition and for being recognized.;

**perception** corresponds to a selection pressure to optimize the total of information received, in order to make use of the knowledge of others (as if one indirectly shares someone else’s *perception*). This pressure is implemented as a score for recognition;

We replace all agents every generation with offspring of the present population. The number of offspring of an agent depends on the total score it has received relative to other agents. Random mutations are applied to the offspring with fixed probabilities for modification of existing rules (“replace”), duplication of a random rule (“add”) or deletion of a rule (“delete”). We also implemented a mutation “shift”, that swaps a rule with the previous rule in the grammar and occurs with a probability per rule. These mutations correspond to conventions in evolutionary programming and allow for optimizing some of the relevant features of grammars, but otherwise they are more or less arbitrary.

### The group effect

Fitness in this model is not a static function of an agent’s grammar (“genotype”), but it depends on the grammars of other agents too. The general observation in experiments with the model with many different parameter settings is that this fact strongly influences the evolutionary dynamics (Hashimoto & Ikegami, 1996). The success of an agent’s individual language is determined by how well it matches the language of the whole group, rather than by how much information it can encode (“expressiveness”). We call this phenomenon the “group effect”.

Figure 1(a) shows an example simulation, with a “communication” scoring scheme and “innovation”, that shows clearly some of the mechanisms that play a role. From the initial level of expressiveness of 1, the

(a) Expressiveness over 9000 generations

(b) The same run in a “phase space”

Figure 1: An example run with very clear epochal evolution. Shown are the running averages and individual agents at every tenth generation. Note that most individual points are hidden under the grey line. (a) During an epoch, expressiveness stays at a fixed level. In fact, in the first stage ( $E=31$ ) the dominant language stays exactly the same for thousands of generations. Individual agents with higher expressiveness occur, but are not able to survive in the group. (b) Grammars do vary, however, which is possible because of the neutrality in the grammar–language mapping (see text). In the phase space, one can clearly see that grammar size fluctuates during an epoch. All jumps to higher levels take place when grammars are relatively large. Such grammars are clearly larger than necessary and have a neutral tails. Parameters: default “communication” run with innovation pressure (see section “selective advantages”)

population evolves within several hundreds of generation to a level of 31. At this point, evolution has developed via selection and random mutations grammars that are redundant and not very structured, and combine several strategies in the rewriting process from the start symbols “S” to a distinct sequence of terminal characters.

For a very long time, from around generation 860 until 5510, the population remains fixed at a level of expressiveness of 31. Analysis of the language reveals that the set of strings of the majority of agents remains unchanged for this whole period. However, frequently agents appear that have a much higher level of expressiveness. This illustrates that (i) the mapping from grammar to language is very non-linear, because a single mutation can make a dramatic change in the size of the language, and (ii) there is a very strong group effect, because agents that have a much higher expressiveness (and thus are “objectively” much better), can nevertheless not persist in the population. The reason is that the languages of these agents differ too much from the language of the group. The agents therefore obtain fewer scores for being recognized and possibly even for recognizing.

Another striking observation in this simulation is that, although the languages remain unchanged for several thousands of generations, the grammars undergo a constant reorganization. This illustrates that the mapping from language to grammar is not only non-linear, but also very redundant.

Figure 1(b) shows a graph of the same simulation in a “phase space” that shows the average grammar size versus the average expressiveness at each generation. As one can clearly see, once a certain level of expressiveness is reached, the evolutionary process “wanders around” for a long time, without significant changes in the expressiveness (“neutrality”). Only when the grammars are relatively large, and thus have many unused, redundant rules, a chance event causes the population to jump to a new level of expressiveness. This chance event is that two agents mutate to the same richer language, and thus can obtain in their mutual communication enough scores to compensate for differing from the group. This mechanism relates to the idea of “neutral networks” — networks of connected points in genotype space that correspond to the same phenotype — that forms a good explanation for the occurrence of “epochs” or “punctuated equilibria” in evolving systems with a fixed fitness function (Van Nimwegen *et al.*, 1999).

### Selective advantages

While the “group effect” occurs under all parameter settings of the model, its role can be quite different for each of the scoring schemes and the initial grammars we considered. We observe compositional and recursive grammars only in about half of the parameter combinations we considered. Even if scores are explicitly discounted with the number of times a string is already used before (“innovation pressure”), expressive syntax does not necessarily emerge.

This fact is surprising, because the intuitive expectation is that expressiveness is selectively advantageous. Indeed, with (i) an *explicit* innovation pressure, the

Figure 2: *Communication with innovation pressure for three different types of initial grammars. With a sufficiently large initial lexical grammar, expressive syntax can not develop.*

average score per agent has its optimum at maximal expressiveness. However, *implicitly* expressiveness influences the scores in other ways as well: (ii) expressive speakers are more likely not to be understood, and (iii) expressive listeners are more likely to understand.

This leads to an interesting interplay between each of these roles of expressiveness and the group effect. Under communication settings (ii) not being recognized is *disadvantageous*, while (iii) recognition is *advantageous* and in both scoring dimensions similarity to the group’s language is important. Under perception settings (ii) not being recognized and (iii) recognition are beneficial, while similarity to the group’s language is important for recognition, but *dissimilarity* is better for not being recognized (and thus hindering one’s competitors). Moreover, the strength of the group effect depends on the size of the group’s language and the variation within the group. In various experiments we obtained the following results:

**communication** does not lead to highly expressive grammars with the default initial grammar and without the innovation pressure. If the initial grammar is an expressive, recursive grammar, the high level of expressiveness can be maintained. In contrast, with a medium size lexical grammar, grammars remain lexical and expressiveness remains limited.

With an innovation pressure and the default initialization expressive syntax eventually does develop. In this type of runs we observe a stepwise development, with typically long intervals at the same level of expressiveness. Expressive syntactic grammars are reached only after very many generations. With an expressive, recursive initial grammar, the high level of expressiveness can be maintained. With a medium size lexical grammar expressiveness remains limited and no syntax develops (see figure 2).

With “communication” as the function of language,

Figure 3: A typical example of a simulation with “perception” settings, the default initial grammar and an innovation pressure. Shown are the average expressiveness over time, and the percentage of failures in derivation. After around 3000 generations this percentage approaches 100, indicating that very little communication is maintained.

syntax can thus be maintained if present, but is hard to obtain. If the initial grammar is of sufficient size and of a lexical type, syntax never develops. These results are particularly interesting, as they resemble the situation that is traditionally thought to precede the emergence of grammar: large, lexical protolanguages, with communication benefits for both speaker and hearer.

**perception** shows rapid growth in expressiveness in most cases considered. With the default initialization and no innovation pressure, expressive syntax develops within a few hundred generations. With the lexical initialization it takes much longer, but the development of syntax was usually observed.

With an innovation pressure and default initial grammars the growth is generally slower than without such an innovation pressure. Infrequently, we even observe runs that remain lexical throughout the simulation. When initialized with an lexical grammar, the runs with innovation pressure show such behavior.

“Perception” thus yields expressive syntax in most cases considered (see figure 3). The benefits of *not being understood* seem to be a strong incentive to develop more expressive language. Interestingly, an innovation pressure makes the development of syntax *less* likely. Apparently, the fact that the hearer benefits from richer input hinders this development.

## Paradox

Another striking feature of perception runs is the high number of failures that occur in derivation (see figure 3). Apparently, agents develop grammars that are able to parse a high number of strings, but nevertheless frequently fail in derivation. This is possible because of the asymmetry in parsing (complete bottom-up search of the derivation tree) and derivation (random top-

down walk). This possibility was not implemented intentionally. Nevertheless, the evolutionary process discovered it and “actively” exploits it.

This observation points at a important assumption in the model: agents are forced to participate in the language game. A classic altruism problem thus arises: if speaking behavior is beneficial only for an individual’s competitors, why would it be retained in evolution? We extended the model with a parameter for probability to speak. Under perception settings this parameter indeed quickly evolves to zero.

Interestingly, these results constitute a paradox: under those circumstances that syntactic expressiveness develops, willingness to speak disappears. Under the circumstances where willingness to speak is retained, syntactic language does not develop. We studied a possible solution for this paradox in a model where agents are localized on a 2D grid and interact only with their immediate neighbors. Such spatial models are known to naturally yield altruism, because spatial patterns make multilevel evolution possible and kin selection more likely (Boerlijst & Hogeweg, 1991b).

The willingness to speak can be retained in the spatial model with perception settings. The parameter that determines the probability of an agent to speak at its turn in the language game, is initialized at 0.1. As one can see in the example of figure 4, the average value rapidly evolves to a high value close to the maximum. Spatial patterns are responsible for this selection pressure towards altruistic behavior. If one destroys the spatial patterns, also the willingness to speak disappears.

Figure 4: Perception in space. Shown is the average fraction of the maximum of expressiveness (maximum is 126) and willingness to speak (maximum is 1). Parameters are: initial population size = 2000, number of games per generation = 1, maximum string length = 6, minimum number of understanders = 0,  $m_{add} = 0.1$ ,  $m_{rep} = 0.01$ ,  $m_{del} = 0.01$ , maximum number of parsing steps = 500, maximum number of derivation steps = 60, self-interaction not allowed, discount factor 1.0, scores proportional to string length

## Discussion

Some of the striking differences in the results of different scoring schemes can be better understood by looking at a very simple game-theoretic model, where there are just two agents and two levels of expressiveness. If we work out the language games that take place in such a set-up, we find that both the low/low and the high/high situations are equilibria in the communication case, but in the case of perception only the high/high situation is an equilibrium. These results qualitatively corresponds to the results we obtained in the simulations.

The essential observation here is that, although homogeneous high expressiveness is the “best” solution, *unilateral* high expressiveness under communication setting is in fact disadvantageous. It seems a promising approach to extend this game-theoretic analysis to a more general case, with more levels of expressiveness and more interacting agents. However, many aspects of the model behavior depend on the non-linear mapping between grammar and language and can not easily be captured in such an analysis.

## Conclusions

Traditionally the origins of language are thought to be explained as either the spontaneous result of human cognitive abilities and social interactions, or the result of an evolution of our innate language capacity. This model study shows an example system where both social interaction and evolutionary updating play a role. Not because one part of language can be explained by “nurture” and another part by “nature”, but because they fundamentally interact: social interactions shape the evolutionary process and vice versa.

Also, traditionally language and the evolution of language are studied in terms of how much information about the outside world can be transmitted. Our results suggest that this might not always be the most interesting way of looking at language, because language can have its own dynamics within a group that is quite independent from how well it represents the outside world.

Moreover, this model study shows results that deviate from the traditional picture that lexical protolanguages became larger and larger until syntax became necessary. If communication is beneficial for both speaker and hearer and the population uses an extensive lexical language, syntax does not develop. If the traditional picture holds, the question arises which mechanisms are responsible for the differences.

Finally, spatial patterns have not played much of a role in speculations about the origins of language. Results from this study suggest that such spatial patterns can be relevant. The fact that present-day language shows obvious spatial patterns indicates that a global approximation perhaps excludes important

mechanisms.

Many open questions remain. For instance, under perception settings there is an *indirect benefit* of speaking that leads to high values of the willingness to speak. Why then, does this indirect benefit not result in the same disadvantage of unilateral high expressiveness that we observe under communication settings? Such intriguing issues are left for future work.

## Acknowledgements

## Abstract

It is well established that people can categorize the same objects at different levels of abstraction (i.e., superordinate, basic, and subordinate). Of these, the basic level is known to have a privileged status that is often attributed to the organization of categories in memory. Here, we argue that the bias could in part arise from the image formation process itself—i.e., the object properties for categorization that arise from the 2D retinal projections of distal 3D objects. In the real world, people do categorize objects from a variety of viewing distances and these modify the availability of object information on the retina. In two experiments, we tested the hypothesis that the information for basic categorizations is more resistant to changes in viewing distance than that of subordinate categorizations.

Casual observers would experience little difficulty to categorize the animals in Figure 1 as exemplars of *dog* and those of Figure 2 as exemplars of *whale*. If they were “experts”, they could categorize these animals as *Saint-Bernard dog*, *Doberman dog*, *Sperm whale*, and *Humpback whale*. People can similarly apply different levels of category abstraction to the 3D distal objects that impinge on their retina.

Rosch et al.’s (1976) seminal research isolated three “natural” levels of object categorization: the superordinate (*animal*, *vehicle*, *furniture*), the basic (*dog*, *car*, *chair*), and the subordinate (*Saint-Bernard dog*, *Porsche*, *Chippendale chair*). Of these, the basic and subordinate are thought to be closer to perception and we will focus on their main differences. The former level is superior to the later in a number of ways:

(1) Categories at the basic-level are verified fastest (see also Hoffmann & Ziessler, 1983; Jolicoeur, Gluck & Kosslyn, 1984; Murphy, 1991; Murphy & Smith, 1982; Murphy & Brownell, 1985; Tanaka & Taylor, 1991).

(2) Objects are named faster at the basic than at the subordinate level (Hoffmann & Ziessler, 1983; Jolicoeur, Gluck & Kosslyn, 1984; Murphy, 1991; Murphy & Smith, 1982; Murphy & Brownell, 1985; Rosch et al., 1976; Tanaka & Taylor, 1991; Johnson & Mervis, 1997).

(3) Objects are preferentially designated with their basic-level names (Berlin, 1992; Brown, 1958; Rosch et al., 1976; Tanaka & Taylor, 1991; Wisniewski & Murphy, 1989).

(4) Throughout development, basic names are learned before subordinate names (Anglin, 1977; Brown, 1958; Rosch et al., 1976; Horton & Markman, 1980; Markman, 1989; Markman and Hutchinson, 1984; Mervis and Crisafi, 1982).

(5) Basic names tend to be shorter (Brown, 1956; Rosch et al., 1976).

The origin of the bias to the basic level is still a matter of debate. In categorization, researchers have proposed that categories at the basic level are more *differentiated* that is, “... have the most attributes common to members of the category and the least attributes shared with members of other [contrasting] categories.” (Rosch et al., 1976, p. 435) The first component of this differentiation definition has been called the *specificity* (Murphy & Brownell, 1985), or the *informativeness* (Murphy, 1991) of a category, and the second component the *distinctiveness* of a category (Murphy & Brownell, 1985; Murphy, 1991). The difference between basic and subordinate categorizations would thus stem from distinct differentiations at these two levels. But the origin of these remain unspecified.

In recognition, researchers have sought to ground the basic level advantage on object properties (i.e., feature content). Rosch et al. (1976) found that basic-level categories are the most inclusive categories at which objects look alike. This suggests that shape is an important factor in the advantage of the basic over the subordinate level. One determinant of shape is part structure. Tversky and Hemenway (1984) found—for a broad range of natural categories including objects and organisms—a little increase in the number of listed parts from the basic to the subordinate level. Parts could therefore be a main determinant of basic-levelness. Jolicoeur, Gluck, & Kosslyn (1984) proposed that objects are initially recognized at the basic level on the basis of their parts, but also that these parts index the entry point to recognition. Entry point categories are usually at the basic-level but not always. To access categories below the entry point, such as Rosch’s subordinates, *additional perceptual information* is required (see also Biederman, 1987). This additional information was, however, left unspecified. Reflecting on the state of the art in object recognition, it is fair to say that the relationships between the basic level preference and its perceptual determinants are at a standstill.

From this brief review of the literature, two main stances emerge regarding the advantage of basic level over the subordinate categorizations:

(1) Categorization researchers have argued that the organization of categories in memory produces the faster access to the basic level (e.g. Murphy, 1991).

(2) Recognition researchers have proposed that categorization is faster at the basic level because the visual system is geared to extract parts from the input, and parts represented categories at the basic level (e.g. Biederman, 1987).

We will here present and test a third, and possibly simpler alternative: The bias for the basic level could arise

from natural constraints on the image formation process that modifies the perceptual availability of object cues with changes of viewing distance.

People who recognize common objects tend to do so over a wide range of viewing distances. For example, you need to recognize your car at a distance in a parking lot, but you also need to recognize it from a closer range, when you are about to unlock its door.

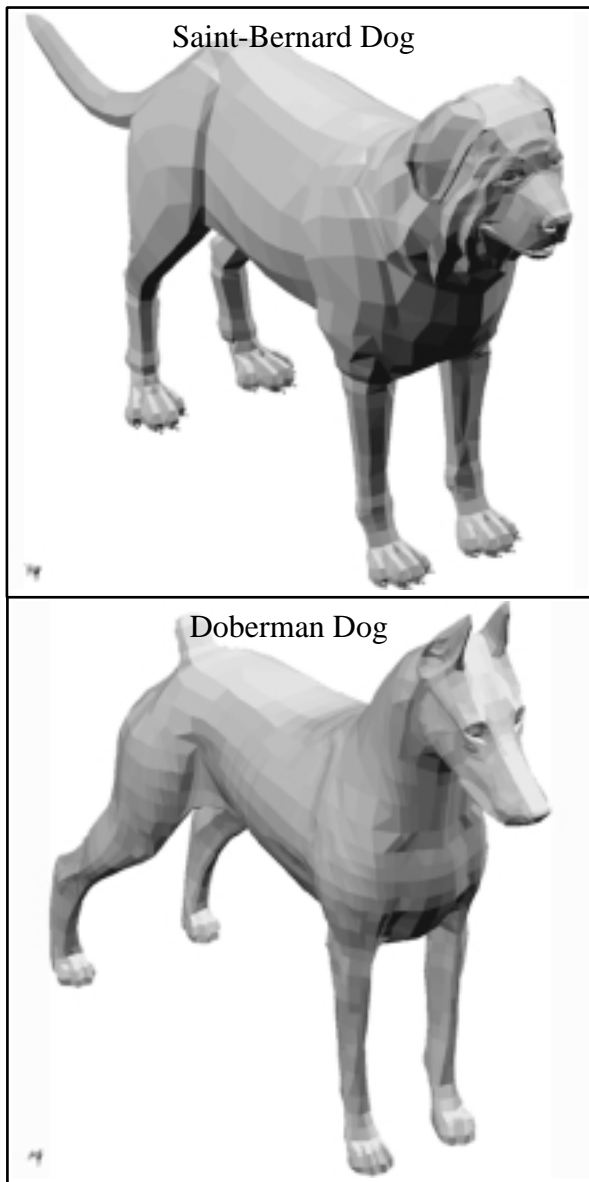

Figure 1. Three-quarter right views of the Saint-Bernard and the Doberman Dogs used in experiments 1 and 2. The figure respects the proportions of the stimuli, not their absolute sizes: the large animals occupied 12 deg of visual angle; the small ones (see dark spots at the bottom-left of each large animal) .38 deg.

However, a simple computational argument can be made that changing the size of the retinal projection also changes the information available in the image for identification. Simply put, reducing the retinal projection of an object by a factor of two reduces its sampling frequency by the same factor. Simplifying a little, if one starts with a 512x512 original image, the reduction samples one pixel every other pixel to produce a 256x256 image.

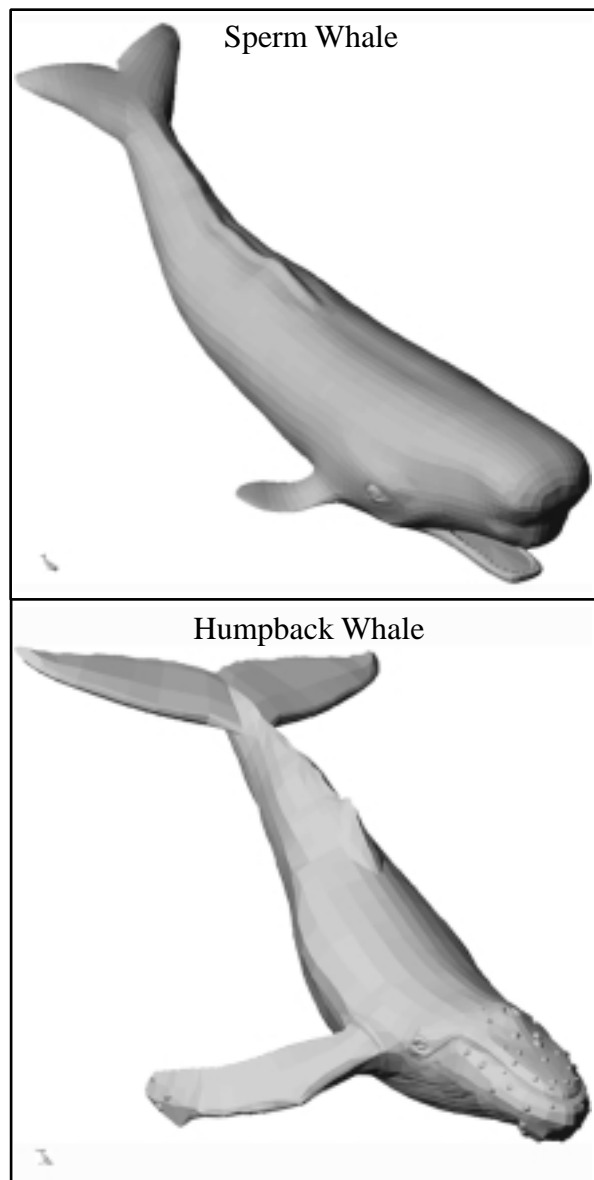

Figure 2. Three-quarter right views of the Sperm and Humpback Whales used in experiments 1 and 2. The figure respects the proportions of the stimuli, not their absolute sizes: the large animals occupied 12 deg of visual angle; the small ones (see dark spots at the bottom-left of each large animal) .38 deg.

Any variation that was expressed between any two adjacent pixels of the original image (e.g. a black and white contrast) is lost in the reduced image. (Technically, shrinking an image eliminates its high spatial frequency information). This produces a marked loss in information for visual categorization.

If we hypothesize that different basic and subordinate categorizations require visual information that resides at different scales of the stimulus, changing the scale of one stimulus could produce markedly different patterns of categorization performance. For example, removing large-scale information by reducing the size of objects could selectively impair the categorization level requiring the most specific details—i.e. the subordinate level. If this were the case, a bias to the basic level could arise from the statistics of categorization attributes over a wide range of viewing distances. Specifically, the attributes

that access the basic level could have a greater resilience over scale changes than those accessing the subordinate level. This natural bias on the availability of perceptual cues would shed a new light on the structure of the basic level. We would still not know exactly what is this “additional information” required for the subordinate, but we would know that it is resistant to scale changes.

## Experiment 1

Experiment 1 was designed to investigate the interaction between the scale of objects and their levels of categorization. Stimuli were three-dimensional (3D) gray-level computer synthesized animal categories (*bird, cow, dog, horse, frog, turtle, spider* and *whale*) (e.g., see figures 1 and 2). A similarity judgment task required participants to establish whether two simultaneously presented animals were the same either at the BASIC level (e.g., are both pictures *cow* exemplars?) or at the SUBORDINATE level (e.g., are the two pictures the same cow?). The animal pairs represented either two identical individuals (e.g., the same cow), two members of the same animal category (e.g., two different cows) or two members of a different animal categories (e.g. a cow and a bird). Animal pairs could appear in one of six possible different sizes. Each pair stayed on the screen as long as participants deemed it necessary (self-paced judgments). If the perceptual cues needed for BASIC and SUBORDINATE judgments are available regardless of the scale of the objects, participants should not differ in performing basic and subordinate similarity judgments. However, if information differs for BASIC and subordinate categorizations, a reduction in stimulus size might differently affect performance.

It is important to stress that this task involves absolute levels of information. That is, participants can use all the information present in a stimulus pair, as the two animals remained on the screen until a similarity judgment was made. Failure to notice a difference in these conditions would imply that the required information had vanished.

### Participants

Twenty Glasgow University students with normal or corrected vision were paid to participate in the experiment.

### Stimuli

Stimuli were computer-synthesized 3D animals. The set of animals was composed of 8 different animal categories (*bird, cow, dog, horse, frog, turtle, spider* and *whale*), each comprising 2 different exemplars. All animals were presented at one of six different sizes. The largest size corresponded to 512 square pixels and the smallest one to 16 square pixels. Successive divisions (by 2) of the largest pictures produced all intermediate sizes. These sizes were 256, 128, 64, and 32 square pixels. They corresponded to about 12, 6, 3, 1.5, .75 and .38 degrees of visual angle, respectively. In total, 96 stimuli were created (8 animal categories \* 2 individuals \* 6 sizes). In addition, each object could be presented from two different viewpoints (separated by 95 degrees of rotation in depth), so that when two objects appeared in a pair they would never be strictly identical pictures and people would need to recognize the represented animals to judge their similarity.

### Procedure

Before starting the experiment, each participant was instructed that they needed to make two different types of similarity judgments. To the question “Same animal category?” participants had to judge whether the two presented animals belonged to the same animal category (e.g., are both animals dogs?). To the question “Same individual?” the task was to decide whether both animals were the same exemplar (e.g., are both dogs the same individual?). Participants were told to take as long as they wished and to look very carefully at each animal pair before making a decision.

A trial started with the apparition of one animal pair on the computer monitor. The two animals appeared simultaneously and were always pictured from a different viewpoint. Participants could observe the animal pair for as long as they wished. A keypress would substitute that animal pair with a question of the screen. The question was either “Same animal category?”, “Different animal categories?”, “Same individual?” or “Different individuals?”. They then entered their judgment by pressing “yes” and “no” keys on the computer keyboard.

Experiment 1 comprised 4 main classes of trials depending on whether there was a match (vs. non-match) at the BASIC (vs. SUBORDINATE) level. Match trials at the BASIC level represented different animals from the same animal categories (e.g., two different dogs), whereas non-match trials represented animals from different animal categories (e.g., a dog and a cow). Match trials at the SUBORDINATE level represented 2 pictures of the same individual from a different viewpoint whereas non-match trials presented pictures of different individuals. With these specifications, BASIC-match and SUBORDINATE-non-match trials comprised the same animal-pairs. The experiment included 768 trials and lasted for about forty minutes. The order of trials was randomized across participants.

## Results and Discussion

Remember that Experiment 1 sought to assess the interaction between the scale of objects and the level of categorization (basic vs. subordinate). Specifically, we tested that participants were equally good at assessing similarity judgments when they were required to do it at the basic level (e.g. same animal category?) and at the subordinate level (e.g., same individual?) when the scale of objects was large. A  $d'$  measure, which includes both Hit (H) rate (saying that two animals are different when they are different) and False Alarm (FA) rate (saying that two animals are different when they are identical), was used as our dependent variable. The top of Figure 3 shows the average  $d'$ s across all subjects at the different scales and categorization levels.

A two-way, within-subjects ANOVA revealed significant main effects of size (512, 256, 128, 64, 32, 16 square pixels)  $F(5, 95) = 38.59, p < .01$ , level of categorization (Basic vs. Subordinate),  $F(1, 19) = 66.29, p < .01$ , and a significant interaction between these factors,  $F(5, 95) = 5.80, p < .01$ . Further analysis revealed that differences between levels of categorization were true for 16 square pixels,  $F(1, 19) = 119.73, p < .01$ , 32 square pixels,  $F(1, 19) = 87.38, p < .01$ , 64 square pixels,  $F(1, 19) = 6.52, p < .01$ , 128 square pixels,  $F(1, 19) = 41.44, p < .01$  and 256 square pixels,  $F(1, 19) = 13.11, p < .01$ , but

not for 512 square pixels,  $F(1, 19) = 7.14$ , *ns*.

Furthermore, the slope of the best subordinate linear predictor in Figure 2, top, is about twice as much as that of the basic (see continuous lines in Figure 3, top;  $R^2 = .63$  and  $.81$  for the best basic and subordinate fits).

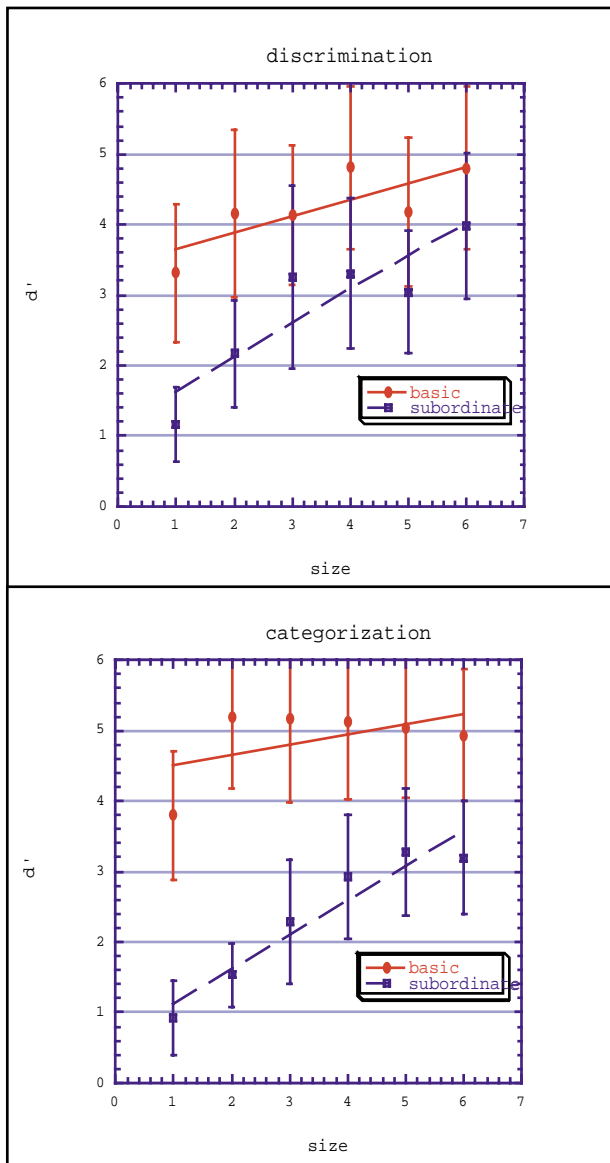

Figure 3. Average  $d'$ s with standard deviations for Experiments 1 and 2 at the basic and subordinate categorization levels. The continuous lines are the best linear predictors. (Note that size 1 = .38 deg and that size 6 = 12 deg.)

Results reveal that at smaller scales (256 to 16 square pixels) identical animals pairs were easier to distinguish at the basic level than at the subordinate level (see Figure 3, top).

## Experiment 2

Experiment 1 revealed that the information of SUBORDINATE-level judgments was less resilient to changes of scale than BASIC-level judgments. This is interesting because participants could use all the information available in the stimuli to resolve the task. It therefore suggests that the information for subordinate categorization vanished before that of basic

categorizations.

However, one could oppose that the matching task of Experiment 1 might solicit representations and processes that are atypical of everyday categorizations. For instance, it is conceivable that participants relied simply on local one feature-difference to decide that two stimuli differed—e.g., if one of the two stimuli had a tail. Of course, this would not explain how they did when the stimuli did not differ, but it still triggers the more basic problem of generalizing from the results of Experiment 1 to realistic categorizations.

Experiment 2 was designed to directly probe everyday categorization processes. One criticism that is often leveled at experiments studying the nature of visual information in categorization tasks is that they use tachoscopic conditions of stimulus presentation. Here, we made sure that the stimuli stayed on the screen for as long as the subjects felt necessary. This approach allows a measure of categorization performance in conditions of absolute information—i.e. information availability is not relative to speed of presentation.

Experiment 2 was a free categorization task. In a learning phase, participants learned to identify each of the sixteen animals at the basic and subordinate levels. They were then transferred to a categorization task where an animal (e.g., a whale) would appear on the screen (at one of 6 possible scales). After a self-paced scrutiny of the picture, participants were asked a question about the membership of the input to either a basic-level (is this a whale?), or a subordinate category (is this a sperm whale?). If the results of Experiment 1 tapped into the absolute levels categorization information then we expect the categorization results of Experiment 2 to follow a similar trend—i.e., a faster decrease of subordinate categorization accuracy with decrease in stimulus scale.

### Participants

Twenty Glasgow University students with normal or corrected vision were paid to participate in the experiment.

### Stimuli

The training set comprised gray-scale pictures of the 16 different individual animals. For each animal two pictures (showing the animals from two different view points—95 degrees apart in depth) were printed onto a white sheet of paper side by side. Pictures measured in total 10 x 10 cm. Each individual was identified by a sentence printed underneath the pictures. For example the two whales were identified as *sperm whale* and *humpback whale* (see Figure 2).

The stimuli used for the categorization task were the ones of Experiment 1 (e.g., see figures 1 and 2). The set consisted again of the 8 animal categories (2 individuals per animal category), the six different sizes and the two different viewpoints.

### Procedure

During the training phase, participants learned to identify each of the sixteen animals at the basic and subordinate levels. We tested their knowledge by presenting them with the pictures alone, one at the time, and asking them to name the animal at the basic and subordinate levels. *Perfect naming* performance was

required before going on to the categorization task. Corrective feedback was provided.

In the categorization task, participants were shown an animal on a computer monitor. Animals were presented from one of the two possible viewpoints and were displayed at one of the six different sizes. Participants were told that they could look at the animals for as long as they wanted. Once they were ready, a key press would initiate the disappearance of the animal and would display a question on the computer monitor. The question could either be basic ("Is it a cow?") or subordinate ("Is it a Friesian cow?"). Participants responded by pressing the appropriate key on the keyboard. The experiment included 768 randomized trials and lasted for about 50 minutes.

## Results and Discussion

Remember that Experiment 2 was designed to replicate results of Experiment 1 with a categorization task. We were thus interested mainly in the proportion of correct responses. For each subject, we computed  $d$ 's for all sizes and categorization levels. The bottom portion of Figure 3 shows the mean  $d$ 's across subjects for the different sizes and categorization levels.

A two-way, within-subjects ANOVA revealed significant main effects of size (512, 256, 128, 64, 32, 16 square pixels)  $F(5, 95) = 36.79, p < .01$ , level of categorization (Basic vs. Subordinate),  $F(1, 19) = 418.62, p < .01$ , and a significant interaction between these factors,  $F(5, 95) = 5.75, p < .01$ . Further analyses revealed that differences between levels of categorization were true for 16 square pixels,  $F(1, 19) = 174.53, p < .01$ , 32 square pixels,  $F(1, 19) = 379.61, p < .01$ , 64 square pixels,  $F(1, 19) = 119.23, p < .01$ , 128 square pixels,  $F(1, 19) = 68.95, p < .01$  and 256 square pixels,  $F(1, 19) = 39.41, p < .01$ , and for 512 square pixels,  $F(1, 19) = 47.91, p < .01$ .

The continuous lines on Figure 3, bottom, are the best linear predictors for the basic and subordinate  $d$ 's ( $R^2 = .26$  and  $R^2 = .92$ , respectively). The slope of the subordinate line is more than three times that of the basic one.

Results thus reveal that, animals were easier to categorize at the basic level than at the subordinate level (see Figure 3, bottom).

## General Discussion

This article tested the prediction that the preference for basic level categorizations could arise from a natural source of biases. When the retinal projection of one object shrinks in size (as happens when the object is moved further away from the observer), scale-specific visual information is lost. We tested the hypothesis that the basic and subordinate categorizations of identical objects require information that resides at different scales of the same distal stimulus. Two experiments tested these predictions.

In Experiment 1, participants in a similarity task were asked to judge whether two simultaneously presented objects had the same basic level, or the same subordinate category. We found that even though subjects could take *as long as they wanted* to inspect the object pairs, subordinate judgments were significantly more affected by a reduction in stimulus size than basic judgments. The

unconstrained inspection licenses the conclusion that we are tapping into the absolute level of information required for basic and subordinate categorizations.

Experiment 2 addressed the objection that a similarity task might trigger processes and representations that are atypical of everyday categorizations. In a categorization task, subjects had to confirm that the input belonged to a basic, or to a subordinate category. Even though subjects could again scrutinize the stimuli without any time constraint, we found that subordinate categorizations were much less resilient to changes of stimulus size.

In sum, the two experiments reported here converge on the idea that the perceptual shape cues required to resolve subordinate categorizations are more sensitive to scale changes than those required of basic categorizations. This has a number of implications for theories of basic and subordinate level categorization and recognition that we consider in turn.

Remember that we hypothesized a natural bias for the shape cues that access the basic level because these might be more resilient to variations in viewing distances. The results confirmed the hypothesis. Our results predict that the more robust default categorization strategy is to categorize objects at the basic, not the subordinate level. It is important to stress that we do not know precisely what the important basic and subordinate cues were in our experiments. However, to the extent that basic categorizations were not much affected by changes in size, we can propose that the cues present at all sizes (i.e. coarse scale cues) supported basic categorizations. For example, silhouettes were clearly present at all sizes and they could very well subtend basic categorizations—at least in the tasks considered here. An alternative could be that different cues residing at different scales can independently index the basic level, a hypothesis that has never been explored. If part extraction relies on the fine-grain edge description outlined in Biederman (1987), it seems unlikely that a part description of the objects subtended basic categorizations in our experiments, because Biederman's (1987) part description process is sensitive to scale.

## Concluding Remarks

We have shown here that size matters for subordinate categorization. One possibility for the basic level bias results from the greater resilience of basic level cues over a range of viewing distances. Future research will need to be conducted to isolate what the scale-independent and the scale-dependent cues are that support basic and subordinate categorizations.

## Abstract

Subgoal learning is examined through the use of equations that are designed to encourage a conceptual rather than computational approach to solving problems (conducting statistical tests). Learners who studied conceptually-oriented examples transferred more successfully to novel problems compared to learners who studied computationally-oriented examples. These results extend prior work on subgoal learning by demonstrating another technique for aiding subgoal learning.

## Introduction

Research suggests that learners typically struggle when they are obligated to solve problems that have different procedural requirements than those demonstrated by training problems or worked-out examples, even if those differences are relatively slight (e.g., Catrambone, 1995, 1996, 1998; Novick & Holyoak, 1991; Reed, Dempster, & Ettinger, 1985). This difficulty may stem in part from the fact that learners often represent the problem solving procedures of training problems or worked-out examples as a set of linear steps rather than forming a hierarchical representation that could permit them to successfully solve novel problems (Dufresne, Gerace, Hardiman, & Mestre, 1992; Singley & Anderson, 1989)

Educators and researchers alike are concerned with this problem. In fact, the Committee on Developments in the Science of Learning (1999) recently suggested that “a major goal of schooling is to prepare students for flexible adaptation to new problems and settings [and that] students’ abilities to transfer what they have learned to new situations provides an important index of adaptive, flexible, learning” (pp. 223). Research indicates, however, that this goal is rarely achieved (Chi, Feltovich, & Glaser, 1981; Larkin, McDermott, Simon, & Simon, 1980).

Presumably, emphasizing the structure of an example through instruction will increase flexible transfer by helping the learner look beyond the surface features of the example and test problem to find the goal-related features that can be used to solve the problem. Thus, instead of committing to memory the details of

equations as the basis for one’s problem solving knowledge, a more productive approach would be to organize this knowledge in such a way that it could support generalizations across problems in a domain. One type of knowledge structure that appears to offer the promise of enhancing this type of procedural generalization is one organized around subgoals.

## Subgoal-Oriented Instruction

As used in the present paper, a subgoal denotes a meaningful conceptual piece of an overall solution procedure. Subgoals are particularly useful to learners because they can assist them in solving novel problems since problems within a domain often share a common set of subgoals, albeit the steps for achieving the subgoals vary from problem to problem within a domain. Once learners become familiar with the typical subgoals in a domain, this knowledge can assist them in identifying which part of a previously-learned solution procedure needs to be modified in order to solve a novel problem (Catrambone, 1996, 1998).

Recently, a line of research has emerged examining the efficacy of subgoal-oriented instruction (Catrambone, 1995, 1996, 1998). In particular, this line of research has explored several techniques for designing examples that help learners to form subgoals to represent the purpose of steps in an example’s solution. Across a series of studies, Catrambone investigated the impact of making the goal structure of an example’s solution explicit by using manipulations such as the use of solution step labels or visually isolating parts of example solutions. These studies indicated that if examples are designed in such a way as to encourage subgoal learning, then learners are more likely to correctly solve new problems that involve the same subgoals but require new steps for achieving them.

These studies also suggest that example solutions that are segregated or labeled encourage learners to self-explain how the steps go together. One result of his self-explanation process is the formation of subgoals (Catrambone, 1998). This work parallels research in the text-comprehension literature on the effects of signals

or cues on text-processing strategies (e.g., Lorch & Lorch, 1995; Meyer & Rice, 1989). Just as organizational signals in text induce learners to change their text-processing strategy by cueing the important text content and its organizational structure, worked-example labels are intended to increase the likelihood that learners will discern the hierarchical conceptual structure of the problem contained in the example.

### Factors that May Influence Subgoal Formation

As previously mentioned, several structural manipulations have been found to successfully make the goal structure of a problem's solution explicit, such as by the use of labels or visual isolation. But, there might be other factors that influence subgoal information. For instance, two potential factors are the nature of equations used in examples and the presence of conceptual elaborations.

**Conceptual vs. Computational Equations.** The process of calculating sum of squared deviation scores or sums of squares (SS) for the variance terms in t-tests and analyses of variance (ANOVAs) can involve two noticeably distinct types of formulas: conceptual and computational. According to Gravetter and Wallanu (2000), the conceptual formula is useful "because the terms in the formula literally define the process of adding up the squared deviations" (p. 121). For instance, the conceptual formula for SS in a t-test,  $\sum (X - \bar{X})^2$ , translates directly into the sum of ( $\sum$ ) squared deviations  $(X - \bar{X})^2$ . This clearly captures how the variance term measures the amount of spread about the mean.

In contrast, the computational formula for SS,  $\sum X^2 - \frac{(\sum X)^2}{N}$ , permits the learner to calculate SS directly from raw scores which can lead to more efficient calculations. However, there is a notable drawback to this convenience: the computational formula conceals the true meaning behind SS. Unlike the conceptual formula, a learner cannot directly translate the terms in the computational formula into a sum of squared deviation scores. As a result, the learner may not grasp that this formula is designed to measure the amount of spread about the mean.

On the one hand, the computational approach might aid performance on problems that are just like the examples that illustrated the approach, but might make far transfer difficult. That is, in the computational approach, the equation is streamlined for doing the calculations, but "hides" what is really going on. On the other hand, the conceptual approach, although typically more cumbersome computationally, clearly shows how the variance is related to the difference of each mean from

the grand mean. Therefore the conceptual approach might aid far transfer by making it easier for the learner to determine how to adapt relevant parts of the procedure.

Thus, we hypothesize that conceptually-oriented equations will be more effective than computationally-oriented equations at helping learners acquire knowledge structured around the goal-related features of the problems they study and this translates to superior far transfer performance.

**Conceptual Elaborations.** Another factor that appears to have the potential to influence subgoal formation is the use of elaborations in example-based instruction and, in particular, conceptual elaborations. The literature contains examples of several types of elaborations that vary in the degree to which they elaborate the problem at hand. They range from elaborations involving problem solutions (Lovett, 1992) to those that focus on rules and procedures (Catrambone, 1996; Reed & Bolstad, 1991; Reed et al., 1985).

To date, the success of these various elaborations has been mixed. Although Lovett (1992) found that far transfer was facilitated by elaborated solutions, Reed and his colleagues (Reed & Bolstad, 1991; Reed et al., 1985) have found virtually no evidence to suggest that rule-based instructional elaborations—those that elaborate on the purpose and appropriateness of applying a rule or procedure in a given problem-solving context—are beneficial to learners.

In one study, Catrambone (1996) examined the relative benefits of rule-based instructional elaborations versus subgoal labels. In this study, Catrambone manipulated two factors: subgoal labels (present or absent) and rule-based elaborations (present or absent), where the elaborations consisted of supplemental material describing an alternate representation or equation that could be used to solve the problems the participants were studying. He found that the labeling manipulation enhanced transfer while the rule-based elaboration manipulation did not.

The rule-based elaborations used in the Catrambone (1996) study, however, offered "what to do" knowledge not "what it means" knowledge. This distinction is important in light of research suggesting that rules conveying "what to do" knowledge might provide little help to learners for developing a deep understanding of the rule-based system they are studying whereas knowledge about "what it means" may facilitate this depth of understanding (Riesbeck & Schank, 1989). For instance, an elaboration that describes what is meant by the term "variance" (see Appendix for an example) might be more effective than one dedicated to elaborating the procedural aspect of the variance formula.

In sum, the impact of conceptual elaborations containing "what it means" knowledge in the context of subgoal-oriented instruction remains an open question.

## Overview of Study

The aim of the study was to compare the effectiveness of conceptual and computational equations, and the use of elaboration, on performance. Performance was assessed in two ways: the time spent studying the training examples and correctness of solutions on near and far transfer problems.

## Experiment

### Method

**Participants and Design.** Participants were 215 students drawn from several educational psychology courses at a small, northeastern college who participated in the experiment for course credit. The participants were randomly assigned to one cell of a 2 x 2 x 2 factorial design. The first factor was the characteristics of the variance formulas (conceptual or computational) in the t-test example, the second was the characteristics of the variance formulas (conceptual or computational) in the ANOVA example, and the third was conceptual elaboration (elaboration or no elaboration) in the examples, described below.

**Training Phase.** Participants received an instructional booklet containing a general overview of statistical hypothesis tests and two training examples, one representing a t-test and another representing the use of an ANOVA for the same 2-group comparison. The introduction to statistical hypothesis tests described the utility of these procedures and provided an overview of the four-step hypothesis testing process common to both tests. Each training example was preceded by an overview of the test that it exemplified. This explanation described the purpose of the test without going into detail regarding how to perform the test's calculations.

Half of the participants were exposed to examples that contained conceptual elaborations designed to provide "what it means" knowledge. That is, they were designed to describe the conceptual meaning behind the various formulas used in the two hypothesis tests. The other half of the participants studied examples in which the elaborations were not present.

With respect to the t-test example, the variance formulas were either conceptual or computational in nature. Similarly, with regard to the ANOVA example, the variance formulas were either conceptual or computational in character.

Regardless of the instructional manipulations, the examples contained a number of invariant structural features. First, all of the equations used across both tests were converted to their verbal equivalents so that they were devoid of any statistical notations. Second, each of the six calculational subgoals in the two examples was either labeled or visually isolated.

The t-test subgoals were to find: sample mean for group 1, variance for group 1, sample mean for group 2, variance for group 2, pooled variance, and t-statistic. The ANOVA subgoals were to find/do: preliminary calculations, sum of squares between, sum of square within, mean squares between, mean squares within, and f-value.

The Appendix shows samples of the materials from the examples.

**Test Phase.** The test booklet contained three test problems for the participants to solve. The first test problem required the participant to apply a t-test. The second problem required them to apply an ANOVA to a 2-group situation and the third problem asked them to apply an ANOVA to novel situation involving three groups. Thus, the first two problems were near transfer while the third problem involved more far transfer in that it required the learner to adapt the equations for variance. The extension is a more straightforward, modular extension of the conceptual equations. However, the extension is less straightforward in the computational equations since it involves changes to the "interior" of the equations.

The test booklet also included two sheets that participants could refer to, one containing the condition-specific formulas for the t-test (conceptual or computational) and the other containing the condition-specific formulas for the ANOVA. Although these sheets represented the formulas in the sequence in which they were applied in the training examples they did not contain any of the values from those examples.

A binary scoring system was developed to score the problem-solving protocols. This system was designed to award participants with points for the accuracy with which they achieved each subgoal. The three test problems each contained six calculational subgoals. The correct numerical answer to the subgoal was awarded one point. For example, the correct answer to the second subgoal in the t-test problem, correct group 1 variance, was 30.2. If a participants' problem-solving protocol contained this answer, he/she was given a point.

Since most subgoals contained subcomponents, the binary system allowed us to award partial credit. This permitted us to capture the proportion of the subgoal's solution—for those participants who did not have the correct numerical answer for the subgoal—that was correct. For instance, the equation associated with the second subgoal (i.e., correct group 1 variance) in the conceptual condition was coded for the presence or absence of seven components, ranging from whether each value was present in the formula to whether the equation had the correct denominator. In this example, if a participant's problem-solving protocol had six of the seven components, he/she was awarded a .86 for the

subgoal. If the subgoal was correct except for a trivial math error, the participant received full credit (one point) for that particular subgoal.

**Procedure.** Participants were asked to study carefully the instructional booklet containing the training examples since after studying it they would be asked to solve several problems. They recorded the amount of time they spent studying each example. The participants were informed that they would not be able to refer to any of the examples while solving the problems but that they would have a copy of the formulas. This constraint was designed to increase the likelihood that participants would focus their attention on studying the examples and how they were solved.

Participants were run in groups ranging in size from 5 to 30 participants. Participants worked for approximately 75 minutes and were asked to show all their work.

## Results

To validate the scoring system that was developed, two raters independently scored a random sample of 10% of the problem-solving protocols and agreed on scoring 98% of the time. Disagreements were resolved by discussion. One experimenter independently scored the remaining problem-solving protocols.

A 2 x 2 x 2 analysis of variance was initially conducted on the study times for the two examples (i.e., t-test and 2-group ANOVA) and the correctness measures for the three test problems, using elaboration, type of t-test formulas, and type of ANOVA formulas as grouping factors. There was no systematic effect of elaboration on correctness and so, in the interest of clarity and brevity, this factor will not be discussed below in the context of correctness. Table 1 presents the mean scores for each condition on the correctness measures for the three test problems.

*Training Times for T-Test Example:* There was a significant main effect of elaboration,  $F(1, 207) = 10.11, MSE = 10.8, p < .01$ , which indicated that the participants presented with the elaborated material ( $M = 8.11$  min.) spent more time studying the examples compared to participants who studied unelaborated materials ( $M = 6.73$  min.). There were no other significant main effects or interactions.

*Training Times for ANOVA Example:* There were no significant main effects or interactions for training times on the ANOVA example.

*Performance on T-Test Problem (Near Transfer):* There was a significant main effect of t-test formula,  $F(1, 211) = 9.18, MSE = 1.32, p = .009$ , which indicated that the participants exposed to the conceptual t-test example outperformed those who studied the computational version. There was no effect on performance as a function of the version of the ANOVA example studied and there was no interaction between the factors.

*Performance on 2-Group ANOVA Problem (Near Transfer):* There were no significant main effects for this dependent measure; t-test:  $F(1, 211) = 1.06, MSE = 2.09, p = .31$ ; ANOVA:  $F(1, 211) = 0.21, p = .65$ . However, the two-way interaction between t-test equations and ANOVA equations was significant,  $F(1, 211) = 5.52, p < .02$ . Examination of the mean scores suggest a disordinal interaction, that is, the effects of the t-test factor reverse themselves as the levels of the ANOVA factor change. Specifically, for the participants provided with conceptual t-test formulas, the conceptual ANOVA group obtained a higher score than the computational group. For participants provided with the computational t-test formulas, the computational ANOVA group obtained a higher score than the conceptual group.

*Performance on 3-Group ANOVA Problem (Far Transfer):* There were no significant main effects for this dependent measure; t-test:  $F(1, 211) = 2.55, MSE = 2.65, p = .11$ ; ANOVA:  $F(1, 211) = 0.10, p = .75$ . The interaction was significant,  $F(1, 211) = 6.01, p < .02$ . Examination of the mean scores revealed the same disordinal interaction found in the 2-group problem. That is, for the participants provided with conceptual t-test formulas, the conceptual ANOVA group obtained a higher score than the computational t-test formulas. For participants provided with the computational t-test formulas, the difference was reversed.

## Discussion

The overall performance differences among the groups can be summarized as follows: the combined t-test

Table 1: Scores on Test Problems as a Function of T-Test and ANOVA Examples

	T-Test Conceptual		T-Test Computational	
	ANOVA Conceptual	ANOVA Computational	ANOVA Conceptual	ANOVA Computational
T-Test Problem (max = 6)	5.43	5.46	4.99	5.07
2-Group ANOVA Problem (max = 6)	4.16	3.61	3.50	3.87
3-Group ANOVA Problem (max = 6)	4.02	3.55	3.12	3.74

conceptual and ANOVA conceptual condition tended to outperform the other conditions consisting of the other possible combinations of t-test formulas and ANOVA formulas on near and far transfer problems. There was little evidence of improved generalization by any group as a function of having been provided with elaborations. The results suggest that the first example sets the tone for the interpretation of the second example and performance on the far transfer problem. If the first t-test example used conceptual equations, then performance on the far transfer (3-group) ANOVA problem was particularly aided if the ANOVA example was also conceptual. If the first t-test example was computationally-oriented, the performance on the far transfer ANOVA problem was better if the ANOVA example was also computationally-oriented. Thus, it appears that in order for a learner to acquire a more subgoal-oriented approach to these problems, the best pedagogical approach would be to make both examples use conceptual equations. Even if the ANOVA example was conceptually-oriented, its benefits on the far transfer ANOVA problem were reduced if the initial t-test example was not also conceptual. Consistency in the examples appears to be important for subgoal learning.

The results advance prior work on subgoal learning by demonstrating that generalization can be enhanced through the nature of the equations used in examples. Thoughtfully-designed examples that include conceptually-oriented equations seem to be an effective way to help learners solve novel problems.

Two caveats remain, however. First, under certain circumstances, the conceptual formula represents the most direct way of calculating sum of squares. In particular, when a data set consists of a small number of whole numbers and its mean is a whole number (which characterizes the data used in the present study), the resulting deviation score will be a whole number, which allows the learner to avoid the computational burden of decimals or fractions. Thus, one could argue that the advantage of the conceptual group in the present study therefore appears to be computational, rather than in increasing understanding. This suggests that a follow up study should explore the impact of presenting computational and conceptual equations to learners in situations in which the latter is clearly more cumbersome computationally (e.g., resulting means are not whole numbers and/or data set contains decimals).

Second, while the present results are consistent with the claims about benefits to transfer for learners who acquire useful subgoals (e.g., Catrambone, 1996, 1998), subgoal-learning was demonstrated only indirectly here. Thus, an important extension of the present work is to add converging measures, such as talk-aloud protocols, to determine if the transfer advantage can be clearly tied back to subgoal learning.

## Appendix

### Sample Materials from T-Test Example and ANOVA Example

#### *SAMPLE OF PROBLEM STATEMENT:*

A car manufacturer that makes a car called the Jupiter just came out with a new model, the Jupiter XL. Some of the modifications made to the car are expected to improve the mpg (miles per gallon) rating of the car while other modifications are not. The manufacturer has hired your firm, an independent consumer research firm, to test the new model. To determine if there is any difference between the mpg rating of the old and new models, you collect a random sample of 5 cars of the old model and 6 cars of the new model. You drive the cars along the same city route and record the average mpg rating of each car. Here are the data:

Old Model		New Model	
<u>Car</u>	<u>MPG</u>	<u>Car</u>	<u>MPG</u>
1	30	1	37
2	34	2	36
3	34	3	40
4	29	4	36
5	33	5	34
		6	33

#### *SAMPLE OF CONCEPTUAL ELABORATION FOR THE COMPUTATIONAL T-TEST VARIANCE CALCULATION*

A variance is a measure of how much the scores that make up a group deviate from the mean of a group. Even though it is not obvious in the calculation below, part of the calculation of the variance involves computing the difference between each score in a group and the mean for the group. Thus, a variance measures the variability of scores around a mean.

#### *SAMPLE OF COMPUTATIONAL T-TEST VARIANCE CALCULATION*

$$s_1^2 = \text{sample variance for group 1} = \frac{\text{sum of squared scores in group 1} - \frac{(\text{sum of the scores in group 1})^2}{\text{number of scores in group 1}}}{(\text{number of scores in group 1}) - 1}$$

$$= \frac{(30^2 + 34^2 + 34^2 + 29^2 + 33^2) - \frac{(30 + 34 + 34 + 29 + 33)^2}{5}}{5 - 1} = \frac{5,142 - \frac{(160)^2}{5}}{4} = \frac{22}{4} = 5.5$$

#### *SAMPLE OF CONCEPTUAL T-TEST VARIANCE CALCULATION*

$$s_1^2 = \text{sample variance for group 1} = \frac{(1\text{st score} - \text{mean})^2 + (2\text{nd score} - \text{mean})^2 + \dots + (\text{last score} - \text{mean})^2}{(\text{number of scores in group 1}) - 1}$$

$$= \frac{(30 - 32)^2 + (34 - 32)^2 + (34 - 32)^2 + (29 - 32)^2 + (33 - 32)^2}{5 - 1} = \frac{22}{4} = 5.5$$

#### *SAMPLE OF COMPUTATIONAL ANOVA SUM OF SQUARES (BETWEEN) CALCULATION*

*SSB* = sum of squares between groups

$$= \left[ \frac{(\text{sum of scores in group 1})^2}{\text{number of scores in group 1}} + \frac{(\text{sum of scores in group 2})^2}{\text{number of scores in group 2}} + \dots + \frac{(\text{sum of scores in last group})^2}{\text{number of scores in last group}} \right] - \frac{(\text{sum of scores in all groups})^2}{\text{number of scores in all groups}}$$

$$= \left[ \frac{(160)^2}{5} + \frac{(216)^2}{6} \right] - \frac{(376)^2}{11} = 12,896 - 12,852.36 = 43.64$$

#### *SAMPLE OF CONCEPTUAL ANOVA SUM OF SQUARES (BETWEEN) CALCULATION*

*SSB* = sum of squares between groups

$$= \text{number of scores in group 1} (\text{the mean for group 1} - \text{grand mean})^2 +$$

$$\text{number of scores in group 2} (\text{the mean for group 2} - \text{grand mean})^2 + \dots +$$

$$\text{number of scores in last group} (\text{the mean for last group} - \text{grand mean})^2 = 5(32 - 34.18)^2 + 6(36 - 34.18)^2 = 43.64$$

# A Comparative Study of Unsupervised Grapheme-Phoneme Alignment Methods

Timothy Baldwin and Hozumi Tanaka  
Dept of Computer Science  
Tokyo Institute of Technology  
2-12-1 Ookayama,  
Meguro-ku, Tokyo 152-8552 JAPAN  
{tim,tanaka}@c1.cs.titech.ac.jp

## Abstract

This paper describes and compares two unsupervised algorithms to automatically align Japanese grapheme and phoneme strings, identifying segment-level correspondences between them. The first algorithm is inspired by the TF-IDF model, including enhancements to handle phonological variation and determine frequency through analysis of “alignment potential”. The second algorithm relies on the C4.5 classification system, and makes multiple passes over the alignment data until consistency of output is achieved. In evaluation, the first algorithm proves to be greatly superior to the second, producing a word accuracy of 96.94%.

## Introduction

The task of grapheme-phoneme alignment is intrinsically related to text-to-speech conversion, and provides the basic toolset of grapheme-phoneme correspondences for use in predicting the pronunciation of a given word. While it is certainly possible to handcraft grapheme-to-phoneme mappings (see, e.g., (Allen et al., 1987; Sejnowski and Rosenberg, 1987; Huang et al., 1994; Divay and Vitale, 1997)), we suggest that it should be possible to automatically extract such data from a database of grapheme-phoneme string pairs *without any form of supervision*. Thus, given a pronunciation-annotated machine-readable dictionary, it should be possible to generate a set of aligned grapheme-phoneme (word-pronunciation) pairs reliably and fully automatically. Theoretically, the grapheme-phoneme alignment output could then be plugged into a reading machine, producing an instant text-to-speech system for any language (as per (Ling and Zhang, 1998; Black et al., 1998)).

The objective of this paper is to analyse the applicability of unsupervised learning methods to automated grapheme-phoneme alignment in Japanese. In particular, we propose an incremental learning algorithm founded upon the TF-IDF metric, and compare this to a multi-pass alignment method drawing on the C4.5 classification system (inspired by the method of (Ling and Wang, 1997)). Alignment data is first constructed by exhaustively generating all alignment mappings for a given grapheme-phoneme pair. We filter off lexically and phonologically implausible alignment candidates from this data, and feed the final set of alignment candidates into the different alignment algorithms. These algorithms then incrementally disambiguate the data to produce a unique alignment candidate for each grapheme-phoneme tuple, through analysis of frequency distribution in the data.

## Definitions

Japanese is made up of the three native orthographies of kanji, katakana and hiragana. **Kanji** characters (e.g.

“消”) derive from the Chinese writing system and are largely ideographic in nature; a single kanji character tends to have multiple pronunciations (a sample of readings for “消” include *syō*, *ki(eru)* and *ke(su)*). **Katakana** and **hiragana** (collectively described as **kana**) are isomorphic syllabaries, with each character describing a unique, mutually exclusive phoneme content; examples of hiragana and katakana are “し” (*si*) and “ゴ” (*go*), respectively. The three orthographies intermingle in modern-day Japanese texts, with hiragana generally used for inflectional affixes, case particles and stop words, katakana for loan words, and kanji for content word stems. This effect is seen in the word 消しゴム [*kesigomu*] “eraser”, which incorporates all three script types.

In targeting “graphemic Japanese”, therefore, we must consider all three writing systems. Phonemic Japanese, on the other hand, can be described through kana characters, as all kanji characters are transcribable into kana, and kana describe the full phonemic inventory of Japanese in the form of phoneme chunks. That is not to say that every kana character maps to a single phoneme, but there is a unique broad phonetic transcription associated with almost all kana characters.<sup>1</sup> It is thus trivial to complete the full grapheme-phoneme conversion process if necessary, and at the same time, our choice of kana characters as phoneme medium frees us from consideration of low-level connective restrictions between phoneme units, as this information is implicitly encoded within the orthography.

Grapheme-phoneme (“G-P”) alignment is defined as the task of *maximally* segmenting a grapheme compound (a single dictionary entry, usually constituting a single word) into morpho-phonetic units, and aligning each such unit to its corresponding phoneme unit in the phonetic transcription for that compound. Segmentation of the grapheme compound is maximal in the sense that no segment can be further segmented into aligning sub-segments. To take the example of the grapheme string 感謝-*su-ru* [*ka-n-sya-su-ru*] “to thank/be thankful”,<sup>2</sup> 感 aligns with *ka-n* in the phoneme string, and 謝 with *syā*, as indicated in *align*<sub>1</sub> of Fig. 1.

<sup>1</sup>The only exception to affect us is the kana *u*, which when not used as an inflecting suffix, is pronounced as /o/ when immediately preceding an /o/ sound within a phoneme segment, and /u/ otherwise. Here, disambiguation is possible given phoneme segment context and part-of-speech information.

<sup>2</sup>So as to make this paper as accessible as possible to readers not familiar with Japanese, kana characters are written italicised in Latin script for the remainder of this paper, with character boundaries indicated by “.” and segment boundaries (which double as character boundaries) indicated by “⊙”.

Figure 1: Candidate alignments for 感謝-su-ru [ka-n-sya-su-ru] “to thank/be thankful”

## Cognitive aspects of G-P alignment

One vital issue in grapheme-phoneme alignment is the determination of ‘atomic’ grapheme segments, that is segments which are not further divisible. Clearly, the lower bound on atom size for Japanese is a single kana or kanji character, but there is no inherent upper bound on the number of characters that can combine to form a segment, for either grapheme or phoneme segments. While it is correct to say that there is a cognitive preference to segment off individual kanji characters (possibly with kana suffices), there is equally potential for (indivisible) multiple-kanji grapheme segments, such as 白-詞 [se-ri-fu] “one’s lines”. Consequently, alignment does not simply consist of segmenting the grapheme string up into individual characters and aligning them with chunks of the phoneme string, and consideration must be given to the granularity of segmentation.

A number of inter-related cognitive factors seem to determine the “segmentability” of a grapheme string and resultant “alignability” with a given phoneme string, namely: (i) the relative frequency of each segment-level G-P sub-alignment; (ii) the cognitive immediacy of adjacent segments; and (iii) phonetic similarity to regular readings in the case of novel G-P sub-alignment.

High relative frequency of alignment refers to the situation of a given grapheme segment  $g$  commonly aligning with a given phoneme segment  $p$  (and phonological variants thereof), such as 感 invariably aligning with the reading  $ka-n$ . Clearly if the  $\langle \dots \circ g \circ \dots \rangle - \langle \dots \circ p \circ \dots \rangle$  alignment sub-schema is observed with sufficient frequency, a natural preference will arise to emulate that same alignment sub-schema wherever possible, for reasons of familiarity.

In the case that there is no alignment schema which produces familiar alignments for all individual grapheme segments, there is a tendency to preserve as much regularity to the overall alignment schema as possible by maximising the number of regular alignments and framing any irregular alignments between segment-level alignments of high cognitive immediacy. Thus, when presented with a G-P tuple such as  $\langle \text{白髮} \rangle - \langle si-ra-ga \rangle$ , where 白 is commonly associated with the reading  $si-ra$  but not  $si$  and there are no independent instances of 髮 taking a  $ga$  or  $ra-ga$  reading, there is a natural preference to uphold the single known sub-alignment for 白 and produce a forced alignment for 髮, as in  $\langle \text{白} \circ \text{髮} \rangle - \langle si-ra \circ ga \rangle$ .

Finally, if a novel alignment must be made such as  $\langle \dots \circ \text{髮} \rangle - \langle \dots \circ ga \rangle$  above, conservatism rules in that irregular readings tend to be chosen so as to be phonetically similar to established readings. In the case of 髮, the established reading is  $ka-mi$  (or  $ga-mi$  in its voiced realisation), from which the deletion of a single character produces the suggested  $ga$  reading.

In the case that the above processes do not apply to any substring of the G-P tuple, the tendency is to chunk unalignable kanji together into a single multi-kanji segment, such as occurred for  $se-ri-fu$  above.

The implications of the above observations to our statistical modelling of G-P alignment are to develop a model which gives preference to sub-alignments of high plausibility, allows irregular alignments given that the surrounding context displays high cognitive immediacy of alignment, and has the facility to “back-off” to multi-kanji segments when necessary. Our interpretation of TF-IDF is suggested to constitute such a model.

## Grapheme-phoneme alignment

Grapheme-phoneme alignment is performed as a three-stage process: (a) detection of lexical alternation and removal of lexical alternates from the input; (b) determination of all possible alignment candidates and subsequent pruning through alignment constraints; and (c) scoring of all final candidate alignments to determine the final solution.

**Lexical alternates** are defined as containing the same kanji characters in the same linear order, and coinciding in phonemic content (i.e. having the same reading). We enforce the constraint that all lexical alternates must be governed by the same basic alternation schema, allowing us to filter off alignment candidates for a given G-P tuple which are incompatible with one or more alternates of that tuple.

Given that both grapheme and phoneme segments can be of arbitrary length, **alignment candidate generation** must encompass all segmentation cardinalities. That is, for the example of a three-character grapheme string, we must consider the maximal segmentation of the string into three segments, and also partial segmentations into two segments or alternatively a single segment encompassing the full string.

Luckily, we are able to rely on strict linearity of alignment between the grapheme and phoneme strings, and in most cases can count on the alignment being isomorphic (the only exception being “grapheme gapping” – see (Baldwin and Tanaka, 1999b)). As a result, the total number of alignments is given by  $\sum_{x=0}^{l-1} C_x^{m-1} C_x^{n-1}$  in the general case, where  $m$  is the character length of the grapheme string,  $n$  the character length of the phoneme string, and  $l = \min(m, n)$ .

We are able to reduce the alignment space considerably, however, through the advent of five lexical and phonological constraints on alignment, as described in (Baldwin and Tanaka, 1999b). These constraints apply to script and syllable boundaries, the character length of aligned segments, and the number of voiced obstruents contained in a single phoneme segment. For the data targeted in evaluation, the average alignment paradigm size was reduced from 12.06 to 3.27 (a reduction of close to 75%), with no instances of the correct alignment candidate being pruned from the alignment paradigm.

It is important to realise that the application of the above constraints not only reduces the search space for statistical scoring, but can actually single out a unique

$$freq(\langle g, p \rangle) = \left| \left\{ \langle GS, PS \rangle : \exists p' \in phon\_var(p) \left\{ \langle \dots \underset{i}{\circ} g \underset{i+1}{\circ} \dots \rangle - \langle \dots \underset{i}{\circ} p' \underset{i+1}{\circ} \dots \rangle \in \{ \langle GS_{seg} \rangle - \langle PS_{seg} \rangle \} \right\} \right\} \right| \quad (1)$$

$$wfreq(\langle g, p \rangle) = SOLVED \cdot freq_{SOLVED}(\langle g, p \rangle) + UNSOLVED \cdot freq_{UNSOLVED}(\langle g, p \rangle) \quad (2)$$

$$tf-idf(\langle g, p, ctxt \rangle) = \underbrace{\frac{wfreq(\langle g, p \rangle) - UNSOLVED + \alpha}{wfreq(\langle g \rangle)}}_{tf(\langle g, p \rangle)} \log \left( \underbrace{\frac{wfreq(\langle g, p \rangle)}{wfreq(\langle g, p, ctxt \rangle) - UNSOLVED + \alpha}}_{idf(\langle g, p, ctxt \rangle)} \right) \quad (3)$$

legal solution, providing what turns out to be vital “free ride” alignment data to bootstrap the different systems with.

The alignment constraints are the only component of the overall formulation which is specific to Japanese, and the different algorithms would be equally applicable to unconstrained alignment data, making them directly transferrable to any other language.

We next turn to description of the two main unsupervised alignment methods.

## Incremental learning with TF-IDF

The first algorithm (originally proposed in (Baldwin and Tanaka, 1999a)) is based on incremental learning or “hill-climbing”, whereby the system disambiguates a single alignment paradigm at a time and incrementally updates the statistical model according to both discarded alignment candidates and the selected alignment solution. Selection of the alignment paradigm to be disambiguated is performed according to an adaptation of the TF-IDF scoring metric (Salton and Buckley, 1990), originally developed within the information retrieval fraternity for term weighting. In this, we score and rank each alignment candidate contained within the current alignment paradigm, and further rank the different alignment paradigms according to the weighted ratio between the top- and second-ranking alignment candidates. The highest-scoring alignment paradigm on each iteration is selected for disambiguation, according to the top-ranking alignment candidate described therein. We then update the statistical model, revise scores for alignment paradigms affected by the changed statistics, and rerank in preparation for the next iteration.

The utility of TF-IDF within the task of G-P alignment, stems from it weighting up terms (aligned G-P segments) which occur frequently within a given document (grapheme segment) context, but relatively infrequently within other documents (left/right adjoining grapheme and phoneme contexts). As described above, we wish to model the cognitive process of G-P alignment by maximally weighting high-frequency (regular) readings for a given grapheme string, but at the same time scoring down readings which occur primarily in a fixed lexical context, as this would tend to point to oversegmentation at the phoneme level (the phoneme context is in actual fact part of the reading for the current grapheme segment) and/or the grapheme level (the grapheme context clusters with the current grapheme segment to form a multiple-grapheme segment).

In addition to facilitating the detection of regular alignments, TF-IDF provides a means of variably “windowing” over the grapheme and phoneme strings, in that it does not involve a pre-conceived notion of segment size. Additionally, by way of taking the mean of the scores for the left/right and grapheme/phoneme contexts for each aligned G-P segment pair, we are able to weight up alignments with more highly regularised segment-level

readings, again mirroring the cognitive processing of G-P alignment.

While TF-IDF offers no immediate solution to the third cognitive issue of conservatism in cases of non-regular readings, it does allow us to handle abbreviations of regular readings—as was seen above for the *ga* reading of 髪—in that they will generally be found within the (undisambiguated) alignment paradigm of G-P tuples drawing on the regular reading.

## Counting frequencies

Clearly, to be able to apply the TF-IDF metric, we require some way of counting frequencies. For disambiguated alignment paradigms, we can rely on the absolute frequencies of segments contained within the alignment solution. For residue alignment paradigms awaiting disambiguation, on the other hand, we have an arbitrary number of alignment candidates to choose from, and no immediate way of producing an all-encompassing frequency value.

We resolve this issue by associating a single frequency count with every segment type occurring independently in a given alignment paradigm, irrespective of the number of alignment candidates it occurs within. In this way, we model the “alignment potential” of each segment. This process can be formalised as in equation (1), in the case of  $freq(\langle g, p \rangle)$  (singleton and triple segment combinations are defined in a similar fashion). Here,  $p$  is the phoneme segment aligning with grapheme segment  $g$ , and  $phon\_var(p)$  describes the set of “phonological alternates” of  $p$ . Phonological alternates are predictable instances of phonological alternation from a base form  $p$ , with the most widespread types of phonological alternation being “sequential voicing” (Tsujimura, 1996) and gemination. Fortunately, phonological alternation occurs only on syllables at phoneme segment boundaries, and phonological alternate “equivalence classes” are mutually exclusive in the main. This allows us to cluster together frequencies for members of each equivalence class, going some way toward combating the effects of data sparseness.

## The basic TF-IDF model

Our interpretation of the TF-IDF model is given in equation (3), where  $g$  is a grapheme segment,  $p$  a phoneme segment and  $ctxt$  a single phoneme or grapheme context for  $\langle g, p \rangle$  within the current alignment. As an additional facet of hill-climbing, we weight up segment frequencies contained within disambiguated alignment paradigms ( $freq_{SOLVED}$ ), over those for unprocessed alignment processes ( $freq_{UNSOLVED}$ ). This is achieved through the  $wfreq$  functions for the various segment combinations, which use the fixed  $SOLVED$  and  $UNSOLVED$  weights to prioritise disambiguated frequencies ( $0 < \alpha < UNSOLVED \leq SOLVED$ ). The subtractions by a factor of  $UNSOLVED$  are designed to discount the single occurrences of  $\langle g, p \rangle$  and  $\langle g, p, ctxt \rangle$  in the current align-

ment paradigm, and  $\alpha$  is an additive smoothing constant designed to counter the effects of low frequency counts.

As described above, consideration of lexical context for a given segment tuple  $\langle g, p \rangle$  is four-fold, made up of the single *character* immediately adjacent to  $g$  in the grapheme string and single *syllable* immediately adjacent to  $p$  in the phoneme string (or the null string in the case of a string-initial/final segment), for both the left and right directions. An individual *tf-idf* score is calculated for each of these contexts *ctxt*, and the resultant scores combined by taking the 4-way arithmetic mean. In the case of full-string segment alignment, the overall score is defined to be  $tf(\langle g, p \rangle)$ .

The overall score for all G-P segment tuples contained in the current alignment is computed according to the arithmetic mean of the respective combined *tf-idf* scores, with the proviso that full kana-based grapheme segments are excluded from computation.

Additional allowances for affixation and conjugation are made according to the method described in (Baldwin and Tanaka, 1999b).

## Selective sampling

As described above, a single alignment paradigm is selected for disambiguation on each iteration, and the statistical model updated by way of incrementing frequencies for segment alignments contained in the alignment solution (according to the *SOLVED* weight), and decrementing frequencies deriving from segments occurring in disallowed alignment candidates and not the alignment solution. The method of “selectively sampling” a single alignment solution on each iteration, is performed by calculating a score for each alignment paradigm, and disambiguating the highest scoring paradigm according to the top-scoring alignment candidate contained therein. The score for the alignment paradigm is calculated according to the “weighted log odds” discriminative ratio  $s_1 \log \frac{s_1}{s_2}$ , where  $s_1$  is the score for the top-ranking alignment candidate and  $s_2$  that for the second-ranking alignment candidate within the current alignment paradigm. Intuitively, this balances up maximisation of both  $s_1$  and the disparity between  $s_1$  and  $s_2$ , such that we are after not only alignment candidates which score well, but also alignment paradigms where the top-scoring alignment candidate has a clear empirical advantage over other candidates.

## Multi-pass classification

The second algorithm is inspired by the research of Ling and Wang (1997), who applied the C4.5 classification system (Quinlan, 1993) to unsupervised alignment of English G-P tuples. Specifically, C4.5 was used to predict the phonemic equivalent of English words (graphemic strings), by way of outputting a phoneme for each constituent character in a given character window and combining phonemes to give an aligned phonemic equivalent for the original word. A phonetic transcription for the original word was then used to independently generate alignment candidates, and the alignment candidate most similar to the C4.5-constructed alignment chosen as the alignment solution. Similarly to our incremental learning method, alignment solutions are then fed back into C4.5 as training data, for use in aligning subsequent words. Ling and Wang implemented a number of heuristics to improve the performance of their basic method, including ordering the system inputs in ascending order of alignment cardinality, delaying making a decision in cases of multiple alignment candidates being equally similar

to the C4.5-constructed alignment, and cross-validating held-out partitions of the alignment data against the remainder of the data. The final alignment precision over 33,121 English words exceeded 99.5%.

The alignment accuracy on English is certainly impressive, and suggests the method as promising for Japanese G-P alignment. Unfortunately, however, the case of Japanese G-P alignment is considerably more complex than that of English. Most importantly, as noted above, Japanese phoneme segments often extend over multiple characters for single character grapheme segments even, whereas in the case of English, grapheme segments almost always map onto single phonemes. It was thus possible for Ling and Wang to enumerate the 40 or so possible phoneme segments and have C4.5 choose between them in predicting the phonemic equivalent of each grapheme segment. If we attempted to do the same for Japanese, we would end up with a total of over 56,000 phoneme segments in the case of the data set used in evaluation, making the classification task unmanageable. Additionally, English uses only 26 letters (assuming uniform case), whereas our test data contains 4429 grapheme character tokens and 167 phoneme character tokens. This blow out in the search space suggests the need for a different classification approach.

On the implementation side, Ling and Wang are unable to use negative evidence from discarded alignment candidates, a possibility we look to. We also use the certainty factor values returned by C4.5 in scoring the plausibility of different alignment candidates.

## Algorithm basics

We apply the basic fixed window method suggested by Ling and Wang, but instead of inputting only grapheme context to return a phoneme, we input both grapheme and phoneme contexts to return a binary judgement on the plausibility of a coincident segment boundary existing at the centre of the two context windows. Grapheme and phoneme context is set to 3 characters on either side of the segment boundary, making for a combined window size of 12 characters. To give an example based on *align*<sub>1</sub> from Fig. 1, the classifier “\_, \_, 感, 謝, su, ru, \_, ka, n, sya, su, ru” should produce a judgement of true, corresponding to the leftmost inter-segment boundary in *align*<sub>1</sub> (the ‘\_’ token indicates an empty character beyond the boundaries of the original word, and the underlined component is the grapheme window). “\_, \_, 感, 謝, su, ru, ka, n, sya, su, ru, \_”, on the other hand, is associated with a negative judgement within the context of *align*<sub>1</sub>, as despite segment boundaries existing at the centres of the two context windows, they do not coincide under alignment.

At the same time as classifying input for segment boundary compatibility, C4.5 can be set to output a certainty factor  $cf : 0 \leq cf \leq 1$  for each class. This is particularly useful in comparing the overall plausibility of alignment candidates with little or no segment boundary overlap. In the case of the tuple 大使 [*ta-i-si*] “ambassador”, for example, we need to choose between the three alignment candidates of  $a_1 = \langle \text{大} \odot \text{使} \rangle - \langle \text{ta} \odot \text{i-si} \rangle$ ,  $a_2 = \langle \text{大} \odot \text{使} \rangle - \langle \text{ta-i} \odot \text{si} \rangle$  and  $a_3 = \langle \text{大使} \rangle - \langle \text{ta-i-si} \rangle$ , the second of which ( $a_2$ ) is correct. In sizing up  $a_3$  against  $a_1$  and  $a_2$ , we are making a judgement as to the plausibility of the single segment boundary distinguishing each alignment candidate pairing. However, if  $a_1$  were determined to be more plausible than  $a_3$ , and equivalently  $a_2$  more plausible than  $a_3$ , how could we choose between  $a_1$  and  $a_2$ ? Here, we apply the certainty factors in transferring evaluation across to a numeric comparison.

So as to limit comparison of alignment candidates to only those determined to be legal by the alignment constraints, we cluster “homogeneous” legal alignment candidates together into “packed alignment arrays” and individually score each alignment candidate described therein. **Packed alignment arrays** are of the form  $\langle \text{大?使} \rangle - \langle \text{ta?i-si} \rangle$ , for example, where ‘?’ indicates an optional segment boundary aligning with the corresponding boundary in the opposing string (note that packed alignment arrays can also contain fixed segment boundaries, the score for which contributes to the overall score of alignment). **Homogeneous** alignment candidates are defined as not having any crossing-over of alignment and having all coincident segments aligning similarly.  $a_1$  and  $a_2$  from above are not homogeneous (due to the “大” and “使” segments aligning differently), producing the two packed alignment arrays  $\langle \text{大?使} \rangle - \langle \text{ta?i-si} \rangle$  and  $\langle \text{大?使} \rangle - \langle \text{ta-i?si} \rangle$  for “大使”. A combined score for each alignment candidate is determined based on the average segment boundary certainty factor, and alignment candidates realised in multiple packed alignment arrays (such as  $a_3$  in the two presented arrays) are given the minimum score out of those realisations. The optimal alignment candidate for a given alignment paradigm is then that which produces the maximum mean certainty factor.

While we do not have any pre-annotated training data (preserving the true unsupervised status of our method), we do have disambiguated positive evidence from the “free ride” data disambiguated by the alignment constraints. We can also construct negative evidence from alignment candidates disallowed by the alignment constraints,<sup>3</sup> although here there is potential for segment-level overlap with the correct alignment. We thus take only those segment boundary windows not found within the final alignment paradigm. Finally, we stretch the boundaries of unsupervised learning somewhat in providing the system with positive instances for each hiragana and katakana character, aligning it as a single character in the grapheme and phoneme strings. These instances combine to form the “bootstrap data” with which the system is initialised.

We further order the G-P tuple data set in ascending order of alignment cardinality, in the manner of Ling and Wang, so as to give the system the chance to make easier decisions early on and use the resulting evidence in making decisions of greater complexity later on.

### First pass

In the first pass over the data, C4.5 is initialised with the bootstrap data from above, and run over each alignment paradigm in turn. The classifying decision tree is then updated each time an alignment paradigm is disambiguated, based on the positive evidence described by the alignment solution. Due to the potentially dubious nature of evidence arising from this first pass, we commit ourselves to an alignment solution only in the case that there is no tie in combined certainty factor; in the case of a tie, we reserve our decision for subsequent passes. Additionally, we feed only positive evidence back into C4.5.

### Second and subsequent passes

In the second and subsequent passes, we classify each alignment paradigm according to the combination of the

<sup>3</sup>We take only negative evidence produced through alignment incompatibility between otherwise legal alignment candidates for lexical alternates, and also that produced by Lyman’s Law (Vance, 1987).

original bootstrap data and any positive or negative data generated for other alignment paradigms in the preceding pass, holding out data pertaining to the current alignment paradigm. Negative data is progressively added into the training data throughout the second pass, and maintained through subsequent passes.

In the case of a tie in alignment score, we take the first alignment producing that score. Note that packed alignment arrays are listed in descending order of the number of individual alignment candidates they describe, such that by taking the first alignment candidate to produce the maximum alignment score, we are giving it credit for having won out over a larger number of alignment candidates.

We continue iterating over the data until the combined alignment output converges, that is we attain consistent output over successive passes.

## Evaluation

The proposed systems were tested on a set of 5000 G-P tuples containing at least one kanji, randomly extracted from the combined EDICT Japanese-English<sup>4</sup> and Shinmeikai (Nagasawa, 1981) dictionaries. Any lexical alternates of the 5000 G-P tuples were further added to the test set to give the alignment constraints full scope for application (expanding the test data out to 6503 instances), and the original 5000 G-P tuples manually aligned for use in system performance evaluation. The extra lexical alternate data is used only in applying the alignment constraints and has no bearing on subsequent evaluation. The annotated alignment data was, of course, not available to any of the system configurations at execution time.

The test data was additionally pre-processed into alignment paradigms and sorted into ascending order of alignment cardinality, so as to ensure that the input to the two systems was identical.

The baseline word accuracy for this test suite, based on random selection of an alignment schema from the final alignment paradigm for each G-P tuple, is 44.75%.

Looking first to the incremental TF-IDF learning method, we tested the algorithm with different settings for the parameters *SOLVED*, *UNSOLVED* and  $\alpha$ , and found that the respective values of 1.0, 0.5 and 0.05 produced the best word accuracy of 96.94%. Higher values of  $\alpha$  tended to produce greater levels of under-alignment (chunking together of grapheme and phoneme segments into single super-segments), whereas lower levels of  $\alpha$  produced greater levels of over-alignment (intra-segment segmentation). Larger values of *SOLVED*, on the other hand, tended to inflate the overall rate of both over- and under-alignment. Interestingly, most errors were homogeneous with the correct alignment.

The multi-pass classification method produced a word accuracy of 47.34% on the first pass and 58.18% on the second and third passes, halting on completion of the third pass due to coincidence of output with the second pass. Ties in alignment score were produced for only 78 of the 5000 annotated G-P tuples on the first pass, such that we were able to produce alignments for 4922 G-P tuples. On the first pass, most errors took the form of underalignment, whereas errors on the second and third passes were generally instances of overalignment or non-homogeneous with the correct alignment.

Based on these figures, the incremental TF-IDF learning method is clearly superior to the multi-pass classification

<sup>4</sup><ftp://ftp.cc.monash.edu.au/pub/nihongo>

method, both in terms of raw accuracy and the degree of error in the case of incorrect output. The 58.18% word accuracy for the multi-pass classification approach also contrasts starkly with the 99.5% word accuracy claimed by Ling and Wang for English G-P alignment, although it does well outperform the baseline word accuracy.

To further compare the accuracies of the different methods, we calculated the progressive alignment accuracy over corridors of 250 alignment solution outputs, based on the order of output. In the case of the multi-pass classification method, the order of output corresponds to the order of the original data, in increasing order of alignment cardinality, whereas for the incremental TF-IDF learning method, the order of output is determined by the discriminative ratio values. For both methods, however, the first 895 outputs are the “free ride” alignment paradigms of cardinality one, at word accuracy 100%. The progressive word accuracies for pass 1 and passes 2 and 3 of the multi-pass classification method are presented separately as “MP-P1” and “MP-P2/3”, respectively. We include evaluation of a number of variations on the basic TF-IDF method (“BASIC”) to verify the efficacy of the discriminative ratio, firstly by way of a random sampling method, where a random alignment paradigm is disambiguated at each iteration (“RAND”), and secondly by way of a non-incremental method where all alignment paradigms are disambiguated according to the initial top-scoring alignment candidate and output in descending order of the discriminative ratio value (“DUMP”). The various progressive word accuracies are given in Fig. 2.

Figure 2: Progressive alignment accuracy

We can see a clear correlation between alignment cardinality and accuracy for the multi-pass classification method, and also a clear performance gain for the second pass over the first pass. The performance gain for the basic TF-IDF method over random sampling (word accuracy 96.64%) and the non-incremental method (word accuracy 96.20%) is more subtle, although the basic method does return higher word alignment accuracy and the output is more consistently accurate over the first 4000 or so annotated outputs, pointing to the success of the selective sampling method.

## Conclusion

In conclusion, we have proposed two fundamentally different methods of unsupervised G-P alignment, and tested them on a set of 5000 Japanese G-P tuples. The first method centres around an adaptation of the TF-IDF met-

ric, and iterates over the data, hill-climbing as it goes. The second method, inspired by Ling and Wang (97), uses C4.5 to determine segment boundary compatibility for combined G-P context windows, and selects the most plausible overall alignment candidate according to the confident factor values returned by C4.5. It makes multiple passes over the data, incrementally enhancing alignment accuracy as it goes. The TF-IDF-based learning method returned a word accuracy of 96.94% in evaluation, surpassing the 58.18% 3-pass word accuracy for the C4.5 multi-pass classification method by a large margin. In the future, we are interested in running the different methods over data for other languages, and expanding evaluation.

# Discovering and Describing Category Differences: What makes a discovered difference insightful?

Stephen D. Bay (sbay@ics.uci.edu)

Michael J. Pazzani (pazzani@ics.uci.edu)

Department of Information and Computer Science

University of California, Irvine

Irvine, CA 92697, USA

## Abstract

Many organizations have turned to computer analysis of their data to deal with the explosion of available electronic data. The goal of this analysis is to gain insight and new knowledge about their core activities. A common query is comparing several different categories (e.g., customers who default on loans versus those that don't) to discover previously unknown differences between them. Current mining algorithms can produce rules which differentiate the groups with high accuracy, but often human domain experts find these results neither insightful nor useful. In this paper, we take a step toward understanding how humans interpret discovered rules by presenting a case study: we compare the responses of admissions officers (domain experts) on the output of two data mining algorithms which attempt to find out why admitted students choose to enroll or not enroll at UC Irvine. We analyze the responses and identify several factors that affect what makes the discovered rules insightful.

## Introduction

Data collection is a daily activity of many organizations in business, science, education, and medicine. Large databases are routinely collected and with the advent of computers to process the information, these organizations want to analyze the data to gain insight and knowledge about the underlying process behind the data. The data usually represents information on their core business, and an important task is understanding the differences between various client groups. For example, bank loan officers may be interested in analyzing historical loan data to understand the differences between people who are good and poor credit risks. Admissions officers at UC Irvine (UCI) are interested in analyzing admissions data to understand the factors which influence an admitted student's choice to enroll at UCI. It is important that the discovered differences both be true and accurate descriptions of the data as well as being acceptable and understandable by the end users.

A common technique for discovering group differences from data is to apply a data mining algorithm to automatically find rules from the data. For example, after analyzing loan data we might find that people with graduate degrees are good loan risks (i.e. grad-degree  $\rightarrow$  low-risk). There have been many studies which investigate the accuracy of rules that describe category differences, but very few which investigate how humans interpret the results.

In this paper, we focus on two issues relating to the interpretation of discovered rules by human domain experts: First, algorithms for automatically finding group differences can be categorized broadly into discriminative and characteristic (or

informative) approaches (Rubinstein & Hastie, 1997). In discriminative approaches, the algorithms attempt to find differences that can be directly used to classify the instances of the groups. In characteristic approaches, the algorithms attempt to find differences in the class descriptions, some of which may also be highly predictive but are not necessarily so. We investigate if human domain experts have a preference for either strategy. Second, there are many objective measures of rule quality and typically mining algorithms seek rules that optimize these measures. For example, with if-then rules of the form  $A \rightarrow C$  (antecedent implies consequent), many algorithms attempt to maximize the confidence which is the conditional probability of the consequent being true given the antecedent ( $P(C|A)$ ). The assumption is that rules that score highly on the objective measure are useful to domain experts. The problem is that while there are many objective measures of pattern quality, such as support (Agrawal, Imielinski, & Swami, 1993), confidence (Agrawal et al., 1993), lift (also known as interest) (Brin, Motwani, Ullman, & Tsur, 1997), conviction (Brin et al., 1997) and many others, none of the measures truly correlate with what human domain experts find interesting, useful, or acceptable. The reality is that most mined results are not useful at all. For example, Major and Mangano (1995) analyzed rules from a hurricane database and reduced 161 rules to 10 "genuinely interesting" rules. In a more extreme, but common case, Brin et al. found over 20000 rules on a census database from which they learned that "five year olds don't work, unemployed residents don't earn income from work, men don't give birth" and other uninteresting facts. Thus we investigate the relationship between human subjective measures of rule usefulness to objective measures of rule quality.

We answer our research questions, "Is a discriminative or characteristic approach more useful for describing group differences?" and "How do subjective and objective measures of rule interest relate to each other?" by reporting on an analysis of discovered rules by human domain experts. We analyzed UCI admissions data to understand the groups of students that decide to enroll or not enroll at UCI given an offer of admission. After discovering rules with two different algorithms, we then showed the rules to human domain experts and asked them to rate the rules according their *insightfulness*, i.e. did the rule expand their knowledge about the admission process? After obtaining experts results, we then analyzed the responses to compare and contrast discriminative and characteristic approaches as well as objective and subjective measures of rule quality.

In the remainder of this paper, we first highlight the differences between discriminative and characteristic approaches and describe the mining algorithms used. We then describe the knowledge discovery task: analyzing admissions data to improve the recruitment process at UCI. We examine domain experts responses and compare them to quantitative measures of rule quality. We conclude by discussing related work and examining possible directions for future work.

## Background: Discovering Category Differences

Mining algorithms for finding category or group differences can be classified as discriminative or characteristic. Discriminative miners attempt to find differences that are useful for predictive classification with a high degree of accuracy. Characteristic miners attempt to find significant differences in the class descriptions. This can result in rules that are highly predictive as with discriminative mining, but predictiveness is not a requirement of the mined rules. Discriminative miners look for one key set of features that distinguish the categories while characteristic miners look for all important differences between the categories.

For example, a discriminative difference would be that students who do not enroll at UCI are much more likely to have a GPA greater than 4 and live more than 100 miles from UCI than students who do enroll. Ninety eight percent of these students (GPA greater than 4 and distance from UCI greater than 100 miles) reject UCI's admission offer and do not enroll. Knowing that a student has these characteristics allows us to classify them with high accuracy.

A characteristic difference would be that 39.8% of students that enroll at UCI are English native speakers compared with 47.9% of students who do not enroll. Clearly this difference affects many students, but knowing that a student is an English native speaker does not give us much information about whether the student will enroll or not. It contains information that is not useful for prediction, but nevertheless may be important to an analyst attempting to understand the two groups.

Formally, we can describe the two approaches as follows: Let  $X$  be the set of attributes and values with which we describe the differences.  $X$  can be a single attribute value pair such as  $X = \{\text{native language} = \text{English}\}$  or it can be a conjunction, e.g.  $X = \{\text{GPA} > 4 \wedge \text{UCI distance} > 100 \text{ miles}\}$ . Let  $y$  be the class or category. Then discriminative approaches attempt to find  $X$  such that the following equation is maximized.<sup>1</sup>

$$|P(y = c_1|X) - P(y = c_2|X)| \quad (1)$$

Characteristic approaches attempt to find  $X$  such that

$$|P(X|y = c_1) - P(X|y = c_2)| \quad (2)$$

is maximized. Note that we can relate these two equations with Bayes Rule:

$$P(y|X) = \frac{P(X|y)P(y)}{P(X)} \quad (3)$$

<sup>1</sup>The exact form of the equation that is maximized can vary somewhat from this definition, but all discriminative approaches concentrate on finding large differences in  $P(y|X)$ .

Thus we can always convert from one to the other. Although the forms can be made equivalent, the difference is that the  $X$  that optimizes/maximizes Equation 1 is not necessarily the same as the  $X$  that is best for Equation 2.

We now describe two algorithms representative of the approaches. C5 (Quinlan, 1993) which is a discriminative approach and STUCCO (Bay & Pazzani, 1999) which is a characteristic approach.

## A Discriminative Approach: C5

A discriminative approach to distinguishing two or more groups from each other is to use a rule learner or decision tree to learn a classification strategy. In this paper, we use the program C5 which is an updated version of C4.5 (Quinlan, 1993). It is a workhorse of the Machine Learning community and is a gold standard to which many new algorithms are compared.

Given two categories  $c_1$  and  $c_2$ , C5 attempts to find sets of variables such that Equation 1 is maximized and so that as many examples in the database are covered by rules as possible. C5 performs greedy heuristic search to develop a decision tree. Starting at the root of the tree, C5 selects an attribute-value test to partition the feature space. Each partition is represented by a child node and is then recursively divided with more tests. The tests are chosen to create child nodes which tend to be mainly of one class.

After finding the tree, C5 can then convert it to rules and remove unnecessary terms imposed by the top down tree structure. It does this by following the path from the root to every leaf and constructing one rule for each path. The rules contain every term that appears in nodes along the path. C5 then tests each term that appears in a rule and removes terms that offer no predictive benefit.

## A Characteristic Approach: STUCCO

Here we briefly review the STUCCO algorithm for mining contrast sets. The reader is directed to (Bay & Pazzani, 1999, 1999b) for a more detailed description.

STUCCO is a complete mining algorithm that searches for contrast sets, conjunctions of attribute-value pairs, that have substantially different probabilities across several distributions or groups. The goal is to find contrast sets where the value of Equation 2 is greater than a threshold  $\delta$ .

STUCCO takes a two stage approach to mining. In the first stage, STUCCO searches for all possible contrast sets that meet the criteria. In the second stage, STUCCO summarizes the mined results to present only a small set of rules.

STUCCO organizes the search for contrast sets using set-enumeration trees (Rymon, 1992) to ensure that every node is visited only once or not at all if it can be pruned. Figure 1 shows an example set-enumeration tree for four attribute-value pairs. STUCCO searches this tree using breadth-first search; it starts with the most general terms first, i.e. those contrast sets with a single attribute-value pair such as  $\text{sex} = \text{female}$  or  $\text{UCISchool} = \text{Engineering}$ . These sets are the easiest to understand and will have the largest support. It then progresses to more complicated sets that involve conjunctions of terms, for example,  $\text{sex} = \text{female} \wedge \text{UCISchool} = \text{Engineering}$ .

During search, STUCCO scans the database to count the support of all nodes for each group. It examines the counts

Figure 1: Example search tree for four attribute-values pairs  $\{1,2,3,4\}$ .

to determine which nodes meet the criteria and which nodes should be pruned. STUCCO also explicitly controls the search error to limit false discoveries by keeping careful track of the number of statistical tests made to verify Equation 2 and adjusting the  $\alpha$  level for individual tests to control the overall Type I error rate.

In the second stage, STUCCO summarizes the mined results by showing the user the most general contrast sets first, those involving a single term, and then only showing more complicated conjunctions if they are surprising based on the previously shown sets. For example, we might start by showing the contrast sets  $\text{sex} = \text{female}$ ,  $\text{UCISchool} = \text{Engineering}$ , and  $\text{GPA} > 4$ . STUCCO would then move on to showing more complicated sets such as  $\text{sex} = \text{female} \wedge \text{UCISchool} = \text{Engineering}$  or  $\text{UCISchool} = \text{Engineering} \wedge \text{GPA} > 4$ , and finally  $\text{sex} = \text{female} \wedge \text{UCISchool} = \text{Engineering} \wedge \text{GPA} > 4$ . The conjunctions are only shown if their frequencies could not be predicted from the subsets using a log-linear model (Everitt, 1992). This hierarchical approach eliminates many uninteresting results and can reduce the number of mined results by more than an order of magnitude leaving a small set of rules for a user to view.

## Analysis of UCI Admissions Data

At UCI, the admissions office collects data on all undergraduate applicants. The second author serves on a campuswide committee whose goal is to analyze this data to identify changes that could be made to admissions policies that would improve the quality, quantity, and diversity of students that enroll at UCI. Currently the admissions officers typically analyze the data by manipulating spreadsheets and thus they can only form simple summaries and do not perform detailed multivariate analyses that would be provided by a data mining algorithm.

Here, we report on an analysis of the 1999-2000 enrollment data to identify differences between students who chose to enroll and those who did not for all students accepted at UCI. There were a total of 13344 students given admission offers, of which 3871 accepted and enrolled at UCI and 9473 who did not. For each student, the data contains information on variables such as ethnicity, UCI School (e.g. Arts, Engineering, etc.), sex, home location, first language, GPA, SAT scores, Selection Index Number (SIN) which is a composite

score formed from GPA and SAT scores, statement of intent to enroll, etc. We joined the data with a zipcode database and added fields for the distance to UCI and to other UC schools. Numeric variables, such as SAT scores and distances were manually converted into nominal variables at thresholds that are meaningful for the admissions office.

We ran STUCCO and C5 on the data to obtain contrast sets. For STUCCO we used the following parameter settings:  $\delta = 1\%$  and global  $\alpha = 1$ . For C5 we used the default parameter settings except we set the misclassification costs to balance the different group sizes (typically only 30% of admitted students will enroll). This was necessary as without cost balancing C5 would fail to find any rules distinguishing the two groups and would resort to a default strategy of always predicting that the students would not enroll (the more common class).

Both C5 and STUCCO produce results in their own particular format. To make interpretation easier and to eliminate any bias from the presentation format, we converted the results into an equivalent set of English sentences describing the differences using an identical sentence structure for both C5 and STUCCO. We translated the numeric results associated with the outputs of STUCCO and C5 into *yield* and *gain* which are meaningful quantities for the admissions officers. Yield is the percentage of students that enroll; gain is the difference in the number of students that would enroll if the yield was identical to the average yield. The results can be ordered by gain to highlight the differences that have the largest effect. Rule 1 shows a sample result converted automatically to English text. The full set of results are too big to be shown in this paper, but Appendix A presents a small subset and all examples used in this paper are actual findings.

*Rule 1.* Students who are Korean and have a Selection Index Number between 6000 and 6500 are more likely to enroll with a 30% higher yield than average. This represents a gain of 66 students.

We expressed yield relative to the average. In this example, the yield was 30% higher than average yield (25.6%) which is the percentage of all students who accepted UCI's offer. Thus the yield for this category is  $55.6\% = 30\% + 25.6\%$ . The gain of 66 students is a measure of the *effect size* of the rule, i.e. how many students does it affect? In general, we believe the effect size is a domain independent factor that contributes to how insightful a rule is. For example, in a loan default problem the effect size would indicate how many additional loans that default can be attributed to customers that meet the conditions of the discovered rule.

The discriminative and characteristic approaches resulted in two very different rules sets describing the differences between students who enroll and do not enroll. Table 1 shows the size (as measured by the number of terms in the conjunction) and number of rules mined by C5 and STUCCO. It shows the results for all of the mined rules and the best 30 as measured by gain (we used only the best 30 rules for our experiment in the next section). Examining the table we see that C5 returned far more results than STUCCO and that the individual sets tended to be larger and more complicated. While more complex results are undesirable, by itself, it is not an indication that one method is better than another. Table 2

summarizes the average gain (magnitude only) of the results and in Figure 2 we plot the discovered rules according to their yield difference (with respect to the average yield) and gain. We summarize the differences as follows:

- C5 tends to produce longer rules than STUCCO. The average number of terms in a C5 rule was 3 whereas for STUCCO the average is 1.7.
- Compared with STUCCO, C5 produced rules with higher yield differences but smaller effect sizes.
- C5 produces many rules that are clearly uninteresting because their effect size is very small. For example, on the full set of returned rules the median effect size was only 5 for C5. In contrast, STUCCO’s median was 132.

Table 1: Summary of Results for C5 and STUCCO (S).

Size	All		Best 30	
	C5	S	C5	S
1	25	42	6	17
2	46	24	16	11
3	62	10	6	2
4	35	1	2	
5	21	1		
6	5			
total	194	78	30	30

Table 2: Summary of Effect Size Results for C5 and STUCCO (S). Values were calculated based on magnitude only.

	All		Best 30	
	C5	S	C5	S
median	5	132	125	273
mean	32	175	173	306
min	0	28	34	165
max	495	683	495	683

## Experimental Evaluation

In this experiment, we showed the results from data mining to admissions officers at UCI and asked them to rate the rules according to the insight they provide.

To give an example of an insightful rule, consider Rule 2. Admissions officers at UCI have been uncertain of the effect that the proximity to UCI and other UC campuses plays in student’s college choice. Students who live at home with their parents substantially reduce the cost of higher education. It was well known that students who live close to UCI are more likely to accept offers, but little was understood about how this interacts with other variables. Rule 2 provides insight into this: it suggests that UCI competes fairly well for students with UCLA, UCSD and UC Riverside.

*Rule 2.* Students who live within 30 miles of UCI and live within 30 miles of another UC school are more likely to enroll with a 10% higher yield than average. This represents a gain of 329 students.

As another example of what an admissions officer would find insightful, consider Rule 3. It suggests that UCI does an extremely poor job of recruiting bright students who have not yet declared a major. This is probably because recruiters treated non-declared majors as confused students who needed help rather than as bright students who wanted to explore their options. Due to this discovery, UCI is changing the way it approaches recruiting undeclared students, particularly those with high GPAs.

*Rule 3.* Students who have a GPA greater than 4, and are undeclared majors are less likely to enroll with a 15% lower yield than average. This represents a loss of 123 students.

**Subjects.** The subjects were 4 faculty and staff at the University of California, Irvine who are actively involved in the admissions process and expressed an interest in viewing the results of a computer analysis of admissions data to find factors relating to student recruitment. The subjects did not receive any compensation.

**Stimuli.** The stimuli consisted of two sets of statements corresponding to the outputs of C5 and STUCCO. Each set consisted of 30 rules, 15 describing students with increased yield and 15 describing students with decreased yield. Appendix A shows the 15 increasing yield statements for STUCCO. Within the group of increasing or decreasing yield statements the rules were sorted by gain (largest first). The yield and gain values were rounded to the nearest integer. The subjects were not aware of the algorithm that generated each set of rules.

**Procedures.** Each subject was shown the two sets of rules and were asked to “consider the statements in the context of being an admissions officer whose goal is to improve the quality, quantity, and diversity of students that enroll.” We then asked the subjects to rate each statement on its insightfulness using a scale from -3 to +3, with -3 corresponding to not insightful and +3 corresponding to insightful. After viewing both sets of statements, the subjects were asked to indicate which set they preferred overall.

**Results & Discussion.** Table 3 shows the mean ratings of the experts for both STUCCO and C5. It is clear from the values that the experts are using different scales and that the rules were not equally insightful to all. Experts 1, 2, and 4 rated STUCCO higher than C5. Using a group  $t$  test, the differences were significant for E2 and E4 at the 0.001 level. The difference in ratings were not significant for Experts 1 and 3.

Expert 1 indicated no preference for STUCCO or C5, but the remainder all stated that they preferred the rules which were learned by STUCCO.

Table 3: Mean Ratings for C5 and STUCCO

	Expert			
	E1	E2	E3	E4
STUCCO	0.7	-0.1	1.57	1.23
C5	0.43	-0.87	1.87	0.23
t(58)	0.69	3.48	-1.38	4.87

We pooled the STUCCO and C5 ratings for each expert and then calculated the correlation of the experts ratings with the objective measures of rule quality: yield difference, gain (effect size), and rule size (number of conjuncts). For our calculations we used the magnitude of the yield difference and gain. The results are shown in Table 4. For yield difference and rule size there were no significant correlations with insightfulness. For gain, we found a significant relation for Experts 1 and 2. With a  $t$  test of a correlation coefficient ( $H_0: \rho = 0$ ), the results are significant at the 0.01 level or better. This suggests that the effect size is a factor in determining how insightful domain experts find the discovered differences. Since STUCCO finds many rules with large effect sizes, experts seem to prefer the STUCCO rules.

Table 4: Correlation of Ratings to Objective Rule Measures

	Expert			
	E1	E2	E3	E4
Yield Diff.	0.1406	-0.0827	0.1664	-0.1139
Gain	0.5598	0.4316	0.2469	0.0848
Rule Size	-0.2449	-0.2224	0.0787	-0.2620

We believe there are other factors that influence the ratings of insight given to a rule. In particular, some rules are already well known to the admissions officers. In addition, some admission officers have a particular focus (e.g., minority students) and would be more interested in rules of that type. We tabulated the inter-correlation of the experts in Table 5 using the pooled C5 and STUCCO responses. The results are surprisingly in that the correlation between experts is very low. Figure 3 plots the ratings of E2 and E4, the experts with the highest correlation. This suggests that insight is very subjective and there are important individual differences, possibly relating to the prior knowledge of the task.

Table 5: Correlation of Ratings Between Experts

	Expert		
	E2	E3	E4
E1	0.2748	0.1028	-0.1329
E2		0.1894	0.2778
E3			-0.1613

## Related Work

Insightfulness is an extremely difficult notion to capture, and this work has only begun to investigate this concept. Blake and Pazzani (2000) have taken an orthogonal approach to understanding when a rule is insightful. They examined how background knowledge encoded in an electronic knowledge base could be used to remove uninteresting rules from a set. In contrast this work examines how the discovery strategy (discriminative or characteristic) affects the insight of rules found and how insightfulness correlates with objective measures of rule quality.

Clearly, before a rule can be insightful to a person, it must be understood and considered valid. In the past, researchers have considered understandable as synonymous with “short” and thus designed mining algorithms with a strong bias towards rules that are short and accurate under this assumption (Karalic, 1996; Craven, 1996). While this makes intuitive sense, there have been no studies which quantitatively confirm this. There have been two studies which indicate that perceived validity of the mined rules affects the credibility and willingness to use mined results: Pazzani, Mani, and Shankle (1997) examined the effect of monotonicity relationships on rule acceptance in diagnosing potential Alzheimer patients. They found that regardless of rule accuracy neurologists were unwilling to use rules which violated the intent of the diagnostic test. Pazzani and Bay (1999) looked at the effect of incorrect signs on the credibility of regression equations and likewise found that equations where the sign of a variable differed from subjects expectations were rated poorly. An interesting result of their study was that longer regression equations were more credible than shorter equations.

Silberschatz and Tuzhilin (1996) suggested that interestness is a subjective quality that depends on the individual. However, they did not test this theory quantitatively with human subjects. Our results with inter-expert agreement support their theory.

<sup>2</sup>A small amount of random jitter has been added to the points.

## Conclusions and Future Work

We asked the following two questions in our paper: “Is a discriminative or characteristic approach more useful for describing group differences?” and “How do subjective and objective measures of rule interest relate to each other?”

We answered these questions by conducting a study of admissions officers and their responses to the outputs of the data mining algorithms C5 and STUCCO. Our main findings are that (1) characteristic differences are more useful to domain experts than purely discriminative differences. (2) Many objective measures of rule quality correlate poorly with expert opinions on what is insightful, but there is some evidence that effect size is important. (3) Rule insightfulness is highly subjective as even experts examining the rules for the same task do not correlate well with each other.

This paper presented an initial study of how experts with a particular task in mind evaluated data mining discoveries. It is important to use experts because they represent the intended users of the mining programs and will have a distinct purpose in mind when evaluating results. However, the limitation is that experts are inherently rare and thus we were only able to obtain the responses from four people. We plan on conducting a larger study on a less specialized domain so that we can involve more subjects.

## Acknowledgments

This research was funded in part by the National Science Foundation grant IRI-9713990.

## Appendix A

We show here the 15 positive yield rules with the largest gain found by STUCCO.

1. Students who live within 30 miles of UCI are more likely to enroll with a 11% higher yield than average. This represents a gain of 455 students.
2. Students who have a Selection Index Number between 6000 and 6500 are more likely to enroll with a 15% higher yield than average. This represents a gain of 443 students.
3. Students who have a GPA between 2.75 and 3.5 are more likely to enroll with a 16% higher yield than average. This represents a gain of 415 students.
4. Students who live within 30 miles of UCI and live within 30 miles of another UC school are more likely to enroll with a 10% higher yield than average. This represents a gain of 361 students.
5. Students who are from Orange County are more likely to enroll with a 13% higher yield than average. This represents a gain of 323 students.
6. Students who are from Orange County and live within 30 miles of UCI are more likely to enroll with a 13% higher yield than average. This represents a gain of 319 students.
7. Students who scored less than 500 on their SAT Verbal are more likely to enroll with a 17% higher yield than average. This represents a gain of 310 students.
8. Students who scored between 500 and 600 on their SAT Math are more likely to enroll with a 8% higher yield than average. This represents a gain of 291 students.
9. Students who have a Selection Index Number between 6000 and 6500 and scored between 500 and 600 on their SAT Verbal are more likely to enroll with a 14% higher yield than average. This represents a gain of 235 students.
10. Students who have a Selection Index Number between 6000 and 6500 and scored between 500 and 600 on their SAT Math are more likely to enroll with a 14% higher yield than average. This represents a gain of 216 students.

11. Students who scored between 500 and 600 on their SAT Verbal are more likely to enroll with a 4% higher yield than average. This represents a gain of 200 students.
12. Students who have a GPA between 2.75 and 3.5 and have a Selection Index Number between 6000 and 6500 are more likely to enroll with a 16% higher yield than average. This represents a gain of 186 students.
13. Students who have a Selection Index Number between 5000 and 6000 are more likely to enroll with a 19% higher yield than average. This represents a gain of 173 students.
14. Students who live within 30 miles of another UC school are more likely to enroll with a 2% higher yield than average. This represents a gain of 166 students.
15. Students who have a GPA between 2.75 and 3.5 and scored between 500 and 600 on their SAT Math are more likely to enroll with a 18% higher yield than average. This represents a gain of 165 students.

## Abstract

Landmarking is a novel approach to inductive model selection in Machine Learning. It uses simple, bare-bone inductive strategies to describe tasks and induce correlations between tasks and strategies. The paper presents the technique and reports experiments showing that landmarking performs well in a number of different scenarios. It also discusses the implications of landmarking to our understanding of inductive refinement.

## Introduction

One of the central goals of cognitive science is to uncover mechanisms that allow agents to produce and manage knowledge. Although informed by existing theories of living organisms, the chief contribution of artificial intelligence, is to investigate knowledge mechanisms in abstract, that is, independently of their psychological or neurological plausibility. Machine learning endeavours to study induction, one of the basis of knowledge production. It considers different inductive strategies, their performance in different scenarios.

Not surprisingly, different inductive strategies are adequate for different inductive tasks. Theoretical results show that there is no inductive strategy that can perform well in every conceivable task (Schaffer, 1994). Some practitioners of machine learning reacted to this predicament by insisting that not every conceivable inductive tasks is equally deserving of attention. If we concentrate on a subset of all conceivable tasks, some people claim that we should restrict ourselves to “real world problems”, we can find a small number of strategies that can handle induction (Rao, Gordon & Spears 1995). The problem arises when we try to give a precise definition for the set of “real world problems”. In any case, we face correlations between sets of tasks, or problems, and induction strategies. Strategies perform well only in a subset of the set of all tasks, this subset is often called the *area of expertise* of a strategy. Machine learning is then left to discover, by induction, correlations between inductive strategies and their area of expertise. One way of doing this is by automating this search for correlations between tasks and strategies. This process is often called *meta-learning* and a number of different approaches has been proposed (see Bensusan (1998,1999), Giraud-Carrier & Hilario (1998), Giraud-Carrier & Pfahringer (1999), Lindner & Studer (1999)). Meta-learning has a number of general consequences for the study of cognition.

This paper explores some of the general consequences of a new way of doing meta-learning, called *landmarking*. The technique has been introduced recently (Bensusan & Giraud-Carrier 2000; Pfahringer, Bensusan & Giraud-Carrier 2000) and some new results are reported here. Landmarking searches for correlations between tasks and inductive strategies by exploring the similarities between different strategies in order to locate the task in a map of areas of expertise. The discovery of similarities between strategies can prove to be a tool to refine inductive strategies and, ultimately, a way to sketch an explanation of human inductive success.

This paper is organised as follows. Next section introduces landmarking. The following section presents experiments that assess its performance. Then we consider some of its implication for the general study of induction and cognition. A last section concludes the paper.

## Meta-learning through landmarking

Meta-learning is the endeavour to automatically discover correlations between tasks and inductive strategies. To simplify without loss of generality, let’s concentrate on supervised learning tasks.<sup>1</sup> These tasks are composed by a set of examples described by attribute values and classified according to a target function. The induction of the difference in extension of the predicates “lemon” and “watermelon”, for example, may include attributes such as COLOUR, SHAPE, SIZE. Something YELLOW, EGG-SHAPED, SMALL qualifies as lemon whereas something GREEN, ROUND, BIG is a watermelon. If the attributes that describe the example are not well-chosen, learning could be very difficult. Consider, as an example, the following worse set of attributes for the “lemon-watermelon” problem above: IS IT A VEGETABLE?, IS IT A FRUIT?, DOES IT FLY?. The two examples are now described as NO, NO, YES. The importance of the example description derives from the fact that inductive strategies rely on representations to generalise. Successful inductive hypotheses are the ones that can represent accurately the similarities and the differences relevant to the task.<sup>2</sup>

<sup>1</sup>Although there are different uses of the terms “induction” and “learning”, in this paper we shall use the terms as interchangeable.

<sup>2</sup>Data representation is important because every learning strategy has what machine learning calls a *representational bias*, a preference for hypotheses with a specific representa-

Meta-learning tasks are inductive tasks. Here, the examples, instead of being lemons or watermelons, are inductive tasks classified according to the best inductive strategy to tackle them. Thus, we have: TASK1 -> NAIVE BAYES, TASK2 -> BACKPROPAGATION, TASK3 -> NEAREST NEIGHBOR etc where each of the inductive strategy mentioned after the arrow is the best strategy for the task before the arrow.<sup>3</sup> The meta-learning task is to use these examples to learn how to classify new tasks in terms of the most suitable inductive strategy. The crucial question for meta-learning is therefore how to describe tasks.

Different approaches to task description have been proposed. These include the use of statistical features of the dataset in the task (Michie et al. 1994) and the use of features of a decision tree representation of the task (Bensusan 1998; Bensusan 1999). In the latter, an inductive hypothesis, namely the one produced by a decision tree induction method, is used to describe the task. Landmarking also makes use of specific inductive methods to describe the task, but makes use of the method's performance rather than the method's induced hypothesis.

The basic idea of the landmarking approach is that the performance of an inductive strategy on a task uncovers information about the nature of the task. Tasks are described by a set of attributes corresponding to the performance of simple, efficient strategies on them. These strategies are expected to indicate which other, more refined strategy is the best to tackle the task. They act, therefore, as landmarkers, indicating where, in the space of all areas of expertise, the task belongs. It explores empirically the relationships between areas of expertise of different learners.

The kind of inference on which landmarking relies can be illustrated with the help of Figure 1. The rectangle represents a set of inductive tasks and the ellipses represent subsets of the set of tasks where a given inductive strategy performs well, that is, areas of expertise. Assume that  $i1$ ,  $i2$ , and  $i3$  are taken as landmarkers. In this case, landmarking concludes that problems on which both  $i1$  and  $i3$  perform well, but on which  $i2$  performs poorly, are likely to be in  $i4$ 's area of expertise etc. Of course, the proximity of the areas of expertise of two strategies indicates some similarity between the inductive mechanisms behind them. For landmarking purposes, however, it is sufficient to concentrate on so-to-speak cartographic considerations. Tasks are described by how some landmarkers fare on them. Exploring the meta-learning potential of landmarking amounts to investigating how well a landmark learner's performance hints at the location of the respective learning tasks in

tion (Haussler, 1989; Russell & Grossof 1990). Thus, most Decision Tree induction algorithms prefer simpler decision trees, most rule induction algorithms prefer simpler rules. There is a trade-off between the need for good input representation and the strength of the strategy's preference (Craven & Shavlik, 1995).

<sup>3</sup>For a survey of the most used inductive strategies including all those to be mentioned in this paper consult Mitchell (1997).

the expertise map.

Figure 1: Example of map of areas of expertise

Landmarking relies on some simple and efficient inductive strategies to signpost the location of a task in a map of expertise areas. Landmarking discovers experimentally which inductive strategies are similar enough to have neighbouring areas of expertise. It therefore finds neighbourhoods of inductive strategies and, ultimately, draws a map of areas of expertise. While other approaches represent tasks in a way only indirectly related to their location in an expertise map, landmarking faces them as points in the map to be described in terms of their distance to some known milestones.

Landmarking is a tool to discover the areas of expertise of a learning device. In fact, this is the very goal of machine learning research: to establish the strength and the scope of different inductive strategies. In addition, it highlights which tasks fail to belong to the area of expertise of any of the existing inductive strategies. It can therefore direct the search of new strategies towards areas of the expertise map not currently covered by any learning method. If successful, it can guide the crafting of new inductive methods and work as the basis for a model of inductive refinement. Let's turn now to some experiments designed to measure its success.

## Experiments with landmarking

A number of experiments to test landmarking are reported in (Bensusan & Giraud-Carrier 2000). The results show that landmarking successfully meta-learns in a number of different scenarios. Successful results mean that selection of inductive strategies can be done through the information contained in the performance of some landmark inductive strategies. In this section, we summarise some of these results and present new ones.

Experiments on landmarking can be done only through selecting a set of landmarkers. The landmarkers change according to what we call the *learners pool*, i.e., the set of target learners from which one must be

selected. It remains to be investigated how close can we get from a universal set of landmarkers that can be used in any learners pool. In the experiments reported here, we used the following set of landmark learners. For each, we include the motivation for its inclusion in the set.

1. *Decision node*: A single decision node is chosen according to C5.0’s information gain-ratio (Quinlan 1993, Mitchell 1997). The node is then used to classify test examples. This landmark learner aims to establish closeness to linear separability.
2. *Randomly chosen node*: A randomly chosen attribute is used to split the training set and classify the test examples. This landmark learner informs about irrelevant attributes.
3. *Worst node*: Here the gain-ratio information criterion is used to pick up the least informative attribute to make the single split. This landmarker, together with the first one, is supposed to tell us something else about linear separability: if neither the best nor the worst attribute produce a single well performing separation, it is likely that linear separation is not an adequate learning strategy.
4. *Naive Bayes*: The training set is used to estimate the probabilities required to use the Bayes theorem to classify test cases (Mitchell, 1997). This landmark learner intends to measure how conditionally independent the attributes are, given the class.
5. *1-Nearest Neighbor*: The test set is classified based on the classification of the closest training example (Mitchell 1997). This landmark learner measures how close instances that belong to the same class are.
6. *Elite 1-Nearest Neighbor*: This computes 1-Nearest Neighbor on a subset of all attributes. This elite subset is composed by the most informative attributes if the gain-ratio difference between them is smaller than  $0.1^4$ . Otherwise, the elite subset is a singleton and the learner acts like a decision node learner. This landmark learner intends to establish whether the task is a relational one, that is, if it involves parity-like relationships between the attributes (Clark & Thornton, 1997). In relational tasks, no single attribute is considerably more informative than others.
7. *Majority-class guesser*: The test set is classified according to the most common class in the training set. This landmark learner intends to inform about the frequency of the majority class.
8. *Linear Discriminant*: A linear approximation of the target function is sought (Gama, 1999). This landmark learner intends to measure closeness to simple linear separation.

---

<sup>4</sup>This threshold is based on the results reported in Ben-susan (1999).

The performance of the different landmarkers are given by the average performance on all the existing examples of the induction problem, the so-called *instance space* of the induction made from 10 different subset of examples (*training sets*) of equal size. This approach, although different from the standard practice of *cross-validation* where the sets of examples are drawn without replacement, is an efficient way to estimate how the landmark learners perform in each task. Therefore, inductive tasks are described by landmarker’s performance values. The task is then labelled by the learner with greater average accuracy on the task, using a 10-fold cross-validation approach. Each task can be labelled by a learner’s name or as “tie” when the difference in performance between the best and the worst learner is less than 10%. A (meta-)dataset with 5 examples described by 4 landmarkers looks as follows:

```
0.42187,0.46875,0.46250,0.30781,Ripper
0.45312,0.42187,0.45000,0.26250,IB
0.54687,0.56250,0.45937,0.29844,C5.0tree
0.51562,0.59375,0.43750,0.28750,MLP
0.43750,0.51562,0.43125,0.27812,tie
```

Given the (meta-)dataset, the meta-learner aims at finding correlations between the performances of the learners in the pool and that of the landmarkers.

In the first experiment, we compared landmarking with an existing approach to task description for meta-learning. This approach uses a number of information-theoretical properties of the data to describe the task (Michie et al. 1994). We implemented this information-theoretical approach by considered the following 6 features defined on literature as meta-attributes: Entropy of the class, Average entropy of the attributes, Mutual information, Joint entropy, Equivalent number of attributes, Signal-to-noise ratio. The task was to select among the following 10 learning algorithms: C5.0, C5.0 with boosting, C5.0 rules, Multi-layer perceptron trained with backpropagation (MLP), Radial-based function networks (RBF), Linear discriminant, Ltree (see Gama, 1999), Naive Bayes (NB), Instance-Based inducer (IB) and Ripper. Landmarkers 1,2,3,4,5,6,8 were used. 320 Boolean tasks were considered. The 10 learning algorithms in the learner pool were also used for meta-learning in all experiments. Error rates were based on stratified 10-fold cross-validation. Results are given in Table 1. The first line reports the error rate of the default class that, in this case, was “tie”.

The table shows that landmarking outperforms the information-based task description and therefore it is a suitable competitor. Notice that landmarking outperforms the information-based approach with all of the 10 meta-learners. Moreover, the difference in error is around 10% with the three C5.0 meta-learners. The table also shows that adding the information-based features to describe the task impairs landmarking performance.

Next, we considered a number of learners pools with two inductive strategies. Learners pools were composed by pairs of the following inductive strategies: C5.0(with boosting), C5.0(rules), Naive Bayes (NB), Instance-

Table 1: Comparison between different ways to describe tasks: performances of the landmarking approach (L), the information-based approach (Info) and the combined approach (Combined) using 10 different meta-learners.

Meta-learner	Land	Info	Combined
Default Class	0.460	0.460	0.460
C5.0boost	0.248	0.360	0.295
C5.0rules	0.239	0.333	0.301
C5.0tree	0.242	0.342	0.314
MLP	0.301	0.317	0.320
RBFN	0.289	0.323	0.304
LD	0.335	0.311	0.301
Ltree	0.270	0.317	0.286
IB	0.329	0.366	0.342
NB	0.429	0.407	0.363
Ripper	0.292	0.314	0.295
Average	0.298	0.339	0.312

Based induction (IB), Ripper and Multi-layer perceptron (MLP). Landmarkers 1,2,4,5,6,7,8 were used. Tasks were classified as a *tie* between the two strategies when the average error difference between the learners in the pool was less than 0.1. We used 927 artificially generated Boolean and MONK-like datasets (Thrun et al, 1991). Boolean instance spaces had between 5 and 12 attributes. The error rates given in table 2 are the average 10-fold cross-validation error of 5 inductive strategies used for meta-learning: IB, MLP, C5.0boost, Ripper and Radial Basis Function Network Induction (RBF).

Table 2: Landmarking to choose between pairs of learners

Learner pool	Error
NB-IB	0.383
NB-MLP	0.179
NB-Ripper	0.181
C5.0boost-MLP	0.246
C5.0boost-NB	0.359
C5.0rules-Ripper	0.204

In a different experiment, we looked at the suitability of inductive strategies and groups of similar inductive strategies. We considered that a task is suitable for a learner if it performs better than the average of 10 standard learners: C5.0, C5.0rules, C5.0boost, MLP, RBF, Linear Discriminant, Ltree, NB, IB and Ripper. For this experiment we used only landmarks 1,2,3 and 6 as they are all decision node based and are arguably enough to diagnose at least whether decision tree induction is a good way to approach the task. We used 222 tasks from the set used in the previous experiment and the 10 standard learners mentioned above to perform the meta-learning induction. We looked at the suitability of IB, NB, C5.0boost, neural network inductive strategies (MLP and RBF) in general (NN), rule induction strate-

gies (Ripper and C5.0rules) and decision tree strategies (C5.0, C5.0boost, Ltree). The error rates given in table 3 are the average 10-fold cross-validation error of the 10 inductive strategies used for meta-learning.

Table 3: Suitability of inductive approaches. Error rates for the default class prediction and for meta-learning with landmarking are given.

Approach	Default class	Landmarking
IB	0.420	0.297
NB	0.380	0.298
C5.0boost	0.510	0.449
NN	0.440	0.386
Rules	0.370	0.281
Trees	0.470	0.390

These results show that most meta-learners produce error levels smaller than the default error class and often the difference is substantial. Notice that error rate figures don't reflect the overall performance, that is the accuracy of the selected learning model. In another experiment, we tried to estimate this by using the 222 Boolean problems as tasks of a meta-learning training set and 18 other tasks to test the hypotheses and compare the selected approach with the best performing one. The 18 tasks of the test set were from the standard repository of benchmark induction problems maintained by the University of California at Irvine (UCI); these are commonly considered to be "real world problems". We chose the following problems: mushrooms, abalone, crx, sat, acetylation, titanic, waveform, yeast, car, chess(king-rook-vs-king), led7, led24, tic-tac-toe, MONK1, MONK2, MONK3, satimage, quiscas.

The results reported for this experiment are the average error difference between the best choice and the selected choice in the 18 UCI problems. If the average is in fact better than the chosen model, we consider the error difference between the chosen model and the average. Similarly if the meta-learner had chosen against the model that in fact is better than the average of the 10 learners. Here we used only C4.5 (Quinlan, 1993) as meta-learner. Average error difference appear in table 4.

Table 4: Average error difference between best and chosen option in the 18 UCI datasets

Approach	Error difference
IB	0.0356
NB	0.0165
C5.0boost	0.0443
NN	0.0314
Rules	0.0360
Trees	0.0211

The small average error difference shows that the chosen strategy, even when is not the best, performs well. It shows that landmarking seldom make choices that per-

form considerably worse than the best alternative. This is confirmed further by an experiment in the same scenario. Now we used only the 14 UCI tasks listed above as training set and tested the C4.5 hypothesis in the remaining four UCI tasks (MONK2, MONK3, satimage, quis-clas). The results obtained have a greater variation than the previous one but shows that in some cases landmarking perform completely accurately. Table 5 summarises the new results.

Table 5: Average error difference between best and chosen option in 4 UCI tasks after training on 14 UCI tasks only

Approach	Error difference
IB	0.0675
NB	0.0605
C5.0boost	0.0000
NN	0.0000
Rules	0.0443
Trees	0.0172

These results, although still preliminary, show that landmarking is capable to select inductive approaches. They suggest that it pays off to run bare-bone, landmark inductive strategies on a number of tasks and learn how their performance relates to that of other, more fleshed-out strategies. This far, we have indicated how the performance of simple inducers in a task can be used for meta-learning. We move now to the significance of landmarking for a general theory of induction.

### Discovering inductive strategies

*For me [...] the problem of induction is a problem about the world: a problem of how we, as we are now [...], in a world we never made, should stand better than random or coin-tossing chances of coming out right when we predict by inductions that are based on our innate [...] similarity standard. Darwin's natural selection is a plausible partial explanation.*  
W. V. O. Quine

One of the problems of explaining human (and animal) cognitive practices in general and inductive practices in particular is to account for success. Humans are remarkably good at inducing in familiar environments and seem to make heavy use of their background knowledge accumulated through inductions made in their lifetime history or received as cultural material. Studies on human induction on tasks similar to the MONK problems have established that prior knowledge influences the rate of concept learning, and the logical form of concepts formed during learning is a function of the logical form of the concepts previously acquired (Pazzani, 1991). In general, humans rely on previous acquisition of concepts and common-sense knowledge about the area to learn new concepts (Wisniewski & Medin, 1994; Heit, 1994). Background knowledge and the ability to meta-learn enable humans, when for instance engaged with scientific

theory building, to perform successful inductions from one or few examples.

Human inductive trajectory from innate instincts to refined theories about the world is Quine's view of the problem of induction: a problem about the world. A plausible partial complement to Darwin's natural selection is to find a model of exploiting previous induction experience to boost performance. Such model, of course, has to accommodate the partial explanation role that natural selection plays. The inductive trajectory towards greater efficiency in familiar environments had its origins in evolutionary selection of relevant inductive mechanisms. Recent there have been attempts to characterise human innate inductive tendencies in terms of learning biases (Elman et al., 1996; Dessalles, 1998). Leaving aside the question of how our inductive practices are guided by our innate instincts, we can sketch a model of the human inductive trajectory according to which our similarity standards by means of which we generalise are partly product of evolution, partly a consequence of a gradual process of refinement. We claim that landmarking can be part of an account of inductive refinement.

Landmarking is a technique to select the most adequate inductive strategy for a task, but it can also be seen as an instrument for inductive refinement. It suggests ways in which better, increasingly appropriate inductive strategies, can be constructed from rudimentary ones. Landmarkers are simple inductive strategies that can characterise tasks. Thus, they can outline new inductive strategies to adequately cover areas of the expertise map; describing the area in terms of how different learning biases fare there is a step towards constructing more refined biases that can tackle it. As a way to describe tasks, landmarking has far-reaching consequences beyond strategy selection: to landmark a group of tasks could be the first step towards the development of an inductive strategy to tackle it. This is arguably what happens when a scientist applies various simple methods to a problem in order to get information about what more sophisticated method to develop. This could also be what happens when new problems had to be addressed by humans with only few, unrefined inductive tools. Landmarking is a way to discover relationships between different strategies and, as such, to establish what is needed to ease learning. In this sense, it not only bears similarities with other methods that exploit the nature of the task to decide which way to go (Clark & Thornton, 1997) but also can be seen as a general framework for those methods as it describes tasks only in terms of a portfolio of learning performances. The emerging picture is one where the records of failure and success of the current induction tools are used to inform how these tools need refinement. Successful learning, landmarking suggests, might require learning with previous mistakes and accomplishments.

### Conclusions

*Wär nicht das Auge sonnenhaft, die Sonne koennt'es nie erblicken.* Goethe, Zahme Xenien, Werke, Weimar 1887-1918, bk 3, 1805.

Landmarking is a strategy to describe tasks so that no more than a small class of efficient learning algorithms is required. Tasks are described by their position in the expertise map. It can also be used to locate and explore expertise *terra incognita*. It can be seen as part of a model of inductive refinement whereby the description of a task in terms of landmarks offers the raw material for the development of new induction tools. The picture offered by this model is one in which human inductive abilities are roughly tuned to their environment; no survival and no refinement could start from a completely alien inductive toolkit. Evolution gives part of the explanation. But the gradual refinement that sharpens the kit and assembles new instruments is what turns the original *harmonia loosely praestabilita* into an inductively adapted species.

### Abstract

Path and manner are important organizing dimensions of verb lexicons. We investigated how priming with path verbs, manner verbs, or no priming might influence event processing. Before watching a videotaped target event, subjects were primed by path and manner verbs accompanying other, unrelated events. We found effects of priming verbs on the verbs subjects produced to describe an unlabeled event. We found effects of verb produced on subsequent recognition. We compare these effects from self-generated verbs with effects from experimenter-produced verbs.

### Introduction

Language and vision provide two powerful systems for learning from the world. Information acquired from what we see and what we are told is the basis for much of our knowledge of the world (Jackendoff, 1987). How does language influence processing of visually presented information? Researchers have tested for effect of language on nonlinguistic cognition within- and between- languages.

Tests for within-language effects vary the term or expression accompanying nonlinguistic information and look for effects of language on nonlinguistic cognition. Typically, this research is motivated by questions about effects of schema or expectations on memory, not questions about language per se. For example, experiments from tests of top-down effects (Carmichael, et al, 1932; Gentner & Loftus, 1979; Schooler & Engstler-Schooler, 1990) to tests of eyewitness testimony (Hall, Loftus, & Tousignant, 1984; Loftus & Palmer, 1974; McCloskey & Zaragoza, 1985) have found effects of accompanying labels or descriptions.

Tests for between-language effects have been motivated by the Whorfian (1956) hypothesis. Recent studies have found effects of languages on a variety of cognitive tasks (Gopnik & Choi, 1990, Hoffman, Lau, & Johnson, 1986, Shatz, Martinez, Diesendruck & Akar, 1995; also noneffects Malt et al, in press) including visual memory (Levinson, 1996). Most relevant to the domain we investigate is the

research on event representation, specifically path versus manner information. Researchers have found between-language effects on how path versus manner is expressed (Berman & Slobin, 1994; Naigles et al 1998) and affects similarity (Naigles, personal communication).

Our research investigates within-language effects on event memory for path versus manner information. Specifically, we look at how alternative, descriptive verbs effects visual recognition. We were particularly interested in how path and manner verbs affect memory for path and manner information because these aspects of events seem particularly prominent and important.

Manner verbs refer to the way in which a figure carries out a motion. "Hop," "skip," and "jump" are examples of English manner verbs. Path verbs refer to the trajectory over which a figure moves, typically with respect to another reference object. "Rise," "arrive," and "cross" are examples of English path verbs. Manner and path are two of only a handful of aspects of motion events which are typically conveyed by the verbs of a language. This privilege suggests both aspects are central, important information in other aspects of event cognition. Languages seem to select one of these aspects to be normally conveyed by the verbs, with other information typically carried by 'satellite' constructions outside the verb (Talmy, 1985). In English the verb lexicon is organized around manner information and path information is typically conveyed by expressions outside the verb, specifically prepositional phrases. Many other languages, including Romance languages, typically convey path information in the verb and manner in satellites. Nevertheless, within any one language there is variation in verb meaning as well: English has a handful of path verbs, most lower frequency and of Latinate origin (Levin, 1993). Thus manner and path are two important aspects of verb representation that are systematically expressed in language, their method of expression differs across languages, but there is also some variation within a language.

Our previous research (Billman & Krych, 1998) capitalized on within-language variation (verb choice) to investigate how language information and visual information might be coupled. We presented participants

with video-taped events accompanied by either manner or path verbs. Participants returned for a visual recognition test in which no verbs or labels were presented. The test required discriminating the old items from new items with changed manner of motion or else changed path of motion. We found that type of verb initially spoken by the experimenter interacted with the type of recognition errors. Specifically, hearing a path verb (“exiting”) made participants more likely to correctly reject a changed path foil relative to hearing a manner verb (“skipping”) and hearing a manner verb aided rejection of changed manner foils relative to hearing a path verb.

The current experiment also looks for this disordinal interaction of language at encoding with type of recognition error. It also uses much the same presentation of events at encoding and test. However, the language manipulation is more indirect.

In the current experiment, the participant generated a verb describing the target events and we looked for effects of this participant-generated verb on recognition. We tried to influence the participants' choice of verb by priming (encouraged by other priming effects in language, Bock, 1990). Our primes were experimenter-provided manner or path verbs for unrelated events shown before the target.

We look for 1) effects of priming condition on the type of verbs generated, 2) effects of self-generated verbs on type of recognition, and 3) also for a direct effect of priming condition on type of recognition errors. We expected that effects of labeling by self and by another would be similar, and to this extent expected to replicate and extend our previous findings. However, there might also be differences. Listening to language generated by others might be more likely to focus a listener on aspects of the event not already attended to. Production processes might be more strongly influenced by language-internal factors such as markedness, frequency, and existence of alternative similar forms.

## Method

### Participants

Ninety-nine Georgia Tech students received course credit for participation. Data from the 75 self-reported, monolingual native English-speaking students are reported here.

### Procedure

On the first day participants viewed a series of everyday events. In the Path and in the Manner Condition, some events were labeled with a verb by the experimenter and these labeled trials served as primes. In the No Language (unprimed) Condition no events were labeled by the experimenter. In all conditions there were a few target events unlabeled by the experimenter, and for these the participants were asked to generate their own descriptive verb. On the second day participants returned for the recognition test. No language was provided or generated for any recognition trial. Participants judged whether a presented

scene was identical to one they had seen on the first day or differed in any respect.

### Encoding Session

Participants were told they would see a series of short video-taped events and that they should watch these very carefully. They were told that for some events the experimenter would ask them to write down a verb describing what was happening in the event and they would be asked to do so by questions such as “what is the woman doing?” presented right before the event began. In the Manner and Path conditions the experimenter spoke a descriptive verb or the question roughly four seconds before the event began; in the No Language condition the experimenter said “next scene” to alert the participants, instead of a descriptive verb. An unrelated filler task followed encoding.

### Recognition Session

On the next day participants took a difficult recognition memory task viewing video clips with no accompanying description. All items concerned the scenarios they had seen the day before. Subjects judged whether each video was “identical” to the original clip or differed in any way. Participants responded by marking one end of six-point scale for old items (“Sure Old”) and the other end for new items (“Sure New”). Responses were scored as correct or incorrect in the analyses here. After the recognition task, subjects described events but this data is not reported here.

### Stimuli

At both encoding and recognition, participants viewed video clips of everyday events involving human agents. They lasted 3 to 20 seconds with five seconds of black between scenes. The critical events were designed in sets of three: one original, target event and two foils. The Path Foil changed the path along which the figure moved in the original, target event, while the Manner Foil changed the manner of movement of the figure. Two orders of encoding and of recognition tapes were used.

### Encoding Stimuli

The originally-presented target events were designed to be good examples of both a path and a manner verb, for example, a child **skipping** through a living room to **exit** through the front door, or a woman **crossing** a road, **jogging**. These were the items for which the participants produced descriptive verbs. There were six target events: skip/exit, jog/cross, tiptoe/ascend, float/rise, hop/enter, and fly/descend. Immediately before a target scene, 2-3 priming items were presented. Priming events illustrated unrelated motion events. In the Manner Condition, the experimenter labeled these priming events with English manner verbs while in the Path condition, the experimenter labeled primes

Table 2.  
Verbs Produced for each Event

Type	1 Ascend/ Tiptoe	2 Exit/ Skip	3 Descend/ Fly	4 Enter/ Hop	5 Cross/ Jog	6 Rise/ Float
PATH	Ascend (1) Gohome(1)	Leave(10) Exit (1)		Enter(22) Arrive (3)	Cross(5)	Rise(43)
MANNER	Walk(11) Tiptoe(5) Step(3)	Skip(56) Frolick(1) Hop(1) Prance(1) Tror(1) Walk(1)	Fly (17) Glide(1)	Walk (24) Hop(5)	Jog(43) Run(22)	Float(24) Fly(1) Soar(1)
COMBO	Climb(40) Climb...(6) Go+Climb(1)	SkipOut (1)		WalkThru(1)		
OTHER	Exercise(2) Go(1) Move(1) Progress(1) Hurt(1)	Play(1)	Land(57)	Knock(6) Visit(5) Move(3) Go(1) Pretend(1)	Exercise(5)	Move(1) Stop(1)

with English path verbs and in the No Language condition they were unlabeled.

Thirty events were presented at encoding: 6 target events, 1 description-practice event, 15 priming events, and 8 fillers (to increase the diversity of events presented). Target events, the practice event, the filler events, and the priming events which immediately preceded each target event were identical across all three conditions.

**Recognition Stimuli.**

The 30-item recognition test presented old and new versions of filler ( 8old/8new) and of the target events (6 old and 12 new). Each original target event had a foil with a changed path and a foil with a changed manner. The changes in these foils were designed to be great enough so that the verb originally generated to describe the original event (e.g., “skipping”) would not describe the foil event. For example, in the manner foil for the skip/exit scene the child galloped rather than skipping and in the path foil the child stopped in the door rather than exiting.

Table 1.  
Design of Target and Foils for Recognition Test

Target	Exit	Skip
Path foil	<i>Approach (not exit)</i>	Skip
Manner foil	Exit	<i>Gallop (not skip)</i>

**Design**

Encoding Condition (Manner Verb Prime/ Path Verb Prime/ No Language Prime), a between-subject variable was

crossed with Recognition Item Type (Path Foil/ Manner Foil/ Old), a within-subject factor.

**Results**

We asked how priming affected verb production, how verb production affected recognition, and whether there was a direct effect of priming on recognition. Data analyses throughout are done by-item. Although this gives us small n, it allows a stable unit of analysis both for effects of condition and for conditionalized effects of verb produced.

**Verbs Produced.**

Details of the verbs produced are shown in Table 2. Events varied in the variety of verbs produced and degree of concentration in a few dominant responses. The scenes had been designed to be good illustrations of specific verbs (listed as the event identifier), but they might also be

described by other verbs. The descend/fly scene was the most homogeneous, with 98.7% of responses in the two most dominant verbs, “fly” and “land.” Interestingly, the plane did not in fact land in the original scene, but was very widely classified in terms of the normal activity in the scenario. The enter/ hop and ascend/tiptoe scenes were the most varied with 64% and 72% of responses in the two most dominant verbs. These were also the most varied in terms of numbers of different verbs used and use of phrases. These scenes also evoked verbs focused on additional or more abstract aspects than the simply the movement of the figure.

**Effects of Priming on Verb Type Produced.**

We were particularly interested in whether priming with path or manner verbs would alter the proportion of path and manner verbs produced. Figure 1 shows how the proportion of manner and path verbs produced was influenced by the priming condition. (The proportion of verbs classified either as Combination or as Other was between 28% and 31% across the three conditions). Since we have other response categories, numbers of manner and numbers of path verbs do not necessarily trade off and can be analyzed as two levels of the production variable.

The interaction of priming condition with type of verb produced was significant ( $F[2,10]=8.33, p=.007$ ). Path-priming produced more path verbs and fewer manner verbs than either Manner-priming or no verb priming, which look

similar. Overall, there was not a main effect of priming condition on proportion of combined path or manner responses; 71% of produced verbs were manner or path in the Path-Primed condition compared to 72% in Manner-Primed and 69% in No Verb Priming ( $F<.01$ ). Overall, 49% of responses were manner verbs and 21% were path verbs. Although this preference for manner verbs seems large, items are highly variable and the difference is not significant in a by-item analysis ( $F[1,5] = 2.20, p = .20$ ).

**Effects of Producing Path vs. Manner Verbs on Recognition.**

Given that a manner or path verb was produced, is this production related to subsequent recognition judgments? Figure 2 shows that producing a path versus manner verb benefits recognition in path foils and old items, with a small harmful effect on manner foils. A 2x3 ANOVA (by-item) found that the type of verb produced interacted with type of recognition item in influencing number correct ( $F[2,8]=6.59, p=.020$ ). [Reduced df reflect loss of one event where no path verbs were produced]. The effect of item type was also significant ( $F[2,8]=6.66, p=.02$ ) with the highest error rates coming from false manner recognition, but in this test there was no overall effect of verb produced because of the tradeoff on path versus manner foils. Follow-up analyses localized the effect. A 2x2 ANOVA including manner and path foils but not old items, now showed a significant effect of item type,  $F[1,4]=7.10, p=.056$ , and a significant interaction  $F[1,4]=10.75, p=.031$ ,

**Figure 2.**  
**All Manner vs All Path**

but no main effect of verb produced. Further, paired t-tests showed an advantage of producing a Path Verb for reducing errors on Path Foils ( $p=.017$ ) and on Old Items ( $p=.035$ ), but not on Manner foils.

**Effects of Producing Dominant ‘Path’ or Manner Verb on Recognition.** A second analysis complemented the Manner/Path Produced analysis reported above. The Manner/Path analysis above mixed very different types and frequencies of verbs for each event. Further, for two of the events it excluded the most frequently used verb conveying path information. These two events had common verb responses which carried path information but

not significant, nor was condition,  $F's < 1$ , but item type was,  $F(2,71)=31.8, p<.001$ .

Table3. Proportion Errors by Condition & Item Type

ERRORS	Old Items	Path Foil	MannerFoil
Path Primed	.07	.13	.38
Manner Primed	.11	.14	.32
No Language	.12	.13	.32

## Conclusion

### Summary

We found an effect of priming condition on what verbs subjects produced to self-describe events. Manner verbs were produced more often in the manner-primed than path-primed condition; path verbs were produced more often in the path-primed than manner primed condition. The unprimed condition looked similar to the manner-primed condition.

The fact that we are able to produce this priming in verb use suggests that the linguistically analyzed dimensions of manner and path may be "psychologically real" and influence on-line performance tasks, such as verb generation.

We found that the nature of the descriptive verb produced by participants predicted their later recognition. Errors on manner foils were more likely when a path rather than manner verb had been produced and errors on path foils were more likely when a manner rather than path verb had been produced.

The pattern of results here replicates and extends our earlier studies with experimenter-provided verbs.

### Interpretation

These findings extend our understanding of how language is implicated in the perception and memory for events. Linguists have analyzed the verb lexicon as organized around distinctions of manner and path (Talmy, 1985). We found that use of path versus manner verbs primes different path or manner verbs used in describing unrelated scenes. This suggests that the dimensions relevant to a formal analysis of the verb lexicon also guide access and verb choice. Manner and path may act as psychological dimensions, perhaps both guiding access in the lexicon and attention in event perception.

The similarity between the recognition findings in this experiment and our prior findings suggests that whether someone hears or produces a verb, the effect is similar: distinctions in meaning carried by that verb influence recognition.

### Future Work

Additional analyses of this data will investigate verb frequency and verb discrimination. Performance with path verbs departs from performance with manner verbs or no language and we are interested in understanding the possible variety of factors which produce this asymmetry between manner and path.

which were not simple path verbs and hence were not included in the Manner-Path Verb analysis. For the “descend/fly” event, no true path verbs were produced and “land” (classified in the Other verb type) was by far the dominant response. For the “ascend/tiptoe” event, “climb” (classified as Combination) was the dominant response, which includes manner as well as path information. Since the path component of these two verbs was clearly the relevant aspect for these scenes, we designed these ‘path-verbs’ for a supplemental analysis. In this Dominant ‘Path’-Manner analysis, we looked at the effect of two verbs for each event: the one most frequently used ‘path’ or the one most frequently used manner-verb. This analysis includes more data than the first, but fewer verbs.

The results parallel the first analysis. In the 3 (Item Type) x 2 (Dominant Verb Produced) ANOVA (by-item), item type was significant,  $F(2,10)=6.70, p=.014$ , the interaction of item type and dominant verb produced was significant,  $F(2,10)=7.25, p=.011$ , but not the effect of verb produced  $F(2,10)=3.85, p=.107$ .

### Direct Effect of Priming on Recognition Type.

We also measured whether the subjects primed with path or manner (or unprimed) differed in recognition error types, not considering what sort of verb they generated, as shown in Table 3. The interaction of condition and item type was

Sometimes participants generated verbs which discriminated the target and foil event and sometimes the verbs did not discriminate. For example, if a participant said "running" this would apply to both to the original jogging scene and to the dash manner-foil, hence not discriminating target from foil. Analyzing effect of whether a path or manner verb does or does not distinguish foil from target will help identify how the verbs have their effect.

We are also interested in identifying what information about an event is made more memorable by different verbs, and what the mechanism of influence is. Verbs might exert their influence in guiding attention at encoding, in providing a more structured or integrated representation, or in serving as a separate retrieval cue during recognition.

## Abstract

Two experiments contrasted the predictions of the similarity-coverage model of category-based induction with those of a structure-based account. We focused on the two theories' ability to account for the paradoxical fact that both monotonicities (increases in argument strength with the addition of premises) and non-monotonicities (*decreases* in argument strength with addition of premises) occur in human reasoning. The results are mainly in accord with the structure-based account and are inconsistent with the similarity-coverage account.

## Introduction

### Monotonicity and Induction

Humans routinely make inductive inferences, and the principles that guide these inferences have received a great deal of empirical attention (López, 1995; McDonald, Samuels & Rispoli, 1996; Osherson, Smith, Wilkie López & Shafir, 1990; Sloman, 1993). One principle that has both intuitive and empirical support is *monotonicity* – the principle that confidence in an inductive inference should increase with the number of supporting premises. For example, Osherson et al. showed that adults preferred Argument B over Argument A.

- A. All FOXES have sesamoid bones,  
All PIGS have sesamoid bones,  
Therefore, all GORILLAS have sesamoid bones
- B. All FOXES have sesamoid bones,  
All PIGS have sesamoid bones,  
All WOLVES have sesamoid bones  
Therefore, all GORILLAS have sesamoid bones.

However, robust *nonmonotonicities* have also been documented. Osherson et al.'s participants chose Argument C over D.

- C. All FLIES have sesamoid bones,  
Therefore, all BEES have sesamoid bones.
- D. All FLIES have sesamoid bones,  
All ORANGUTANGS have sesamoid bones,  
Therefore, all BEES have sesamoid bones.

Sloman (1993) and McDonald et al. (1996) have also documented nonmonotonic responding in adults. Even more strikingly, Lopez, Gelman, Gutheil & Smith (1992) showed nonmonotonicity effects very early in development; in fact, nonmonotonicity effects were reliably obtained earlier than monotonicity effects. People appear to believe that more premises make for a stronger argument, except when more premises make for a weaker argument. How can we reconcile these apparently contradictory phenomena?

### Similarity-Coverage Model

A pioneering theory of argument strength is the Similarity-coverage model (SCM) of Osherson et al. (1990). The two components of SCM are *similarity* -- the extent of feature overlap between premise and conclusion categories -- and *coverage* -- the average similarity of the premises and the instances of the lowest level taxonomic category that includes both the premises and the conclusion. The similarity-coverage model predicts monotonicity when the additional premise is a member of the same lowest level superordinate category as the initial premises and the conclusion. It predicts nonmonotonicity when the additional premise is not a member of the lowest level superordinate category. Thus nonmonotonicity can be seen as a kind of dilution effect, as illustrated by Osherson et al.'s (1990) data in (1) and (2), respectively.

- (1) a. ROBINS, SPARROWS / SEAGULLS >  
b. ROBINS / SEAGULLS<sup>1</sup>
- (2) a. ROBINS, RABBITS / SEAGULLS <  
b. ROBINS / SEAGULLS

Argument (1) is monotonic; adding the extra premise SPARROW in (1a) adds an additional piece of premise support without diluting the category coverage, because it fits within the lowest-level category (BIRDS) that applies in the single premise case (1b). In contrast, the additional premise RABBITS in (2a) raises the lowest-level common category to ANIMALS, thus diluting the category coverage. Thus the SCM can successfully predict some instances of monotonicity.

---

<sup>1</sup> Research in this area typically uses so called "blank" or opaque properties – such as 'has sesamoid bones' to ensure that belief in the conclusion is derived from the premise statements, rather than from prior beliefs about the truth of the conclusion. We will omit property names from further examples.

However, as Sloman (1993) noted, there are other instances of nonmonotonicity that are not explainable by dilution of category coverage. His participants found (3b) to be stronger than (3a).

- (3) a. CROCODILE, KINGSSNAKE / ALLIGATOR
- b. CROCODILE / ALLIGATOR

Even though the lowest level taxonomic category (REPTILE) does not change across these arguments, nonmonotonicity<sup>2</sup> is observed. Sloman acknowledges, however, that his own feature-based induction theory is also unable to explain nonmonotonicities.

### Structure-Based Induction

We propose a *structure-based induction* approach that uses structural overlap instead of overall similarity or feature overlap to predict argument strength. Our model is very different from the previous theories in that we explicitly assume that the evaluation of argument strength is accomplished by a process of aligning the representations of the premise(s) and the conclusion.

Specifically, we assume that the perceived strength of an induction from premise to conclusion depends on the goodness<sup>3</sup> of the common schema. For the one-premise case, this idea is closely related to similarity in Osherson et al.'s account and with feature overlap in Sloman's account. But when there are multiple premises, we postulate a *premise comparison process* whereby a common schema is derived from the premises. This schema is then aligned with the representation of the conclusion statement.

This variant of the *progressive alignment hypothesis* (Kotovsky and Gentner, 1996; Kuehne, Gentner & Forbus, 2000; Kuehne, Forbus, Gentner & Quinn, 2000) states that carrying out a comparison involves alignment of structured representations (e.g. Gentner & Markman, 1997).

There is evidence that structure-mapping theory captures some important aspects of inductive reasoning. Wu and Gentner (1998) told participants that a conclusion had attribute  $a_1$ . They were also told that two different premise kinds  $P_1$  and  $P_2$  also had  $a_1$ . Participants were then given the option of inferring an attribute from  $P_2$  that was causally connected to  $a_1$  or an attribute from  $P_1$  that was not causally connected to  $a_1$ . Results indicated that people strongly preferred to reason from a causal base ( $P_2$ ) over an attribute base ( $P_1$ ). See Clement & Gentner (1996) and Lassaline (1996) for related findings.

The SBI view makes several specific predictions. First, it predicts that *monotonicity* (in at least the weak sense)

<sup>2</sup> Monotonicity can be interpreted in the strong sense of *increasing monotonicity* or in the weaker sense of *non-decreasing monotonicity*. Note that even the latter, weaker sense is violated by these examples.

<sup>3</sup> We will use the term *goodness* of the common schema as a shorthand for *structural evaluation*; it depends on the size and depth of the common schema.

will result when the additional premise is alignable with the other premises and the conclusion. Second, conversely, *nonmonotonicity* should result when the additional premise is not alignable with the premises (even if it is alignable on other grounds with the conclusion).

These two assertions predict the monotonicity of argument (1) and the nonmonotonicity of (2). A further point is that the predictions of the SBI model do not rely on taxonomic category structure. Neither monotonicity nor nonmonotonicity are influenced by whether the additional premise belongs to the lowest common category that includes the premises and the conclusion. Thus SBI explains Sloman's example (3) above by noting that the goodness of alignment between the premise CROCODILE and the conclusion ALLIGATOR is diminished by first aligning CROCODILE with KINGSSNAKE.

The third prediction of SBI is that the properties inferred depend on the particular aligned schema. That is, people base their inferences (even about nominally blank properties) on the specific alignment between premises and conclusion, and not on a general sense of similarity. Because the quality of the premise-conclusion alignment determines both the specific properties people are willing to infer *and* the argument strength, we expect a strong association between these two (see Heit & Rubinstein, 1994, for a related proposal).

### Experiment 1. Two vs. three premises

In this experiment, we varied category coverage and alignability in order to contrast the predictions of the similarity-coverage model and the structure-based approach. We used five variants of each argument: a two-premise item plus four kinds of additional premises that were added to make three-premise arguments (Table 1).

Table 1. Sample base two-premise item and the additional premise in the four variant conditions in Experiment 1.

ROBINS, EAGLES, ... / BATS			
Coverage			
Alignment	C+	C-	
	A+	SEAGULLS	AIRPLANES
	A-	DOGS	TV's

The premises and the conclusion of the two-premise arguments shared a common relational schema, such as *flight* or *underwater habitat*. The three-premise arguments were constructed by adding an additional premise to the two-premise arguments. There were four types of additional premises, constructed according to a 2x2 design of *alignability* with the two-premise schema and *category coverage* – i.e., whether the additional premise belonged to the lowest level category spanning the two premises

and the conclusion (hereinafter abbreviated *spanning category*).

For example, given the two-premise argument ROBIN, EAGLE / BAT, the aligned schema presumably involves flight and the spanning category is ANIMAL. The four kinds of additional premises are as follows:

1. **A+C+** type: Alignable with the 2-premise schema (*High Alignment*) and a member of the lowest-level spanning category (*High Coverage*).  
e.g., ROBINS, EAGLES, SEAGULLS / BATS
2. **A-C+** type: Not alignable with the 2-premise schema (*Low Alignment*), but a member of the spanning category (*High Coverage*).<sup>4</sup>  
e.g., ROBINS, EAGLES, DOGS / BATS
3. **A+C-** type: Alignable with the 2-premise schema (*High Alignment*), but not a member of the spanning category (*Low Coverage*).  
e.g., ROBINS, EAGLES, AIRPLANES / BATS
4. **A-C-** type: Not alignable with the 2-premise schema (*Low Alignment*), nor a member of the spanning category (*Low Coverage*).  
e.g., ROBINS, EAGLES, TV'S / BATS

## Method

37 Northwestern University undergraduates were presented with 40 inductive arguments, one at a time on a computer, and asked to rate them according to “how well the conclusion follows from the premises.” There were eight sets, each with five argument types (8 two-premise arguments plus 4 x 8 = 32 three-premise arguments).

For example,

*Fact:*

All ROBINS have property F.

All EAGLES have property F.

*Therefore,*

All BATS have property F.

After rating all the arguments, participants were given a printed packet with the forty arguments they had just rated and were asked to write down their best guess about the property associated with each argument. They were also given the option of skipping any items for which no property had come to mind.

## Predictions

Table 2 summarizes the predictions of the two models. The structure-based induction model predicts monotonicity for alignable types (A+C+ and A+C-) and non-monotonicity for non-alignable types (A-C+ and A-C-),

<sup>4</sup> The extra premise for the A-C+ type always belonged to the same superordinate as the conclusion. This had the effect of giving the A-C+ type the highest relative coverage of any of the 3-premise arguments, as defined by the similarity-coverage model. Importantly, the A-C+ type had higher coverage than the A+C+ type, providing a very strong test of the alignment model against the coverage model.

relative to the two-premise arguments. The similarity-coverage model predicts monotonicity for high coverage types (A+C+ and A-C+), and nonmonotonicity for low coverage types (A+C- and A-C-).

Table 2. Summary of predictions of the two models

Theory	Prediction
SCM	<b>A+C-</b> , <b>A-C-</b> ≤ 2P ≤ <b>A+C+</b> , <b>A-C+</b>
SBI	<b>A-C+</b> , <b>A-C-</b> ≤ 2P ≤ <b>A+C+</b> , <b>A+C-</b>

Another line of prediction concerns the subjects' guesses about the blank properties. According to the structure-based view, the same process of structure-mapping that gives rise to the goodness of the common schema also gives rise to its specific content. Thus we predict (1) people's *confidence* in their property guesses will increase with their subjective argument strength; (2) the *uniformity* of property guesses will increase with their subjective argument strength; and (3) both the confidence and the uniformity of property guesses will be greater for alignable types than for non-alignable types.

## Results

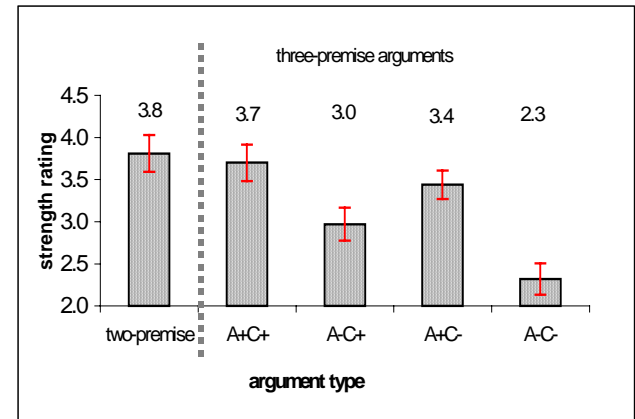

Figure 1. Argument strength ratings for five argument types in Experiment 1 (error bars are 95% confidence intervals).

**Argument Strength Ratings.**<sup>5</sup> Figure 1 shows the mean ratings across items. As predicted by the structure-based account, monotonicity (in the weak, though not the strong form) held when the additional premise was alignable. That is, there were no significant differences in judged strength between two-premise arguments ( $M = 3.81$ ;  $SD = 1.31$ ) and either the A+C+ type ( $M = 3.70$ ;  $SD = 1.28$ ) or the A+C- type ( $M = 3.44$ ;  $SD = 1.25$ ),  $t(36) = 1.46$ ,  $p > .008$ ,  $t(36) = 2.49$ ,  $p > .008$  respectively. Also as predicted, nonmonotonicity held when the additional premise was nonalignable. Arguments of the A-C+ type ( $M =$

<sup>5</sup> We performed six planned comparisons on the mean argument strength for each subject within a type, setting the two-tailed Bonferroni corrected alpha value at 0.008.

2.97;  $SD = 1.15$ ) and the A–C– type ( $M = 2.32$ ;  $SD = 1.14$ ) were rated reliably lower than two-premise arguments,  $t(36) = 4.34$ ,  $p < .008$ ,  $t(36) = 5.96$ ,  $p < .008$ , respectively.

There were no significant differences based on category coverage. In the crucial comparison of the two models, we found that A+C– arguments were rated reliably stronger than the A–C+ type,  $t(36) = 3.01$ ,  $p < .008$ , suggesting that alignability, not category coverage, best predicts the effects of adding a third premise to a two-premise argument.

**Property Guesses.** To test the relation between argument strength and likelihood of listing a property (confidence), we scored the listings on whether a participant chose to guess a property. There were 1241 guesses and 439 (26% of the total) “no guess” responses. The highest proportion of guesses was elicited by the two-premise and the A+C+ argument types (94% and 90%, respectively). The A+C– argument type also elicited a high proportion of guesses (85%). The A–C+ and A–C– types elicited substantially fewer property guesses (65% and 36%, respectively). Overall, the proportion of property guesses closely mirrored the argument strength ratings,  $r = .82$ ,  $p < 0.0001$ .

To test our predictions concerning property uniformity, we rated the content of the property guesses. When subjects were presented with alignable arguments (i.e., two-premise, A+C+ or A+C– types), subjects almost unanimously provided guesses specific to the hypothesized common schema. When presented with a non-alignable argument, subjects tended to provide general and haphazard guesses and tended to disagree about the nature of the blank property. To test this intuition, we asked two naive raters to score the property listings on the basis of *coherence*. Confirming our hypothesis, alignable arguments elicited highly focused patterns of property guesses, while non-alignable ones displayed little agreement between subjects, as observed by our independent raters. Mean coherence rating across the forty different arguments were correlated with argument strength at  $r = 0.599$ ,  $p < 0.0001$ .

## Discussion

The results of Experiment 1 largely bear out the predictions of the structure-based induction model. The effect of adding a premise to a two-premise argument depends entirely on whether the third premise is alignable with the schema that holds in the two-premise argument. If the third premise is alignable, the argument strength remains constant; if the third premise is nonalignable, the argument strength decreases. The predictions of the similarity-coverage model were not borne out for either monotonicity or nonmonotonicity. The SCM predicts monotonicity if the third premise belongs to the lowest-level spanning category of the two-premise argument; and nonmonotonicity when the third premise forces an increase in the level of the spanning category. Neither prediction held.

The most direct contrast between the models is to compare A–C+ items (low alignability but high coverage) with A+C– items (high alignability but low coverage). Participants found the A–C+ premise sets to be a far weaker inductive base than A+C–, with its specific schema. For example, argument (4a) was weaker than (4b):

(4a) ROBINS, EAGLES, DOGS / BATS

(4b) ROBINS, EAGLES / BATS

Thus increasing in the number of premises even while holding coverage constant can result in nonmonotonicity if the alignment is diminished. Indeed, (4c) is judged stronger than (4a), despite clearly having poorer coverage

(4c) ROBINS, EAGLES, AIRPLANES / BATS

In short, our nonmonotonicity findings support the claims of the structure-based framework over those of the coverage model.

The property guess findings were also consistent with the predictions of the structure-based framework. There was a strong connection between considering an argument strong and having a clear idea of what property was being inferred. This observation is consistent with our claim that the process at work here is an alignment process that results in a specific common schema.

Overall the results are encouraging. However, one point requires discussion. We found evidence of *nondecreasing* monotonicity but not of *increasing* monotonicity. There was no *increase* in argument strength for any argument type. This contrasts with Osherson et al.’s (1990) report that strength increased from two- to three-premise arguments. We suspect much of the difference stems from the fact that, whereas we used a single-argument rating task, Osherson et al. used a choice task. Comparing arguments to choose the stronger could have led to heightened contrast between the two- and three-premise arguments.

Structure-mapping does not predict a steady increase in argument strength as additional premises are added.<sup>6</sup> However, it does predict an increase when going from one-premise to two-or-more-premise arguments (always provided the added premise(s) are alignable), because alignment highlights the common structure (Gentner & Wolff, 2000). To test this prediction, we asked subjects to rate single-premise arguments matched to the multi-premise arguments used in Experiment 1. This will allow us to compare (albeit across experiments) the strength of one-premise vs. three-premise arguments.

A second motivation for Experiment 2 was to rule out a possible confound, namely, that the gain in strength for the additional premises was simply due to an increase in overall similarity (or feature overlap, on Sloman’s (1993) account) brought about by the additional premise, rather than by interactions among the premises as claimed by the structural account.

<sup>6</sup> This is because progressive alignment cannot *increase* the size of the common schema. Thus if increases in argument strength do occur when, say, 11 premises are increased to 12, the explanation must lie with other factors beyond alignment.

## Experiment 2. Single-premise arguments

Participants evaluated single-premise arguments. For each argument, the premise was the *additional premise* used in Experiment 1. For example, for the BATS item in Table 1, the four arguments tested in Experiment 2 were

- (A+C+)<sup>7</sup> SEAGULLS / BATS
- (A-C+)<sup>7</sup> DOGS / BATS
- (A+C-)<sup>7</sup> AIRPLANES / BATS
- (A-C-)<sup>7</sup> TELEVISIONS / BATS

The first question is whether, as predicted by structure-mapping, single-premise arguments will be weaker than their three-premise alignable counterparts in Experiment 1. The second question is whether the relative strengths of the three-premise arguments in Experiment 1 are mirrored by the strengths of the corresponding single premises (Thus undermining our premise-comparison account.)

### Method

16 Northwestern University undergraduates saw 32 single-premise arguments (8 items x 4 types) and rated them for strength. The procedure was identical to that in Experiment 1, except that the arguments were given in printed form, rather than on a computer.

### Results

We contrasted the mean argument strengths by argument type between Experiments 1 and 2.<sup>8</sup> Figure 2 presents the mean strength ratings across argument types.

As predicted by structural framework, among alignable types, there was a reliable advantage for three-premise over one-premise arguments (a difference of 1.28,  $t(51) = 3.90$ ,  $p < 0.001$ ). For non-alignable types, this difference was 0.53,  $t(51) = 1.84$ ,  $p > 0.05$ , n.s. Also, as predicted, planned comparisons within alignable types revealed reliable differences between the three-premise A+C+ ( $M = 3.70$ ,  $SD = 1.28$ ) and the single-premise (A+C+)<sup>7</sup> types ( $M = 2.49$ ,  $SD = 0.88$ ),  $t(51) = 3.43$ ,  $p < 0.005$ . A reliable contrast was also observed between the three-premise A+C- ( $M = 3.44$ ,  $SD = 1.25$ ) and the single-premise (A+C-)<sup>7</sup> type ( $M = 2.08$ ,  $SD = 0.85$ ),  $t(51) = 3.95$ ,  $p < 0.001$ .

Planned contrasts for the non-alignable types revealed a non-reliable difference between the three-premise A-C+ type ( $M = 2.97$ ;  $SD = 1.15$ ) and the single-premise (A-C+)<sup>7</sup> type ( $M = 2.85$ ;  $SD = 1.22$ ),  $t(51) = 0.34$ ,  $p > .70$ , n.s.

So far, the results are consistent with the structural account. However, a reliable difference was also observed between the three-premise A-C- type ( $M = 2.32$ ;  $SD = 1.14$ ) and the single-premise (A-C-)<sup>7</sup> type ( $M = 1.38$ ;  $SD = 0.54$ ),  $t(51) = 3.15$ ,  $p < 0.005$ . This result is not predicted by the structural account.

<sup>7</sup> We will refer to single-premise versions arguments by adding a prime to the three-premise symbol: e.g., (A+C+)<sup>7</sup>.

<sup>8</sup> Because the sample sizes across the two experiments were not equal, we also performed a set of more conservative non-parametric analyses, which revealed the same pattern.

Figure 2. Argument strength ratings for four argument types in Experiment 2 and Experiment 1 (Error bars are 95% confidence intervals).

Turning to the second question, we found that the pattern of strength among single-premise arguments could not account for the three-premise results in Experiment 1. Indeed, the mean strength in the one-premise arguments was significantly *higher* for the nonalignable premises than for the corresponding alignable premises.<sup>9</sup> This is the *opposite* direction from what happened in Experiment 1, where there was an alignability advantage for the three-premise versions of these arguments. This means that the alignability advantage in Experiment 1 cannot result simply from independently accruing similarity or feature overlap across the premises.

### Discussion

Our hypothesis that alignable three-premise arguments would exhibit strong monotonicity relative to their single-premise counterparts was supported. For both of the alignable types (A+C+ and A+C-), three-premise arguments received higher ratings than their respective single-premise counterparts.

<sup>9</sup> That is, the mean strength of (A-C+)<sup>7</sup> arguments was significantly higher than for (A+C+)<sup>7</sup> arguments ( $M = 2.87$ ,  $SD = 1.21$ ;  $M = 2.49$ ;  $SD = 0.85$ , respectively,  $t(16) = 2.665$ ,  $p < 0.025$ ). (A-C+)<sup>7</sup> arguments were also rated reliably higher than the (A+C-)<sup>7</sup> arguments ( $M = 2.05$ ;  $SD = 0.83$ ),  $t(16) = 3.407$ ,  $p < 0.025$ .

## General Discussion and Conclusion

These experiments offer support for the structure-based model of induction. The alignment approach predicts both nonmonotonicities and monotonicities accurately. When the additional premises are alignable, argument strength increases between one- and multiple premises, and is weak-monotonic from two- to three- premises. Strong monotonicity holds for alignable added premises.

Osherson et al's (1990) similarity-coverage model predicts monotonicity except when the additional premise forces a taxonomically higher spanning category. But the results of Experiment 1 showed nonmonotonicity even when category coverage was constant, as well as weak monotonicity despite a decrease in coverage. Across the board, (weak) monotonicity was observed between two- and three-premise cases for just those cases where the additional premise was alignable. The pattern in Experiment 2 was similar: With one exception, monotonicity between one- and three-premise arguments was observed only for alignable arguments.

Further evidence that argument strength judgments involve thinking about the specific relational schema, as opposed to overall similarity, comes from the property listings in Experiment 1. When given alignable third premises, subjects not only rated the arguments as strong, they also had clear opinions on what "Property P" might have been, and those guesses were highly uniform. These findings are consistent with there being a specific schema that emerged from the alignment.

What is the broader significance of these findings? First, premise comparison process must be a part of argument strength models. We have documented both (A) and (B) occurring *simultaneously*:

(A)  $P1, P2, P3 / C > P1, P2, P4 / C$  [Exp. 1]

(B)  $P3 / C < P4 / C$  [Exp. 2],

Since the same premises are added to both sides in going from B to A, this reversal cannot be explained in terms of accruing overall similarity or total feature overlap. It requires an explanation in terms of premise interactivity. People are not integrating individual premise-conclusion argument strengths (e.g. "P1/C + P2/C + P3/C") but aligning premises to determine what aspects of the premises *as a set* are relevant to the argument.

The evidence for premise interactivity presented here poses a challenge to the feature-based induction theory (Sloman, 1993). As an important theoretical alternative to the coverage model, the feature-based theory assumes that instead of computing category coverage, people are assessing total feature overlap between the premises and the conclusion. Monotonicity is predicted because the addition of a premise must either increase total feature overlap or maintain it. The addition of a premise can never decrease total feature overlap, so nonmonotonicities cannot be predicted. The systematic nonmonotonicities we have observed, as well as the evidence of premise interactivity, are inconsistent with the current formulation of the feature-based induction model.

Sloman (1993) has suggested an extension to the feature-based model -- a premise comparison mechanism that weighs common features of the premises more heav-

ily than unique attributes. This might allow the feature-based model to predict some nonmonotonicities. However, it is unclear which common features of the premises will be weighted over others. An important forte of the structure-based model is that it *constrains* similarity by treating matching attributes that play similar roles in their respective concepts as more similar than matching attributes that do not (Medin, Goldstone & Gentner, 1993). Thus, inductive inferences are appropriately constrained.

## Acknowledgments

This research was supported by the National Science Foundation and the Office of Naval Research. We thank Ken Kurtz, Sven Kuehne, Jeff Loewenstein and Kathleen Braun for their assistance at all stages of this project. We are also grateful to an anonymous reviewer for helpful comments on an earlier draft of this paper.

## Abstract

Problem solving has been the study of a set of phenomena rather than a set of theories. Newell & Simon's (1972) concept of search has proved very useful for describing problem solving but it is not a testable theory. We point out that without testable theories, thought about problem solving cannot progress through the interaction of thesis and antithesis. Problems solving requires theories and we propose a specific form of multispace search theory. The hierarchical three-space theory of problem solving can be derived from existing literature, and proposes that interactive search occurs in instance space (states of the problem), rule space (possible rules that govern the problem), and model space (the general understanding of the problem). This theory could be used to generate testable predictions regarding the interaction of spaces and provides a way to try to unify diverse phenomena.

## Problem Solving: What is the theory?

Sixty years ago, Maier (1940) noted that problem solving was frequently cited as a barren field of inquiry. He argued that this blandness is due to the proliferation of experimental tasks which render generalization difficult. It is bland because there is a set of phenomena, but no underlying explanation of them.

Has this blandness diminished since Maier wrote this? If one examines the way the field presents itself to its first line of consumers, undergraduates taking introductory courses in cognitive psychology, then it is arguable that the same problems identified by Maier (1940) continue to bedevil problem solving research. When one picks up a typical introductory cognitive psychology book and turns to the sections on perception, attention, or memory, then one finds a lively description of competing theories and the evidence used to support/discredit them. These are on-going debates so different books present these debates in different ways depending on the biases of the author. In contrast, there is a remarkable similarity between different books when one turns to the section on problem solving. Anderson (2000) is a typical example. He covers procedural knowledge and search, operators (including analogy), operator selection (including means-ends analysis and the Tower of Hanoi),

representation (including functional fixedness), and set effects. Other books may differ in their details, but cover the same basic ground. What is noticeable by their absence, are theories of problem solving.

There has been progress since 1940, in particular Newell and Simon's (1972) idea of problem solving as search of a problem-space. This has been very valuable both for psychological and computational approaches to problem solving, but it is not a complete theory (as others have also noted, such as VanLehn, 1989). As a language for thinking about problem solving, search has proved to be useful and enduring. However, it makes no testable predictions, so there can be no competing theory.

Sternberg (1995) emphasizes the dialectical progression of ideas in psychology. As described by Hegel (1807/1931), the dialectic begins with a viewpoint that is proposed and believed (a thesis), but in response a competing view arises (an antithesis), and eventually the best features of both are melded into a synthesis. Then the process starts again. Sternberg argues that much of the history of psychology can be seen in terms of the dialectic. This progression cannot occur in the field of problem solving because there is no thesis, therefore there can be no antithesis, and there can be no synthesis. Anderson (2000) and other introductory cognitive psychology books illustrate that we know quite a lot about the phenomena of problem solving, but there is no thesis for the phenomena. VanLehn (1989) provides a list of robust empirical findings regarding problem solving. (Space precludes us from taking on a related difficulty with problem solving research, its definition. The definition has varied from very narrow [essentially the study of solving the Tower of Hanoi] to the very broad [every goal oriented activity]. For the purpose of this paper we use VanLehn's characterization of problem solving as multistep goal-directed tasks that last a few minutes to a few hours.)

The aim of this paper is to try to present a thesis, or to at least struggle towards that aim. In doing this we do not wish to throw away the power of treating problem solving as search, instead we want to try to wield it into a form that presents a testable thesis. We do this by taking seriously another part of Maier's (1940) paper, that problem solving is not a single process, but a set of processes. This leads to multispace search theories, and we propose a specific form of a hierarchical three-space search theory of problem solving. As may already be apparent this paper is

speculative and, merely uses existing ideas, but we wish to show how these ideas can be put together in such a way that a hierarchical three-space theory falls out.

## Multispace Search

**Problem Solving as Search.** Newell and Simon (1972) proposed that for every problem there exists a problem space which is defined by three components: 1) the *initial state* of the problem; 2) a set of *operators* that can transform a problem state; 3) a *test* for whether a problem state constitutes a solution (this may be a particular *goal state* or set of goal states). Finding a solution is a process of searching the set of states logically defined by the initial state and the operators that can be applied, until a solution is found. This terminology has proved to be useful for describing a wide range of problem solving behavior. However, to encompass a wider range of phenomena, this framework has been extended in two ways. In order to include induction and problem solving within the same framework, Simon and Lea (1974) claimed that search occurs in a *dual-space*. In order to capture the influence of different representations, Hayes and Simon (1974) claimed that an *understanding process* is required as well as a search process.

**Dual-Space Search.** Simon and Lea (1974) proposed that problem solving does not necessarily consist of search of a *single* problem space. To encompass multiple spaces they generalize the components of Newell and Simon's (1972) description of problem solving in the following way: 1) the elements of a problem space are *knowledge states*; 2) operators are *generative processes* that take a knowledge state as input and produce a new knowledge state as output; 3) there are one or more *test processes* for determining solution and for comparing knowledge states; 4) there are *selection processes* for which of these generators and tests to employ, on the basis of the information contained in the knowledge states. Induction can then be related to problem solving by allowing a dual-space search to be conducted. The search for rules that describe a task is conducted in a *rule space*, the states of which are all possible rules, and the operators are processes for generating, modifying and testing rules. Testing, however, requires movement within *instance space*, consisting of all possible states of the task, and the operators are processes allowed by the task for moving between instance states. Thus the two problem spaces are conceptually distinct, but intimately related; test processes for rule space lead to the generation of instances, whereas information that results from such instances leads to movement in rule space.

Simon and Lea (1974) suggested that many induction tasks can be described in this dual-space framework. For example, in concept attainment tasks learners generate possible rules from instances. They then test or select between alternative rules by observing or creating relevant instances. Thus concept attainment can be seen as a dual-space search, in which the goal is in rule space.

Problem solving may involve search of instance space only, but it is a dual-space search if a problem solver tries to learn rules which can be generally applied to reaching

different goal states. Simon and Lea (1974) pointed out that the Tower of Hanoi problem is usually thought of as search of instance space: find a sequence of moves that transfers all disks to the goal peg. This is a single space search. But the task could be described as: find a *rule* for transferring disks from one peg to another (e.g., the first move depends on whether the number of disks is odd or even). This requires a dual-space search.

Dual-space search has been extended to scientific reasoning by Klahr and Dunbar (1988) in their Scientific Discovery as Dual Search (SDDS) model. They proposed that in scientific reasoning people have an *hypothesis space* (similar to rule space) and an *experiment space* (similar to instance space). Reasoners propose hypotheses, and test them by conducting experiments. Klahr and Dunbar (1988) and Dunbar (1993) found that subjects who tested hypotheses performed a learning task better, a finding which supports SDDS.

More evidence that dual-space search occurs in problem solving was found by Vollmeyer, Burns, and Holyoak (1996). They had participants learn to control a complex system called *biology-lab* in which they could manipulate inputs and observe the changes to the outputs. Ultimately they had to bring the system to a set of output states, but participants were not told the nature of the set of equations linking inputs to outputs. Vollmeyer et al. manipulated the goals of problem solvers by either telling them what the goal state was before they started exploring the system (a specific goal), or delaying informing them of the goal until after they had explored (a nonspecific goal). They found that a group given a specific goal learned less about the structure of the biology-lab task and transferred more poorly to a new goal, than did the nonspecific goal group. The strategies of the specific goal group indicated search of instance space (i.e., find a path to the goal), but the nonspecific goal group instead appeared to test rules (i.e., search hypothesis space).

**Understanding Processes.** Before a problem solver can attempt a problem, the problem instructions must be understood. The importance of understanding processes in natural language has been well illustrated (e.g., Bransford & Franks, 1971). Hayes and Simon (1974, 1977) explored the impact that understanding can have on problem solving. Hayes and Simon (1977) gave subjects different isomorphic versions of the Tower of Hanoi problem and found a dramatic effect on solution ease from the ease of understanding the problem description. The importance of representation in problem solving was a point emphasized long ago by the Gestaltists (e.g., Maier, 1930).

Hayes and Simon (1974) incorporated understanding into Newell and Simon's (1972) framework by proposing understanding as a subprocess that cooperates with search of the problem space. The search process is driven by the result of understanding processes, rather than the problem itself. However, it may not be that understanding processes first produce a representation of the problem, and then search takes over. The two processes may alternate or even blend together (see Hayes & Simon, 1974). That representations may be fluid and interact with attempts to

solve a problem, is a point also made by researchers working within other frameworks (e.g., Burns, 1996; Hofstadter, 1995).

## A Hierarchical Three-space Theory

**Integrating Understanding Processes.** If understanding processes create the representation of problem space, then in a dual-space search theory these processes must create the representation of not only the instance space, but of the rule space as well. Thus understanding processes define the instance states that can be searched, and do so via the candidate rules that might govern instance states. The research on functional fixedness (e.g., Maier, 1930) can be seen in terms of the problem solver's understanding processes defining the wrong rule space. Similarly, the research on how false assumptions can be a barrier to solution can be viewed in this way. Weisberg and Alba (1980) showed that problem solvers attempting the nine-dot problem could only solve it when their assumption that they could only draw lines within a restricted area was removed. In our terms, they were searching the wrong rule space. Of course, having the correct rule space does not guarantee success (as Weisberg & Alba found) as having the correct rule space to search is not equivalent to having the correct rule.

Given that representations may change during problem solving, understanding processes can be seen as conducting a form of search. VanLehn (1989) suggested that schema selection can be a form of search when a person is uncertain as to which schema to select. For example, Larkin (1983) gave expert physicists a straightforward, but difficult, physics problem to solve. Although two of the five physicists immediately selected the correct schema for solving the problem, the other three physicists tried two or more schemas. In this way, understanding processes can be seen as operators that search a space consisting of different representational states. These operators generate, modify, and test the adequacy of representations. We see representational states as encompassing more than just what type of diagram is used, additionally they reflect the problem solver's current model of how a task works. Thus we term this space *model space*.

**Model Space.** In our hierarchical three-space theory of problem solving we propose that model space provides not only the representation of instances, but also defines the rule space to be searched. Which rules appear plausible will depend on how a problem solver thinks the task works. For example, if each component of a system is thought to be independent, then rules proposing interactions will not be considered. If the model changes, then interactions may become part of states in rule space.

Current utility is the criteria for assessing one's state in model space as there is no final goal state, a better understanding of the task may always be possible. So instead of a test for "solution", there may be tests for the adequacy of a model state, that is, does this model seem to work?

Although it violates our application of the term "problem

solving" to tasks completed within a few hours, for expository purposes we will illustrate model space with the debate over competing models of light. Two models of light were proposed: a wave model and a particle model. The hypothesis that a scientist would test depended on which model the scientist believed. The wave model suggested that light is a wave, therefore a relevant hypothesis to test was whether light shows interference patterns. The particle model suggested that light is a particle, therefore a relevant hypothesis to test was whether light exerts pressure. Testing these hypotheses led to movement in the model space for light. Neither model was accepted as completely correct, instead the competing models were synthesized into a model in which light was both a particle and a wave. Although this particular movement in model space was slow, it still had the characteristics of a movement in a problem space. There were clearly defined states (initially two different models states, which expanded in number when the possibility of combinations arose), and there were processes for comparing and moving between states (driven by search of rule space). There were no processes for deciding whether the final goal state in model space had been reached, only utility. The current model of light does not rule out the possibility that a new model may emerge.

During problem solving, movement in model space may occur much faster than did movement in the model space for light. Whenever people are faced with a new task, it is necessary to form a model of that task, the current state of which may need to quickly and often be revised, just as Larkin's (1983) physicists did.

Search in rule space can drive movement in model space. For example, if the rules suggested by a model fail, then eventually the response will be to change the model. If the rules make a false claim or mandate an impossible action, then the problem solver can be said to have reached an *impasse* (Brown & VanLehn, 1980). Such impasses require repair procedures, such as when Larkin's (1983) physics experts changed their schemas when faced with a contradiction. In our terms this is movement in model space.

Success in rule space could also lead to movement in model space. While less likely to result in wholesale change to a model, success can lead to modification of the current model, such as through *elaboration*. Elaborations (see VanLehn, 1989) are assertions about the problem without having any impact on previous assertions. Simply filling in slot values in a schema is a form of elaboration, but so are new statements about the representation of the problem which may arise from the testing of rules through the generation of instances.

The hierarchical three-space model of problem solving is represented diagrammatically in Figure 1. In this model, the problem description provides the initial model state, which in turn defines the rules space consisting of all possible rules that the model suggests are plausible. The problem solver's state in rule space defines what are the relevant instances and how they should be represented in order to test rules. Instances are then generated by invoking experiments (i.e., interaction with the world) or from memory. The results of generating instances can be used to

modify rules, that is, cause movement in rule space (confirmation can be seen as a form of movement too in that the confidence in the rule state would be enhanced). Repeated failure for the rules in the rule space may lead to modification of the model, either directly (e.g., the failed rules may suggest different types of rules), or by evoking search mechanisms in model space in order to overcome the impasse. For each space, memory provides knowledge that is used by the search processes.

Figure 1. A hierarchical three-space theory of problem solving

We can illustrate these spaces using Vollmeyer et al's (1996) biology-lab task. Initially participants had to construct a model of what sort of system they thought they were faced with. Their model defines a rule space consisting of all possible links between inputs and outputs. If participants hit on the right model immediately, that biology-lab is a straightforward linear system, then they can solve it quickly. To test rules, instances are generated consisting of particular sets of inputs. Such a model defines a constrained, and thus quickly searchable, rule space. However, most participants start out with less precise models. For example, they have models that include the possibility of interactions, or random effects. A model including such possibility defines a larger rule space, and searching these parts of the rule space are at best a waste of time, and at worst confusing.

**Search Processes.** An advantage of treating problems solving as search of multiple spaces, is that it suggests a series of questions about the nature of the search processes.

For each space we have to ask Simon and Lea's (1974) questions: 1) what are the knowledge states, 2) what are the generative processes, 3) what are the test processes, 4) what are the selection processes?

Table 1 is a proposal for the nature of the search processes. Most of the processes invoked are processes already studied. For *instance space* the processes are those normally invoked for problem solving as search of a problem space, but Table 1 also specifies relationships between other processes, such as induction, hypothesis testing, metacognition, and analogy. Table 1 suggests a specific organization between different processes involved in problem solving and learning from problems solving. For *rule space*, induction and hypothesis testing are clearly distinguished as the generative and test processes respectively, and they are both distinguished from analogy. Table 1 also highlights processes we know little about, in particular, the selection processes for rule and model space.

It is clear from Table 1 that we understand least about model space. This is not surprising given that it encompasses the questions of "How do we form representations?" Table 1 implies though a useful way to think of research into analogy, a common topic in recent years (see Holyoak & Thagard, 1995). If analogies give people a new way of looking at a situation or problem (e.g., the water analogy for electricity) then they can be seen as a generative process in model space. Analogies of this type are therefore distinguished from induction.

Table 1: The four generalized problem space components for each of the three spaces.

	Instance space	Rule space	Model space
<b>knowledge states</b>	states of a task	hypothesized rules	possible models of the tasks
<b>generative processes</b>	operators for changing the state of the task	operators for generating rules (e.g., induction)	operators for generating new models (e.g., analogy)
<b>test processes</b>	evaluate how close current state of task is to its goal state	hypothesis testing (e.g., generate critical instance)	evaluate how well current model fits (e.g., metacognitive processes)
<b>selection processes</b>	select operator or evaluation method	decide which rule to test, or how to generate a rule	select method for evaluating or generating new model

**Formalising a Hierarchy of Spaces.** In Figure 1, the hierarchical nature of the three-space theory is made clear. We aimed to create a hierarchy because it makes the spaces clearly distinct. We agree with the proposed constraint of Baker and Dunbar (1996) that in multispace theories the spaces at different levels of abstraction (e.g., rule and instance space) should be isomorphic, whereas those at the same level (e.g., different representational forms of the same problem) should be homomorphic. Figure 1 presents the spaces as hierarchical, and we can describe them as

being hierarchical, but to truly impose this constraint we need to propose a formal definition that is hierarchical.

To give the spaces a formal definition, we start with the claim that any task can be seen as defined by a set of inputs, a set of outputs, and a set of rules relating those inputs to the outputs. Productions can have this form, so the generality of this claim is wide. In this formalism each output can be seen as a function of the inputs and constants associated with the inputs. Thus, a task with a set of  $X_1$  to  $X_M$  inputs and  $Y_1$  to  $Y_N$  outputs can be defined by the following set of very general functions:

$$\begin{aligned} Y_1 &= f_1(c_{10}, c_{11}, X_{11}, c_{12}, X_{12}, c_{13}, X_{13}, \dots, c_{1M}, X_{1M}) \\ Y_2 &= f_2(c_{20}, c_{21}, X_{21}, c_{22}, X_{22}, c_{23}, X_{23}, \dots, c_{2M}, X_{2M}) \\ &\dots \\ Y_N &= f_N(c_{N0}, c_{N1}, X_{N1}, c_{N2}, X_{N2}, c_{N3}, X_{N3}, \dots, c_{NM}, X_{NM}) \end{aligned}$$

The relationship between different hierarchical spaces can be specified in terms of the different components of these equations that a state in each space will specify. A *model state* specifies a set of functions with constants left unspecified; a *rule state* specifies a set of constants; whereas a particular set of  $X$  values (with resulting  $Y$ 's) represent *instance states*. For example, consider a task that could be described as a single output with two inputs. This would be defined by a single equation:  $Y = f(c_0, c_1, X_1, c_2, X_2)$ . A model suggesting that inputs are additive specifies the equation  $Y = c_0 + c_1X_1 + c_2X_2$ . The rule that " $X_1$  has twice the effect of  $X_2$  but there is no constant effect," is expressed by the equation:  $Y = 2X_1 + X_2$ . This hypothesized rule could be tested by generating an instance with values of 5 for  $X_1$  and 5 for  $X_2$  and testing if the resulting value of  $Y$  is 15. Biology-lab fits easily into this framework as  $X$  values can be seen as changes to inputs, constants define particular possible links, and the shape of the functions are the nature of possible rules. However our argument is that any task could be seen in these terms, so applying the hierarchy constraint when determining the exact nature of the spaces for a task can be seen as requiring a specification of how the task fits into this formalism. The mathematics of this formalism are not in themselves insightful, but fitting spaces to this formalism creates constraints on the definitions of the search spaces.

## Comparison to Other Approaches

**Other Multispace Models.** Ours is not the only work on multispace models. Another is the four-space model of Schunn and Klahr (1996) for scientific discovery. This model differs in various ways from the hierarchical three-space theory, but there is not space here to fully explore the differences. An important difference is that the four-spaces are not constrained to be hierarchical. The scope of the four-space model is not clear, but if it can be a general model of problem solving, then we would welcome it as another attempt to address the lack of theory in problem solving research. Dialectic progress requires competing alternatives.

How do multispace models in general relate to Soar (Newell, Rosenbloom, & Laird, 1989) and ACT-R (Anderson, 1993)? Soar and ACT-R are frameworks in

which detailed models of problem solving can be built. Because Soar constructs a new problem space whenever the need arises, Newell (1989) proposed that Soar could model Klahr and Dunbar's (1988) theory, so by extension it can model all multispace theories. Whereas it should be possible to build multispace models in the Soar architecture, they are not equivalent just because they both involve multiple problem spaces. The spaces in multispace models are conceptually distinct and interact in specified ways, so a compatible model built in Soar would have to incorporate these assumptions.

Anderson's (1993) ACT-R does not explicitly incorporate the idea of interactive search of multiple spaces, but there appears to be no reason why it could not model such processes. The current goal in ACT-R is critical, because subgoals encourage the firing of certain sets of productions. Such sets could be considered to define different spaces, so perhaps rapid transition between different subgoals could simulate an interactive search between spaces. The implications of such an approach are unclear.

**Situated Cognition.** We started by decrying the lack of alternatives theories in problem solving research, but there exists an approach to problem solving that does not focus on search: situated cognition. Situated cognition places a great emphasis on the context of cognition and denies (or at least de-emphasizes) that symbolic processing (such as search of a problem space) lies at the heart of cognition. The extent to which situated cognition is an antithesis to problems solving as search, is not clear. Vera and Simon (1993) tried to place situated cognition into the symbolic framework, but the replies to their article suggested that researchers taking the situated cognition approach see it as fundamentally different. However the problem with situated cognition emerging as an antithesis to the thesis of problem solving as search may be that neither the thesis nor the antithesis is clear enough to begin with.

Like any clearly stated antithesis we would welcome the emergence of a competitor such as situation cognition. Within the three-space model, in general we could try to explain the phenomena that cognition is often heavily context dependent as the claim that movement in the model space is difficult, and may usually define only a restricted rule space. Perhaps this is the general condition, and the implications of this would have to be worked out.

## Conclusions

We have argued that a hierarchical three-space theory of problem solving can be derived from existing studies and ideas about problem solving. In constructing this theory we have been guided by Schunn and Klahr's (1996) three criteria for when to propose additional problem spaces in multispace search theories. The first criterion is logical, do the spaces involve search of different goals and entities? (We would also add, do they use different operators for search?) The three spaces we propose clearly involve different kinds of states, goals, and ways of searching that space, so we think we meet this criterion. The second criterion was, do the spaces differ empirically? There is

evidence from existing literature that different factors influence behavior, so we think we can meet this criterion. Schunn and Klahr's third criterion was implementational, spaces should be able to be represented distinctly in a computational model that can perform the task. At the moment we can do more than suggest how such a model using the our theory would work, but constructing such a model is an important aim.

To test the hierarchical three-space theory we intend to examine the testable implications it has for how people may best learn from encountering novel tasks. It suggests that whether hypothesis testing will be a good strategy for learners depends on the quality of the learner's model. Learners with a poor model may be disadvantaged by being encouraged to test hypotheses. A current weakness with the theory is that we may be able to define relatively what are good and poor models in terms of some metric of the size of the rule space the model state defines, but it may be hard to define absolute model goodness. Specifying the distinction between good and poor models precisely is an important aim of future research, especially if we are to investigate the practical implications of the theory. Also required is further study into the reality and properties of the links between spaces proposed by the theory.

Have we met our aim of proposing a theory for problem solving? We are trying to develop the hierarchical three-space theory so that it can generate predictions in terms of the interactions between different spaces, and hope to make the theory a tool for organizing the different processes involved in problem solving. However, we recognize that the theory requires more development, both computationally and empirically, before it is truly more than a framework. Such attempts by problem solving researchers are necessary though because until there are such theories, problem solving will remain just a set of diverse and sometimes unrelated phenomena.

## Abstract

The representational effect refers to the phenomenon that different isomorphic representations of a common structure can generate dramatically different representational efficiencies, task difficulties, and behavioral outcomes. This paper presents a study of applying distributed representations to systematically analyze the representational effect in complex real world systems. Distributed representation is a representational system that is composed of internal and external information that is processed in a dynamic, interactive, and interwoven manner. The representational effect is observed and studied in a series of experiments involving various navigational instruments used in aviation. The cognitive task was decomposed into its components and the information distribution across internal and external representations for each component was identified. The experimental results showed that the task difficulties of different instruments correlate positively with the amount of external information for the component tasks, as predicted by the distributed representation analysis.

## Introduction

The information necessary for the performance of almost any everyday task is distributed across information perceived from the external world and information retrieved from the internal mind. These tasks are known as distributed cognitive tasks (Zhang & Norman, 1994). The external representations constructed from the information extracted from external objects (such as written symbols) and the internal representations in the mind (such as schemas) dynamically integrate and interweave to result in a rich pattern of cognitive behavior. The principle of distributed representations is that a distributed cognitive task involves a system of distributed representations that consists of internal and external representations (Zhang & Norman, 1994, 1995). The task is neither exclusively dependent on internally nor exclusively dependent on externally processed information, but rather on the interaction of the two information spaces formed by the internal and external representations.

In the aviation industry, there are a wide variety of navigational systems. Among them there is a set of very basic navigational instruments. These instruments are selectively tuned to transmitting radio stations on the ground. The received signals are then presented in a display in the cockpit for the pilot to interpret. There is only so much information that a navigation instrument needs to display: azimuth or directional information, and distance information. However, different instruments present these two pieces of information differently and result in different degrees of precision and efficiency as interpreted by the pilot.

Cockpit information displays are examples of distributed representation systems. Navigational information in a cockpit information system can and is represented through a variety of isomorphic navigation instruments. Although these instruments are isomorphic and provide the same information, they vary in their relative degrees of directness and efficiency in their representation of scale information (Narens, 1981; Stevens, 1946; Zhang, 1995). The scale information of the orientation and distance dimensions in a cockpit information display is represented across internal and external representations and can dramatically affect the representational efficiency of the display and the navigator's behavior (Zhang, 1997). This research examines the cognitive properties of the representations that such instruments produce. The specific assumption to be tested is that with the most direct system, scale information is maximally represented externally, resulting in higher efficiency, faster and more direct responses.

## Distributed representations

External representations are the representations formed from information gathered from the external environment. External representations include physical objects and/or symbols, relations and constraints between physical objects and their configurations relative to each other, and external physical rules, such as laws of physics. Through the human perceptual processes, the information necessary to form external representations is picked up by the sensory and

perceptual systems. External representations are characterized as providing information that is directly perceived and applied toward a cognitive task without being explicitly interpreted. External representations contribute information that is otherwise unavailable from representations internally generated from memory, or from representations that are internalized from perceptual information (Zhang, 1997). Perceived information from within the external environment that must be represented internally in order for cognition to operate on it is, by definition, recreated as internal representations.

Internal representations are the representations that originate from within the mind and are not initiated from the perception of external stimuli. These internal representations are in the form of, but not limited to, mental images, propositions, production rules, and schemata. Cognitive processes retrieve information from long-term memory. This information may be selectively or incidentally retrieved, and is then employed to formulate internal representations.

Internal and external representational spaces together form a distributed representational space, which is where the representation of the task (its abstract structures and properties) resides. External representations are not represented redundantly as internal representations. In combination with internal representations, external representations can directly activate and provide perceptual information necessary for responses and actions.

### Representational effect

The representational effect is the phenomenon that different isomorphic representations of a common structure can generate dramatically different representational efficiencies, task difficulties, and behavioral outcomes (Zhang & Norman, 1994). It is ubiquitous in problem solving, reasoning, and decision making across many task domains.

### Navigational Displays

The cockpit informational displays in this experimental study are navigational instruments that provide directional guidance. As the experimental task is a position-fixing task, only the instruments that have the

necessary information were provided and will be discussed here briefly. (A more in-depth review of cockpit navigational displays is provided in Zhang, 1997.). VOR (very high frequency omnidirectional range), ADF (automatic direction finder), RMI (radio magnetic indicator), and the Moving Map display are four of the more prevalent navigation systems used for such a position fixing task. The generic moving map display refers to the more advanced cathode ray tube displays found in newer airlines that provide multiple information sources over a moving map within one display.

#### VOR indicator

The VOR equipment in the aircraft receives and interprets transmitted radio signals from the ground and shows directional information of the aircraft in relation to the VOR station on the ground. The VOR indicator is usually used to show the intended course of the aircraft and the lateral position of the aircraft in relation to that intended course. The VOR indicator in Figure 1A shows a selected 315° course. The TO indication at the right of center of the display indicates that proceeding on such a course will lead the aircraft to the station. The vertical needle (CDI, course deviation indicator), when in the center as shown, indicates the aircraft is on that selected course. If the CDI pivots to the left, this will indicate to the navigator that the aircraft is off the 315° course and needs to make a correction by navigating the aircraft towards the left to get back on course. The VOR indication (course selected) is independent of the heading of the aircraft.

The VOR indicator can also be used to determine the location of the aircraft relative to the VOR station. By tuning the VOR until the CDI centers with a TO indication, the displayed course will be the magnetic bearing of the aircraft to the VOR station. Likewise, by tuning the VOR until the CDI centers with a FROM indication, the displayed course will be the magnetic bearing of the aircraft from the VOR station.

#### ADF indicator

The ADF indicator in the aircraft can also be used for directional guidance to or from the radio station, or position fixing to determine one's location. The ADF indicator

Figure 1: The four navigation instrument displays.

shows the orientation of an aircraft relative to the radio station (see Figure 1B). It only displays the relative bearing of the aircraft to the station, which is the angular distance between the lateral axis of the aircraft and the course to the station. In order to obtain a magnetic indication, which is necessary to navigate or determine one's position, the relative bearing indication must be summed with the magnetic heading of the aircraft (obtained off another instrument not shown). This sum is the magnetic bearing to the station; in order to derive the magnetic bearing from the station, the pilot would need to determine the reciprocal.

### RMI indicator

The RMI indicator is similar in its display to that of the ADF indicator. The major difference between the ADF and RMI indicators is that the ADF display is fixed and the RMI display rotates as the aircraft changes direction. The RMI display is essentially the aircraft's heading indicator with the RMI pointer(s) providing navigational information (see Figure 1C). As a consequence, the RMI provides angular distance, and orientation of the aircraft relative to the radio station as magnetic indications. It is unnecessary for the navigator to do any computations to obtain magnetic bearing information.

### Moving Map display

The primary navigational display mode of a Moving Map display shows a map of the immediate surrounding environment of the aircraft, as well as the radio stations. Magnetic bearing information is displayed alongside lines extending from the center to the radio stations. Angular distance is also provided.

Figure 2: The experimental task display.

## Experimental Study

The experimental hypothesis is that although the four navigation instruments provide the same and all the necessary information, the different distributions of the same information across internal and external representations make some instruments harder to use while make others easier to use, with the easiest one the instrument that has most external information. Experimental participants were provided with bearing information as displayed by the instruments, and were then required to determine the current position of the aircraft on a map.

### Representational study of experimental task

A representational analysis of the experimental task identifies the abstract structures of the task and the representational properties that are responsible for the representational effect. To successfully perform the position-fixing task with the given bearing information, it is necessary to perform a triangulation using the radio stations as end points and extending from them along the bearings. The intersection of the bearings indicates the current position of the aircraft relative to the radio stations.

The four types of instruments have different representational spaces. The representational system with the largest amount of external information will be more efficient and direct (Norman, 1993; Hutchins, 1995; Zhang & Norman, 1994). Furthermore, the position-fixing task requires a triangulation method to determine the aircraft position. Both the VOR and RMI provide the necessary magnetic bearing information immediately. It is not necessary to represent the information internally. The ADF does not provide the information readily, and it is necessary to derive the magnetic bearing information through mental calculations using the heading information with the relative bearing information provided by the instrument. With the moving map display, the magnetic bearing information is also readily available. Furthermore, the information is presented in a graphical and spatial layout with the instrument displaying the position of the aircraft relative to the radio stations. There is little effort required in comparing the displayed spatial relations with the map and determining the aircraft position. The other three instruments require cognitive effort in subtending bearing lines extending from the radio stations to create an intersection in order to determine aircraft position.

Table 1: Properties of the navigation systems.

Information readily available (externally represented)	Type of navigation system			
	VOR	ADF	RMI	Mov. Map
Aircraft heading			√	√
Magnetic bearing	√		√	√
Orientation		√	√	√
Angular distance between aircraft and radio station		√	√	√
Spatial and graphical layout of information				√

The prediction is that the moving map display will outperform the other three instruments because it provides the largest amount of external information and graphically and spatially presents the information in such a manner where the operation of determining the location of the aircraft is also provided externally. The representational effect will be that the experiment participants within that navigation instrument condition will outperform the other navigation instrument conditions. Table 1 summarizes the properties of the four navigation systems. For the other instruments, RMI should be easier than ADF, which should be in turn easier than VOR.

### Method

**Subjects.** Eighty-five participants participated in the experiment for course credits in an introductory psychology course at The Ohio State University.

**Materials and Equipment.** Three Pentium computers were used with 17-inch monitors set at similar SVGA resolutions. The displayed image consisted of a large map covering most of the screen area, an instrument panel with the navigation instruments unique to each experimental condition, and a control panel that served as the experiment

interface. The map area displayed two radio stations and a square icon that represented the aircraft. The positions of the radio stations and aircraft were randomized at every trial. Figure 2 shows a screen capture of an experimental trial.

**Design and Procedure.** The experiment was a between-subject design with four conditions, one navigational instrument for each condition. Each participant had 24 trials in the experiment. For each trial, the navigation instruments were displayed, providing the necessary and essential information. The participants would then read and interpret the navigation information and, by clicking and dragging the square aircraft icon, re-position it to where they believed the actual position of the aircraft was. They would commit their decision by clicking on the OK button. If the participants were correct to within a radius of 5% of the screen diagonal dimension, they moved on to a new trial. If they were incorrect, they were given two more attempts to locate the position.

Due to the complexity of the experimental task, the instructions were carefully administered, which limited the number of participants for each experimental session to two. Participants were first given a set of written instructions, then the experimenter provided with verbal explanations and further instructions. Each participant was

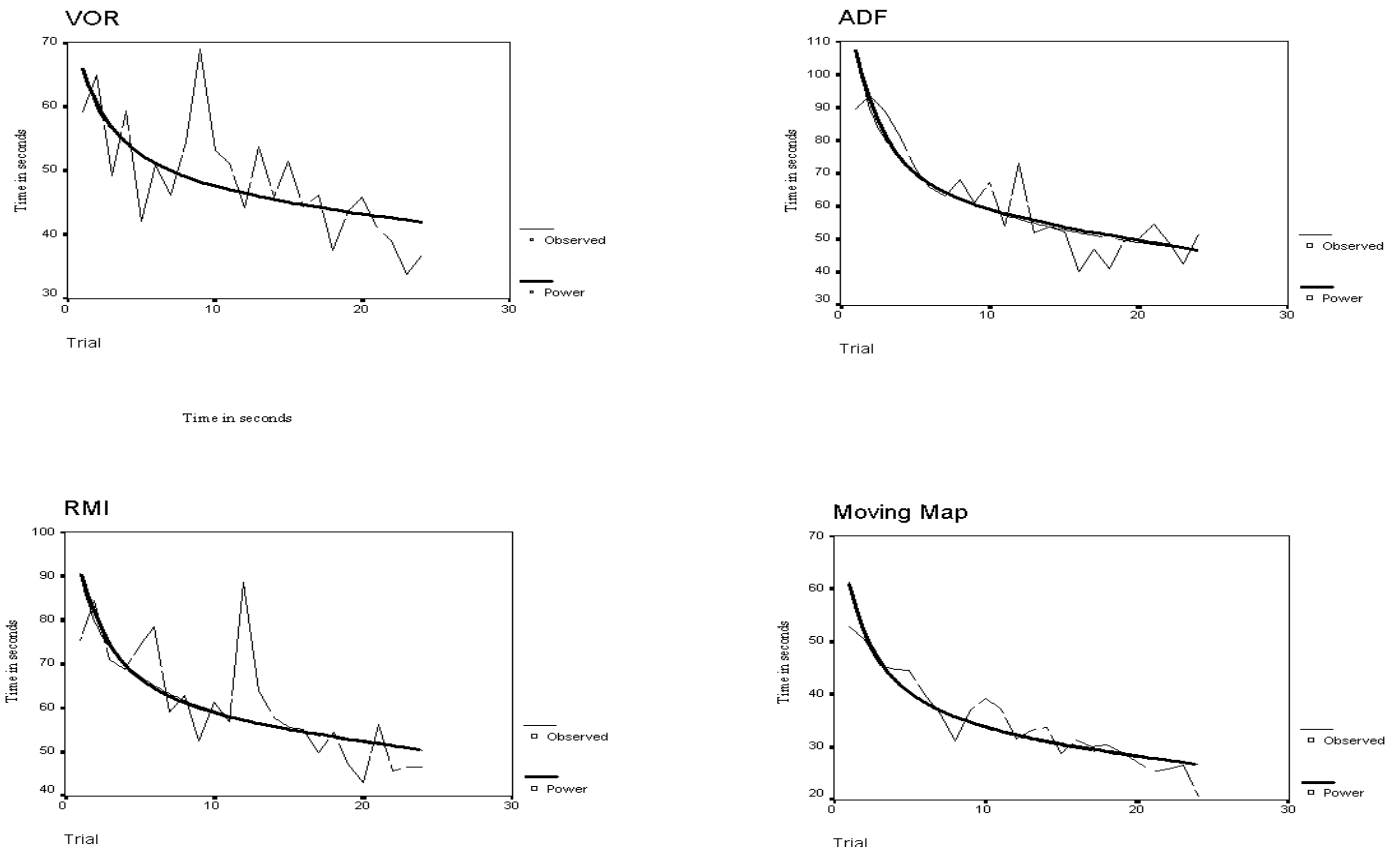

Figure 3: Performance data regressions.

given at least 3 trials to demonstrate his/her comprehension of the task prior to the start of the experiment. As the experiment required some manual dexterity to maneuver the computer pointer over the monitor screen, the computer mouse was configured for lefthanded participants when necessary.

### Results and Discussion

The performance data from all subjects were averaged by trial within each of the four conditions. Regressions were then performed for each condition.

There was an observation of a dramatic and robust power curve of learning for each condition that corresponded with the standard power law of practice. Figure 3 shows each condition with its raw averaged data and its best-fit regression. The variation in the VOR condition is the largest, as indicated by the lowest

Figure 4: Regression comparison.

regression fit ( $r$ -squared value = 0.44). The other conditions have higher fits to raw data ( $r$ -squared values: ADF = 0.78, RMI = 0.57, Moving Map = 0.84).

Figure 4 shows all four regressions within one graph for easy comparison. Table 2 below summarizes the task completion times for a trial set that was used for analyses.

Table 2: Comparison of mean times.

	VOR	ADF	RMI	Mov. Map	sig.
Trial 1	92.6	104.7	78.1	62.3	0.04
Trial 6	68.1	82.1	64.1	51.1	0.05
Trial 12	54.2	99.3	60.9	40.4	0.01
Trial 18	41.8	52.9	44.9	43.0	0.60
Trial 24	42.7	63.4	41.2	28.0	0.00

The prediction was for participants in the Moving Map condition to outperform all other conditions, to be followed with the RMI and ADF conditions, and the VOR condition

participants were expected to be the slowest to complete the experimental task.

As the data show, there were significant differences between the four conditions at four of the five trials used for analyses in the ANOVA test. A posthoc analysis performed using the Tukey test for multiple comparisons revealed that there were significant differences in task completion times ( $\alpha$  level = 0.05) between the ADF and RMI conditions and between ADF and Moving Map conditions, with the ADF times higher than either of the other two conditions.

Performances levels of the four conditions got closer after 24 trials, although there was a significant difference between the ADF and Moving Map conditions. The individual power curves of learning between all four conditions resulted in this performance convergence. After 24 trials, the performance times between the conditions followed the predicted trend.

### Discussion

According to the hypothesis, the representational effect observed will favor the performance of the Moving Map over that of the RMI, ADF, and VOR. This assumption arose from the representational analysis that decomposed the cognitive task and identified the components and properties that would be responsible for such a representational effect. It was identified that the Moving Map navigation display provides all the necessary information externally and in a spatial and graphical layout and other displays provide more information that needs to be represented and computed internally, with a high cognitive cost. All the necessary information for the task is available as directly perceptible forms of external representations for the Moving Map condition. Furthermore, the information is provided in an instrument display that maps directly to the map displayed on the monitor since the instrument itself is a map. None of the instrument components has to be represented or re-represented in an internal representation, thus reducing mental workload and increasing task efficiency.

The RMI condition posted consistently faster times against the ADF condition, with significance for trials 12 and 24. The RMI displays bearing information to the user in the magnetic compass scale, as opposed to the ADF instrument that provides the information in a relative degree scale. As a result, the navigator avoids costly mental workload by obtaining more of the information from the external representational space.

The VOR task completion times were not expected to be as fast as the Moving Map display. It was anticipated that VOR times would be slightly slower than ADF times. But there were no significant differences between the VOR and ADF. The difference, if it existed, might be too small to be observed. Additionally, there is an obvious and noticeable learning process that is occurring, as the participants become more proficient and familiar with the instruments and the task itself. This may be attributed to simple skill acquisition or familiarization of the interface.

## Conclusion

The experimental results were generally consistent with the predictions of the distributed representation analysis. The prediction was that the instrument with more external information would be easier. This prediction was supported by the observed representational effect. The representational effect predicted that isomorphic representations could produce different behaviors due to the variant distributions of internal and external representational information.

The resulting behavior variance from the experiment indicates that some representations are more 'efficient' in extending the necessary information for a task. Although the different isomorphic representations result in different initial levels of performance and learning curves, performances appear to converge after a sufficient period of learning.

One argument can be made about the learning behavior: learning and practice may eliminate the representational effect after enough trials. However, further research needs to be done in more complex and dynamic settings. The current experimental task was a simple position-fixing task in a very controlled and static environment. In an unpredictable and complex environment such as that of the cockpit of an aircraft, the representational effect could be more pronounced and a possible regression to initial performance levels should be studied. Another issue that is worth of further study is whether the converged performance after learning for different representations will diverge again under extreme conditions such as high cognitive workload and time pressure.

## Abstract

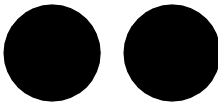

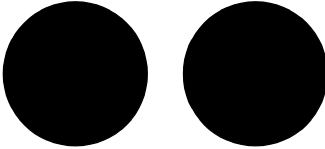

How does our understanding of number develop? There is evidence suggesting that even infants have primitive concepts of “more”, “less”, and “the same”. Some researchers have concluded that humans have an innate number sense, present from birth. In this paper, we present a two-part model which explains these results in terms of continuous amount. The first part is a quantitative model addressing the results of infant habituation studies. The second, more tentative part of the model addresses object individuation, subitizing, and number estimation.

## Amount vs Number

In this paper, we use the word *amount* to refer to the total area of the objects in view; this is a continuous quantity. *Number*, a discrete quantity, refers to how many objects are present. As shown in Table 1, these two aspects can be varied independently.

A complete model would have to take into account other features, such as total contour length (edge length), shape, and color. Except where otherwise stated, we disregard these details.

Table 1: Amount vs Number. Both pictures in each column have the same total area.

	Small Amount	Large Amount
Small Number (2)		
Large Number (3)		

## Habituation Studies on Infant Numerical Abilities

Three studies are addressed directly by the first part of our model: Starkey & Cooper (1980), Antell & Keating (1983), and Clearfield & Mix (1999). All three studies use the same habituation paradigm, described below.

An infant is shown a series of images of black circles or squares on a white background, such as those in Table 1.

The infant is shown several more images. They may differ in arrangement, but they are the same on some critical dimension, such as the number of dots. If the infant habituates (stops looking at new images as long), this is taken as evidence that the infant detected the invariant property and became bored with it.

After habituation, the infant is shown a test image which differs on the critical dimension. If the infant dishabituates

(spends significantly more time looking at the test image), he or she presumably noticed that the property changed—the test image is new and exciting. If the infant does not dishabituate, he or she presumably did not notice anything special about the test image.

In Starkey & Cooper’s study, 22-week-old infants who had been habituated on images of 2 dots dishabituated when tested on images of 3 dots (and vice versa). Infants, it appeared, can tell the difference between 2 and 3.

To discount the possibility that the infants were simply reacting to amount, Starkey & Cooper tried 4 vs 6 dots. The relative difference between the images in this condition is the same as in the 2 vs 3 condition: the larger number has 1.5 times as much area as the smaller one. If infants are using amount of area, they should be at least as likely to dishabituate in the 4 vs 6 condition.

On the other hand, older children and adults have a much easier time enumerating sets of up to 3 or 4 objects than larger sets. Enumerating large sets requires use of an explicit, learned counting procedure; smaller sets can be enumerated quickly and subconsciously, through a process called “subitizing”. The nature of subitizing remains controversial. In any case, if infants are subitizing, the 2 vs 3 condition should be more likely to produce dishabituation.

In fact, Starkey & Cooper’s subjects did *not* dishabituate in the 4 vs 6 condition. It was therefore suggested that subitizing may be innate.

Antell & Keating replicated these results in newborns (less than a week old).

Clearfield & Mix’s study reexamined the amount hypothesis. By changing the sizes of the objects (squares) in their displays, they were able to independently vary the number of objects and the total amount of area and contour length. (This study used 6- to 8-month-old infants, and only the 2 vs 3 condition was considered.)

They found that if the number remained the same, but the total area and contour length changed significantly, the infants dishabituated. Moreover, the infants *did not* dishabituate if the test image had approximately the same total area and contour length as the habituation image, *even if the number of objects was different*. In other words, infants do not appear to distinguish between 2 large objects and 3 small ones.

One problem remains: if infants are using amount to discriminate quantities, why don’t they dishabituate in the 4 vs 6 condition?

Clearfield & Mix proposed that the 4 vs 6 displays might simply contain too much visual complexity. There is no question of comparison; the infants are overwhelmed by the displays.

The current model focuses instead on the way amount is represented internally<sup>1</sup> by the infants.

If the perceived magnitude grows linearly with the actual amount, then the 4 vs 6 condition should be more likely to produce dishabituation than the 2 vs 3 condition, because the

absolute difference in amount of stuff is larger in the former condition.

Fechner (1860) suggested that the perceived amount grows as the logarithm of the actual amount. This almost does the trick, but not quite: whenever ratios are the same (as in the 2 vs 3 and 4 vs 6 conditions), differences of logarithms are equal. This would make the two conditions equally likely to produce dishabituation.

To explain the greater difficulty of the 4 vs 6 condition, we need a perception function which grows *more slowly* than a logarithm. One such function is the sigmoidal “squashing” activation function commonly used in connectionist “neural network” models (Rumelhart, McClelland, et al., 1986).

### A Quantitative Model

We presume that the photoreceptors (rods and cones) in the retina provide (indirect) input to a neuron (or, more likely, a group of neurons) which codes for the total area of the objects in view. If the total area is larger, this *area unit* is more active; if the area is smaller, it is less active.

This does not require that the image be individuated into objects or preprocessed in any other way. The area unit is actually recording the total amount of light (or lack thereof) received by the retina. For the studies mentioned in the previous section, which use simple, black objects on a white background, this is equivalent to the total area.

The activity of the area unit does not vary linearly with its input. Instead, it varies according to a function of the form:

$$f(x) = \frac{1}{1 + e^{-\alpha x}}$$

In this equation,  $x$  is the total input to the area unit, and  $\alpha$  is a parameter of the model.

The consequence of all this is that the same difference is perceived as being smaller if the absolute amounts involved are larger. This is the well-known magnitude effect, and is shown in Figure 1.

Figure 1: The magnitude effect as a result of a squashing function. Differences are perceived as smaller if the absolute magnitudes involved are larger.

<sup>1</sup> By “represented internally”, we mean “represented as a pattern of neural activation”. We do not mean to imply that infants are deliberately manipulating abstract, symbolic representations of amount.

In the context of the infant studies, our model predicts that the infant dishabituates if the perceived difference in area (between the habituation and test images) exceeds some threshold.

Just as the total activity of photoreceptors reflects the total visible area, the total activity of center-surround “edge detector” retina cells (ganglion cells) reflects the total visible contour length. A *contour unit*, analogous to the area unit, takes input from these neurons. A sufficiently large perceived difference here also induces dishabituation.

In order to make predictions, the model must be defined formally. Let  $AREA_{hab}$  be the total area (in square radians of visual angle) in the habituation images, and  $AREA_{test}$  be the total area in the test image. Similarly, let  $CONT_{hab}$  be the total contour length (in radians) in the habituation image, and  $CONT_{test}$  be the total contour length in the test image.

The model predicts that the infant will dishabituate if and only if

$$|f(AREA_{test}) - f(AREA_{hab})| > \tau_{AREA}$$

OR

$$|g(CONT_{test}) - g(CONT_{hab})| > \tau_{CONT}$$

where

$$f(x) = \frac{1}{1 + e^{-\alpha_{AREA}x}}$$

is the activation function for the area unit and

$$g(x) = \frac{1}{1 + e^{-\alpha_{CONT}x}}$$

is the activation function for the contour unit.

The model has four parameters: the thresholds  $\tau_{AREA}$  and  $\tau_{CONT}$  and the activation function sharpnesses  $\alpha_{AREA}$  and  $\alpha_{CONT}$ .

### Setting the Parameters

We begin by calculating the total area and contour length of the stimuli from each study. The distance from the infants to the screen was different in each study, so we first convert all lengths into radians of visual angle. The data are shown in Table 2.

Table 2: Data from habituation studies. Areas are in square radians of visual angle; contour lengths are in radians. The test image is assumed to be larger (in terms of area and/or contour length) than the habituation image; because of the absolute value in the formula, the model would make identical predictions for the converse condition.

Study	Dishabituation Condition				No Dishabituation Condition			
	Habituation		Test		Habituation		Test	
	Area	Contour	Area	Contour	Area	Contour	Area	Contour
Starkey & Cooper	0.00044	0.10	0.00065	0.16	0.00087	0.21	0.0013	0.31
Antell & Keating	0.0031	0.28	0.0046	0.42	0.0062	0.56	0.0093	0.84
Clearfield & Mix	0.0089	0.53	0.020	0.80	0.0089	0.53	0.0059	0.53

We were able to find parameters for which the model gives the correct predictions for all of these studies. In other words, at least one of the thresholds is exceeded in each dishabituation condition, and neither are exceeded in any no-dishabituation condition.

One satisfactory set of parameters is:

$$\alpha_{AREA} = 3000$$

$$\tau_{AREA} = 0.075$$

$$\alpha_{CONT} = 3.5$$

$$\tau_{CONT} = 0.075$$

Admittedly, there is some degree of coincidence involved

in our being able to find parameters consistent with all three studies. Variables such as lighting level, size of the card on which the object appear, and subject age may affect these values. Still, it is satisfying that none of the studies disagree qualitatively with the model, and intriguing that the same value can be used for both thresholds.

### Problems With the Quantitative Model

In addition to the variables just mentioned, we have some reservations about the quantitative model.

The model assumes that each image is registered in a single eye fixation. In fact, infants move their eyes around quite a bit while looking at an image. There are two ways this may not matter. First, if the infant is keeping a running average of the area and contour length in the image, minor eye movements should have little effect. Second, the infant

may be building an internal map of the image, and then extracting area and contour information from this “mind’s eye” view.

Another problem arises from studies on visual complexity. Karmel (1969) has given evidence that infants prefer to look at pictures with a certain amount (varying with age) of contour length. The total contour lengths in question are so huge (tens of radians) that, after passing through the activation function in our model, they would be indistinguishable. If, as our model predicts, these images are indistinguishable, how could infants have a preference? Karmel’s data come from a significantly different paradigm, and additional factors such as visual frequency may be coming into play. Still, these results will eventually have to be addressed.

### Estimation and Subitizing

The model presented thus far may go a long way to explaining infant habituation data, but it can’t be the whole story for adults. In addition to the explicit, sequential counting procedure, we are able to estimate number. This estimation ability appears to operate in parallel—unlike counting, it doesn’t take twice as long when the number of objects is twice as large. The magnitude effect appears here, too: estimation of large numbers is less accurate. Estimation is only precise within the subitizing range, up to 3 or 4 objects.

Before number can even be estimated, it is necessary to individuate objects. In this section, we propose a model of object individuation which can underlie the estimation ability.

### Temporal Synchrony

Animal studies (Eckhorn et al, 1988) have suggested an intriguing hypothesis about the visual system: in certain parts of the brain, cells which are responding to the same object fire at the same time. This is shown in Figure 2.

Figure 2: Temporal synchrony. Three cells are responding to the first object, two to the second. Cells responding to the same object fire at the same time.

Because the neural hardware is inherently noisy, there is a limit to the number of synchronized phases that can be kept

distinct. This has implications regarding parallel vs sequential visual search, attention, variable binding, short-term memory capacity (the magical number  $7 \pm 2$ ), and other areas of cognitive science. In the rest of this section, we explore how temporal synchrony may aid in number estimation.

### Subitizing

Temporal synchrony provides a simple explanation for the subitizing phenomenon. Suppose there is a unit which fires whenever any other unit fires. This *subitizing unit* repolarizes faster than the other units, but not so fast that it fires more than once in response to a synchronized pulse. This is shown in Figure 3.

Figure 3: Subitizing with temporal synchrony. The subitizing unit fires whenever any other unit fires.

The frequency with which the subitizing unit fires encodes the number of objects visible. Beyond 3 or 4 objects, the phases begin to blur together; the subitizing unit fires at its maximum rate and the subject perceives “many” objects.

### Estimation

Numbers beyond the subitizing range can still be estimated with the help of temporal synchrony. If a unit accepts input only from others firing at a particular phase, it only receives input regarding one object. Even if there are too many objects to subitize, this can provide some useful information: the size of a typical object. If this amount is used to scale the total amount of area visible (effectively dividing the total by the size of one object), a continuous representation of the number of objects is produced. This is not a terribly accurate mechanism (it suffers from the magnitude effect), but it is much faster than counting.

## Related Work

An alternative model of nonverbal numerical abilities is the accumulator model proposed by Meck & Church (1983; Gallistel & Gelman, 1992). This model proposes an accumulator which integrates over time. As each object is perceived, the activity of the accumulator increases by a fixed amount. The accumulator's activity then serves as a representation of number.

The imprecision of larger numbers is explained as variability in the pulses passed to the accumulator. The more pulses there have been, the less accurate the resulting value in the accumulator.

Our model differs in two ways. First, we explain the lower precision of larger amounts with the squashing function. We have difficulty conceiving of a neurally plausible accumulator which is capable of both taking on very large values and providing precision for small values.

A second difference is that our model is strictly parallel, while the accumulator model is sequential: the stimuli are "fed into" the accumulator one after another. In a static image, this would require a pointing strategy, with the infant carefully "counting" each item exactly once. Since this is not a trivial task even for 3-year-olds (Fuson, 1988), it is difficult to believe that infants would have this ability. Our model does not ask so much; indeed, the quantitative model does not even require the infant to break the image down into separate objects.

## Conclusions and Future Work

We have presented a two-part model of proto-numerical abilities. The model reproduces human data on numerical perception without any explicit counting. The abilities granted by the model may provide useful grounding to children as they learn conventional counting.

The quantitative model predicts that infants will dishabituate to a sufficiently large change in either total area or total contour length. The exact meaning of "sufficiently large" depends on four parameters, and we have found values for these parameters which are consistent with several existing studies.

The quantitative model makes an interesting, counterintuitive prediction: infants will *not* dishabituate in Starkey & Cooper's 2 vs 3 condition with dots of certain sizes (e.g., extremely large ones). Conversely, the model predicts that infants *will* dishabituate in the 4 vs 6 condition for other dot sizes.

More specific predictions can be cautiously made based on the particular parameter values we found. The perceived difference between images is graphed as a function of stimulus size in Figure 4. Where this magnitude exceeds the threshold, habituation is predicted. Specific predictions are given in Table 3. We have begun empirical studies to test these predictions.

The second, more tentative part of the model accepts the temporal synchrony hypothesis of object individuation. Each visible object (or some of them, if there are too many) is bound to a particular phase. Within the subitizing range, the density of the phases indicates the number of objects. Beyond this range, the amount of area present at a particular

phase indicates the size of an individual object, which can in turn be used to estimate the number of objects.

The second part of the model makes a less surprising prediction: estimating the number of objects visible should be difficult if the objects vary greatly in size.

We are now working on a connectionist implementation of our model, based on Gasser and Colunga's (1997) Playpen model of object individuation and spatial relations.

# Subjacency Constraints without Universal Grammar: Evidence from Artificial Language Learning and Connectionist Modeling

Michelle R. Ellefson (ellefson@siu.edu)

Morten H. Christiansen (morten@siu.edu)

Department of Psychology  
Southern Illinois University - Carbondale  
Carbondale, IL 62901-6502 USA

## Abstract

The acquisition and processing of language is governed by a number of universal constraints, many of which undoubtedly derive from innate properties of the human brain. However, language researchers disagree about whether these constraints are linguistic or cognitive in nature. In this paper, we suggest that the constraints on complex question formation, traditionally explained in terms of the linguistic principle of subjacency, may instead derive from limitations on sequential learning. We present results from an artificial language learning experiment in which subjects were trained either on a “natural” language involving no subjacency violations, or an “unnatural” language that incorporated a limited number of subjacency violations. Although two-thirds of the sentence types were the same across both languages, the natural language was acquired significantly better than its unnatural counterpart. The presence of the unnatural subjacency items negatively affected the learning of the unnatural language as a whole. Connectionist simulations using simple recurrent networks, trained on the same stimuli, replicated these results. This suggests that sequential constraints on learning can explain why subjacency violations are avoided: they make language more difficult to learn. Thus, the constraints on complex question formation may be better explained in terms of innate *cognitive* constraints, rather than linguistic constraints deriving from an innate Universal Grammar.

## Introduction

One aspect of language that any comprehensive theory of language must explain is the existence of linguistic universals. The notion of language universals refers to the observation that although the space of logically possible linguistic subpatterns is vast; the languages of the world only take up a small part of it. That is, there are certain universal tendencies in how languages are structured and used. Theories of language evolution seek to explain how these constraints may have evolved in the hominid lineage. Some theories suggest that the evolution of a Chomskyan Universal Grammar (UG) underlies these universal constraints (e.g., Pinker & Bloom, 1990). More recently, an alternative perspective is gaining ground. This approach advocates a refocus in evolutionary thinking; stressing the adaptation of linguistic structures to the human brain rather than vice versa (e.g., Christiansen, 1994; Kirby, 1998). Accordingly, language has evolved to fit sequential learning and processing mechanisms existing prior to the appearance of language.

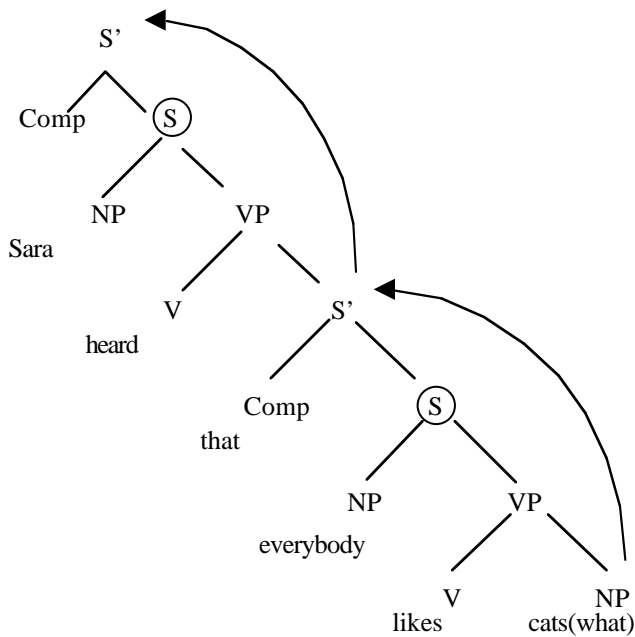

These mechanisms presumably also underwent changes after the emergence of language, but the selective pressures are likely to have come not only from language but also from other kinds of complex hierarchical processing, such as the need for increasingly complex manual combinations following tool sophistication. Thus, many language universals may reflect non-linguistic, cognitive constraints on learning and processing of sequential structure rather than innate UG.

This perspective on language evolution also has important implications for current theories of language acquisition and processing. It suggests that many of the cognitive constraints that have shaped the evolution of language are still at play in our current language ability. If this is correct, it should be possible to uncover the source of some linguistic universal in human performance on sequential learning tasks. Christiansen (2000; Christiansen & Devlin, 1997) has previously explored this possibility in terms of a sequential learning explanation of basic word order universals. He presented converging evidence from theoretical considerations regarding rule interactions, connectionist simulations, typological language analyses, and artificial language learning in normal adults and aphasic patients, corroborating the idea of cognitive constraints on basic word order universals.

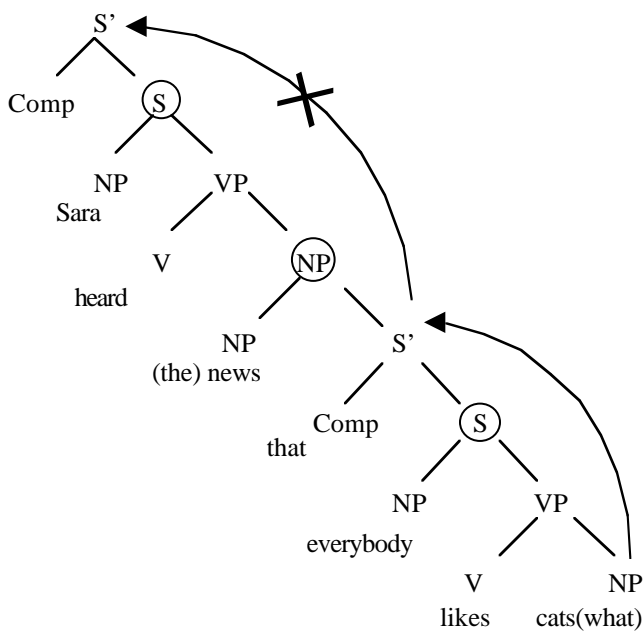

In this paper, we take a similar evolutionary approach to one of the classic linguistic universals: subjacency. We first briefly discuss some of the linguistic data that have given rise to the subjacency principle. Next, we present an artificial language learning experiment that investigates our hypothesis that limitations on sequential learning rather than an innate subjacency principle provide the appropriate constraints on complex question formation. Finally, we report on a set of connectionist simulations in which networks are trained on the same material as the humans, and with very similar results. Taken together, the results from the artificial language learning experiment and the connectionist simulations support our idea that subjacency violations are avoided, not because of an innate subjacency principle, but because of cognitive constraints on sequential learning.

## Why Subjacency?

According to Pinker and Bloom (1990), subjacency is one of the classic examples of an arbitrary linguistic constraint that makes sense only from a linguistic perspective. Informally, the subjacency principle involves the assumption of certain

- 2a. Sara heard that everybody likes cats.
2. What (did) Sara hear that everybody likes?

1. Sara heard (the) news that everybody likes cats.
3. \* What (did) Sara hear (the) news that everybody likes?

principles governing the grammaticality of sentences. "Subjacency, in effect, keeps rules from relating elements that are 'too far apart from each other', where the distance apart is defined in terms of the number of designated nodes that are between them" (Newmeyer, 1991, p. 12). Consider the following sentences:

1. Sara heard (the) news that everybody likes cats.  
N V Wh N V N
2. What (did) Sara hear that everybody likes?  
Wh N V Comp N V
3. \*What (did) Sara hear (the) news that everybody likes?  
Wh N V N Comp N V

According to the subjacency principle, sentence 3 is ungrammatical because too many boundary nodes are placed between the noun phrase complement (NP-Comp) and its respective 'gaps'.

The subjacency principle, in effect, places certain restrictions on the ordering of words in complex questions. The movement of *wh*-items (*what* in Figure 1) is limited as far as the number of so-called bounding nodes that it may cross during its upward movement. In Figure 1, these bounding nodes are the S and NP's that are circled. Put informally, as a *wh*-item moves up the tree it can use comps as temporary "landing sites" from which to launch the next move. The subjacency principle states that during any move only a single bounding node may be crossed. Sentence 2 is therefore grammatical because only one bounding node is crossed for each of the two moves to the top comp node. Sentence 3 is ungrammatical, however, because the *wh*-item has to cross two bounding nodes—NP and S—between the temporary comp landing site and the topmost comp.

Not only do subjacency violations occur in NP-complements, but they can also occur in Wh-phrase complements (Wh-Comp). Consider the following examples:

4. Sara asked why everyone likes cats.  
N V N Comp N V N
5. Who (did) Sara ask why everyone likes cats?  
Wh N V Wh N V N
6. \*What (did) Sara ask why everyone likes?  
Wh N V Wh N V

According to the subjacency principle, sentence 6 is ungrammatical because the interrogative pronoun has moved across too many bounding nodes (as was the case in 3).

In the remainder of this paper, we explore an alternative explanation of the restrictions on complex question formation. This alternative explanation suggests that subjacency violations are avoided, not because of a biological adaptation incorporating the subjacency principle, but because language *itself* has undergone adaptations to root out such violations in response to non-linguistic constraints on sequential learning

### Artificial Language Experiment

Artificial language learning has been shown to be an effective tool in the understanding of the acquisition of language (e.g., Gomez & Gerken, 1999; Saffran, Aslin, & Newport, 1996). More recently, artificial language learning has been used to explore how languages themselves may have evolved in the human species (Christiansen, 2000).

### Subjects

Sixty undergraduates were recruited from an introductory psychology class at Southern Illinois University, and earned course credit for their participation.

### Materials

We created two artificial languages, natural (NAT) and unnatural (UNNAT). Each artificial language consisted of a set of letter strings. The letters in the strings each represented a specific grammatical class (see Table 1). The letters Z and X represented nouns. V and M stood for verbs. The letter S designated a complementizer. Interrogative pronouns were denoted by the letter Q. These strings were constructed based on the sentence structure of the six examples discussed above. Unique letter strings were created for training and testing sessions.

**Training Stimuli** Twenty letter strings, 10 of each for NAT and UNNAT, were created to represent grammatical and ungrammatical complex question formation structures (SUB). The grammatical SUB items used for the NAT training, while the ungrammatical SUB items were used for UNNAT training. Examples of SUB letter strings for both conditions can be seen in Table 1 as sentences 5 and 6.

An additional 20 general training items were constructed to represent general grammatical structures (GEN) that do not involve subadjacency. These items were the same for both languages. Examples of GEN letter strings for both conditions are sentences 1 through 4 in Table 1. In summary, 10

SUB and 20 GEN training strings were created for each language.

**Test Stimuli** An additional set of novel letter strings was created for the test session. For each language there were 30 grammatical items and 30 ungrammatical items. Twenty-eight novel SUBs were constructed. For these unique SUB letter strings there were 14 each, of grammatical and ungrammatical complement structures. Grammaticality in both languages was based on what the grammar for that condition specified as legal sentences (Table 1)—not by what may be a grammatical/ungrammatical sentence in English. Thus, for the UNNAT language, the ungrammatical SUBs (from the viewpoint of English) were scored as grammatical and the grammatical SUBs (from the viewpoint of English) were scored as ungrammatical. Grammaticality in the NAT language corresponded to English, with grammatical SUBs scored as grammatical and ungrammatical SUBs scored as ungrammatical. Testing in both groups also included 16 novel grammatical GEN items and 16 novel ungrammatical GEN items in which one of the letters, except those in the first and last position, were changed.

Previous artificial language learning research has established that distributional “surface” information, computed over fragments consisting of two or three consecutive letters (bigrams/trigrams), may affect how well a language is learned. In order to ensure that the NAT language was not more “regular” than the UNNAT language, in terms of distributional information, and therefore potentially easier to learn, we controlled our stimuli for five different kinds of fragment information.

1) *Associative chunk strength* is measured as the sum of the frequency of occurrence in the training items of each of the fragments in a test item, weighted by the number of fragments in that item (Knowlton & Squire, 1994). E.g., the associative chunk strength of the item ZVX would be calculated as the sum of the frequencies of the fragments ZV, VX and ZVX divided by 3. Two-tailed t-tests indicated that there were no differences between the languages in associative chunk strength for the grammatical ( $t < 1$ ) and the ungrammatical ( $t < 1$ ) items.

2) *Anchor strength* is measured as the relative frequency of initial and final fragments in similar anchor positions in the training items (Knowlton & Squire, 1994). E.g., the anchor strength of the item QXMSXV is calculated as the sum of the frequencies of the fragments QX and QXM in initial positions in the training items and of the fragments XV and SXV in final positions in the training items. Again, there were no differences between the two languages in the anchor strength of the grammatical ( $t(58)=1.75, p>.085$ ) or the ungrammatical items ( $t<1$ ).

3) *Novelty* is measured as the number of fragments that did not appear in any training item (Redington & Chater, 1996). E.g., if the fragments XVS and VS from the item QXVSZM never occurred in a training item, then the test item would receive a novelty score of 2. Here there is a significant difference between the novelty scores for the grammatical test items in the NAT language (.43) and the UNNAT language (0) ( $t(58)=3.50, p<.001$ ). However, given that items with novel fragments will seem less familiar they are more likely to not to be accepted as grammatical, making it more difficult to correctly classify the test items from the NAT language. Thus this difference provides a bias against our hypothesis that the NAT language should be easier to learn. There were no differences between the ungrammatical items ( $t<1$ ).

4) *Novel fragment position* is measured as the number of fragments that occur in novel absolute positions where they did not occur in any training item (Johnstone & Shanks, 1999). E.g., if the fragment VQZ from the item QZVQZV never occurred in this absolute position in any of the training items then this item would be assigned a novel fragment position score of 1. There were no differences between the novel fragment scores for the grammatical ( $t(58)=1.54, p>.13$ ) or ungrammatical items ( $t<1$ ) across the two languages.

5) *Global similarity* is measured as the number of letters that a test item is different from the nearest training item (Vokey & Brooks, 1992). E.g., if the test item QZM has QZV as its closest training item then it would be assigned a global similarity score of 1. There were no differences between the two languages for the grammatical ( $t=0$ ) and ungrammatical ( $t<1$ ) items.

## Procedures

Subjects were randomly assigned to one of three conditions (NAT, UNNAT, and CONTROL). NAT and UNNAT were trained using the natural and unnatural languages, respectively. The CONTROL group completed only the test session. During training, individual letter strings were presented briefly on a computer. After each presentation, participants were prompted to enter the letter string using the keyboard. Training consisted of 2 blocks of the 30 items, presented randomly. During the test session, participants decided if the test items were created by the same (grammatical) or different (ungrammatical) rules as the training items. Testing consisted of 2 blocks of 60 items, again presented randomly.

Figure 2. Overall correct classification for NAT and UNNAT languages.

Figure 3. Correct classification of GEN items for NAT and UNNAT languages.

Figure 4. Correct classification of SUB items for NAT and UNNAT languages.

## Results and Discussion

**Control Group** Since the test items were the same for all groups, but scored differently depending on training condition, the control data was scored from the viewpoint of both the natural and unnatural languages. Differences between correct and incorrect classification from both language perspectives were non-significant with all  $t$ -values  $<1$  (range of correct classification: 49.5%–50.5%). Thus, there was no inherent bias in the test stimuli toward either language.

**Experimental Group** An overall t-test indicated that NAT (59%) learned the language significantly better than UNNAT (54%) (Figure 2;  $t(38)=3.27, p<.01$ ). This result indicates that the UNNAT was more difficult to learn than the NAT. Both groups were able to differentiate the grammatical and ungrammatical items (NAT:  $t(38)=4.67, p<.001$ ; UNNAT:  $t(38)=2.07, p<.05$ ). NAT correctly classified 70% of the grammatical and 51% of the ungrammatical items. UNNAT correctly classified 61% of the grammatical and 47% of the ungrammatical items. NAT (66%) exceeded UNNAT (59%) at classifying the common GEN items (Figure 3;  $t(38)=2.80, p<.01$ ). Although marginal, NAT (52%) was also better than UNNAT (50%) at classifying SUB items (Figure 4;  $t(38)=1.86, p=.071$ ). Note that the presence of the SUB items affected the learning of the GEN items. Even though both groups were tested on exactly the same GEN items, the UNNAT performed significantly worse on these items. Thus, the presence of the subjacency violations in the UNNAT language affected the learning of the *language as a whole*, not just the SUB items. From the viewpoint of language evolution, languages such as UNNAT would loose out in competition with other languages such as NAT because the latter is easier to learn.

### Connectionist Simulations

In principle, one could object that the reason why we found differences between the NAT and the UNNAT groups is because the NAT group is in some way tapping into an innately specified subjacency principle when learning the language. Another possible objection is that the NAT language follows the general pattern of English whereas the UNNAT language does not, and that our human results could potentially reflect an “English effect”. To counter these possible objections and to support our suggestion that the difference in learnability between the two languages is brought about by constraints arising from sequential learning, we present a set of connectionist simulations of our human data.

### Networks

For the simulations, we used simple recurrent networks (SRNs; Elman, 1991) because they have been successfully applied in the modeling of both non-linguistic sequential learning (e.g., Christiansen & Devlin, 1997; Cleeremans, 1993) and language processing (e.g., Christiansen, 1994; Elman, 1991). SRNs are standard feed-forward neural networks equipped with an extra layer of so-called context units. The SRNs used in our simulations had 7 input/output units (corresponding to each of the 6 letters plus an end of sentence marker) as well as 8 hidden units and 8 context units. At a particular time step  $t$ , an input pattern is propagated through the hidden unit layer to the output layer. At the next time step,  $t+1$ , the activation of the hidden unit layer at time  $t$  is copied back to the context layer and paired with the current input. This means that the current state of

Figure 5. MSE differences for grammatical (low error) and ungrammatical (high error) items for NAT and UNNAT networks.

the hidden units can influence the processing of subsequent inputs, providing an ability to deal with integrated sequences of input presented sequentially.

### Materials

For the simulations we used the same training and test items as in the artificial language learning experiment.

### Procedures

Forty networks, with different initial weight randomizations (within  $\pm .5$ ), were trained to predict the next consonant in a sequence. The networks were randomly assigned to the NAT and UNNAT training conditions, and given 20 passes through a random ordering of the 30 training items appropriate for a given condition. The learning rate was set to .1 and the momentum to .95. After training, the networks were tested separately on the 30 grammatical and 30 ungrammatical test items (again, according to their respective grammar).

Following successful training, an SRN will tend to output a probability distribution of possible next items given the previous sentential context. Performance was measured in terms of how well the networks were able to approximate the correct probability distribution given previous context. The results are reported in terms of the Mean Squared Error (MSE) between network predictions for a test set and the empirically derived, full conditional probabilities given the training set (Elman, 1991). This error measure provides an indication of how well the network has acquired the grammatical regularities underlying a particular language, and thus allows for a direct comparison with our human data.

### Results and Discussion

The results show that the NAT networks had a significantly lower MSE (.185; SD: .021) than the UNNAT networks (.206; SD: .023) on the grammatical items ( $t(38)=2.85, p<.01$ ). On the ungrammatical items, the NAT nets had a slightly higher error (.258; SD: .036) compared with the UNNAT nets (.246; SD: .034), but this difference was not significant ( $t<1$ ). This pattern resembles the performance of the human subjects where the NAT group was 11% better

than the UNNAT group at classifying the grammatical items, though this difference only approached significance ( $t(38)=1.10, p=.279$ ). The difference was only <3% in favor of the NAT group for the ungrammatical items ( $t=1$ ). Also similarly to the human subjects, there was a significant difference between the MSE on the grammatical and the ungrammatical items for both the NAT nets ( $t(38)=7.69, p<.001$ ) and the UNNAT nets ( $t(38)=4.33, p<.001$ ). It is plausible to assume that the greater the difference between the MSE on the grammatical (low error) and the ungrammatical (higher error) items, the easier it should be to distinguish between the two types of items. As illustrated in Figure 5, the NAT networks have a significantly better basis for making such distinctions than the UNNAT networks (.072 vs. .040;  $t(38)=4.31, p<.001$ ). Thus, the simulation results closely mimic the behavioral results, even though the SRNs clearly do not have a built-in subadjacency principle nor do they have prior knowledge of English. The results therefore corroborate our suggestion that constraints on the learning and processing of sequential structure can explain why subadjacency violations tend to be avoided: they were weeded out because they made the sequential structure of language too difficult to learn.

### Conclusion

In this paper, we have provided evidence in favor of an alternative account of the universal constraints on complex question formation. The artificial language learning results show that not only are constructions involving subadjacency violations hard to learn in and by themselves, but their presence also makes the language as a whole harder to learn. The connectionist simulations further corroborated these results, emphasizing that the observed learning difficulties in relation to the unnatural language arise from non-linguistic constraints on sequential learning. These results, together with the results on word order universals (Christiansen, 2000; Christiansen & Devlin, 1997), suggest that constraints arising from general cognitive processes, such as sequential learning and processing, are likely to play a larger role in sentence processing than has traditionally been assumed. This means that what we observe today as linguistic universals may be stable states that have emerged through an extended process of linguistic evolution. When language itself is viewed as a dynamic system sensitive to adaptive pressures, natural selection will favor combinations of linguistic constructions that can be acquired relatively easily given existing learning and processing mechanisms. Consequently, difficult to learn language fragments, such as our unnatural language, will tend to disappear. Furthermore, if we assume that the production system is based conservatively on a processing system acquired in the service of comprehension, then this system would be unlikely to produce subadjacency violations because they would not be represented there in the first place. In conclusion, rather than having an innate UG principle to rule out subadjacency violations, we suggest they

may have been eliminated altogether through an evolutionary process of linguistic adaptation constrained by prior cognitive limitations on sequential learning and processing.

### Acknowledgments

We would like to thank Takashi Furuhashi, Lori Smorzynski, and Brad Appelhans for their help with data collection.

# Reflective Introspective Reasoning Through CBR

Susan Eileen Fox  
fox@macalester.edu  
Macalester College  
1600 Grand Avenue  
Saint Paul, MN 55105 USA

## Abstract

In recent years, “introspective reasoning” systems have been developed to model the ability to reason about one’s own reasoning performance. This research examines “reflective” introspective reasoning: introspecting about the introspective reasoning process, itself. We introduce a reflective introspective reasoning system that uses case-based reasoning (CBR) as its central reasoning method. We examine the advantages of such a system, and attempt to classify the reasoning failures within introspective system that indicate a need to reflect higher.

## Introduction

In artificial intelligence, meta-reasoning systems have been used for a variety of purposes: to predict the behavior of other agents, to guide the acquisition and application of domain knowledge, and to “learn” by adjusting the system’s own reasoning processes in response to experience. Meta-reasoning systems model the ability humans have to reason about our own and others’ reasoning performance. Systems that apply meta-knowledge and meta-reasoning to improvement of their own reasoning processes are called “introspective learning” systems.

The ability to reason introspectively requires knowledge of one’s own reasoning methods, and observation, evaluation, and alteration of those methods when needed. A similar ability has been documented in studies of human reasoning behavior, and modeled with a variety of artificial intelligence techniques. Introspective reasoning systems often lack a critical component of human meta-reasoning: the ability to introspect about our introspections themselves. Introspective reasoning is often applied only to reasoning in service of some underlying task, such as navigation planning. An introspective reasoner that can apply its reasoning to its own introspective processes and repeat this reflection upon itself indefinitely is called “reflective” (Ibrahim, 1992).

We have developed a reflective introspective reasoner that learns by altering its reasoning methods at all levels. RILS<sup>1</sup> analyzes both its task-level planning process and its introspective reasoning process, using a unified reasoning method, case-based reasoning (CBR), for all its tasks. Re-using CBR simplifies the introspective model of the system’s reasoning processes and facilitates reflection.

A key issue for a reflective reasoner is deciding when to reflect. RILS uses failure-driven learning; reflective introspection occurs when an impasse is reached.

In the next section, we provide some background on “reflection,” introspective learning in humans, and other introspective reasoning systems. We then describe the RILS approach to reflective introspection, and we classify the kinds of reasoning failures RILS uses to trigger reflective introspective reasoning.

## Background

### Reflection

The term reflection, as it is used in this paper, refers to systems which can shift the focus of their processing from the current task to the problem-solving task itself, and can repeat this shift of processing indefinitely (Ibrahim, 1992). As a system shifts to a higher-level task, it constructs a “reflective tower” of reasoning processes. Each process analyzes and alters the one beneath it, which is suspended until the higher-level process completes its task.

While not a requirement, Reflection is easiest to achieve if the same reasoning method is used at all reasoning levels. In order to introspect, the system must have a model of its own reasoning processes. The model becomes more complex as the number of different reasoning methods grows. Simplicity in the model enables the system to meaningfully alter more features of its processing, leading to greater flexibility.

The strength of a reflective system is its flexibility: every aspect of the system is open to adaptation and improvement, as the system responds and learns from its experiences. The drawback to a reflective system is the potential of the system to reflect infinitely without making forward progress at any level. The system, when in doubt, must choose not to reflect and continue processing. Many reflective systems only shift attention to a higher level when an explicit failure, particularly a catastrophic failure occurs.

### Human Introspective Reasoning Behavior

Several studies have found evidence that humans engage in introspective learning behavior: altering their reasoning strategies as their experience grows.

Chi & Glaser (1980) found differences between the reasoning strategies of experts and novices: experts approach problems in a more playful way, spend more time

---

<sup>1</sup>Reflective Introspective Learning System

analyzing of a problem before attempting to solve it, and understand better the important features of a problem. They suggest these strategies are learned as part of the process of becoming an expert.

Flavell, Friedrichs, & Hoyt (1970) found that older children were better than younger children at monitoring how well they had performed a given task and judging when they had completed it. The development demonstrated here indicates an awareness of one’s own reasoning processes, as well as learning from that awareness to perform better. Kreutzer, Leonard, & Flavell (1975) found that children improved their understanding of their own memory processes as they became older: asked to describe strategies for remembering things, older children tended to describe many strategies and their outcomes, younger children very few.

Kruger & Dunning (1999) found that competence at a task was related to the ability to accurately judge one’s own competence. This suggests that introspective skills are integrally intertwined with particular domain skills.

In all these cases humans show an improved performance on a domain task when they also show evidence of playful, introspective learning behaviors.

### Introspective Reasoning Systems

A variety of approaches to introspective reasoning systems exist. A few have examined reflective introspection.

SOAR is a rule-based system which does deliberately address reflection (Rosenbloom, Laird, & Newell, 1993). SOAR’s rule base may contain rules which control the rule selection process, among others. SOAR can learn new behaviors by creating new meta-rules. Its meta-rules cannot affect all portions of its reasoning process.

The Massive Memory Architecture performs both introspective reasoning and case-based reasoning in a task-driven manner (Arcos & Plaza, 1993). Autognostic uses a “Structure-Behavior-Function” model to represent reasoning processes (Stroulia & Goel, 1995). RAPTER uses model-based reasoning: an explicit model of “assertions” describing the ideal reasoning behavior is used to diagnose failures (Freed & Collins, 1994). These systems do not include reflective capabilities.

Meta-AQUA maintains reasoning trace templates (Meta-XPs) which describe the patterns of reasoning that indicate reasoning failures (Cox, 1996). Meta-AQUA’s Meta-XPs could be applied to the introspective process itself, but reflection is not the focus of the project.

IULIAN integrates introspective learning with the overall domain task in a way that permits reflection (Oehlmann, Edwards, & Sleeman, 1994). IULIAN uses case-based planning to generate both domain introspective plans, but, as in SOAR, its introspective plans have incomplete access to the mechanisms which use them.

The ROBBIE system (Fox & Leake, 1995), the precursor to RILS, is related to the model-based reasoning systems described above. It contains an explicit collection of assertions which describe the ideal reasoning process of its case-based planner. ROBBIE’s uses its model to perform detection, diagnosis, and repair of reason-

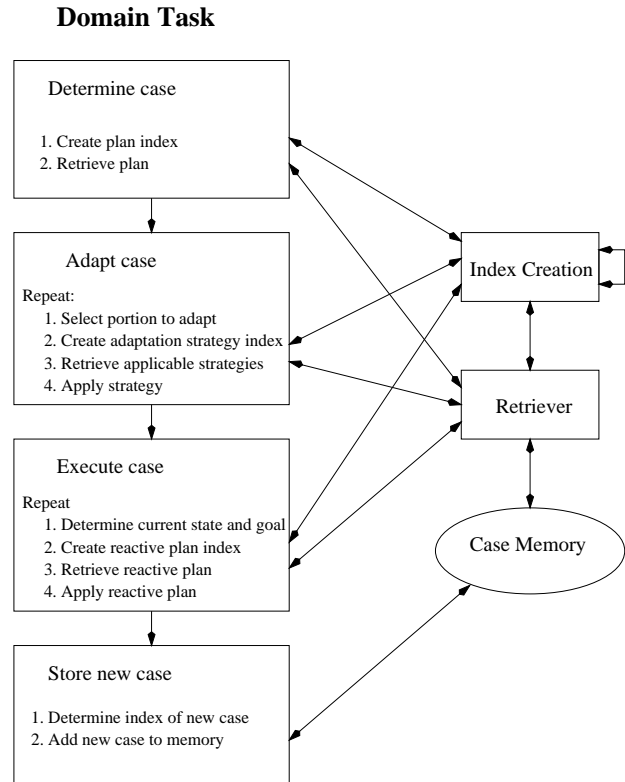

Figure 1: The domain task architecture of RILS: reuse of CBR

ing failures. It is not reflective; its introspective model describes only its underlying planning system. ROBBIE does reuse its CBR processes for multiple planning tasks. RILS was developed from ROBBIE as a *case-based* introspective learner that retains an explicit model of its reasoning embodied in a set of introspective cases.

### The Reflective Introspective Learning System

RILS performs route planning for a simulated robot, supported by case-based and introspective learning. Case-based reasoning is the central reasoning method for all RILS tasks. The case memory stores cases for creating and executing route plans, and also stores “assertion cases” that, taken together, comprise its introspective model. The model captures the reasoning processes of both planning and introspective tasks.

#### RILS’ Domain Task

RILS operates in the same domain as the ROBBIE system (Fox & Leake, 1995); it navigates a simulated robot through a domain of streets, using case-based planning to create high-level plans and case-based reactive planning to interactively execute the plans in its simulated domain. Figure 2 shows a sample of RILS’ domain.

RILS reuses its case-based index creation, retrieval, and case memory for multiple domain tasks: creation of an index, selection of a high-level plan, adaptation of the plan, and selection of reactive planlets to execute

Figure 2: A sample of RILS' domain

its goals. Learning occurs at the domain level through the storage of new high-level plans once they have been successfully executed, and through the addition of index creation rules which are learned through introspective reasoning. The introspective reasoner recognizes and repairs those times when the plan case retrieval retrieves a suboptimal match to a given situation.

The following example demonstrates how RILS' operates at the domain level, and how introspective learning occurs to the domain reasoning. Suppose that RILS has as a new goal to move from the corner of Maple and Elm Streets to the corner of Cherry and Maple Streets. It has in its case memory two potential matches to this problem: a plan from the corner of Maple and Elm to the corner of Birch and Oak, and a plan from the corner of Apple and Elm to the corner of Apple and Oak. Without any learned indexing rules, RILS prefers the first plan to the second one, because it shares the same starting location as its current problem. RILS adapts the selected plan and successfully executes it to arrive at its goal.

The process of executing the plan also streamlines it, so that the plan RILS stores back into its case memory involves merely turning east and moving along Maple to Cherry Street. The storage of new plan cases is the most basic level of learning in RILS.

The introspective reasoning system monitors the domain-level reasoning process, and detects a reasoning failure: the plan being stored into memory is more similar to an unretrieved case (from Apple and Elm to Apple and Oak) than to the retrieved one. This triggers introspective reasoning to diagnose and repair the domain level reasoning. The ultimate repair is to add an indexing rule to detect and prefer case matches where the general direction of movement is the same (i.e., "move straight east"). We discuss the introspective task in more detail in the next section.

Figure 3: The introspective task architecture of RILS: monitoring applies only to domain-level reasoning; diagnosis and repair apply to both domain and introspective modules.

### RILS' Introspective Task

The goal of the introspective reasoning system is to detect reasoning failures in all portions of the system itself and, where possible, to correct the system's processing to avoid repeating the reasoning failure in the future. A "reasoning failure" is any situation which is not predicted by the system itself, whether it is a failure or a success in terms of the domain task. For example, an unanticipated opportunity to achieve a goal is as much of a reasoning failure as a failure to achieve a goal.

In order to reason about its own reasoning, RILS has a model of its ideal reasoning behavior. Figure 1, which shows RILS' domain reasoning, also represents abstractly one portion of the introspective model. Figure 3 shows RILS' introspective reasoning, represents the rest of its introspective model, as well. For each component of the reasoning process, RILS has a collection of "assertions" at multiple levels of abstraction which describe in detail RILS' expectations about its own performance.

RILS actively monitors each step in the domain reasoning to verify that the actual behavior corresponds to its model. When an assertion fails to be true of the system's actual behavior, RILS suspends the lower-level reasoning task and takes over, attempting to diagnose and repair the detected failure. The diagnosis module searches through its model, examining those assertions which are causally related to the detected failure, until it finds a related assertion which has a repair recommended for it. Once a repair is performed, control returns to the planning process.

While RILS may actively monitor its underlying reasoning task, it cannot actively monitor its introspective reasoning process. To do so would lead immediately to an infinite reflective tower: RILS would monitor<sub>1</sub> its

monitoring, then have to monitor<sub>2</sub> the monitoring<sub>1</sub>, and so forth. Instead, RILS waits for “impasses” in its introspective process: places where the reasoning process cannot continue, including unexpected catastrophic failures at the domain task level. If RILS discovers explicit evidence that the introspective reasoning process itself is flawed, it suspends the introspective process and reflectively applies its diagnosis and repair processes to the introspective task. These impasses are detailed in the next section.

It seems intuitive that RILS should actively monitor its domain-level reasoning and passively monitor its introspective reasoning. Route planning and execution interact with a highly complex, poorly understood world, where reasoning failures are common. RILS’ understanding of the state of the world at any time is limited. On the other hand, the introspective reasoner has a much more restricted domain: the reasoning of the system itself, and must be assumed to be more reliable.

Each component of RILS’ introspective reasoning is implemented using the same case memory and case retrieval mechanisms as are used in the planning task. The introspective model, rather than being a monolithic collection of assertions, is represented by “assertion” cases stored separately in the case memory. When monitoring the planner’s reasoning, RILS constructs an index representing the current point in the reasoning process, and uses it to retrieve those assertion cases which are applicable to that point. When diagnosing a reasoning failure, RILS retrieves cases based on causal links which are stored in each assertion case. RILS’ repair module retrieves and applies repair plans from the case memory.

Assertion cases must contain sufficient information to retrieve them when needed. Consider the sample assertion case show in figure 4: the assertion case says that the diagnosis module will only consider assertions causally relevant to the current problem. Each assertion case contains an assertion (and information to help apply it), links to other causally-related assertions, applicable repair strategies, and statistics on the assertion’s use and success. Assertion cases are retrieved to support monitoring and diagnosis of reasoning failures. As part of the ROBBIE process, a general vocabulary was developed which describes a wide range of assertions about reasoning processes: the generality of this vocabulary is demonstrated by the ease with which the introspective model was transformed to include a reflective component.

We illustrate the reflective aspect of RILS with the following example, extending the example in the previous section. Suppose that RILS experiences the reasoning failure described above: it selects an inappropriate case, diagnoses the failure, and learns a new indexing rule to avoid the faulty selection in the future. All this requires introspection only about the planner. RILS performs reflective introspection when the introspective reasoner itself is faulty. In this case, suppose that the repair module incorrectly instantiated the new indexing rule, so that it will not be retrieved when it is applicable. Some time in the future, RILS plans a route from the corner of

Figure 4: An assertion case for the diagnosis component: “Every assertion retrieved during diagnosis will have a link to one already under consideration”

Birch and Elm Streets to the corner of Birch and Oak. It should apply the new indexing rule, but fails to find it. It therefore retrieves an inappropriate case in exactly the same manner as described above. When the domain-level reasoning failure is discovered and diagnosed, RILS notices that this is exactly the same error as it supposedly corrected earlier. This is the evidence RILS needs in order to invoke reflective introspection. It will suspend the introspective task, and apply the diagnosis and repair modules to the introspective task itself.

Diagnosing and repairing this type of introspective reasoning failure is difficult, because of the long time lag between the actual failure and its detection. RILS keeps a history of its past reasoning decisions in order to be able to diagnose an unbounded distance into its past reasoning. At present this history is used to attempt a diagnosis on introspective reasoning failures: repairing such failures is still work in progress. In the next section we classify the kinds of impasse situations and reasoning failures RILS uses to determine opportunities for reflective introspection.

### Reflective reasoning failures in RILS

RILS responds reflectively only to explicit failures which indicate a flaw in the introspective reasoner. Because each module reuses CBR for its reasoning, the sorts of failures RILS must look for are similar for each module. The underlying cause of each failure type differs depending on the module in question: we will examine each module in turn below. The basic categories of failures are:

1. Case memory lacks a required case;
2. RILS fails to retrieve a relevant case;
3. RILS retrieves an irrelevant case; and
4. RILS improperly applies a retrieved case.

Currently, RILS detects these reasoning failures and attempts to reflectively introspect about them. It does not yet repair its introspective process, though work on that aspect is underway.

## The Monitoring Module

The monitoring process examines only the route planner. It retrieves those assertions which are currently relevant and checks that no assertion is violated.

If an assertion case is missing from the case memory, that implies that the introspective model is incomplete, and hence inaccurate. This is a troubling failure, because RILS alters its reasoning processes based on the assumption that its introspective model captures the ideal behavior of the system. If a case is missing, then it is possible that RILS would alter itself incorrectly. This is not a failure type that we anticipate RILS handling in any deep manner: It might be able to conjecture that a case is missing and then let a human user/programmer assist in correcting the situation.

Failing to retrieve a relevant case is an easier problem to detect, though detection may be delayed some period from the occurrence of the failure. A failure to retrieve reflects some flaw in the index of the assertion case, or a flawing the index creation and retrieval mechanism. RILS can examine its case memory for cases that are referred to by other assertion cases in memory but that have not been retrieved along with them. RILS keeps statistics on the application of assertion cases to help with this analysis. Correcting this failure requires the alteration of the indexing and retrieval methods for assertion cases; we expect RILS to incorporate this repair in the future.

Because the monitoring module knows the context of the planner at a given moment, recognizing an irrelevant assertion case is easy to detect on the spot: one case in which reflection can occur at the moment of the reasoning failure. As before, this indicates either a flaw in the index of the particular case retrieved, which is easy to check and correct, or a flaw in how the system creates indices and retrieves assertion cases. RILS can alter the indexing rules for plan cases; we should be able to extend this to altering the indexing of assertion cases as well.

A misapplication of a retrieved case could be detected if the lack of it leads to an unexpected catastrophic failure of some sort. RILS examines catastrophic failures at the route planning level to determine if the monitoring process failed to detect a problem before the catastrophic failure occurred, and considers the possibility that an assertion was misapplied.

## The Diagnosis Module

The diagnosis module retrieves assertion cases and evaluates them in much the same way as the monitoring module. Therefore, many of the comments made about monitoring also apply to diagnosis. The main difference is in how the diagnosis module chooses which cases to retrieve: it starts with an assertion case which is known to be a failure, and then performs a heuristic-guided breadth-first search through those assertions which are causally related to the detected failure. It uses the causal links each assertion contains.

For reflective diagnosis, it may be initially unclear which assertion has failed, RILS creates a set of potential failed assertions and searches in parallel starting from

each possibility.

A missing assertion case is just as much of a problem for diagnosis as for monitoring. RILS could distinguish between diagnosis and monitoring by which module was most recently in use, but would have just as much difficulty recognizing the lack and determining a repair.

Failing to retrieve a relevant case for the diagnosis module could be due to two different failures. Like the monitoring module, diagnosis could miss a case due to indexing problems. Because diagnosis is performing highly targeted retrievals, however, this is a problem likely to be discovered as it happens. Alternatively, if assertion A should contain a link to a causally related assertion B, but lacks that link, then B could be overlooked. This problem must be detected by examining the cases in memory and their usage statistics. Retrieving an irrelevant case is, again, easy to detect.

Circumstances that indicate a problem with the diagnosis module include times when the diagnosis process fails to find any applicable repair. Alternatively, the diagnosis module may attempt to evaluate an assertion whose value depends on one that was overlooked or misapplied, and may be unable to complete its evaluation.

## The Repair Module

The repair component retrieves and uses repair cases which describe how to change the system to correct a diagnosed reasoning failure.

A missing repair case is, as for assertion cases, difficult to detect, unless a repair is referred to in an assertion case and does not exist in the case memory.

Failing to retrieve a relevant repair or retrieving an irrelevant one may be detected immediately, as the repair module performs very targeted case retrieval. It would be repaired, as above, by either altering the indexing of the repair case, or altering the index and retrieval methods of the system.

Misapplying a repair strategy is a difficult failure to detect. A repair could be executed, and might not correct the experienced failure. As in the example in the previous section, RILS may detect this type of failure if it faces a similar situation again and generates an identical repair.

## Conclusions

RILS demonstrates the power of case-based reasoning to serve as the central reasoning method of a system performing a wide range of reasoning tasks. By having one approach to reasoning, RILS has a fairly simple, powerful model of its reasoning processes. It uses that model to introspect about its reasoning process: learning from failures of its domain-level reasoning, detecting opportunities to reflectively introspect and, eventually, learn by improving its introspective reasoning processes.

A system that combines task reasoning with a reflective introspection capability should be able to respond with flexibility to a complex environment, by re-tooling its knowledge and processes at all levels of abstraction. This seems to be a talent which humans possess, as we

improve our reasoning strategies with experience. RILS provides one possible abstract model of this process.

Reflection permits a system to adapt itself to its surroundings, but poses a hazard if left unchecked. We have demonstrated here a “failure-driven” approach to controlling reflection: only when clear evidence exists that the introspective reasoning is flawed will RILS choose to reflect. Our future work on RILS will complete the reflective skills it has by giving it the tools to repair, not just diagnose, its introspective reasoning processes,

## Abstract

It is time to view John Searle’s Chinese Room thought experiment in a new light. The main focus of attention has always been on showing what is wrong (or right) with the argument, with the tacit assumption being that somehow there could be such a Room. In this article I argue that the debate should not focus on the question “If a person in the Room answered all the questions in perfect Chinese, while not understanding a word of Chinese, what would the implications of this be for strong AI?” Rather, the question should be, “Does the very idea of such a Room and a person in the Room who is able to answer questions in perfect Chinese while not understanding any Chinese make any sense at all?” And I believe that the answer, in parallel with recent arguments that claim that it would be impossible for a machine to pass the Turing Test unless it had experienced the world as we humans have, is no.

## Introduction

Alan Turing’s (1950) classic article on the Imitation Game provided an elegant operational definition of intelligence. His article is now exactly fifty years old and ranks, without question, as one of the most important scientific/philosophical papers of the twentieth century. The essence of the test proposed by Turing was that the ability to perfectly simulate unrestricted human conversation would constitute a sufficient criterion for intelligence. This way of defining intelligence, for better or for worse, was largely adopted as of the mid-1950’s, implicitly if not explicitly, as the overarching goal of the nascent field of artificial intelligence (AI).

Thirty years after Turing’s article appeared, John Searle (1980) put a new spin on Turing’s original arguments. He developed a thought experiment, now called “The Chinese Room,” which was a reformulation of Turing’s original test and, in so doing, produced what is arguably the second most widely read and hotly discussed paper in artificial intelligence. While Turing was optimistic about the possibility of creating intelligent programs in the foreseeable future, Searle concluded his article on precisely the opposite note: “...no [computer] program, by itself, is sufficient for intentionality.” In short, Searle purported to have shown that real (human-like) intelligence was impossible for any program implemented on a computer. In the present article I will begin by briefly presenting Searle’s well-known transformation of the

Turing’s Test. Unlike other critics of the Chinese Room argument, however, I will not take issue with Searle’s argument per se. Rather, I will focus on the argument’s central premise and will argue that the correct approach to the whole argument is simply to refuse to go beyond this premise, for it is, as I hope to show, untenable.

## The Chinese Room

Instead of Turing’s Imitation Game in which a computer in one room and a person in a separate room both attempt to convince an interrogator that they are human, Searle asks us to begin by imagining a closed room in which there is an English-speaker who knows no Chinese whatsoever. This room is full of symbolic rules specifying inputs and outputs, but, importantly, there are no translations in English to indicate to the person in the room the meaning of any Chinese symbol or string of symbols. A native Chinese person outside the room writes questions — *any questions* — in Chinese on a piece of paper and sends them into the room. The English-speaker receives each question inside the Room then matches the symbols in the question with symbols in the rule-base. (This does not have to be a direct table matching of the string of symbols in the question with symbols in the rule base, but can include any type of look-up program, regardless of its structural complexity.) The English-speaker is blindly led through the maze of rules to a string of symbols that constitutes an answer to the question. He copies this answer on a piece of paper and sends it out of the room. The Chinese person on the outside of the room would see a perfect response, even though the English-speaker understood no Chinese whatsoever. The Chinese person would therefore be fooled into believing that the person inside the room understood perfect Chinese.

Searle then compares the person in the room to a computer program and the symbolic rules that fill the room to the knowledge databases used by the computer program. In Searle’s thought experiment the person who is answering the questions in perfect written Chinese still has no knowledge of Chinese. Searle then applies the conclusion of his thought experiment to the general question of machine intelligence. He concludes that a computer program, however perfectly it managed to communicate in writing, thereby fooling all human questioners, would still not understand what it was writing, any more than the person in the Chinese Room

understood any Chinese. Ergo, computer programs capable of true understanding are impossible.

### Searle's Central Premise

But this reasoning is based on a central premise that needs close scrutiny.

Let us begin with a simple example. If someone began a line of reasoning thus: "Just for the sake of argument, let's assume that cows are as big as the moon," you would most likely reply, "Stop right there, I'm not interested in hearing the rest of your argument because cows are demonstrably NOT as big as the moon." You would be justified in not allowing the person to continue to his conclusions because, as logical as any of his subsequent reasoning might be, any conclusion arising from his absurd premise would be unjustified.

But when are we justified in accepting demonstrably false premises for the sake of argument? If a discussion began by supposing that the work week was 30 hours long, instead of 40, it would be ridiculous to reply, "But the work week is demonstrably NOT 30 hours long, therefore I am not interested in hearing the rest of your argument." On the other hand, if a discussion began by assuming that Lee Harvey Oswald was an ice-cream cone — however *logically* possible this might be — one would certainly be justified in evoking the I-don't-want-to-hear-anymore response. Space prevents us from attempting to delineate these two types of counterfactual premises, but suffice it to say that the mere logical possibility of a premise is not necessarily enough for it to serve as the basis of an argument in which we hope to derive truths about the real world, especially if we can demonstrate the nomological impossibility of the premise. Dennett (1996) makes a similar point regarding Davidson's (1986) Swampman argument.

In this light, let us consider the central premise on which Searle's argument hangs — namely, that there could be such a thing as a "Chinese Room" in which an English-only person *could actually fool* a native-Chinese questioner. I hope to show that this premise is no more plausible than the existence of lunar-sized cows and, as a result, we have no business allowing ourselves to be drawn into the rest of Searle's argument, any more than when we were asked to accept that all cows were the size of the moon.

Ironically, the arguments in the present paper *support* Searle's point that symbolic AI is not sufficient to produce human-like intelligence, but do so not by comparing the person in the Chinese Room to a computer program, but rather by showing that the Chinese Room itself would be an impossibility for a symbol-based AI paradigm.

## Subcognitive Questioning and the Turing Test

To understand why such a Room would be impossible, which would mean that the person in the Room could never fool the outside-the-Room questioner, we must look at an argument concerning the Turing Test first put forward by French (1988, 1990, 2000a). French's claim is that no machine that had not experienced life as we humans had could ever hope to pass the Turing Test. His demonstration involves showing just how hard it would be for a computer to consistently reply in a human-like manner to what he called "subcognitive" questions. Since Searle's Chinese Room argument is simply a reformulation of the Turing Test, we would expect to be able to apply these arguments to the Chinese Room as well, something which we will do this later in this paper.

It is important to spend a moment reviewing the nature and the power of "subcognitive" questions. These are questions that are explicitly designed to provide a window on low-level (i.e., unconscious) cognitive or physical structure. By "low-level cognitive structure", we mean the subconscious associative network in human minds that consists of highly overlapping activatable representations of experience (French, 1990). Creating these questions and, especially, gathering the answers to them require a bit of preparation on the part of the Interrogator who will be administering the Turing Test.

The Interrogator in the Turing Test (or the Questioner in the Chinese Room) begins by preparing a long list of these questions — the Subcognitive Question List. To get answers to these questions, she ventures out into an English-language population and selects a representative sample of individuals from that population. She asks each person surveyed all the questions on her Subcognitive Question List and records their answers. The questions along with the statistical range of answers to these questions will be the basis for her Human Subcognitive Profile. Here are some of the questions on her list (French, 1988, 1990).

### Questions using neologisms:

"On a scale of 0 (completely implausible) to 10 (completely plausible):

- Rate *Flugblogs* as a name Kellogg's would give to a new breakfast cereal.
- Rate *Flugblogs* as the name of start-up computer company
- Rate *Flugblogs* as the name of big, air-filled bags worn on the feet and used to walk across swamps.
- Rate *Flugly* as the name a child might give to a favorite teddy bear.
- Rate *Flugly* as the surname of a bank accountant in a W. C. Fields movie.

- Rate *Flugly* as the surname of a glamorous female movie star.

“Would you like it if someone called you a *trubhead*? (0= not at all, ..., 10 = very much)”

“Which word do you find prettier: *blutch* or *farfaletta*?”

Note that the words *flugbogs*, *flugly*, *trubhead*, *blutch* and *farfaletta* are made-up. They will not be found in any dictionary and, yet, because of the uncountable influences, experiences and associations of a lifetime of hearing and using English, we are able to make judgments about these neologisms. And, most importantly, while these judgments may vary between individuals, their variation is not random. For example, the average rating of *Flugly* as the surname of a glamorous actress will most certainly fall below the average rating of *Flugly* as the name for a child’s teddy bear. Why? Because English speakers, all of us, have grown up surrounded by roughly the same sea of sounds and associations that have gradually formed our impressions of the prettiness (or ugliness) of particular words or sounds. And while not all of these associations are identical, of course, they are similar enough to be able to make predictions about how, on average, English-speaking people will react to certain words and sounds. This is precisely why Hollywood movie moguls gave the name “Cary Grant” to a suave and handsome actor born “Archibald Alexander Leach” and why “Henry Deutchendorf, Jr.” was re-baptised “John Denver.”

Questions using categories:

- Rate *banana splits* as *medicine*.
- Rate *purses* as *weapons*.
- Rate *pens* as *weapons*.
- Rate *dry leaves* as *hiding places*.

No dictionary definition of “dry leaves” will include in its definition “hiding place,” and, yet, everyone who was ever a child where trees shed their leaves in the fall knows that that piles of dry leaves make wonderful hiding places. But how could this information, and an infinite amount of information just like it that is based on our having experienced the world in a particular way, ever be explicitly programmed into a computer?

Questions relying on human physical sensations:

- Does holding a gulp of Coca-Cola in your mouth feel more like having pins-and-needles in your foot or having cold water poured on your head?
- Put your palms together, fingers outstretched and pressed together. Fold down your two middle fingers till the middle knuckles touch. Move the other four pairs of fingers (i.e., your two index

fingers, your two thumbs, etc.). What happens to your other fingers? (Try it!)

We can imagine many more questions that would be designed to test not only for subcognitive associations, but for internal physical structure. These would include questions whose answers would arise, for example, from the spacing of a human’s eyes, would be the results of little self-experiments involving tactile sensations on their bodies or sensations after running in place, and so on.

People’s answers to subcognitive questions are the product of a lifetime of experiencing the world with our human bodies, our human behaviors (whether culturally or genetically engendered), our human desires and needs, etc. (See Harnad (1989) for a discussion of the closely related *symbol grounding problem*.)

I have asked people the question about Coca-Cola and pins-and-needles many times and they overwhelmingly respond that holding a soft-drink in their mouth feels more like having pins and needles in their foot than having cold water poured on them. Answering this question is dead easy for people who have a head and mouth, have drunk soft-drinks, have had cold water poured on their head, and have feet that occasionally fall asleep. But think of what it would take for a machine that had none of these to answer this question. How could the answer to this question be explicitly programmed into the machine? Perhaps (after reading this article) a programmer could put the question explicitly into a vast CYC-like computer database (Lenat & Guha, 1990), but there are infinitely many questions of this sort and to program them all in would be impossible. A program that could answer questions like these in a human-like enough manner to pass a Turing Test would have had to have experienced the world in a way that was very similar to the way in which we had experienced the world. This would mean, among many other things, that it would have to have a body very much like ours with hands like ours, with eyes where we had eyes, etc. For example, if an otherwise perfectly intelligent robot had its eyes on its knees, this would result in detectably non-human associations for such activities as, say, praying in church, falling when riding a bicycle, playing soccer, or wearing pants.

The moral of the story is that it doesn’t matter if we humans are confronted with made-up words or conceptual juxtapositions that never normally occur (e.g., *dry leaves* and *hiding place*), we can still respond and, moreover, our responses will show statistical regularities over the population. Thus, by surveying the population at large with an extensive set of these questions, we draw up a Human Subcognitive Profile for the population. It is precisely this subcognitive profile that could not be reproduced by a machine that had not experienced the world as the members of the sampled human population had. The Subcognitive Question List that was used to produce the Human

Subcognitive Profile gives the well-prepared Interrogator a sure-fire tool for eliminating machines from a Turing test in which humans are also participating. The Interrogator would come to the Turing Test and ask both candidates the questions on her Subcognitive Question List. The candidate most closely matching the average answer profile from the human population will be the human.

### The English Room

Now let us see how this technique can be gainfully applied to Searle's Chinese Room thought experiment. We will start by modifying Searle's original *Gedankenexperiment* by switching the languages around. This, of course, has no real bearing on the argument itself, but it will make our argument easier to follow. We will assume that inside the Room there is a Chinese person (let's call him Wu) who understands not a word of written English and outside the Room is a native speaker/writer of English (Sue). Sue sends into the Room questions written in English and Wu must produce the answers to these questions in English. Now, it turns out that Sue is not your average naive questioner, but has read many articles on the Turing Test, knows about subcognitive questions and is thoroughly familiar with John Searle's argument. She also suspects that the person inside the (English) Room might not actually be able to read English and she sets out to prove her hunch.

Sue will not only send into the Room questions like, "What is the capital of Cambodia?", "Who painted *The Mona Lisa*?" or "Can fleas fly?" but will also ask a large number of "subcognitive questions." Because the Room, like the computer in the Turing Test, had not experienced the world as we had and because it would be impossible to explicitly write down all of the rules necessary to answer subcognitive questions in general, the answers to the full range of subcognitive questions could not be contained in the lists of symbolic rules in the Room. Consequently, the person in the Room would be revealed not to speak English for exactly the same reason that the machine in the Turing Test would be revealed not to be a person.

Take the simple example of non-existent words like *blutch* or *trubhead*. These words are neologisms and would certainly be nowhere to be found in the symbolic rules in the English Room. Somehow, the Room would have to contain, in some symbolic form, information not only about all words, but also non-words as well. But the Room, if it is to be compared with a real computer, cannot be infinitely large, nor can we assume infinite fast search of the rule base (see Hofstadter & Dennett, 1981, for a discussion of this point). So, we have two closely related problems: First, and most crucially, *how* could the rules have gotten into the Room in the first place (a point that Searle simply ignores)? And secondly, the number of explicit

symbolic rules would require essentially an infinite amount of space. And while rooms in thought experiments can perhaps be infinitely large, the computers that they are compared to cannot be.

In other words, the moral of the story here, as it was for the machine trying to pass the Turing Test, is that no matter how many symbolic rules were in the English Room they would not be sufficient for someone who did not understand written English to fool a determined English questioner. And this is where the story should rightfully end. Searle has no business taking his argument any further — and, ironically, *he doesn't need to*, since the necessary inadequacy of an such a Room, regardless of how many symbolic rules it contains, proves his point about the impossibility of achieving artificial intelligence in a traditional symbol-based framework. So, when Searle asks us to accept that the English-only human in his Chinese Room could reply in perfect written Chinese to questions written in Chinese, we must say, "That's strictly impossible, so stop right there."

### Shift in Perception of the Turing Test

Let us once again return to the Turing Test to better understand the present argument.

It is easy to forget just how high the optimism once ran for the rapid achievement of artificial intelligence. In 1958 when computers were still in their infancy and even high-level programming languages had only just been invented, Simon and Newell, two of the founders of the field of artificial intelligence, wrote, "...there are now in the world machines that think, that learn and that create. Moreover, their ability to do these things is going to increase rapidly until — in a visible future — the range of problems they can handle will be coextensive with the range to which the human mind has been applied." (Simon & Newell, 1958). Marvin Minsky, then head of the MIT AI Laboratory, wrote in 1967, "Within a generation the problem of creating 'artificial intelligence' will be substantially solved" (Minsky, 1967).

During this period of initial optimism, the vast majority of the authors writing about the Turing Test tacitly accepted Turing's premise that a machine might actually be able to be built that could pass the Test in the foreseeable future. The debate in the early days of AI, therefore, centered almost exclusively around the validity of Turing's operational definition of intelligence — namely, did passing the Turing Test constitute a sufficient condition for intelligence or did it not? But researchers' views on the possibility of achieving artificial intelligence shifted radically between the mid-1960's and the early 1980's. By 1982, for example, Minsky's position regarding achieving artificial intelligence had undergone a radical shift from one of unbounded optimism 15 years earlier to a far more sober assessment of the situation: "The AI

problem is one of the hardest ever undertaken by science” (Kolata, 1982). The perception of the Turing Test underwent a parallel shift. At least in part because of the great difficulties being experienced by AI, there was a growing realization of just how hard it would be for a machine to ever pass the Turing Test. Thus, instead of discussing whether or not a machine that had passed the Turing Test was really intelligent, the discussion shifted to the question of whether it would even be possible for any machine to pass such a test (Dennett, 1985; French, 1988, 1990; Crockett 1994; Harnad, 1989; for a review, see French, 2000b).

### **The Need for a Corresponding Shift in the Perception of the Chinese Room**

A shift in emphasis identical to the one that has occurred for the Turing Test is now needed for Searle’s Chinese Room thought experiment. Searle’s article was published in pre-connectionist 1980, when traditional symbolic AI was still the dominant paradigm in the field. Many of the major difficulties facing symbolic AI had come to light, but in 1980 there was still little emphasis on the “sub-symbolic” side of things.

But the growing difficulties that symbolic AI had in dealing with “sub-symbolic cognition” were responsible, at least in part, for the widespread appeal of the connectionist movement of the mid-1980’s. While several of the commentaries of Searle’s original article (Searle, 1980) briefly touch on the difficulties involved in actually creating a Chinese Room, none of them focus outright on the impossibility of the Chinese Room as described by Searle and reject the rest of the argument because of its impossible premise. But this rejection corresponds precisely to rejecting the idea that a machine (that had not experienced the world as we humans have) could ever pass the Turing Test, an idea that many people now accept. We are arguing for a parallel shift in emphasis for the Chinese Room *Gedankenexperiment*.

### **Can the “Robot Reply” Help?**

It is necessary to explore for a moment the possibility that one could somehow fill the Chinese Room with all of the appropriate rules that would allow the non-Chinese-reading person to fool a no-holds-barred Chinese questioner. Where could rules come from that would allow the person in the Chinese Room to answer all of the in-coming questions in Chinese perfectly? One possible reply is a version of the Robot Reply (Searle, 1980). Since the rules couldn’t have been symbolic and couldn’t have been explicitly programmed in for the reasons outlined above (also see French, 1988, 1990), perhaps they could have been the product of a Robot that had experienced and interacted with the world as we humans would have, all the while

generating rules that would be put in the Chinese Room.

This is much closer to what would be required to have the appropriate “rules,” but still leaves open the question of how you could ever come up with such a Robot. The Robot would have to be able to interact seamlessly with the world, exactly as a Chinese person would, in order to have been able to produce all the “rules” (high-level and subcognitive) that would later allow the person in the Room to fool the Well-Prepared Questioner. But then we are back to square one, for creating such a robot amounts to creating a robot that would pass the Turing Test.

### **The Chinese Room: a Simple Refutation**

It must be reiterated that when Searle is attacking the “strong AI” claim that machines processing strings of symbols are capable of doing what we humans call thinking, he is explicitly talking about programs implemented on *computers*. It is important not to ignore the fact, as some authors unfortunately have (e.g., Block, 1981), that computers are *real machines* of finite size and speed; they have neither infinite storage capacity nor infinite processing speed.

Now consider the standard Chinese Room, i.e., the one in which the person inside the Room has no knowledge of Chinese and the Questioner outside the Room is Chinese. Assume that the last character of the following question is distorted in an extremely phallic way, but in a way that nonetheless leaves the character completely readable to any reader of Chinese: “Would the last character of this sentence embarrass a very shy young woman?” In order to answer this question correctly — a trivially easy task for anyone who actually reads Chinese — the Chinese Room would have to contain rules that would not only allow the person to respond perfectly to all strings of Chinese characters that formed comprehensible questions, but also to the infinitely many possible legible *distortions* of those strings of characters. Combinatorial explosion brings the house down around the Chinese Room. (Remember, we are talking about real computers that can store a finite amount of information and must retrieve it in a finite amount of time.)

One might be tempted to reply, “The solution is to eliminate all distortions. Only standard fonts of Chinese characters are permitted.” But, of course, there are hundreds, probably thousands, of different fonts of characters in Chinese (Hofstadter, 1985) and it is completely unclear what would constitute “standard fonts.” In any event, one can sidestep even this problem.

Consider an equivalent situation in English. It makes perfect sense to ask, “Which letter could be most easily distorted to look like a cloud: an ‘O’ or an ‘X’?” An overwhelming majority of people would, of course, reply “O”, even though clouds, superficially and

theoretically, have virtually nothing in common with the letter “O”. But how could the symbolic rules in Searle’s Room possibly serve to answer this perfectly legitimate question? A theory of clouds contained in the rules certainly wouldn’t be of any help, because that would be about storms, wind, rain and meteorology. A theory or database of cloud forms would be of scant help either, since clouds are anything but two dimensional, much less round. Perhaps only if the machine/Room had grown up scrawling vaguely circular shapes on paper and calling them clouds in kindergarten and elementary school, then maybe it would be able to answer this question. But short of having had that experience, I see little hope of an a priori theory of correspondence between clouds and letters that would be of any help.

### Conclusion

The time has come to view John Searle’s Chinese Room thought experiment in a new light. Up until now, the main focus of attention has been on showing what is wrong (or right) with the argument, with the tacit assumption being that somehow there could be such a Room. This parallels the first forty years of discussions on the Turing Test, where virtually all discussion centered on the sufficiency of the Test as a criterion for machine intelligence, rather than whether any machine could ever actually pass it. However, as the overwhelming difficulties of AI gradually became apparent, the debate on the Turing Test shifted to whether or not any machine that had not experience the world as we had could ever actually pass the Turing Test. It is time for an equivalent shift in attention for Searle’s Chinese Room. The question should not be, “If a person in the Room answered all the questions in perfect Chinese, while not understanding a word of Chinese, what would the implications of this be for strong AI?” Rather, the question should be, “Does the very idea of such a Room and a person actually be able to answer questions in perfect Chinese while not understanding any Chinese make any sense at all?” And I believe that the answer, in parallel with the impossibility of a machine passing the Turing Test, is no.

## ABSTRACT

Routine interactive behavior reveals patterns of interaction among the cognitive, perceptual, and motor elements of embodied cognition and the task and artifact used to perform the task. Such interactions are difficult to study, in part, because they require collecting a large quantity of mostly correct behavior. The current study varied conditions that were designed to affect the ease and likelihood that information would be stored in-the-world versus in-the-head. The data are examined to determine how subtle differences in the source and cost of information access may lead to different patterns of correct and errorful behavior.

## INTRODUCTION

Interactive behavior emerges out of the constraints and opportunities provided by the interaction of embodied cognition (Kieras & Meyer, 1997) with task goals and the artifact used to perform the task (the ETA,  $\eta$ , triad). The interactions among the components of the ETA triad that determine interactive behavior may be extremely subtle with small changes in costs leading to large shifts in performance. For example, changing information gathering from an eye movement to a mouse movement influenced the decision-making strategies adopted in a classic decision-making paradigm (Lohse & Johnson, 1996). When the cost of making a move in solving simple puzzles increased from one keystroke to several (O'Hara & Payne, 1998; O'Hara & Payne, 1999; Svendsen, 1991) the strategy used to solve the puzzles shifted from one in which search was "reactive and display-based" to one in which search was more plan-based. The subtlety of change in response to minor variations in interface design should not be underestimated. For example, by increasing the cost of information acquisition from a simple saccade to a head movement, Ballard (Ballard, Hayhoe, & Pelz, 1995) induced a shift from a memoryless strategy to one that required holding information in working memory.

In the work reported here, we were interested in how the requirement to access information *in-the-world* versus *in-the-head* would influence routine interactive behavior. Almost by definition, most routine interactive behaviors are successfully executed. Hence, our focus is not on outcome measures of success, but on process measures of performance. Two important sources of clues regarding

process are patterns of information access and errors that are made, detected, and corrected during performance.

Unfortunately, errors in routine interactive behavior are relatively rare and collecting enough such errors to discover underlying patterns requires collecting a large quantity of correct interactive behavior. For example, Gray (in press) found only 96 keypress errors in a data set of 1,946 keypresses collected from 9 people as they programmed 56 shows on a simulated VCR.<sup>1</sup> For this reason, we collected massive amounts of data under a variety of conditions that were designed to vary the ease and likelihood that show information would be stored in-the-world versus in-the-head. The raw data were analyzed to yield three categories of information; patterns of information access during performance, types of erroneous goals attempted (*push errors*), and correct goals that were abandoned prematurely (*premature pops*). These categories were then interrogated to determine how subtle differences in information access may lead to different patterns of correct and errorful behavior.

The next section introduces the model and the approach on which the determination and classification of errors was based. We then present the methods and procedures used in the current study. The empirical results are discussed in three sections. The first provides an overview of performance, the second discusses the fit of the data to model, while the third presents error data. We conclude with a summary and discussion of how varying the cost of information access during routine performance influences correct as well as errorful behavior.

---

<sup>1</sup> Participants used a mouse to interact with the simulation. The actual VCR was operated by pressing and sliding various physical buttons. Hence, neither the simulated nor the actual VCR required key presses. Few task analysis methods analyze behavior down to the level of physical actions (see, e.g., the survey of task analysis methods reported by Kirwan & Ainsworth, 1992). Throughout this paper, our use of the terms "keypress" reflects the fact that by including mouse clicks (or button presses) in the analysis, the task analysis is at the "keystroke level." This usage of the term "keystroke level" follows the distinction made by Card, Moran, and Newell (1983).

## CONSTRAINED INTERACTIVE BEHAVIOR IN UNDERCONSTRAINED INTERFACES

Task goals for programming a VCR include setting a program's day-of-week, start time, channel, and end time (see Figure 1). Unfortunately, programming an actual VCR entails mapping these simple task goals into a variety of device specific goals. The result is a task-to-device rule hierarchy such as is shown in Figure 2.

Figure 1: Task goals for programming a VCR.

The controversial part of what is being asserted is not that there is such a mapping, but that, in many cases, there is one least-effort mapping that, if left to themselves, most users will discover and use. If this least-effort mapping is taught, most users will conform to it despite a plethora of alternatives. The task-to-device rule hierarchy is encouraged, not mandated, by soft constraints derived from principles of cognitive least-effort (described in Gray, in press).

For many interactive devices, the sequence and methods of operation are highly constrained by design. For example, if your task goal is to take \$100 out of your checking account using an ATM, you must find an ATM; insert your card; key in your pin number; press fast cash; take the money; and then take the card. For any one ATM, there is not much variability in the set of methods or their sequence.

In contrast, if you are programming the VCR simulated in our study, the device does not prevent you from clicking on the start mode button, setting the start hour, clicking on the end mode button, setting the end hour, clicking on start mode button (again), setting the channel to 10, setting the day of week to Saturday, going back and setting the channel to 11, clicking on the clock set mode button, clicking on PROG REC, clicking on end mode (again), setting the 10min, setting the min, clicking on start mode (yet again), setting the 10min, setting the min, and finally, clicking on the clock set mode button (again).

Although somebody could program the VCR in this way, in fact, nobody does. In the study reported by Gray (in press), out of 9 participants who were not taught how to program the VCR, but discovered the methods by themselves, seven adopted the task-to-device rule

hierarchy of Figure 2 and two adopted minor variants. In the studies reported below, of the 72 participants shown Figure 2 as the experimenter programmed the first show, all but two used the task-to-device rule hierarchy to program the next four shows. Although extreme variation was possible, little variation was found.

The task-to-device rule hierarchy shown in Figure 2 was derived (Gray, in press) from three sources. The first was a simple task analysis of the methods available for programming shows on the simulated VCR. The second was an analysis of participant behavior during the instructionless learning phase of the study. The third was the analyses of the unsuccessful trials – those that ended without the VCR being successfully programmed. The resultant task-to-device rule hierarchy was used to analyze the 56 trials which were successfully programmed. By definition, any errors made on these *okay* trials were detected and corrected by the participants before telling the experimenter that they were done programming the VCR.

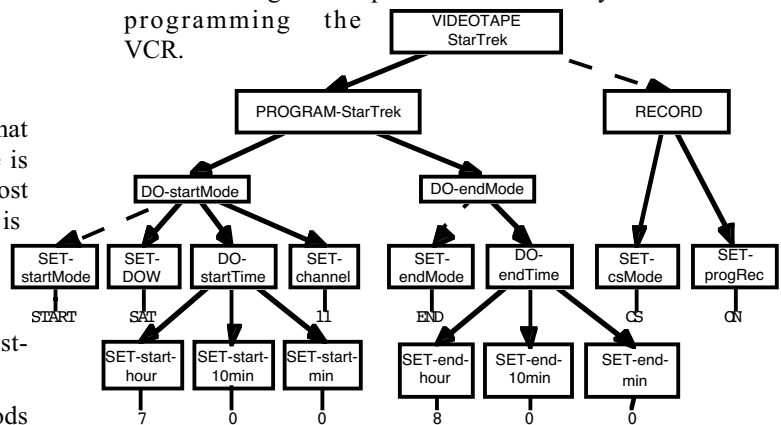

Figure 2: A mapping of the task goals from Figure 1 onto the device. This task-to-device rule hierarchy is largely determined by soft constraints. (Subgoals are represented by boxed nodes. Leaf nodes are unboxed and may represent multiple keystrokes. The dashed line leading from DO-startMode and DO-endMode indicate that subgoals SET-startMode and SET-endMode must be performed before the others. Contrariwise, the dashed line from VIDEOTAPE to RECORD indicates that RECORD must be performed last. With those three exceptions, the subgoals of a goal may be performed in any order.)

## EXPERIMENT

The current study used a new simulation of the VCR task adopted by Gray (in press). One of our goals for the current study was to determine whether new groups of participants in slightly different task conditions would conform to the task-to-device rule hierarchy shown in Figure 2. Another goal was to verify and extend the error taxonomy.

Although these goals are important, they are not the main goals of this paper. Rather, our main goal is to explore how correct as well as errorful interactive behavior is

affected by changing the cost of information access. For the *control* group, the show's start time, end time, day-of-week, and channel were clearly visible to participants.

The *gray-box* condition was designed to increase the effort required to obtain show information. For the control condition, information access required an eye movement to the show information window. In contrast, for the gray-box condition, the labels in the show information window were visible but the fields were covered by gray boxes. For example, to see the channel field, the participant had to move the cursor to and click on the gray box covering that field. The value stayed visible as long as the cursor remained in the field.

The *memory-test* condition encouraged the storage of show information in long-term memory. For each trial, clicking on the START button removed the show information window and opened a memory test window. The memory test required the participant to select the show's start and end hour, 10min, min, as well as day-of-week and channel from a series of pop-up menus. Prior to programming the show, the participant iterated between the show information window and the memory test until the test was passed.

When the VCR was being programmed, we encouraged the memory-test condition to retrieve show information from memory by discouraging the use of the show information window. As per the gray-box condition, the fields of the information window were covered by gray boxes. In addition, moving the cursor out of the VCR window caused the VCR to be covered by a black box. The black box stayed until the participant moved the cursor back to and clicked on the VCR window. Hence, for the memory-test condition, when a participant moved to and clicked on a gray box, the corresponding setting of the VCR (indeed, all settings of the VCR) was covered by the black box.

## Method

The experiment used VCR 2.0, a simulation of a commercial VCR built in Macintosh Common Lisp. All keypresses on any button object in VCR 2.0 were time stamped to the nearest tick (16.667 msec) and saved to a log file along with a complete record of the information in the VCR's displays (e.g., mode, time, day-of-week, channel, and so on).

## Participants

Sixty-four George Mason University undergraduates participated in the experiment for course credit. Participants were randomly assigned to conditions and were run individually. Each session took approximately 30 min.

## Procedure

The study began with the task-to-device rule hierarchy (Figure 2) in front of the participant. The experimenter programmed the first trial of show-0. As the show was programmed, the experimenter pointed to the figure, relating each step of programming to a node in the figure. After the first trial, the experimenter watched as the participant programmed show-0 to criterion. At that point, the experimenter left the room while the participant programmed shows 1 through 4 to the criterion of two successive correct trials. (As show-0 was an instruction and practice show, it is excluded from the analyses reported below.)

For all conditions each trial began with the VCR covered by a black box and a clearly visible information window that contained the current show's name, start time, end time, day of week, and channel. This information could be freely studied before the trial began. The information window also contained the START button. Clicking on the START button began the trial, changed the label from START to STOP, and either removed the black box that had covered the VCR (for control and gray-box) or opened the memory test window (for the memory-test condition).

At the end of each trial, the participant was given feedback as to how long the trial took and as to whether the show had been programmed correctly. If the show was not programmed correctly, the participant was provided feedback on the first error that the software found. The order in which errors were checked was: clock time, start time, end time, day of week, channel, and program record.

## OVERVIEW OF PERFORMANCE

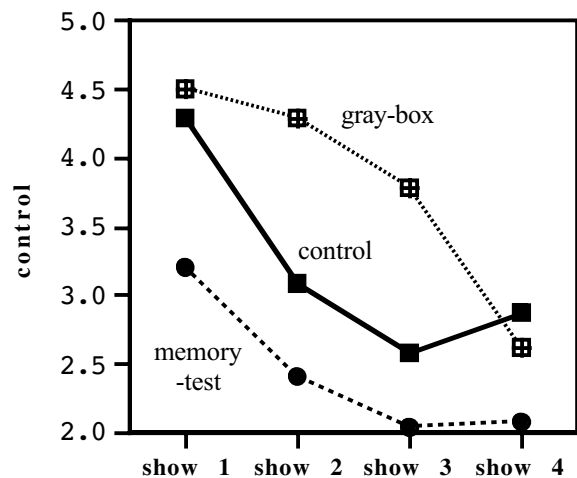

Figure 3: Mean trials to criterion.

## Trials-to-criterion

A two-way analysis of variance (ANOVA) was conducted on the number of trials to reach the criterion of two successive correct shows. Condition (control, gray-box,

memory-test) was a between-subjects factor and show (1-4) was within-subjects. The main effect of condition was significant,  $F(2, 69) = 4.478$ ,  $p = .015$  ( $MSE = 10.035$ ), as was the main effect of show,  $F(3, 207) = 5.896$ ,  $p = .0007$  ( $MSE = 5.053$ ). The interaction of condition by show was not significant ( $F < 1$ ) (see Figure 3).

Planned comparisons by condition yielded a significant difference between gray-box and memory-test ( $p = .0002$ ) as well as between control and memory-test ( $p = .0370$ ). The difference between the control and gray-box condition was not significant.

### Checking the Show Information Window

In all conditions, participants were free to study the show information before each trial began. During the trial we expected the greatest reliance on the show information window for the control condition, less reliance for the gray-box condition, and the least reliance for the memory-test condition. Unfortunately, as we did not collect eye movement data, any discussion of what the control group did is speculation. However, we do have data that supports our interpretation of the tradeoff between information in-the-head versus in-the-world for the other two conditions.

For trials that were successfully programmed (for which all errors were detected and corrected before the participant clicked on the STOP button), the gray-box condition checked information 293 times (a mean of 1.31 checks per show). In contrast, participants in the memory-test condition checked an information field 10 times (0.05 checks per participant per show). This contrast suggests that the memory-test group almost exclusively relied on memory as their source of show information.

For the gray-box condition, 149 of the information checks were made immediately prior to the use of the information (e.g., checking the day of week field and then setting day of week). In contrast, only 33 checks were made on an information field immediately after the corresponding VCR display was set.

These patterns of checking suggest that the gray-box participants did not memorize show information to the degree forced on the memory-test condition. However, the low number of information checks per show (a mean of 1.31 fields checked per show) suggests that the perceptual-motor strategy was the backup strategy, not the primary strategy for this group. Furthermore, the 149:33 (or 4.5 to 1) disparity between information acquisition checks versus information verification checks suggests a trust in working memory that the trials-to-criterion data indicates was not justified.

These data are consistent with the notion that the cognitive system minimizes local effort, not necessarily total effort (see also Gray, in press). For the gray-box condition, the failure to verify saved several seconds worth of effort during a good trial, but may have resulted

in more trials ending in error and, when compared to the memory-test condition, more trials needed to reach criterion. A similar conclusion is suggested by some of the error data that we review below.

### FIT OF DATA TO MODEL

A goal and subgoal analysis was conducted on trials that ended successfully. This restriction meant that any errors made during the trial had to be detected and corrected before the participant pressed the STOP button.

For these analyses, ACT-PRO (Fu & Gray, 1999) was used to parse the log file into goals, subgoals, and operators. Each deviation from the task-to-device rule hierarchy shown in Figure 2 was noted and classified by ACT-PRO. (The classification categories used here are an expansion of those reported by Gray, in press).

Over the course of the study 36,877 keypresses were collected. ACT-PRO parsed these into 12,704 goals and subgoals. Of this number, 98.4% (12,560) are goals that are captured by the task-to-device rule hierarchy.

Of the uncaptured goals and subgoals, 56 can be readily interpreted as the participant returning to a mode to double-check a setting. These additions increase the percentage of goals and subgoals accounted for to 98.8%.

The remaining 148 goals can be examined to determine if they represent errors or are simply alternatives to the task-to-device rule hierarchy used by the model. Of these potential errors, 16 represented alternative ways of correctly programming the VCR. These alternatives were manifested by five participants. Only two of these five participants used the alternative on a majority of trials. Hence, although there may be hundreds of ways of segmenting and sequencing the task of programming this VCR, the model shown in Figure 2 accounts for the vast majority of correct behavior shown by the overwhelming majority of participants.

### ACCOUNTING FOR ERROR

The taxonomy developed by Gray (in press) relied on model-tracing (Anderson, 1993) to identify deviations from the task-to-device rule hierarchy as *push errors* or *pop errors*. Any key that is pressed at a time or place where the model would not press it is a push error. Any goal or subgoal that is abandoned, or popped, before the model would end it is a pop error.

#### Push Errors

As discussed above, ACT-PRO classified 148 goal pushes as violations of the model's task-to-device rule hierarchy. After we subtract those behaviors that can be interpreted as alternative rule-hierarchies we are left with a data set of 132 push errors. In this paper, space constraints force us to limit our discussion to the 31 erroneous attempts to

increment rather than decrement (or vice versa) the channel setting.

Except for channel, each of the other settings had only one button. For day-of-week, hour, 10min, or min this button would only increment, never decrement the setting. In contrast, channel had two buttons; one to increase the displayed setting and one to decrease it. Hence, whereas if an erroneous attempt to decrement the day-of-week, hour, 10min, or min, was detected and corrected by the participant, it would have gone unnoted by the experimenter. In contrast, any goal to decrement the displayed channel setting when it should have been incremented (or vice versa) would be obvious from the log file. (Note that the target channel setting was higher than the default setting for two shows and lower than the default for the other two shows.)

An ANOVA of errors by conditions for incrementing versus decrementing the channel revealed a marginally significant effect,  $F(2, 69) = 2.787, p = .069, MSE = .683$ . The mean per trial error rate was higher for memory-test (0.750) than for gray-box (0.333) and lowest for control (0.208). Planned comparisons showed that the difference between memory-test and control was significant ( $p = .027$ ) while the difference between memory-test and gray-box was marginally significant ( $p = .087$ ).

While programming, participants in the memory-test condition checked show information a total of 10 times. The reliance on information in-the-head versus in-the-world resulted in an increase in errors. However, the information was well-learned and participants soon retrieved the correct information and set the channel to the correct setting. The transient nature of this error suggests a momentary fluctuation in strength of the memory trace due to noise (Altmann & Gray, 1999; Anderson & Lebière, 1998).

### Pop Errors

By the analysis introduced by Gray (in press), not only can pushing a goal be an error, but popping can be errorful as well. Popping a goal before its target setting has been reached is a *premature pop*. The data set collected by Gray (in press) was too small to distinguish between various types of premature pops. However, the 182 premature pops collected in the current study is an order of magnitude larger than that previously obtained. This set permits us to distinguish between three types of premature pops.

Local premature pops (pp-local) entail beginning to program a VCR setting but stopping before the target setting is achieved. For example, if the target day-of-week is Saturday and the current day-of-week is Tuesday, pressing the DOW key twice and then going off and doing something else would be classified as a pp-local. Time premature pops (pp-time) entail completing one or two of the DO-startTime or DO-endTime subgoals (see Figure 2)

but abandoning the goal before the remaining subgoals are completed. Similarly, mode premature pops (pp-mode) entail popping the DO-startMode or Do-endMode goal before all of their subgoals are completed.

Across the three types of premature pops a repeated measures ANOVA showed no main effect of condition ( $F < 1$ ), a significant effect for type of premature pop [ $F(2, 138) = 12.868, p < .0001, MSE = .041$ ] as well as a significant interaction of condition by type [ $F(4, 138) = 2.989, p = .021$ ]. As Figure 4 shows, the gray-box condition made the most pp-local errors with the memory-test condition making the least. This pattern was reversed for pp-mode errors.

Figure 4: Premature pops by condition. (Error bars show the 95% confidence interval of the SEM.)

The higher pp-local error rate for gray-box is consistent with their pattern of fewer checks to verify show information. These errors – which were caught – as well as the errors that were not caught (i.e., those that led to greater trials-to-criterion for this group) may have resulted from the low rate of verification shown by this group.

Likewise, the higher rate of mode errors for memory-test may be the result of their reliance on memory. Although the gray boxes covered up the values of the information fields, they did not cover the labels for those fields. Hence, the labels may have served as a type of goal posting. The control and gray-box conditions would have been reminded of the goals for the current mode every time they glanced at the show information window.

### SUMMARY AND CONCLUSIONS

The most striking aspect of the between group differences in errors and performance is that all were avoidable. All performance differences can be traced to differences in willingness to either memorize or visually access show information. For each trial, the memory-test group had

quick and reliable access to show information in memory. The other groups made more undiscovered errors that resulted in more trials-to-criterion. Apparently verification is lower cost – and hence more likely – if based on knowledge in-the-head rather than accessing knowledge in-the-world.

On trials for which any error made was eventually detected and corrected, we found an interaction between group and type of premature pop. The gray-box condition was more likely to abandon the current key (pp-local) before completing a setting, whereas the memory-test condition was more likely to switch modes before all subgoals were completed (pp-mode). The pattern for pp-local errors is consistent with that for trials-to-criterion. In both cases, errors were made because the gray-box group was unwilling to invest in the time and effort needed to obtain reliable information.

Our interpretation of pp-mode errors suggested an advantage to relying on information in-the-world rather than in-the-head. Both the control and gray-box conditions accessed the show information throughout performance. In addition to obtaining the value of the information fields, accessing the show information window may have served as a type of goal posting to remind participants what settings they had programmed and what remained to be done. In contrast, the memory-test condition would have had to keep a corresponding checklist in-the-head. Unlike the show information that they memorized, the state of this mental checklist was dynamic and changed throughout task performance.

We interpreted the push error that we analyzed as evidence for fluctuations in the strength of items encoded in long-term memory. The fact that the misretrieved settings were detected and corrected without recourse to the show information window is consistent with the ACT-R assumption of transient fluctuations in strength (Altmann & Gray, 1999; Anderson & Lebière, 1998).

The study of routine interactive behavior is not itself routine. To study how small changes in artifact design affect performance, massive amounts of correct behavior must be collected. The analysis of routine interactive behavior enhances our understanding of how the cognitive, perceptual, and motor elements of embodied cognition interact with task and artifact to affect correct and errorful performance. This report suggests that small changes in the cost of information access may result in differences in the trials needed to reach criterion and the patterns of errors made.

## Abstract

Conceptual learning in mathematics involves more than getting to the right answer. Recent efforts in math education reform have focused on having students work in groups on open-ended projects that are based in realistic contexts. We extend previous analyses with hypotheses about conceptual and interactional aspects of understanding and solving problems by groups. The conceptual hypothesis focuses on integration of information in the group's *situation model* and its *problem model*. The interactional hypotheses involve patterns of interaction that make it easy or hard for the group to open up a discussion of assumptions in its reasoning, and that make the group accountable to a wider audience for explaining relations between the situations and mathematical operations involved in their solutions. Regarding educational practice, these findings highlight a way in which student groups must coordinate their conceptual and interactional work to arrive at satisfactory solutions to the problems posed. The present study suggests the importance of students in these environments not only connecting the contextual situation and the attending mathematics, but also reconsidering the situation in light of their new mathematical understanding (bringing the mathematics back into play in their understanding of the situation). Interactional patterns in a group make this relatively easier or harder, and this must be accounted for in implementing new curricula and conducting teacher education.

## Introduction

When a group works together on a problem involving mathematics, how does that work get done? How does the group arrive at its understanding of the problem on which they are working? How do they go about conducting the work? What happens when someone questions what another member of the group is doing or proposing to do? The person questioned may offer an explanation that justifies the claim or action. Alternatively, the group might collectively take up the question, and construct a new understanding. Or the question could be ignored, deflected, or dismissed.

When students are involved in solving open-ended mathematics problems without one correct answer, it's not immediately obvious when an error has been made. So when a mistake *is* recognized by a member of a group, how does that happen? This paper reports results from an analysis of a student group engaged in a mathematical

modeling unit. We present two episodes in which the group's problem solving involved mistaken assumptions. In one episode the group identified and corrected the mistake, but in the other they did not. In this paper we illustrate how a mistake was recognized and resolved, and how that differed from more common instances in which mistakes are not corrected. Implications for cognitive theory and for the design of learning environments are discussed.

## An Interactional Aspect of Reasoning

The interactional aspect of activity that we focus on involves explanatory practices. We develop our analysis using the schema of conversational contributions provided by Clark and Schaefer (1989) and adapted for analyzing discourse in problem solving by Greeno and Engle (1995). In this schema, each contribution to the process of understanding and solving a problem includes a presentation of information or action and an acceptance, resulting in grounding the contribution in the participants' mutual understanding.

In much ordinary discourse, explanations occur mainly when someone questions or disagrees with something that someone else says or does (McLaughlin, Cocy & Reed, 1992). In Clark and Schaefer's scheme, occasions for explanation often arise when one participant presents some information and another other participant responds with a question, a challenge, or an alternative. When this happens, the group can take up the question, challenge, or the suggested alternatives. This "taking up" involves a kind of negotiation in which the question or challenge may be resolved, one of the alternatives may be chosen, or the group may leave the issue with the understanding that their uncertainty or disagreement remains. In such a negotiation, explanations may occur frequently between group members.

The discourse patterns of different groups or of groups in different situations vary in how open they are to presenting and considering questions, challenges, or alternatives. A presentation provides a possible continuation of a trajectory in the activity. A question, challenge, or alternative proposal presents a potential diversion from that trajectory, and the resolution may bring about a change in the group's direction. It is reasonable—perhaps necessary—for groups to maintain some level of inertia in their interactions in order to enable them to function productively. The amount of that inertia can vary depending on which participant has the floor. It is easier to challenge and

question some participants than others, and some participants are more likely than others to discuss an issue rather than to forge ahead, ignoring the intrusion, or to simply give a justificatory explanation.

Mathematics educators such as Lampert (e.g., 1990) and Cobb (e.g., Cobb Yackel & Wood, 1992) have emphasized the importance of students' developing practices of explanatory discourse that support valid reasoning and understanding in mathematics. Cobb and Yackel (1996) distinguished between *social norms*, *sociomathematical norms*, and *mathematical practices* in the activity patterns of mathematics classrooms. Social norms, or *participation structures* (Erickson, 1986; Lampert, 1990), include the extent to which participants expect each other to provide explanations and conduct their conversations so that it is easy to present questions, challenges, or alternative proposals and have them taken up. Sociomathematical norms include what counts as acceptable and valued mathematical explanation. Mathematical practices include methods that are established as acceptable without need for explanation.

### **A Conceptual Aspect of Reasoning**

The conceptual activity that we focus on involves the coordination of cognitive resources from different conceptual domains in activities of reasoning. Like heterogeneous reasoning (e.g., Stenning & Sommerfeld, this volume), the cognitive process that we consider involves reasoning that is informed by different kinds of information sources. In heterogeneous reasoning, the sources are different representations (e.g., a diagram and a set of logical formulas). In the reasoning that we observed, the information sources were from different conceptual domains—one primarily involving ecology and the other primarily involving mathematics.

In professional practices that use mathematics, such as architecture or scientific research (e.g., Hall & Stevens, 1996), the integration of information drawn from mathematics and another domain is often seamless; often one cannot be understood without the other. This ubiquitous, implicit coordination of mathematics with another conceptual domain informs professionals' evaluations of their work, including identification of mistakes.

In school problem solving, the coordination of mathematics with other domains is often more problematic. In a study of primary-grade students solving word arithmetic problems, Kintsch and Greeno (1985) hypothesized two forms of understanding that they called *situation models* (following Kintsch & van Dijk, 1978), and *problem models*. According to this hypothesis, solving a mathematical problem includes understanding properties and relations of objects and events in the problem (the situation model), and using that information to construct an understanding in mathematical terms (the problem model). The problem model is often supported by material representations such as equations, which aid students in carrying out appropriate mathematical procedures. Nathan, Kintsch, & Young (1992)

hypothesized that difficulty in forming a model of a situation and coordinating that situation with a problem model is a significant impediment to students' success in learning algebra. They designed an interactive computer system that supports students' construction of algebra problem situations and makes relations needed for the problem model salient. Use of this program facilitated students' problem solving and learning.

### **Learning Environment**

The curriculum materials in this study came from the Middle school Mathematics through Applications Project (MMAP), which was organized as a design experiment (Brown, 1992; Collins, 1992). The design team, housed at the Institute for Research on Learning at Stanford, included teachers and curriculum developers as well as cognitive science researchers. The team developed a middle-school mathematics curriculum in which students work in groups to solve extensive design problems using mathematics (Goldman, Moschkovich, & MMAP, 1995). Students work in interactive learning environments that are middle-school aged versions of design work in architecture, population biology, cryptography, or cartography. The purpose of the curriculum is to have students use math to address problems situated in non-mathematical contexts, often with the assistance of computer applications.

The data we analyzed came from an 8th grade MMAP classroom in the San Francisco Bay Area. They were collected by Rogers Hall and his colleagues (Hall, 1999; Hall, this volume). In the approximately 30-day unit we discuss, called Guppies, students created mathematical models of biological population growth. For their study, Hall and colleagues had collaborated with the teacher in designing a revision of the unit that had been taught and observed earlier. This revision included further emphasis on how to construct mathematical models of population growth and about the exponential functions that underlie them. In addition, they included more explicit attention to the relation between assumptions about guppies' reproduction and parameters of the mathematical model. Our analysis in this paper focuses on one group of students (Manuel, Lisa, Kera & Ned) whose improvement on pre/post assessments placed them about midway in learning of the focus groups videotaped by Hall.

### **Analysis**

We examine two episodes from a videotape record of one student group. These episodes were chosen because each of them included a proposal for a move in the problem space that was incorrect. However, in one case the group identified the error and corrected it, while in the other the group did not identify the error, but instead proceeded using a flawed piece of information. We explain this difference between the successful episode and the unsuccessful one with two hypotheses about collaborative understanding and problem solving in interaction.

First, we hypothesize that the interaction of the group included a kind of threshold for taking up questions, challenges, and alternative proposals that could change the course of activity. Specifically, we hypothesize that detection of a misalignment between the group's situation model and its problem model could occur by a participant's questioning of an operation that was proposed or performed. Both episodes began with an operation initiated by one participant. In the first episode, another participant presented a new interpretation of the situation (which we hypothesize was based on her understanding of the situation model), which illustrated that the current operation was incorrect. In the second episode this participant questioned the initiated operation and expressed a lack of understanding of it. The first of these episodes resulted in the group changing their mathematical approach to accurately reflect their new understanding. In the second episode, the group did not change the operation it was carrying out. We hypothesize, then, that at least in these two cases, presenting a persuasive interpretation based on a situation model was sufficient to bring about a change, while merely expressing uncertainty and lack of understanding of the operation was not.

Second, we hypothesize that in both episodes the initial error involved an inadequate alignment between what the participants understood about the world of guppies (their situation model) and the mathematics (their problem model). That is, the students either did not attend to all the relevant details in the text of the problem when formulating their situation model, or they did not attend to all of the details of the situation model when formulating the problem model. This is consistent with the findings of Nathan, Kintsch & Young (1992), who suggested that when numbers are abstracted from their context, it is possible for students to perform operations that aren't faithful to the situations they are meant to represent (cf Hall et al., 1989). However, such mistakes can be recognized when the context the math is supposed to represent is considered, often using a simulation of some type. In the first episode such a simulation occurred, which led to a reconceptualization of both the problem and situation models. In the second episode however, the problem and situation models were not integrated, and the mistake was not recognized. It is important to note that we do not believe that situation models and problem models are static states, but that they ideally develop in coordination with each other in a recursive process. We suggest that although mathematics problems can be completed successfully without coordination of problem and situation models, integration of the two can highlight when mistakes have been made, leading to more successful problem solving.

### Episode 1 - Pretest

Our first episode comes from the pretest in which the students were trying to answer the question: "Given an initial population of twenty mice who reproduce every season, how large will the population be at the end of two years?" The students had decided that each mouse couple

would have four babies during each breeding season, and that the mice would reproduce eight times in four years. They were asked to show their solutions, which the students did by drawing a graph that depicted the size of the mouse population after each breeding season. Manuel had proposed that the vertical axis would need to extend to 340 mice. When questioned by Lisa and Kera, he explained this conclusion by repeating the mathematical procedures he used: there would be 40 mice born each season, resulting in 320 births, which would be added to the initial 20. When they began to construct the graph, the following exchange occurred:

180 **Manuel:** SO there's sixty... so let's see the first season is over here [*making a mark on the graph*]

185 **Lisa:** Wait a minute

186 **M:** and then sixty plus... is going to be a hundred

189 **L:** Wait a minute, it's forty, and then it's like [*put pencil down and placed fingertips together*] OK. It's forty, right?... And then you have to pair those up [*pressed palms of hands together*] and then they have kids [*spread the palms of her hands apart*]

195 **Kera:** pair the-

196 **M:** oh yeah [*laughing*]

202 **K:** ...my gosh, that's a lot of nasty mice.

Manuel's participation at the beginning of this episode was consistent with the group's usual pattern, in which Manuel initiated actions and responded to questions by explaining why his proposals were satisfactory. Lisa indicated a question ("Wait a minute") then, when Manuel proposed adding 40 to the first data point to infer the next data point, Lisa took the floor, capturing attention with a gesture along with her speech, presenting a reasoned explanation for a different operation that would take account of the 40 mice that were in the population after the first season when they calculated the number born in the second season.

As the students began to graph their results, Lisa realized that the ending population had been miscalculated, and she interrupted the trajectory of the group with a suggestion that was recognized, acknowledged and finally implemented. Lisa's suggestion (line 189) recalled the context of the problem—how mice reproduce—which enabled the students to evaluate the mathematical model they were creating. The linear model that they had previously created had made sense to all three of the members until Lisa simulated a model of the situation they were supposed to be addressing. Thinking about the population growth in those terms enabled her to recognize the error of adding the same number of newborn mice every season. This served to relate the problem model back to the situation model, as the students were forced to think incrementally about the growth of their population.

We interpret this conceptually as follows. First, Manuel's proposal that there would be 320 births involved applying a familiar schema of mathematical practice. A process that increases a quantity may do so by producing a constant quantity during each of several intervals. Inferences about

this kind of process can be made using a schema with three variables: an amount per unit, a number of units, and a total amount. We hypothesize that Manuel applied this schema, using the number of mice the group had calculated for the first year as the amount per unit (births per season) and the number of seasons as the number of units. When Manuel specified and represented 60 as the number mice after the first season, Lisa related this to a situation model in which the number of births in each season depends on the number of mice in the population that season. In that model, the number of births during the second season had to be calculated by considering how many mouse couples there were during the second season. This contradicted Manuel's method and required a change in the problem model, one in which there was a separate calculation of the number of births for each season, rather than a single calculation of the total number of births during eight seasons

### **Episode 2 - Birthrate worksheet**

Our second example is more typical of the type of error recognition that we observed in this group. This episode comes from the middle of the unit. Students were trying to create their own model of guppy population growth. They were told that a population of ten guppies would be coming from Venezuela, and the students' task was to determine how large a tank they would need to hold the guppy population at the end of two years. In order to solve the problem the students needed to determine the specific composition of their original ten guppies (gender and age) and tabulate their birth rate- a complex equation that used multiple variables (see also Stenning & Sommerfeld, this volume).

The interaction in this episode was different than the first episode: although in this group ideas and questions were almost always acknowledged and attended to, one member's suggestion did not always serve to stop or change the trajectory of the group. In this episode Manuel proposed a "shortcut" through the mathematics of a worksheet (line 444). Apparently realizing that this suggestion did not fit into the expectations of the worksheet, Lisa questioned Manuel many times and attempted to stop the group. In this case however, Lisa's interjections (lines 451, 497, 501 and 505) did not successfully redirect the group.

444 **M**: ...If four percent of the frys survive, why don't we just forget about the fry survival and just put that amount for the, for how much are born.

447 **L**: 'cause the number born are not how much survived.

448 **M**: Yes. Yes, the ones who survive are the ones we count, not the ones who are dead, because we don't make room for the ones that are dead.

451 **L**: ...I'm kinda confused

462 **M**: ...why don't we just put four percent on the guppies' birth, because that's how many are going to survive.

497 **L**: but what's that four percent?

498 **K**: the ones that survive

501 **L**: yeah, I know, but how many... of the guppies are four percent?

503 **M**: we don't know, we'll let that mechanical thing work and tell us

505 **L**: wait, are you answering assumption-

506 **M**: let's just try it out.

The group was working on a worksheet for calculating a value of the birth rate to enter into the computer model. The worksheet included four steps. First, the students made assumptions about the gender and age distribution of an initial population of ten guppies. Second, they were to calculate the total number of guppy fry that would be born according to data provided about the number of fry per female of each age in the population. Third, they were to apply a percentage of infant mortality, due to the fact that about 95% of newborn guppies are eaten by their mothers. Fourth, they were to calculate an effective birth rate by dividing the number of surviving fry by 10, the size of the initial population, and converting this to a percentage.

Manuel proposed that the survival rate (which he incorrectly remembered as 4% instead of 5%) could be entered in the computer model as the birth rate. Lisa questioned this, ("how many ... of the guppies are four percent?") but Manuel did not take up the question.

We interpret this episode using a hypothesis about a problem model that was based on an incomplete use of a situation model. The computer program and the worksheet required an entry labeled "birth rate," intended to be expressed as a percentage of the population in the previous season. The group understood that the value of this parameter should reflect the loss of most of the guppies that had been born. The percentage of surviving guppy fry — 4% — fit these specifications, and Manuel proposed to use that as the birth rate. Lisa's questions about this operation were analogous to the challenge she presented in Episode 1. The correct value should have taken into account the number or percentage of guppy fry born in relation to the previous total population, and then take 5% of that (or 4%, on Manuel's misremembered figure). If Lisa's questions had specified the neglected quantity in this case, as she did in Episode 1, she might have succeeded in having her alternative taken up and considered.

In this interaction, Lisa's question was not sufficient to force the group to recognize the mathematical error they had made. In the earlier episode, Lisa stopped the group with a suggestion that simulated the situation model they were supposed to be working from, enabling the group to identify an error in their mathematical reasoning. In this case, Lisa attempted to stop the trajectory of the group without either making a specific suggestion about the relation of the problem model to the situation model, or proposing a new situation model. The other members of the group were not forced to think differently about what they are saying, and consequently, no change was made.

## Comparison

We chose these two episodes because they present a useful contrast for thinking about group problem solving. In both episodes, the group was working along a mathematically incorrect path, and one student questioned that path; but in one case the group corrected itself, and in the other it did not. Specifically, both episodes began with a proposal by one student (Manuel), which involved a mathematical shortcut. These shortcuts appear to have made some sense to the other students in the group, but neither proposal would have led to a successful solution to the problem at hand. What factors may have been involved in the first episode becoming a successful problem solving effort, while the second did not?

We hypothesize that the principal conceptual difference between these two interactions lay in the students relating the situation model and the problem model. The curriculum was designed so that students necessarily developed a situation model about guppies, and used that situation model to construct their mathematical problem model. When they constructed problem models that neglected significant aspects of the situations, incorrect assumptions and conclusions could be easily missed.

The patterns of interaction between the two episodes also differed. In this group, one student (Manuel) consistently took the function of directing the process, initiating and performing operations. Two other students (Lisa and Kera) frequently asked questions or expressed uncertainty. Generally Manuel responded to these by justifying the operation he had initiated or performed. In the first episode (the pretest problem), Lisa not only questioned Manuel's line of thinking, she presented a definite alternative to Manuel's operation. It appears that this met the threshold required for Manuel and Kera to attend to Lisa's idea and to accept it. In the second episode (the birthrate worksheet), Lisa questioned Manuel's shortcut and referred to a critical property of the situation. But, apparently, raising a question rather than proposing an alternative was insufficient to meet the threshold needed to open up a negotiation of how they should proceed.

## Discussion

The hypotheses arising from analysis of these two episodes point to potential contributions both in fundamental cognitive science and the design of learning environments.

First, consistent with Nathan, Kintsch, and Young (1992), we see that students working on contextual problems get into conceptual difficulty when they do not adequately align their situation model with their domain-specific problem model. However, we extend that finding to suggest that for problem solving in real-world contexts it is also important to realign the problem model to the situation model, checking for sensibility in the integrated understanding of the context-mathematics relationship. In this way the problem and situation models develop in coordination with each other and are constantly changing in response to one another. The details of this mapping

between situation model and problem model and back again are subject to further study. From an educational standpoint, it seems that it is important to do more than provide students with a contextual situation from which they can extrapolate a problem model. Another important step is for students to connect the numbers back to the situation model, for it is all too easy to get lost in the abstract world of numbers and forget about their meanings. (See also, Stenning and Sommerfeld, this volume.)

Links between a situation model and a problem model could also be accomplished through the use of material representations. In this unit the students are given worksheets and a computer program in an effort to help them understand the components of making a model, and to guide their understanding of how math can work to create that model. In its current state, the MMAP technology presents a problem model in the form of a network of problem quantities. However, it does not have provisions to facilitate relating the math back to a situation model. One way that the technology might be changed is to present a mathematical representation (as it currently does) alongside a simulation of the components that are taking place. Simulations of that sort might serve to create more links from the problem model back to the situation model, forcing students to think situationally about the math they are producing, making it more likely that they will notice their own mistakes if the simulation doesn't work as they expected.

Still another way to increase students' attention to links between situation models and problem models would be to develop a socio-mathematical norm (Cobb & Yackel, 1996) in which students expect to be accountable for explanations that justify mathematical operations and representations in terms of properties and relations of quantities in situations.

Additionally, interactional patterns create thresholds for questioning, which affect how a suggestion is taken up or explained. Although in this group the students seemed to feel that a mutual understanding was important in order to proceed, oftentimes that understanding was not a consensus. One potential way that such a pattern may be altered is through the larger classroom learning practices, including aspects of reasoning and explaining for which students are accountable to each other and to the teacher. Accountability is provided through discourse activities at different levels, as Hall and Rubin (1998) discussed in their analysis of Magdalene Lampert's teaching. Lampert had an explicit policy that any member of a group could be called on to provide an explanation for any of the group's results. This policy made each group of students accountable for achieving mutual understanding so that the individual members could satisfy the expectation that they would be able to understand the group's results.

Introducing this order of accountability into classroom practices can serve the conceptual linking as well. It is necessary to include some sort of provision for making sure that students understand that finding the "correct" mathematical answer is only part of their responsibility. They also should be responsible for relating what they

found back to the model that they were trying to create and to share that information with their peers. In another example involving FCL classrooms (Brown and Campione, 1994), at the end of a unit students are made accountable for what they have learned by sharing their findings with the rest of their class. Therefore, assumptions that are made throughout the unit need to be accounted for and explained. In the course of doing the birthrate sheet, Manuel made many assumptions about the number of guppies, their survival rate, and how that affected the birth rate. If the group had felt some accountability to a “larger audience,” that is, if they had to present their findings to the class and explain the elements of their model, they might have been less likely to take logical leaps without trying to understand how they related to the model being created.

### Acknowledgements

This research was conducted under a grant from the Spencer Foundation. We are very grateful to Rogers Hall and his associates, Anthony Torralba and Susan John, in the Math at Work research group at UC Berkeley for sharing the videotapes with us. Ongoing conversations with them continue to inform these analyses. We also thank Randi Engle, Keith Stenning, and Rogers Hall for their comments and assistance on this paper.

# Work at the Interface between Representing and Represented Worlds in Middle School Mathematics Design Projects

Rogers Hall (rhall@socrates.berkeley.edu)

Graduate School of Education  
University of California, Berkeley, CA 94720

## Introduction

A central process in scientific or mathematical thinking involves being able simultaneously to look *at* and *through* the interface between representing and represented worlds (Gravemeijer, 1994; Latour, 1999). This is particularly true of thinking practices in which people construct and then explore models to gain access to situations that do not yet exist or that occur across scales of time and space that prevent direct observation. While this flexible use of modeling is central to many disciplines, pedagogy has until recently focused primarily on the notational structure of formal systems of representation. This approach can trap learners in the situation of looking *at* complex representational systems, without being able to look *through* them to construct and explore represented worlds (Greeno & Hall, 1997).

This paper adds to a line of work in cognitive studies of mathematics education that examines how learners work at the interface between representing and represented worlds to make inferences, identify and recover from conceptual errors, and manage calculation (Cobb, Yackel, & McClain, 1999; Hall, 1996; Nathan, Kintsch, & Young, 1992; Nemirovsky, in press). Empirical materials are drawn from group modeling efforts in project-based middle school mathematics classrooms (Hall, 1999). In particular, I focus on how a group of students develops an increasingly sophisticated capacity for working with the concept of predation, treated as a functional relation between animal populations (i.e., predator and prey) that can be implemented in particular computational media. In my analysis, these media and other resources available through talk and embodied action develop into systems of activity (Goodwin, 1994) that make up conceptual understanding. From this perspective, concepts and their implementation in diverse representational technologies are inseparable.

## Background to the Student Design Project

Data for this paper (also for papers by Greeno, Sommerfeld, & Wiebe and Stenning & Sommerfeld, this volume) come from studies conducted in middle school mathematics classrooms where students worked on design projects. These projects were supported by curriculum units developed to embed important mathematical concepts in realistic applications (Greeno & MMAP, 1998). In the study reported in this paper, students were asked to act as biological consultants who would devise a proposal for

preserving and then returning a population of guppies to a Venezuelan stream environment. As adopted for use in their classroom, the project lasted approximately four weeks and included the following: task memos directing the activities of student groups, worksheets and supporting case material for the contexts of design problems, a software tool (HabiTech™) that allowed students to model and investigate structures and processes in population biology (see Figure 2), and a set of extension scenarios asking students to model hypothetical events within the Venezuelan stream environment (e.g., harvesting by farmers or the introduction of a predatory fish).

Just before and after working on this project, student groups attempted a 20-minute design challenge in which they were asked to model the relation between mice and cat populations living in a barn over a period of several years. Both the design challenge and students' daily activities during the longer unit were filmed, and various design documents (intermediate and final) were collected. An analysis contrasting pre/post unit performance of groups on the design challenge provides evidence *that* students' understandings of population biology and associated mathematical concepts changed over time. In this paper, I focus on *how* these understandings changed, by following the work of a typical group (labeled the MLKN group) with a particular concept through the longitudinal record of their daily activities on the unit. Data materials are divided into six segments: Segments 1 and 6 come from the pre- and post test design challenge (respectively); Segments 2 through 5 come from the longitudinal record of group work during the unit.

## Evidence of Conceptual Change from a Pre/Post Design Challenge

An utterance-level comparison of the MLKN group's performance on a pre and post-unit design challenge showed that they, like the majority of groups in their classroom (5 of 7 groups), were able to construct and explore a more complete functional model of population growth and predation at the end of the four week unit. At the pretest challenge, this group failed to mention deaths for either population, they did not link together overlapping timelines for otherwise correct models of mouse and cat births, and they made no mention or use of the concept of predation until questioned about it.

As evident in the following exchange<sup>1</sup>, which was recorded at the end of the pre-test, members of this group did understand the qualitative effect of predation, in the sense that cats eat mice and so “reduce” their population. But they had no way to implement this understanding as a functional relation linking together their isolated, hand-calculated models (i.e., for mice and cat populations).

### Segment 1: Predation at the Pre-test (4/21/98)

- 1 Rogers: So if the mice are eating grain...
- 2 Manuel: Uh, huh.
- 3 Rogers: What are the cats eating?
- 4 Lisa: [Mice.
- 5 Manuel: [Mice.
- 6 Rogers: What does that do to the mouse population?
- 7 Manuel: Reduce them.
- 8 Rogers: Ok, [so, as you were doing the mice calculations]
- 9 Manuel: [Ah! Oh::]  
(Lisa and Kera look at Manuel)
- 10 Rogers: Sounds like you were just kinda goin with, four per litter for the mice and letting them... go=
- 11 Kera: =Go, ok.
- 12 Rogers: So they're gonna be getting rubbed out by the cats, right?
- 13 Manuel: [Uh huh.
- 14 Kera: [Right.

The absence of predation as a functionally explicit concept strikes Manuel first (line 9), then he and Kera agree that their models allow cats to grow without bound. As they go on to acknowledge (not shown), this is something that violates the entire premise of the design challenge, and they are eager to get another chance at this kind of problem.

At the post test design challenge, the MLKN group's understanding of population concepts was still unstable and dependent on particular means of implementation (see papers by Greeno et al. and Stenning & Sommerfeld, this volume), but they were also able to implement and explain a functional model of predation. For example, as Manuel struggled to combine timelines for mice and cat populations into an integrated model, Lisa recalled their earlier use of a “Special 2 thing” (i.e., a user-defined function) to model the predation of guppies by wolf fish during the classroom design project. This recalled use of a special function provided a starting point for a fully explicit implementation of predation on the post test.

In the following exchange, recorded near the end of the MLKN post test, Lisa asks Kera for an update on what they

are doing, while Manuel and Ned (silent) work to repair an error with their combined timeline. As Kera explains, they started the combined model with too many mice, generated in an earlier model of mice living alone.

### Segment 6: Predation at the Post Test (5/26/98)

- 1 Lisa: ((to Kera)) Could you run that by me?
- 2 Kera: Um, we ran the model for two years. But we forgot that one year, the cats were living with them. So then they were dying [(inaudible).
- 3 Manuel: [Forty eight. ((resets Moose/Mice<sup>2</sup> to 48))
- 4 Lisa: ((looking at interface)) Uh huh.
- 5 Kera: [(Not in this year.)
- 6 Manuel: [Ok, so now... bring that... to negative. ((relinks Special 2 to Moose/Mice negative pole)) And we started with, how many? ((scrolls down to check Wolves/Cats)) Six, ok. Here we go. Now build... to two thousand and four. ((resets timeline)) Two thousand and four... Now, to the end. ((runs To End))
- 7 HT: ((huge negative value for Moose/Mice population))
- 8 Manuel: Oo::
- 9 Lisa: So how many... [That's only]
- 10 Manuel: [After], after two thousand and four there's negative [mice.
- 11 Lisa: [Can we bring in some dogs there! ((laughing))
- 12 Manuel: Ok:: ((laughing, opens graph window)) Kaboom.
- 13 HT: ((huge negative decline for Moose/Mice))
- 14 Lisa: Oh gosh!

At the end of this design challenge, I (as a research interviewer) asked the group exactly when mice die off. Their first idea was to narrow the timeline, a simplification that increased the resolution of their graph in both axes for time and population abundance. They eventually used this more fine-grained graph and a table of linked values to find that, in their implementation of predation, cats consumed all the mice after only one month.

Comparing pre and post test performances (Segments 1 and 6), it is clear that the concept of predation—along with technical means for implementing, using, and interrogating this concept—changed within the working capacity of the MLKN group. While they neither mention nor implement predation on the pre-test, at the post test this group makes several important advances: (1) They combine partial results from an investigation of mice to model the introduction of cats; (2) They define a predation function that explicitly links cat and mouse populations; (3) They display, investigate, and explain a resulting crisis in the mouse

<sup>1</sup> Transcript conventions include: ((activity descriptions)) appear in double parens, (uncertain hearings) in single parens; [overlapping [onset of talk is shown with left brackets; dynamic computer responses are transcribed as turns at talk.

population; and (4) They notice that cats will, in turn, face a related crisis brought about by a lack of food.

Particularly important for an analysis of work at the interface between representing and represented worlds, these students appear to be able to move fluidly between their roles as middle school collaborators (e.g., Lisa asks for and Kera provides an explanation), technical designers (e.g., Manuel and Ned implement the network, but Kera follows and can explain their implementation), and observers/consultants for a Venezuelan stream environment (e.g., Lisa's proposal that they add dogs to the environment). How students move between these figured worlds (Holland, Lachicotte, Skinner, & Cain, 1998) in a way that helps to develop and explore functionally explicit population models is a question for longitudinal analysis.

### A "Net Wall" Solution to Predation

In this and the following section, I analyze several selections from MLKN's work during the unit on population modeling. First (Segments 2 and 3), I examine their elaborated response as fictional consultants to Venezuelan farmers, in the form of a "net wall" that will serve as a mechanical barrier to predatory fish. The MLKN group sees this as a solution to the problem of losing all the guppies, which farmers need to control mosquito growth, to an exotic population of upstream predators (i.e., the wolf fish). Second (Segments 4 and 5), I examine their computational implementation of predation more closely, asking how their experiences during the unit may have contributed to a more sophisticated performance on the post test design challenge.

After successfully modeling the growth of a guppy population in captivity, the MLKN group chose an extension scenario in which predatory wolf fish were released up stream from the guppies' pond, and farmers later noticed that these guppies were disappearing. The group predicted that the guppy population would flourish in the stream environment before the arrival of wolf fish, then die out as guppies were eaten by newly arriving predators.

Engaging their fictional role as consultants to Venezuelan farmers, the MLKN group began working on solutions that would preserve the guppy population, eventually settling on Kera's proposal for a mechanical "net wall." In the following exchange, Kera reprises the idea of a net in which mesh openings capture wolf fish but allow guppies to swim through. By installing this net at the upstream boundary of the pond, she proposes they can catch and remove wolf fish before they reach the farmers' guppies (see Figure 1).

Figure 1. Kera (middle) animates the path of a guppy swimming through a hole in the net during turn 1 of Segment 2: ((R hand forms opening; L hand, fingers wiggling, traces through)). Lisa (right) forms her own version of the net with her hands as Manuel (left) looks on.

### Segment 2: Blocking the Arrival of Wolf Fish (5/18/98)

- 1 Kera: =Ok, this is (the idea with) the guppies. ((R hand forms opening; L hand, fingers wiggling, traces through)) And it goes sh:::, straight through the net. ((R hand holds opening; L hand traces in and sticks)) And the big fishes go... and they get caught=
- 2 Lisa: =Caught, yeh. And then, they=
- 3 Kera: =(hands grab at center then rise) You pull::: it up and then you take it out.
- 4 Lisa: But why should we pull it out?
- 5 Manuel: No::: [The stream is like fi::ve fee::t deep.
- 6 Lisa: [Do you know...?
- 7 Manuel: No not even five feet, three feet[... deep.]
- 8 Lisa: [Ok, ok, ok, come on.]
- 9 Manuel: You can just pick em out.
- 10 Lisa: So, yeh yeh, so, so it should be like... no no, we can't HIRE anyone to pick it out. It should just like, flow::: naturally. Stuff like that, you know? You know, cause see the [guppies
- 11 Kera: [You gotta pull it out!
- 12 Lisa: No... they won't be CAUGHT in there, cause they're like, HUGE, ok? The hole will be this big.

In this first selection of work from the classroom, several phenomena are important for understanding how students shift between representing and represented worlds. First, a world of Venezuelan streams, farmers, and interacting fish populations is densely inhabited by members of the MLKN group. They literally construct the stream, fish, and a mechanical barrier in the gestural stage between Kera and Lisa, as Manuel reaches in from "downstream." Fish, the stream, and human actors are all

animated (Goffman, 1979; Ochs, Jacoby, & Gonzales, 1994) within this shared space.

Second, while the technical details of the “net wall” barrier are still underway, the importance of isolating guppies from these predators is clearly their emergent goal. Animated from the perspective of a consultant to Venezuelan farmers, this is a response to the consequences of predation, now articulated with the developing notion of a habitat that has semi-permeable boundaries.

The importance of predation in MLKN’s consulting proposal becomes clear later during this class meeting, when the group calls me over to discuss the boundaries of the stream environment. When I ask about the effect of their “net wall” on a graph of the guppy population they had drawn earlier, Kera starts a conditional response (Segment 3).

### Segment 3: The Graphical Shape of Predation (5/18/98)

- 1 Rogers: The graph of the guppy population. Manuel thinks its gonna continue to... [be wavy] and you all think its gonna go down and then [come back up.
- 2 Manuel: [Be wavy.]
- 3 Lisa: No we=
- 4 Kera: =It depends. ((points to drawing of stream in notebook)) Are there still, like... wolf fish in here that are eating the guppies?
- 5 Rogers: Um[:: you can
- 6 Kera: [If there is, ((traces upward path)) then its gonna go a little wavy. But if NOT, then the guppies are just... gonna have their own... ((points to computer)) Like before, when... like our other, um... thingie? (You know what I'm talking about?) [Cause the guppies are living alone, and they're gonna die and (inaudible)
- 7 Rogers: [Ok... I mean if you killed, if you get rid of ALL the wolf fish... then the guppies should... recover with no trouble.
- 8 Kera: =Yeh.
- 9 Rogers: =If there's still some wolf fish, [the wolf fish are gonna continue to grow and stuff.
- 10 Kera: [Then they're gonna ((hands trace oscillation))

According to Kera (turn 6), if any wolf fish get through the net wall the graph of the guppy population will “go a little wavy.” This is because “there’s still wolf fish in there eating them,” as she mentions several times. But if the net wall successfully closes the pond to wolf fish, then guppies will grow in isolation “like before” (i.e., referring to their earlier model of guppies alone in the pond).

Another point is important for understanding how students begin to coordinate movement between representing and represented worlds. Kera’s conditional explanation crosses worlds in the sense that shapes in the

representing world (i.e., graph shapes coming out of their “thingie”) depend upon conditions in the represented world (i.e., the passage of fish through a net opening). As the beginning of an activity system that was intended by the curriculum, types of outcomes, as graph shapes, are being associated with types of models, as determined by their assumptions about habitat (i.e., is the pond open or closed to exotic predators) and relations between populations. And critical to a broader understanding of modeling as such an activity system, results are seen to depend upon starting assumptions.

### Implementing and Exploring Predation in an Integrated Model

The “net wall” consulting proposal is an elegant solution to an emergent design problem, and it works at several levels. Guppies will be preserved for rice farmers, since the wolf fish will be blocked from moving down stream. And this can be done without killing any of these predators. As these students have elaborated the fictional world of the task, this will also keep upstream Venezuelans happy (i.e., those who, according to Lisa, must own wolf fish). Up to this point, the group’s work on this proposal is closely tied to a qualitative understanding of the effects of predation. Yet they are far from a functional implementation in computational media that could produce the graphs in question. As Manuel announces at the beginning of their next class period, “Now how do we make it work?”

The three final conversational segments in this paper illustrate the kind of work these students undertook to construct a plausible (if not entirely correct) functional model of predation. In Segment 4, the group has already constructed a user-defined function that links Caribou/Wolf Fish and Guppies population nodes. With this stable network topology in view, they repeatedly adjust node parameters and run the model in an effort to produce a reasonable number of guppies. Just before this segment starts, Lisa complains that they have a “river full of not plants, not insects, but just fishes.”

### Segment 4: Opening Boxes and Adjusting Parameters (5/19/98)

- 1 Lisa: It’s not enough! As long (as you go over) ten thousand ((changes Caribou/Wolf Fish births to 30% every month)) (inaudible) per cent.
- 2 HT: ((huge positive population value for Guppies))
- 3 Lisa: It's still a lot. (inaudible) about guppies. Yeh, that's the problem.
- 4 Manuel: Yeh, see, but the special two is gonna, do (3 sec)
- 5 Lisa: Alright. Could you guys explain this to us? hh
- 6 Manuel: Uh, explain what?
- 7 Lisa: What's a... special two.
- 8 Manuel: Special two is like when you die because of the caribou.

- 9 Lisa: OH! Really?  
 10 Manuel: Yes.  
 11 Lisa: ((mouse circles over Special 2/Predation node)) Oh this is eighteen? And um... how many guppies do they=  
 12 Manuel: =No, let's do three... times thirty is... thirty, ninety. So its caribou times ninety. ((Lisa changes Special 2/Predation)) Every month, and (then) go... That's it, just... Go to build, go to the thing that says build. Then go to the end.  
 13 HT: ((huge negative population value for Guppies))  
 14 Lisa: Negative? [That's a little too (much), yeh.]  
 15 Manuel: [Oh ok ((sighs))] Now we need to reduce the births. Go to births. No don't touch that, do the births. Reduce the births to ten percent every month.  
 16 Lisa: ((changes Caribou/Wolf Fish births to 10% every month))

With the work of implementing predation in these particular computational media well underway, several phenomena are worth noticing. First, Lisa has been adjusting model parameters without understanding how the predation function works. When she asks “you guys” (Manuel and Ned) for an explanation, Manuel describes what the node does from the perspective of Guppies: it is a type of death caused by Caribou/Wolf Fish.

Second, as Lisa looks inside this function and questions how many Guppies are eaten by Caribou/Wolf Fish (turn 11), Manuel proposes and Lisa executes a change in how the predation node is defined. Manuel’s proposal unpacks the monthly value into a daily rate of consumption (i.e., 3 per day, times 30 days in a month, gives 90 guppies per Caribou/Wolf Fish per month).

This exchange is one of many in which students move back and forth between changing model parameters and running their updated model (these are called “Build” and “Play” modes in the interface) to produce a new set of population values. Over the entire series, each adjustment is sensible within the network topology of their model, but none of these changes produce an outcome that the group finds reasonable (e.g., negative assessments after turns 2 and 13). In the face of this stalled progress, Manuel recalls from their earlier research that overcrowding will cause the guppy birth rate to fall. He reduces this parameter and runs the updated model.

### Segment 5: Arriving at a Guppy Crisis (5/19/98)

- 1 HT: ((running Fast))  
 2 Lisa: Too much.  
 3 Manuel: [No:: its not gone into the e's yet. And it hasn't.  
 4 HT: [((Guppies value in population node rises for awhile, but becomes negative and ends with - 2.71826 \* 10^6 Guppies))  
 5 Manuel: ((opens a graph))

- 6 HT: ((graph shows Guppy population rising, then an extinction crisis part way into third year))  
 7 Manuel: Oh my [god:::  
 8 Rogers: [YES::::!  
 9 Lisa: Oh, it's so funny! [What?  
 10 Rogers: [Yes::  
 11 Manuel: Yes what?

Lisa begins to classify this as another unsuccessful run of their model (turn 2), but Manuel, who has been monitoring the value displayed in the Guppy population node, announces that the positive growth of guppies has not yet reached scientific notation. Then as they watch the interface, the value displayed in the Guppy population node goes hugely negative (i.e., the software automatically shifts into scientific notation) and Manuel opens a graph window (see Figure 2).

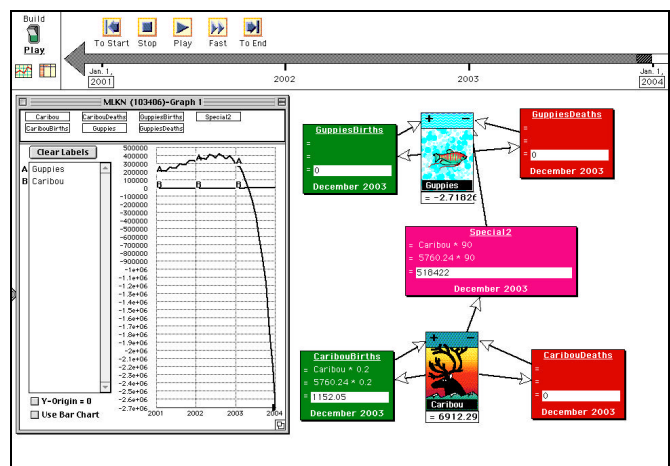

Figure 2. MLKN’s network model of predation and a graph showing an extinction crisis for Guppies during their third year in a Venezuelan pond. The predation node is at the center of the network (right), linking together Guppies (above) and Caribou/Wolf Fish (below).

This graph is striking for members of the MLKN group both because it shows an extinction crisis for Guppies, but also because it catches my eye (lines 8 and 10) as I was working with a group on the other side of the classroom. In a subsequent conversation about this network model and graph, Manuel insists on the influence of overcrowding in lowering Guppies births, while both he and Lisa recount their decision to increase the level of Caribou/Wolf Fish predation. As a final part of their modeling effort, they implemented Kera’s “net wall” as an emigration function, something that was suggested by their teacher as a general strategy for modeling negative influences on population growth.

### Discussion

By the end of the curriculum unit from which these longitudinal selections were drawn, the MLKN group had a sensible and fully implemented model of their consulting proposal, and its behavior was consistent with what they

hoped to achieve in Segment 3 (i.e., Kera's conditional explanation, lines 4 and 6). Since the net wall was implemented as a yearly reduction in the Wolf Fish population, these predators still made it into the pond environment. As a result, some level of predation was ongoing (i.e., this appeared as a scalloped or "wavy" graph of the Guppies population over seasons). But the mechanical "net wall," which they used to remove predators at a regular interval, reversed the outcome of their earlier crisis scenario (i.e., the Guppies population grew steadily over the duration of their scenario).

Predation, as a concept that can be implemented within these particular computational media, was one among several influences in a more complex model of the Venezuelan pond habitat. These influences included (with varying levels of correctness): (a) the starting value established over an earlier period in which Guppies lived alone in the pond, (b) the production of a Guppy crisis after the unregulated arrival of predators, (c) the regulated influence of predation during smaller time cycles within the "net wall" model, and (d) the idea of birth rate suppression during conditions of overcrowding in the pond.

These explicit model components, worked out through repeated cycles of adjusting parameters and holding outcomes accountable to students' qualitative expectations, provided a rich set of resources for their activities on the post test design challenge.

Across these selections from a longitudinal record of group work, more complex forms of coordination appear in the ways that students move between representing and represented worlds. While still far from a technical implementation of their model in computational media (Segment 2), students were able to develop an elegant solution to the problem of stopping or limiting predation. Their work included conversations carried out over a stream gestural stage. Also central in these conversations were processes of animation in which students spoke for (or as) fish in the constructed stream environment, Venezuelan farmers who had diverging interests in these fish, biological consultants concerned with finding a solution for the loss of guppies to predation, and middle school students working on a design project (i.e., as themselves).

As these elaborations of the represented world were carried into computational media, new forms of coordination were required (Segments 3 and 4). These included forms of explanation that linked computational media to aspects of worlds being modeled (e.g., Kera's conditional explanation associates graph shapes with physical events at the net wall in Segment 3). As the structural components of their network model were settled, members of the MLKN group also managed to establish cycles of modeling activity in which they adjusted parameters and compared results with their qualitative expectations.

Through these kinds of activities, students encounter the need to simultaneously look *at* and *through* the interface between representing and represented worlds. As they work through design problems, new conceptual understanding depends upon putting existing concepts and a broader set of representational technologies into coordination. In this sense concepts—as systems of activity—develop in ways that are inseparable from the representational technologies that implement them.

## Abstract

Recent models employing split neural networks have demonstrated that such architectures are effective for processing visual information. Furthermore, it has been shown that certain emergent strategies of processing are particular to these split architectures. We investigate one such strategy, the exterior letters effect, extending and generalizing it, and go on to discuss the implications that effects which are marked in split architectures bring to bear on lateralization and hemispheric specialization in human cognition.

## Introduction

What might be the advantages for bi-hemispheric processing of visual information? How does real-time high-density information management—such as that employed in the human visual system—cope with the fact that processing of the same thing is done in two halves, in two different places? What is it about the interaction between the hemispheres that allows for the apparently automatic co-operation between them? The answers to these central questions inform almost all other areas of cognition, and discussion of them abounds in the literature. And yet modeling studies on such aspects of gross brain morphology remain relatively under-developed, in spite of the nervous system's clear division centralised in two cerebral hemispheres. The complex relationship that comes into play between particular architectural features and general processing strategies, as well as distinct variations in the nature of the stimuli involved, can play a large role in empirical studies. Although clearly the techniques implicit in learning and execution of a task could be multifarious, models such as the one presented here assist in teasing apart the details of dual processing. Split-architecture connectionist models of cerebral function take as their motivation the well known psychology of the hemispheres, but open out onto a field that is largely uncharted.

## Background

When cognitive science per se was still in its infancy, studies on split brain phenomena were well underway (Gazzaniga, 1970). Work with patients who had undergone commissurotomy made it clear that the two halves of the brain could function autonomously when disconnected. The highlight of this discovery was the apparent inability of the right hemisphere to speak for itself in any real sense (Gazzaniga, 1983). Thus, a century after its initial stipulation, Broca's hypothesis gained even more secure footing. At the same time, the disparate activity resulting from two hemispheres out of touch with each

other, and, in particular, the speechless fumbblings of the right-side, gave a real sense to the distance neuro-anatomically (and thus perhaps experientially) that lay between the hemispheres. This was a distance that was unbridgeable through subcortical structures in the event that the corpus callosum was cut (although see (Sergent, 1987)).

Such severe unlinking is by no means the only evidence of separate identity of the hemispheres. The visual field is split vertically about the fovea in the retina, the right and left halves of the visual field projecting contralaterally into the cortical regions of the left and right hemispheres respectively (Sperry, 1968; Fendrich & Gazzaniga, 1989). Because of this, large scale degradations which are specific to one hemisphere, can lead to marked behavior in tasks reliant on apprehension of the entire visual field, as in cases of unilateral neglect. This deficit, afflicting right-hemisphere stroke victims, manifests itself commonly in the line-bisection task (Halligan & Marshall, 1998; Reuter-Lorenz & Posner, 1990), where the affected portion of the visual field is essentially omitted by subjects asked to designate the midpoint of a line.

The clear contralateral routing of information to opposite hemispheres by the visual system affords a lot of ground for research in normals as well. Key issues about general pattern recognition, symmetry and particularly face recognition can be addressed (Bruce, Cowey, Ellis, Perrett, 1992). Similarly, work in word recognition (e.g. Rumelhart & McClelland, 1981) must at some level be affected by the constraints of the visual processor; assuming the gaze is focussed around the midline of a word, interactionist accounts of processing have to deal at least with the transference of visual information to the locus of letter activation, if not simultaneous activation in different hemispheres.

Jordan's account of letter activation (1990, 1995) bears on the current study. With subjects focusing on a fixation point, stimuli of 200msec or less, containing letter strings of a fixed length but without a full complement of letters (e.g. "d\_k" is a two letter string of length four) were presented and masked with a null string of identical length. Subjects were asked to report the letters that appeared. Significantly, letters coming at the edge points of the string length were more robustly reported than letters that came from interior positions. This "exterior letters effect" (ELE) forms the vehicle for the current discussion on split architectures, and has already been successfully replicated in a connectionist network using a divided "visual field" (Shillcock and Monaghan, in press) each side of which projects separately to one of two hidden layers.

Reggia, Goodall, & Shkuro (1998) describe a word read-

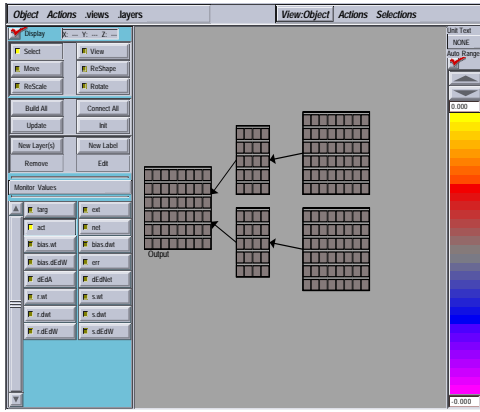

Figure 1: A typical instantiation of a split architecture network, shown here with the aid of the PDP++ graphical interface.

ing task which is learned by a split network. The task is a vehicle for gauging the effects different network parameters have on the degree of lateralization in the fully trained net, lateralization being determined by a “winner take all” competition between two hidden layers given a single input layer. Other modeling work on lateralization deals with the nature of the respective topographies, in terms of cortical organization (Alvarez, & Reggia, 1998; Levitan & Reggia, in press), while elsewhere Shestova & Reggia (1999) do relate a visual identification task to which our models bears an implicit resemblance, insofar as there is a “dual route” strategy for the reception of input.

### Qualitative data using split network

Shillcock and Monaghan (in press) describe a network in which the input field and the hidden units are split in two. With a network similar to that pictured in Figure 1, they present lexical input to the network, but include a positioning technique which allows the four letter words to move across the visual field, being presented in any one of five positions (from occupying only the left hemi-field to occupying only the right hemi-field, passing through the midpoint, where two letters of the four are projected to each side, halfway). It is at root this method of data presentation that ensures that the split net can and will develop a strategy for solution that is not found in the non-split control.

This effect, which relates to Jordan’s work as described above, manifests itself as a diminished reliance in the trained network on the interior letters of words, with a related robustness for recognition for letters in word-final and word-initial positions. Such networks seem to exploit the exterior letters to a greater extent than the nonsplit networks. We claim that the preferential treatment of the exterior letters is provoked by the manner of presentation and the current study is intended to expand upon this idea.

To sum up Shillcock and Monaghan’s findings: there is an ELE, comparable to that found with human subjects, demonstrated by their model. After training the networks with a split architecture showed a significant advantage in recognition of the exterior letters when degraded stimuli consisting of the original words with either the interior or exterior letter pair

“masked” with an ambiguous activation pattern. This finding was true in their study for all positions across the two visual fields. The study was slightly limited however; only four-letter words were used. These are a special case, containing two interior and two exterior letters. Below we explore the affect in the six letter case, also expanding on the criteria used to measure the effect.

## Modeling with a Split Architecture

Rarely are claims made that align connectionist models directly with cellular components of the cortex, upon which the design and operation of simulated neural nets may nevertheless be based.

This caveat is even more salient within the split architecture paradigm, each of the hidden layers ostensibly standing for an entire hemisphere to which input is projected. Other things being equal, it is important to avoid such direct correlations between the neural level and the grain of the model.

## Experiments

Two experiments were performed. For each one, a number of different simulations were run using split and non-split network designs. Each simulation was repeated 10 times and the results all reflect averages for the 10 runs. Subsequent tests using degraded stimuli employed each of the 10 trained nets for that class, the results again being averaged. Details of the nets and the stimuli are given below.

### Materials

A series of simulated neural networks, employing a back-propagation learning algorithm, was trained using the top 60<sup>1</sup> four and six letter words of English respectively. Also used was a list of 60 random strings of the same length<sup>2</sup>. The words were coded following the system of Plaut and Shallice (1994), assigning 8-bit features to each letter, each feature representing an aspect of letter orthography such as “contains closed area” etc. The coded words were then presented to the network through a shift invariant identity mapping (SIIM) task which maintains the integrity of the stimulus organization, while moving it sequentially along the input window. Input nodes that fall outside the location of the word at any time have activation zero, as do the inactive bits within the eight bit feature vector of each letter. The vertical split in the input reflects that of the fovea and thus, as a word is repeatedly presented to the network from all possible positions across the input, it crosses from one “visual hemifield” to the other, activation being redirected to the associated hidden layer accordingly.

Separate networks were used for the four and the six letter tasks, but the number of hidden units, 20, remained the same in each case. Nets not possessing a split hidden layer were used for a control task in which a simple visual field (containing the same number of input units as the non-split network). Networks featured full feed forward connectivity between the layers, save in the case of the non-split models,

<sup>1</sup>Ranking of the words was based on frequency counts from the celex lexical database.

<sup>2</sup>The distribution of letters in these strings was absolutely flat, in opposition to the skewed frequency counts for high frequency words of English.

Figure 2: Comparison of nonsplit and split models when networks trained to recognize a set of random strings are fed degraded stimuli, where only the exterior letters are present. The error for the exteriors in the split model is much diminished.

in which the connectivity between the input and hidden layers underwent a random pruning of half of the connection. This was to ensure that the network’s power was consistent with its split counterparts, network power being directly proportional to number of weighted connections.

For all simulations the PDP++ Neural Nets software from CMU was used, running on an Ultra 5 work station.

## Results

### Experiment One: Replication of previous Results

In attempting to replicate the exterior letter effect that Shillcock and Monaghan showed, we trained split and non-split networks on the English and non-word stimuli. As their simulations mirror Jordan’s recognition task for exterior letters, and this involved the presentation of degraded or masked letter strings to trained nets, we used a similar technique. However, it is worth pointing out that we also found a general advantage in *word* recognition for the split networks. This, of course, relates to the size and nature of the lexicon and overall error at the output layer, whereas the letter recognition task is defined in terms of individual letter positions.

On the individual letter scores, for stimuli in which the interior letters were rendered ambiguous, Shillcock and Monaghan found an effect similar to Jordan’s empirical finding, namely that recognition of exterior letters was favorable in such conditions, but significantly more so when the network employed a split architecture. This preference is seen in Figure 2 for non-words and Figure 3 for words. Paired t-tests (two-tailed) checking relative error of exterior letters across networks ( $df = 19$ ) gave  $t = 14.73, p < .0005$  for the study in non-word strings and  $t = 23.32, p < .0005$  for that involving English words, a highly significant effect representing an advantage for the split net in both cases.

Rather than the specific presentation of degraded stimulus that Shillcock and Monaghan demonstrate, to generalize the effects of the split architecture, if they are indeed robust, a more general technique is helpful. The effects of masking letter pairs in strings becomes inordinately complex with

Figure 3: Comparison of nonsplit and split models when networks trained to recognize the English word set are fed degraded stimuli, where only the exterior letters are present, and the interiors masked.

strings even of 6 letters, as we later found (five types of masking means at least a 10 way comparison of masked *on each network*) and generally, we would like to find a more all-encompassing and straightforward view of network behavior, in terms of letter position error after training, for example. To this end we compared the two models, without using masked words.

However, although we were able to replicate and even generalize Shillcock and Monaghan’s findings to a degree, by using degraded stimuli, we found that the effect itself did not significantly cross over into analysis of error levels by letter position as a whole, as Figure 4 shows.

### Experiment Two: Extension of ELE

In the second experiment, our attention was directed to the networks’ performance on the learning task with the six letter stimuli. Again, training consisted of learning over all positions in the visual field, with two different stimulus sets; the top 60 six letter words of English and 60 pseudo words, or random letter strings.

While in the case of the four letter stimuli no significant difference could be demonstrated using error by letter position, for the six letter case there was indeed a notable difference in network performance as seen below. Figure 5 shows the error for each letter position after non-split and split networks had both been trained on the non-word stimuli. In this case a fairly significant drop in error was registered. Taking the difference in error between exterior letters and their adjacent interior letters, we then compared the differences in these (i.e. has the network error dropped significantly for one of the networks on the exterior letters?).  $df = 9$  for each of the following two tailed t-tests: the word initial pair, for each network,  $t = 6.64, p < .0005$ ; the word initial pair in the split network compared with the word final pair in the non-split network,  $t = -3.47, p < .007$ ; the word final pair in the split network compared with the word initial pair in the non-split network  $t = -2.49, p < .034$ ; and the word final pair for both networks  $t = 4.65, p < .001$ . These figures in the main corroborate the story told by the graph: that the split network

Figure 4: Comparison of nonsplit and split models for the top 60 4 letter words of English. The error is registered after 400 training epochs. Although the error drops across the board for the split model, it does so uniformly, the exterior letters showing no advantage (the best result from 4 separate interior-exterior letter error comparisons between different networks architectures, using a two tailed t-tests,  $df = 9$ , gave  $t = -2.89, p < .018$ )

purchases more success using outside letters than the non-split network. This is statistically clearest for the first and last of the above comparisons, where the only difference was the network architecture (cross word comparisons, e.g. word initial with word final, admit interference from the stimuli). A similar comparison within each network (i.e. seeing if there was a significant drop in performance between interior pairs and exterior pairs not linked to a change in network architecture) yielded,  $t = .97, p < .359$ , for the non-split net,  $t = .54, p < .603$ , for the split, or, no difference.

Figure 6 shows the results for the different nets after training with the English word stimuli. As above,  $df = 9$  for each of the following two tailed t-tests: the word initial pair, for each network,  $t = 6.30, p < .0005$ ; the word initial pair in the split network compared with the word final pair in the non-split network,  $t = -12.07, p < .0005$ ; the word final pair in the split network compared with the word initial pair in the non-split network  $t = -6.81, p < .0005$ ; and the word final pair for both networks  $t = 2.84, p < .019$ . The significant dip in the error of exterior letters reiterates the trend shown in the graph. Of particular interest here is the form of the “arch” in the error by position of the split network, as well as the quasi-sinusoidal effect the non-split net seems to find when presented with the English word strings. These topics are taken up in the general discussion.

## Discussion

In this study we have performed experiments with a series of split and non-split neural networks. The results re-affirm the main finding of Shillcock and Monaghan, that a difference in network performance is based on the architecture, split or non-split, that that network employs. Shillcock and Monaghan’s model produced an ELE, which says exterior letters of strings are favored in conditions of stimulus degradation. This effect was demonstrated by them under very spe-

Figure 5: Comparison of nonsplit and split models for 60 random strings of 6 letters each. The error is registered after 400 training epochs. See text for details.

Figure 6: Comparison of nonsplit and split models for the top 60 6 letter words of English. The error is registered after 400 training epochs. See text for details.

cific conditions, which we were able to generalize as holding across the board for degraded stimulus<sup>3</sup>. The effect, a large drop in relative error by the split network for exterior letters only, is clearly seen in the corresponding figures (2 and 3). We tried but were not able to extend Shillcock and Monaghan’s results still further using simple error monitoring criteria, whereas with six letter strings the simple error metric not only revealed the ELE, but did so strongly.

In general, the ELE can be seen as the benefit of having a split hidden layer. With a single hidden layer, the mapping learned by the network for each pattern at each letter position is highly interdependent. Thus instantiations of letters at one position are much more likely to be conflated with their immediate neighbors. What a separate layer for each visual field buys is a foothold for representational independence. The same mapping is learned in either case, but with

<sup>3</sup>It is worth noting that in their actual task, Shillcock and Monaghan read error at single presentation positions of input, as well as the corresponding letter position at output; that is, although they examined every position, we demonstrated the cumulative effect of the error at different positions.

the split network, error back-propagated from the output to hidden layers during learning brings each hidden layer into line with the other through an indirect coordination. Thus a modicum of independence in each layer is retained, and this is used as collateral against an investment, or specialization, that that layer makes in direct proportion to the input it is exposed to. And this input favors, in the case of each hidden layer, the exterior letters of the stimulus, by simple fact of relative exposure (interior letters disappearing across the “fovea” and into the other hemi-field sooner for every pattern presented). This potential “separateness” for marginal phenomena (i.e. exterior letters) licenses, amongst other things, the robust behavior in the face of degraded input the split network demonstrated.

Other questions remain, however. For example, although for the six letter case we were able to show preferential learning for exterior letters just by monitoring error by letter position, the four letter case yielded no such view. A possible reason for this is network competence in terms of the capacity of the hidden layer to find a secure mapping from input to output. The total number of hidden units was the same in both nets; yet the six letter strings required not only a larger input area (two visual hemi-fields of *six*, as opposed to four, letters each), but they also constituted a much larger input set in general, as each word appeared in each possible position (five for the four letter model, but *seven* for the six letter case). Thus at the lower end of the extreme, the smaller net manages its quarry rather elegantly, the residual shape of the error by letter (Figure 4) probably reflecting nothing other than the structural regularities present in English orthography. When this competence envelope is pushed, as in the case of increasing the task load on the hidden units with the introduction of a six letter mapping, the hidden layer is forced to resort to economic measures, visible as the ELE. Indeed, this would provide some explanation of why, at the four letter level, the ELE can only be detected with finer method, the presentation of corrupted input.

If the effect is a conflation of these two trends, then that goes some way to explaining the “arch” of the split bars in figure 6: the pressure on the net to retain as much as it can means a sacrificing of the representations of interior letters in favor of the exterior representations which are easier for each hidden layer to maintain. The contrary shape of the nonsplit network in the same figure suggests that it needs to resort to a different strategy<sup>4</sup> in order to degrade gracefully under the increased weight of the six letter task.

These suggestions form but a part of a larger set of topics to which modeling with a split architectures gives rise. There are many others besides, not the least of which is a retention of the intuitive notion known as “modularity” at some level in the brain. At one time, connectionist models threatened to rule out the idea of “separate parts” altogether. The current study is one which demonstrates the integration of two concepts: the benefits brought by separation—e.g. the independence of the hidden layers as a means of exploiting presentational regularities, like exposure to exterior letters, which are themselves brought about *for free* through the relation-

<sup>4</sup>Perhaps one not unlike taking English C-V-C phonological regularities, or rather the way they manifest in orthography, as a template for resolving input.

ship that obtains between the model and the environment; and the importance of concentration, as that of the units within the hidden layers, without which the error driven learning of such problems would not be possible at all.

# Eye-Tracking and Conceptual Combination

Dietmar Janetzko

## Abstract

Processing conceptual combinations has been shown to be based on interactive activation of the concepts involved (Coolen, van Jaarsveld, & Schreuder, 1993). In this paper an approach for investigating conceptual combinations of nouns in an online way by using eye-tracking data is described. Words fixated in a compound-production task form a sequence of symbolic data that can be analyzed by a psychometric method called knowledge tracking (KT) that is based on Markov processes. Empirical evidence has been found that conceptual combinations assessed as medium acceptable attract eye movements more frequently than other ones (especially clearly acceptable or clearly unacceptable conceptual combinations).

## Introduction

Understanding compounds is an ubiquitous cognitive process. Many languages are rich in compounds, and conceptual combination is one of the most important ways of forming new concepts. Currently there are five major theories of concepts: the classical approach, the prototype theory, the exemplar approach, the theory-based model, and the theory of psychological essentialism (Hampton, 1998). It is, however, well known in the literature on concepts that none of these theories provides a convincing explanation to a key issue encountered when processing concepts: conceptual combination. Regarding prototype theory of concepts, for instance, Osherson & Smith (1981, 1984) made evident that there is no generally applicable function that maps the prototypes of PET and FISH to the prototype of the resulting compound PET FISH. However, in many languages – including, e.g., German – conceptual combination is a basic mechanism in both generation and understanding of natural language. In a word: while previous work on concepts had a narrow focus on simple concepts, it is now generally accepted that a theory of concepts can not do without a theory of compounding and methods to carry out empirical investigations accordingly.

There are two general strands of theories that react to the failure of the major theories of concepts. One of these strands has a clear semantic orientation. Theories in this tradition seek to explain conceptual com-

bination by referring to the meaning of compounds. A case in point is the concept-specialization theory (Murphy, 1988), which regards conceptual combination like HOUSE BOAT as a refinement or specialization of the more general concept BOAT. The other strand of theories on compounds has a more syntactic orientation and is rooted in linguistics, in particular in the syntax of words (Selkirk, 1982). Work on compounds in this tradition is based upon the observation that there are striking parallels to fundamental phenomena well known in sentence processing: First, we can generate and understand an unlimited number of compounds on the basis of a small number of simple concepts. Second, we can assess the well-formedness of compounds indicating that there is a “grammar of concepts” with some classes of concepts being more prone to form combinations with others. Recent work on conceptual combination tries to link both approaches, e.g., by analyzing semantic constraints to the compounding process (Keane & Costello, 1997) or by trying to establish a catalogue of semantic relations that link concepts together (Gagné & Shoben, 1997). The methods applied, however, can hardly capture the process of compounding, which has been shown to be highly interactive with the concepts involved in a compound activating each other mutually (Coolen, van Jaarsveld, & Schreuder, 1993).

While rating studies, analysis of thinking aloud protocols and reaction time studies clearly provide valuable insights into conceptual combinations they have difficulties to capture the interactive nature of processing conceptual combinations. We take the view that investigations of conceptual combinations could profit very much from methods that take the interactive nature of processing conceptual combinations into account. Information of this type establishes constraints concerning theories about conceptual combination.

The goal of this paper is to present a method that allows for an approach to online-investigation of conceptual combinations. The paper is organized as follows: First, we briefly report on previous work on Markov processes in cognitive science. Second, an overview of *knowledge tracking* (Janetzko, 1996; 1998; in press) is given. Knowledge tracking is a method that is based

on Markov processes and tailored to analyzing sequential symbolic data so that underlying cognitive structures become explicit. Third is an outline of an empirical validation study that shows more specifically how this approach can be brought to bear in empirical research. In particular, it is described in which way eye-tracking protocols are recorded while subjects build conceptual combinations. Finally, we discuss possible consequences for investigating concepts.

### Eye-Tracking and Markov Processes

The method used to analyze eye-tracking protocols rests on Markov processes, which are usually explained by referring to stochastic processes. A stochastic process is defined by a random variable  $X_n$ , a state space (potential values of the random variable), and transition probabilities between the states. Processes with every state depending on one or many preceding states are called Markov processes. Models based on Markov processes are quite common in fields like pattern recognition – in particular speech recognition – or DNA sequencing. In speech recognition, hidden Markov models (HMMs), viz., a special type of Markov process, are widely used. In HMMs, the states are unknown. Markov processes have also been used and adopted to the analysis of sequential data in cognitive science, in particular eye-tracking data (Suppes, 1990; Salvucci & Anderson, 1998). Here, fixations form a sequence of states, and the outcome of analysis is the identification of a model that accounts best for some observed sequence of states. When using a method based on Markov processes like knowledge tracking for analyzing cognition it is important to remember some of their defining features. In particular, the fact that this technique derives prediction in a strict history-based way has to be considered. For this reason, modelling controlled cognitive processes (e.g., goal-directed cognition like some types of planning or problem solving) via Markov processes raises severe problems. In this case, the phenomenon analyzed clearly conflicts with features of the formal model used. By the same token, modelling cognitive processes that underlie conceptual combination by analyzing eye-tracking protocols appears to be a suitable field for applying this type of models. The reason for this is that processing conceptual combination is (even for novel compounds) often extremely fast (e.g., Zwitserlood, 1994) and thus apparently not a goal-driven process.

### Knowledge Tracking

Knowledge tracking (KT) is a psychometric method that carries out a diagnosis of cognitive representations. Knowledge tracking can be used in confirmative or in a generative mode. The former provides a rationale to decide which of some candidate theories (concept structures) explains a sequence of data

best.<sup>1</sup> The latter may be taken to generate a concept structure on the basis of some start-up structures such that the newly generated structure fits to the data best (Janetzko, in press). We will, however present only the confirmative mode of knowledge tracking. Knowledge tracking rests on Markov processes models (Gardinger, 1990), but it is tailored to analyzing cognition. For instance, knowledge tracking provides more flexibility when calculating goodness of fit scores between empirical data and models. The models may be parametrized such that spreading activation in models is realized (Janetzko, in press). Furthermore, models set up within knowledge tracking are empirically testable, which is not the case in standard HMMs (Dijkstra & de Smedt, 1996).

### The Data: Sequence of Concepts

The input of data required by knowledge tracking is a sequence of symbolic data or concepts (e.g., the sequence of the concepts CAT, DOG, FISH, MOUSE etc.) that refer to the sequence of states in a Markov process. This kind of data may be obtained in eye-tracking studies, thinking aloud studies or studies of HCI (human computer interaction).

### The Theory: Relations and Structures

Knowledge tracking needs a theory to analyze sequences of symbolic data. To specify a theory we have to select one or many relations (e.g.,  $x$  is-a  $y$ ,  $x$  eats  $y$ ). On the basis of a relation we may then add a set of concepts that are taken to instantiate the relations. We end up with concept structures. A very simple concept structure can be described in a Lisp-like notation as (is-a (MOUSE MAMMAL) (HORSE MAMMAL) (SHARK FISH) (HERRING FISH) (FISH VERTEBRATE) (MAMMAL VERTEBRATE)) (cf. Fig. 1). Every network (e.g., hierarchies ontologies, partonomies, semantic networks) of concepts, be it a cyclic or an acyclic graph, can be called a concept structure. Other formalisms of knowledge representation like, e.g., schemas or scripts may also be redescribed as concept structures (Janetzko, 1996).

### Calculating Scores for Goodness of Fit

In KT, the theory, viz., one or many concept structures, is taken to calculate goodness of fit scores on the basis of sequences of symbolic data. The goodness of fit scores describe how well a sequence of symbolic data can be explained by a concept structure. Usually, a number of concept structures is brought to bear, all of which are competing as far as the explanation of the data is concerned. The structure that yields the best goodness of fit score will then be taken as the most suitable model for the cognitive structure explaining the

<sup>1</sup>By explanation we refer to the theory-based prediction of data.

Figure 1: Simple Concept Structure organized by the Relation is-a

empirical data. To compute scores for goodness of fit we have to transform all concept structures into transition probabilities. The technical details behind the calculation of the goodness of fit scores are described in Janetzko (1996; in press).

### Knowledge Tracking in five Steps

In sum, analyzing cognitive structures via knowledge tracking involves five steps:

- eliciting concepts and relations in the domain under study and setting up concept structures,
- recording empirical data (sequences of concepts), e.g., in eye-tracking studies,
- expressing the concept structures by transition probabilities; this is essentially the transformation of knowledge-based models into probabilistic models,
- explaining empirical data by using concept structures and calculation of goodness of fit scores
- selecting the structure that produces the best goodness of fit score.

Empirical validation studies carried out with data collected in human-computer interaction support the claim that the structure that gives the best account of the empirical data is in fact the structure that has dominated cognition while producing the data under study (Janetzko, 1996).

### Eye-Tracking and Conceptual Combination

We used a simple production task to record eye-tracking data while subjects were engaged in conceptual combinations. Subjects were presented with a computer screen where randomly simple German nouns were displayed in circular way (cf. Fig. 2).<sup>2</sup> Presenting the stimuli (nouns) in a circular way does not lead to one big path of overlapping eye-tracks. Nilly-willy, this would have been the consequence, if we had

<sup>2</sup>Translation (in clockwise order beginning with the concept at the 12 o clock position): Way, Fence, Castle, Garden, Guest, King

presented the stimuli in a list-form. Thus, a circular arrangement of the stimuli allows us to analyze the eye tracking more conveniently (cf. Fig. 2).

Figure 2: Arrangement of Concepts in Study 2

The subjects were requested to form noun-noun-compounds by using the concepts presented on the screen. In so doing, subjects had to rely on their eye-movements in order to combine concepts. In preliminary studies, it became obvious that some subjects throw one glance on the screen and rely then heavily on their working memory. Clearly then, in these cases the eye-tracking data are not indicative for the compounding process. To impede this memory-based strategy we introduced a secondary task: Subjects were requested to count backwards from 10 to 0. Whenever they were able to produce a compound they could pause during counting backwards, state the compound and start again counting backwards. Eye-tracking was recorded while the subjects were producing compounds. The fact that our subjects could combine concepts while doing a second task provides supporting evidence to our initial assumption that conceptual combination is not a goal-directed process. Every indication to the contrary would have raised problems concerning the application of a technique based on Markov processes. To balance out sequence effects, we set up a computer program that arranged the items randomly in a circular way for each trial. The presentation of items was never in one line (cf. Fig. 3). In this way, a possible bias towards reading from one item to the next one to the right was minimized. The whole procedure of recording the eye-traces is presented in Zugenmaier and Janetzko (1998). By presenting the stimuli in the way described we are in a position to record the eye-movements while subjects were carrying out the task of conceptual combination (cf. Fig. 4). Note that the sequence of eye-movements can easily be conceived as a sequence of symbolic data. Knowledge tracking allows us to analyze these data by calculating goodness of fit scores with respect to con-

cept structures.

Figure 3: Eye Movements recorded in Conceptual Combination

### Empirical Validation Study

The goal of the empirical validation study was to test the sensitivity of analyzing eye-tracking data with respect to underlying structures by using knowledge tracking. The general steps when applying this approach are as follows:

- Setting up concept structures that slip into the role of hypotheses used to analyze sequential symbolic data via knowledge tracking.
- Administering a compound-production task and recording the eye-tracking protocols.
- Converting the sequence of eye-movements into a sequence of symbolic data.
- Analyzing the sequence of symbolic data via knowledge tracking.

In the following sections we present the steps of this examination in more detail

#### Study 1: Specification of Concept Structures

The purpose of this study was to elicit acceptability scores for compounds that could possibly be of predictive value for eye-tracking behavior as examined in the next study. We used compounds built by the concepts that were also used in the following study.

#### Participants

Participants were 12 subjects (6 male, 6 female). According to a simple questionnaire administered before the investigation all subjects spoke German as their first language.

### Materials

Subjects had to assess the acceptability of 49 nominal compounds that were systematically produced by using the words AUTO, HAUS, PARK, TÜR, SCHIFF, STUHL, ZAUN (Translation: car, house, park, door, ship, chair, fence). All words used for conceptual combinations can be considered as simple German words that are very common according to word frequency indexes like CELEX.

### Procedure

On the basis of the seven concepts stated above all possible noun-noun compounds were produced (AUTOHAUS, AUTOPARK, AUTOSCHIFF etc.<sup>3</sup>) Some of these concepts are true lexicalized compounds that are in everyday usage of German speakers (e.g., HAUSTÜR, engl: housedoor) while other compounds sound rather odd for German speakers (e.g., ZAUNSCHIFF, engl: fenceship). Still other compounds are with respect to their acceptability between these extremes. The subjects assessed the acceptability of each compound on a 5-point rating-scale.

### Results

The results of study 1 was a simple classification into 5 classes of compounds that differed with regard to their level of acceptance. Moreover, each of these classes had an internal structure (Fig. 4), which was employed in the following study. For ease of presentation, we will just give an outline of the summary scores obtained in this rating study (cf. Tab. 1).

### Discussion

The acceptability ratings were transformed into concept structures that could easily be used by knowledge tracking as hypotheses required to analyze symbolic sequential data. If, for instance, we transform the class of highly acceptable compounds into a concept structure, we obtain a structure like (class-1 (AUTO HAUS) (AUTO TÜR) (HAUS TÜR) (PARK HAUS)). The meaning of this structure is simply that by using the nouns listed in pairwise brackets highly acceptable nominal compounds can be built. Similar concept structures can be constructed by the data that lead us to establish the other classes of compounds (Tab. 1).

#### Study 2: Compound-Production Task

In study 2 we collected eye-movement protocols (sequences of symbolic data) that reflect cognitive processes in a compound-production task. Before specifying details of study 2, it is important to see the linkage between both studies. By using the results of study 1 we have established concept structures that express the acceptability of compounds. In study 2 data

<sup>3</sup>In an agglutinative language like German compounds usually form a single compound word.

Table 1: Stimuli and results of study 1

Class	Compound	Rating
1	AUTOHAUS, AUTOTÜR, HAUSTÜR, PARKHAUS	$\bar{x} = 1$
2	AUTOPARK, HAUSSCHIFF, HAUSZAUN, PARKTÜR, PARKZAUN, ZAUNTÜR	$1 < \bar{x} \leq 2$
3	AUTOSCHIFF, HAUSPARK, PARKSTUHL, SCHIFFPARK, STUHLPARK	$2 < \bar{x} \leq 3$
4	AUTOSTUHL, HAUSAUTO, HAUSSTUHL, SCHIFFSHAUS, TÜRZAUN	$3 < \bar{x} \leq 4$
5	PARKSCHIFF, STUHLAUTO, STUHLSCHEIFF, TÜRHAUS, TÜRPAK, TÜRSCHIFF, TÜRSTUHL, ZAUNAUTO, ZAUNSCHEIFF	$4 < \bar{x} \leq 5$

are collected that will be analyzed by using these concept structures. In so doing, we can address the question whether or not acceptability of compounds is important for the eye-movement behavior. We hold the hypothesis that subjects will fixate more often compounds that are at a medium level of acceptability. This should be so since compounds considered very high or very low in acceptability should be analyzed more quickly. Hence they should lead to less pair-wise fixations. In contrast, compounds on a medium level of acceptability should be considered more intensively. Here, we expect a high rate of “jumping” back and forth between the concepts involved.

Figure 4: Concept Structures based on Study 1

The types of arrows indicate different levels of acceptance for compounds. Note that only the compounds of classes 1 and 2 are presented (Park=parc, Haus=house, Tür=door, Schiff=ship, Zaun=fence, Auto=car).

## Participants

Participants of study 2 were 5 subjects of whom 2 were female. According to a simple questionnaire administered before the investigation, all subjects spoke German as their first language.

## Materials

The 7 German words, the compounds of which have already been described in study 1, were also used in study 2.

## Procedure

Subjects had to produce compounds according to the procedure described above. Eye-tracking data were recorded by IVIEW, a video-based tool for eye-tracking by Sensomotoric Instruments that uses the corneal reflection technique. The analysis software allowed us to specify rectangular areas laid over the concepts to decide whether or not a word has been fixated.

## Results

The eye-movements were automatically recorded and transformed into a sequence of symbolic concepts (trace). This trace has been analyzed by using the five concept structures that were obtained as a result of study 1 (cf. Table 1). We carried out a descriptive analysis of the data. Figure 5 shows the results of our analysis (goodness of fit scores) on the y-axis. These were obtained by analyzing the eye-tracking data of five subjects across five classes of compounds that are lined up on the x-axis (cf. Fig. 5). The results provide supporting evidence to our hypothesis that highly acceptable (class 1) and also highly unacceptable (class 5) compounds do not lead to intensive processing while compounds that are on a mediate level of acceptability do. Clearly, we need further data to establish a firm empirical ground. However, the tendency of the data testifies to the usefulness of this method.

Figure 5: Analysis of Eye-Tracking Protocols via Knowledge Tracking

## General Discussion

The purpose of this study was to show the feasibility of knowledge tracking as a method to analyze eye-tracking in compounding. Knowledge tracking is a general method that can be taken to analyze each type of sequence of symbolic data on the basis of some concept structures (cf. Janetzko, 1998; 1999; in press). In our analysis of eye-movement protocols via knowledge tracking three aspects became apparent: First, the method employed gives a good indication of cognitive processes in conceptual combination. In particular, it is an online-method, and it thus provides insights into conceptual combination by measuring the effort put into this task. However, eye-tracking protocols especially when recorded in exploratory tasks like ours suffer from a bad signal-noise ratio. This is due to the fact, that subjects very often generate and test compounds. Second, we only applied concept structures that essentially express whether or not a compound is or is not acceptable. If knowledge tracking is used to investigate the knowledge used in compounding the concept structures applied have also to represent knowledge. This can be done, if we take compounding relations like *x is\_made\_of y* or *x causes y* (Gagné & Shoben, 1997) to analyze the conceptual combination. Third, we may assume that vast amounts of knowledge are applied in a task like the compound-production task introduced in this paper: Possible relations are tested, and analogues to well-known similar compounds are generated. For a more complete analysis of the knowledge involved in a task like this, a method is required that can tap the theories applied by a problem-solver once he or she forms a compound. To meet this requirement, we have developed a version of knowledge tracking that is no longer restricted to be a confirmative method. This type of knowledge tracking specifies the plausible bridging inferences that may be drawn between pairs of concepts in a symbolic trace. Then, it adds up these inferences to a theory underlying the production of the symbolic trace (Janetzko, in press).

## Acknowledgments

I like to thank Gerhard Strube for valuable comments to this paper. I am grateful to Marc Klinger, Oliver Jäschke, and Dirk Zugenmaier for the programming work put into this project.

# The Role of Mental Imagery in Understanding Unknown Idioms

Armina Janyan (ajanyan@cogs.nbu.acad.bg)

## Abstract

In studies of the cognitive processing of idioms, the role of mental imagery in understanding idioms remains a controversial issue. Cacciari and Glucksberg (1995) conducted an experimental study to investigate whether generating mental images of idioms can facilitate their comprehension. Their results appeared to reject both the possible connection between the literal mental image of an idiom and the figurative meaning of the idiom, and the facilitatory effect of mental imagery on comprehension. Our study aims at exploring the facilitatory role of mental images in understanding unknown idioms. We used a paraphrase verification task for transparent and opaque unknown idioms translated from foreign languages into Bulgarian. The results demonstrate that literal mental images of transparent unknown idioms can facilitate their comprehension in terms of error scores in a simple paraphrase verification task. No facilitation effect for opaque unknown idioms was obtained. This points towards a link between the literal mental images of transparent idioms and their figurative meanings.

## Introduction

The bulk of cognitive research on idioms is devoted to comprehension processes. Some have investigated the contribution of the literal and figurative meanings of idioms in the comprehension process, and whether both meanings are computed serially or in parallel (Needham, 1990; Estill&Kemper, 1982; Glass, 1982; Swinney&Cutler, 1979); other studies have shown that at some recognition point literal processing stops and the figurative interpretation becomes available (Cacciari&Tabossi, 1988; Tabossi&Zardon, 1993; Titone&Connine, 1994). Another research area explores the tenet that conceptual metaphors constrain or mediate our understanding of idioms (Gibbs&O'Brien, 1990; Nayak&Gibbs, 1990; Gibbs, 1992). Finally, researchers have also studied the strategies that people use to understand tropes and idioms, for example, using the semantics of the constituent words, analogies, metaphorical extensions, etc. (Cacciari, 1993; Flores d'Arcais, 1993). However, relatively little attention has been paid to the role of mental imagery in the process of understanding figurative language. In some theoretical frameworks, imagery is regarded as an important component

in discovering the figurative meaning of tropes and idioms (Lakoff, 1994; Paivio&Walsh, 1998), although experimental studies have produced contradictory results (Gibbs&O'Brien, 1990; Cacciari&Glucksberg, 1995).

Following Lakoff and Johnson's framework (1980), Gibbs and O'Brien (1990) argue that the meanings of idioms are motivated by conceptual metaphors. For example, the idiom *spill the beans* is motivated by the CONDUIT metaphor which specifies the conceptual mapping that THE MIND IS A CONTAINER and IDEAS ARE ENTITIES. Their claim is that people have conventional images and knowledge for the meanings of idioms. To test this, in Gibbs and O'Brien's experiment, subjects were asked to form a mental image of an idiom and describe it verbally. The results suggest that these images have a dynamic nature and people are able to determine the causes and consequences of the actions in them. The data obtained also confirm the expectation of a high degree of consistency in mental images for idioms with similar figurative meanings. Thus, Gibbs and O'Brien (1990) emphasize that conventional images are "unconscious, automatic, and independent of modularity" (p. 39). They do not propose any algorithm of constructing mental images for idioms but they investigate "the products of speakers' mental images for idioms as a way of discovering the knowledge and information that potentially motivate the figurative meaning of idiomatic phrases in English" (ibid.). Finally, they do not claim that people use mental imagery during 'normal' idiom comprehension given that idioms are processed very rapidly. It is children and non-native speakers of a language but not experienced speakers that may form mental images as a way of understanding idioms.

Contrary to the findings of Gibbs and O'Brien (1990), Cacciari and Glucksberg (1995) claim that the images associated with idioms do not reflect their meanings, moreover, forming mental images does not facilitate the comprehension of idioms. They argue that people cannot bypass the literal meaning when processing idioms and forming a mental image, and that it is much easier to form a literal image of an idiom than a figurative abstract one. In this case the images that reflect the literal meaning of an idiom could not refer to the underlying conceptual

metaphors and should interfere with the comprehension of the figurative meaning of an idiom. Thus, these “wrong” literal images would make comprehension more difficult. Note, however, that Lakoff (1994) does not claim that these conventional images must be figurative; on the contrary, they are rather “literal” and include our general knowledge about the world which maps onto the knowledge of the corresponding conceptual metaphor.

Cacciari and Glucksberg's (1995) study includes three experiments. In the first experiment, subjects were asked to give a paraphrase of the idiom, to form a mental image and describe it. Results showed that of the two -- literal vs. figurative -- predominantly images reflecting the literal meanings of the phrases were generated.

Cacciari and Glucksberg's (1995) second experiment explored the issue whether literal images can facilitate comprehension. They reason that if literal images reflect somehow conceptual analogies, then such images would facilitate comprehension; otherwise, if literal images are unrelated to figurative meanings, they would interfere with comprehension or, at the very least, make it more difficult.

Cacciari and Glucksberg (1995) used a sentence-verification task. Subjects were presented with a sentence which they read and then presented with a second sentence that was either a paraphrase of the first sentence or not. In a between-subject design, subjects either performed the verification task while also generating an image of the first sentence; or without generating images. The results show that verification times were longer when influenced by imagery. In addition, the longer times were not associated with a reduction of errors. It is worth noting here that the rate of errors for idioms did not exceed 3% in any of the conditions, although they used four different types of idioms: familiar transparent, familiar opaque, unfamiliar transparent, and unfamiliar opaque. One possible explanation for the strikingly low rate of comprehension mistakes may be that all idioms were in fact highly familiar since in the familiarity pre-test, subjects were explicitly asked to rate their frequency and not familiarity; alternatively, the idioms were semantically transparent.

Overall, Cacciari and Glucksberg's (1995) results obtained suggest that mental imagery interferes with comprehension and does not facilitate it whether measured by reaction time or by error rate, and literal images of idioms have nothing in common with figurative meanings.

In our view, however, forming literal mental images may facilitate the understanding of completely unknown idioms. If images involve general knowledge of the world, if they can be involved in understanding metaphors alongside linguistic knowledge, then understanding may be an interaction of several processes such as applying knowledge, reasoning, mapping, associations. This combination of processes does not necessarily mean that they entail an equally active participation in comprehension. The degree of involvement may depend on the idiom that is being perceived and its properties, as well as on individual experience and contextual factors.

Let us consider the cognitive processing of an unknown idiom. If the unknown idiom reflects a well-known situation, or if it requires reasoning, applying knowledge, or making associations, then it may be that a literal mental image of the idiom can facilitate the comprehension process. For example, consider the Russian idiom *плавает как монополи* (“swims like an axe”). One possible way to understand it is to imagine an axe in water and “see” the axe sinking immediately. The next step could be realizing that the idiom could be referring to a person who cannot swim. So, the concrete-literal mental image can, in principle, lead to an abstract-figurative meaning.

This path from the literal image of an unknown idiom to its figurative meaning, may certainly depend on what kind of idiom it is. Not all idioms have a literal meaning, hence, a literal image that could be created. Moreover, even if such images are easy to produce, not all imageable unknown idioms could thus be understood. For instance, it is hard to understand the Armenian idiom *if a donkey falls, it will break all its teeth* although it is absolutely cartoon-imageable but not transparent in meaning (the idiom refers to ‘a very rocky area’). So, if foreign/unknown idioms are to be understood, they should be semantically transparent and may include some culturally shared concepts. This study attempts to answer some of these controversial issues.

The main aim of the study is to investigate whether generating a literal image of an unknown foreign idiom can facilitate its comprehension. Facilitation here is measured by the error rate and not differences in processing speed. Cacciari and Glucksberg's (1995) line of reasoning that the two phrases to be compared would need to have the same coded representation is indeed convincing. Here an error is defined as failure to recognize the paraphrase of an idiom.

Another purpose of the study is to examine the differences (if any) in comparing an idiomatic meaning with either a literal paraphrase or with an idiomatic equivalent. Such differences may arise because a literal phrase is much more concrete and clear than an idiom. In the case of idioms, often the exact meaning is known but sometimes difficult to put into words, to explain in a succinct and precise form in a short period of time (an analogy with the recognition and naming of a picture). Moreover, idiomatic meanings are often semantically much richer than literal phrases, and idioms can readily map onto much more diverse situations than literal phrases. Hence, comparing the meaning of a known (or the possible meaning of an unknown) idiom to the overall idiomatic meaning of its equivalent would be different from comparing the meaning of an idiom with a literal paraphrase in terms of reaction times (RTs) and/or in terms of the error rate (in percentages).

This experiment examines the on-line processes of generating images, understanding idioms and comparing meanings with two kinds of paraphrases: literal and idiomatic. The method is similar to that used by Cacciari and Glucksberg (1995). The main difference is that unknown foreign idioms were used as target phrases. These idioms were translated from Armenian and Russian word-

by-word into Bulgarian. Subjects had to verify paraphrases under two main conditions, one with, and the other without forming a literal mental image of the target idiom (in a within-subject design). The following is an example of the experimental material (the set) and its translation.

**target idiom**

*чета проповед в ухото на глух*

(to read a sermon into a deaf person's ear)

**paraphrases:**

**related**

**idiomatic phrase** *преливам от пусто в празно*

(to pour from one empty place to another)

**literal phrase** *правя усилия безполезно*

(to make useless efforts)

**unrelated**

**idiomatic phrase** *хвърлям последния си коз*

(to throw down one's last trump card)

**literal phrase** *не си върша задълженията*

(to not complete one's duties)

## Method

**Subjects** A total of 80 subjects (28 males and 52 females) participated in the experiment. All were native Bulgarian speakers, university students. The age range was from 17 to 28. Subjects were paid for their participation.

**Design and Stimuli** A factorial 2x2x2x2 design was used, with RTs and rate of errors as dependent variables. The within-group factors were Imagery task (Imagery, Non-imagery), Source Language of the target idiom (Foreign, Bulgarian), Type of Paraphrase (Literal, Idiomatic), Relatedness of paraphrase to the target (Related, Unrelated). The stimuli consisted of the word-by-word translations of 30 foreign target idioms (16 Armenian and 14 Russian) and 30 Bulgarian target idioms. All target idioms had the form V(PP)NP, and the verb-form was in the first person, singular, present tense. 30 literal and 30 idiomatic paraphrases for the targets were used in the Related paraphrase condition, and 30 literal and 30 idiomatic phrases were used as "false" paraphrases, i.e., unrelated to the target. The average length (in words) of target phrases was 4.2, of literal paraphrases - 2.9, and of idiomatic paraphrases - 3.7 words. The selected foreign target stimuli did not include similes, and paraphrases did not include words semantically related to the targets.

All 150 Bulgarian idioms were selected after a pre-test with independent familiarity and frequency ratings using a 5-point scale (5 -- most familiar or most frequent, respectively). A total of 28 subjects participated in the pre-test. The age range was from 18 to 30. None of them participated in the main on-line experiment later. The idioms thus selected from the pre-test had the mean value of 4.3 for familiarity and of 3.2 for frequency of use.

**Procedure** 16 randomized lists of 60 sets of stimuli each were constructed so that each subject was presented with all the 60 target idioms and one out of four paraphrases. The

experiment was divided into two main parts, named Non-imagery and Imagery, after the two tasks. Every subject was run on both parts. In the first Non-imagery condition the procedure was the following. The target idiom appeared on a white background, at the center of the screen. Subjects had to read the idiom, decide whether they know it or not (familiarity decision) and press a corresponding button (Yes or No). Immediately after the response (zero inter-stimulus interval), a paraphrase appeared on a light grey background. Subjects then performed a phrase-verification task, i.e., they had to decide whether the meaning of the paraphrase matches the meaning of the target idiom, and press the corresponding button (Yes or No). Each trial began with a central black fixation marker ('+') for 500 ms and the inter-trial interval was 3 sec. The reaction time was measured from the onset of the stimulus (paraphrase) till the subject's response. After the first Non-imagery condition, subjects had a 5-minute break. In the second, Imagery condition, subjects had to read the target idiom, imagine it as a "picture" and press a Yes button immediately afterwards. The remaining procedure was the same as in the first experimental condition (Non-imagery), i.e., subjects performed a phrase verification task. Both experimental conditions started with 8 practice trials.

Every 60-trial list of stimuli was randomly divided into two subsets, consisting of 30 paired stimuli for each of the two experimental conditions (Imagery and Non-Imagery). The assignment of Yes and No values to the buttons was counterbalanced across subjects. The experiment lasted approximately 30-40 min. Subjects were tested individually in a sound-proof room. A Power Macintosh 6400/200 equipped with PsyScope software controlled stimuli presentation, timing, and response collection.

## Results and Discussion

The analysis was carried out by items averaged over subjects. RTs and responses for the phrase verification task were analyzed in a 2 (Imagery vs Non-imagery) x 2 (Foreign vs Bulgarian targets) x 2 (Literal vs Idiomatic paraphrases) x 2 (Related vs Unrelated paraphrases) analysis of variance.

### Analysis of Phrase Verification Task

**Reaction Times (RTs)** Main effects for all four independent variables on RT were obtained. There was a significant main effect of Imagery ( $F_{(1,420)}=37.91$ ;  $p<0.00$ ); the phrase-verification task took longer to complete in the imagery condition (mean response time of 2475 ms,  $SD=589$ ) than in the non-imagery condition (mean  $RT=2179$  ms,  $SD=537$ ). This may mean that the mental image of the target idiom interferes with the linguistic representation of the paraphrase which replicates the results of Cacciari and Glucksberg (1995).

A main effect of Source Language was also obtained ( $F_{(1,420)}=77.46$ ;  $p<0.00$ ). For Bulgarian target idioms, paraphrase verification took less time ( $MRT=2116$  ms,  $SD=506$ ) than for Foreign targets ( $M=2539$  ms,  $SD=578$ ).

Thus, phrase verification was significantly faster for the familiar-familiar pairs than for the unknown-familiar pairs.

The main effect of the Type of Paraphrase also reached significance ( $F_{(1,420)}=8.16$ ;  $p<0.00$ ). The mean RT for verification of literal paraphrases was shorter (2259 ms,  $SD=617$ ) than for idiomatic paraphrases (2396 ms,  $SD=542$ ). This may be due to the different lengths of the paraphrases and/or the less ambiguous meaning of the literal phrase compared with the idiomatic one.

The main effect of Relatedness of Paraphrase was also significant ( $F_{(1,420)}=14.72$ ;  $p<0.00$ ). The mean RT for the Related Paraphrase condition was faster (2235 ms,  $SD=602$ ) than for Unrelated (2420 ms,  $SD=552$ ).

A significant interaction between Source Language and Relatedness ( $F_{(1,420)}=18.60$ ;  $p<0.00$ ) was also found, i.e. the main effect of Relatedness of Paraphrase was not observed in the Foreign condition. Mean response times are presented in Table 1.

Table 1: Mean RTs (ms) for Source Language by Relatedness

	Bulgarian	Foreign
Related	1917 ms	2551 ms
Unrelated	2314 ms	2537 ms

The main effect of Relatedness is visible in these results as well in that the phrase verification task took less time when there was a real paraphrase (the phrase was related to the target). Note, however, that this effect holds only for the familiar Bulgarian targets. Relatedness did not make a difference to the processing of the semantic comparison between paraphrases and unfamiliar targets. Not surprisingly, the task was performed overall faster with familiar than with unfamiliar targets.

**Error Rate (%)** Three main significant effects were found. In the main effect of Source Language the familiarity (Bulgarian target) advantage was obtained ( $F_{(1,420)}=50.20$ ;  $p<0.00$ ); the error rate was lower for Bulgarian targets (12.5%) than for foreign ones (24.6%). The main effect of Type of Paraphrase ( $F_{(1,420)}=16.87$ ;  $p<0.00$ ) showed the advantage of literal paraphrases (15.3% error rate) over idiomatic ones (21.9%). The main effect of Relatedness ( $F_{(1,420)}=37.40$ ;  $p<0.00$ ) revealed fewer comprehension errors for unrelated paraphrases (13.6% of "false alarms") vs. related ones (24.0% of "misses"). These results may be partly explained by the fact that unrelated literal paraphrases were concrete and unusual to serve as possible paraphrases of idioms. Subjects may have chosen a strategy to reject these cases due to their obvious unrelatedness to the target idioms. No significant overall main effect of the Imagery factor was found.

The only significant interaction obtained was that between Relatedness and Source Language ( $F_{(1,420)}=5.06$ ;  $p<0.03$ ). Mean rates of errors are presented in Table 2.

Table 2: Mean Percentage of Errors for Source Language by Relatedness

	Bulgarian	Foreign
Related	16 %	32 %
Unrelated	9 %	18 %

Significant differences across all combinations of the four conditions were found (except for Bulgarian Related and Foreign Unrelated conditions). In both cases unrelated paraphrases were verified with better success than related ones. This again may be partially explained by the way the unrelated literal paraphrases were selected. Overall, paraphrases for Bulgarian target idioms were verified with a lower error rate than the foreign ones.

### Separate analysis by Source Language, Error Rate (%)

In order to reveal the contribution of imagery, a separate analysis over the two levels of Source Language was conducted. For Bulgarian target idioms, no effect was found but for Foreign target idioms, there was a main effect of Imagery ( $F_{(1,215)}=3.94$ ;  $p<0.05$ ). The Imagery condition showed an advantage (only 22% of errors) over the Non-imagery condition (27% error rate). The absence of the imagery effect on Bulgarian targets showed that imagery had no facilitatory effect on the processing of familiar idiom but it did on unfamiliar ones.

To explore the nature of the Imagery effect further, a post-test on the levels of transparency of foreign idioms was carried out.

**Post-test** The 30 foreign idioms were randomly assigned to two separate questionnaire lists, with each idiom placed on a separate sheet of paper. Subjects were 26 native Bulgarian speakers who were asked to guess the meanings / paraphrases of these unfamiliar idioms. There was no time limit in completing the task. The responses were evaluated for accuracy by two independent judges and averaged as the percentage of correct answers for each idiom. On this basis, idioms were categorized as transparent (correct guesses exceeding 60%) and opaque (lower than 60%). As a result, 15 transparent (Mean=74%,  $SD=14$ ) and 15 opaque (mean=20%,  $SD=14$ ) idioms were identified.

### Analysis of Phrase Verification for Foreign targets only

Responses and RTs for items averaged over subjects for the phrase verification task were analyzed in a 2 (Imagery vs Non-imagery) x 2 (Transparent vs Opaque) x 2 (Literal vs Idiomatic paraphrases) x 2 (Related vs Unrelated) analysis of variance.

**Reaction Times (RTs)** The overall main effect of imagery on RT was repeated here as well ( $F_{(1,207)}=19.79$ ;  $p<0.00$ ) with subjects being faster in the Non-imagery condition (2375 ms,  $SD=503$ ) than the Imagery (2706 ms,  $SD=601$ ) one. A significant two-way interaction of Transparency and

Relatedness ( $F_{(1,207)}=15.22$ ;  $p<0.00$ ) was also found. Mean response times are presented in Table 3.

Table 3: Mean RTs (ms) for Transparency by Relatedness

	Transparent	Opaque
Related	2364 ms	2731 ms
Unrelated	2647 ms	2432 ms

There were significant differences across all combinations of the four conditions. It is important that a similar trend is observed here in verifying familiar-familiar pairs and transparent unknown-familiar pairs. In both cases Related paraphrases were verified faster than Unrelated (cf. Tables 1 and 3), with the implication that transparent idioms may be treated as familiar, and similar mechanisms may be involved in their processing in the verification task. For Opaque idioms, the verification time changed in the opposite direction.

**Error Rate (%)** Four significant main effects were found on the rate of errors as a dependent variable: Type of Paraphrase ( $F_{(1,207)}=13.91$ ;  $p<0.00$ ), Relatedness ( $F_{(1,207)}=37.36$ ;  $p<0.00$ ), Imagery ( $F_{(1,207)}=5.38$ ;  $p<0.02$ ), that were replications of the previous discussed, and Transparency ( $F_{(1,207)}=16.65$ ;  $p<0.00$ ) that showed lower rate of errors for transparent idioms than for opaque (20% vs 29%). Two significant two-way interactions were also obtained: Transparency by Relatedness ( $F_{(1,207)}=21.73$ ;  $p<0.00$ ), and Paraphrase by Relatedness ( $F_{(1,207)}=5.97$ ;  $p<0.02$ ). Two significant three-way interactions, Imagery by Transparency by Relatedness ( $F_{(1,207)}=4.38$ ;  $p<0.04$ ) and Imagery by Transparency by Type of Paraphrase ( $F_{(1,207)}=4.03$ ;  $p<0.00$ ), are shown in Figures 1 and 2, respectively. The mean error values for every condition are shown in Tables 4 and 5.

As Figure 1 and Table 4 demonstrate, there was a significant shift in the rate of errors for transparent idioms in the Related paraphrase condition (29% in the Non-imagery vs 14% in the Imagery condition). No imagery effects were found on either semantically transparent or opaque idioms in the Unrelated paraphrase condition, as well as on the opaque idioms in the Related paraphrase condition. The lack of significance and rather low rate of errors in the Unrelated paraphrase condition can be partially attributed to the way the stimuli for the literal unrelated phrases were selected.

Figure 1: Imagery by Transparency by Relatedness interaction

Table 4: Mean Error Rates for Imagery by Transparency by Relatedness

	Transparent		Opaque	
	Image	N-image	Image	N-image
Related	14 %	29 %	41 %	43 %
Unrelated	18 %	18 %	14 %	19 %

The facilitatory role of imagery (Figure 2, Table 5) was also observed in the verification task results particularly for idiomatic paraphrases of transparent idioms. In the Imagery condition the rate of errors was reduced down to the level of literal paraphrases in both Imagery and Non-imagery conditions. Literal paraphrases of transparent idioms were verified with the same success (low rate of errors) as paraphrases for familiar Bulgarian target idioms (Table 2). There was no imagery effect on opaque idioms although a trend toward improved comprehension in the Imagery condition may be observed in the case of literal paraphrases.

Figure 2: Imagery by Transparency by Type of Paraphrase

Table 5: Mean Error Rates for Imagery by Transparency by Type of Paraphrase

	Transparent		Opaque	
	Image	N-image	Image	N-image
Idiomatic	19 %	32 %	33 %	32 %
Literal	13 %	16 %	22 %	30 %

## Conclusion

The main goal of this study was to explore the facilitatory role of mental images in comprehending unknown idioms. Results have shown that indeed, constructing literal images of unknown idioms can help in understanding the idiom, not in terms of faster processing but in terms of decreasing percentage of mistakes in recognizing a paraphrase of the idiom. This effect is particularly salient in the processing of semantically transparent idioms and is stronger when unknown idioms are compared with an idiomatic paraphrases and not with literal ones. Furthermore, the contribution of mental imagery is such that it produces fewer mistakes of the “miss” type for transparent idioms, i.e., subjects improve their ability to recognize a real paraphrase as equivalent in meaning to the target. Semantically opaque idioms, on the other hand, seem to be indifferent to the imagery task, though a trend toward better

understanding may be observed in the case of literal paraphrases.

Another aim of the study was to test whether different types of paraphrases (literal and idiomatic) could influence the degree of understanding unknown idioms. The hypothesis was that since idioms may be viewed as semantically broader or more vague than literal paraphrases subjects would more readily match idiomatic paraphrases with unknown target idioms than literal paraphrases. As a result they would make fewer mistakes with idiomatic paraphrases than with literal ones. This hypothesis was rejected by the results which revealed the opposite picture - subjects made considerably fewer mistakes with literal paraphrases than with idiomatic ones. One possible explanation derives from the same feature of idioms, i.e., their semantic and 'situational' broadness which may have caused subjects to reach a negative decision on the verification task much more frequently than necessary, hence, these results.

To conclude, the results show that transparency plays only a minor role in comparison with familiarity, and that familiarity itself is only useful as a concept in its own right, not by proxy of frequency. The results also demonstrate that constructing a literal image helps our understanding of unknown transparent idioms whether by unconscious applying general knowledge of the world, unconscious reasoning or some other process involved in understanding. Thus, there exists a close link between figurative meanings of transparent unknown idioms and their literal mental images.

This study, however, has helped to explain further the mechanisms of comprehension of unknown idioms and the role of mental imagery in this process. It remains to be seen whether mental imagery facilitates not only the comprehension but also the process of learning and retrieving from memory of figurative speech.

## Abstract

This study investigated whether collaborative learning leads to the construction of shared knowledge among participants. In this study, college student pairs collaborated to learn a biology text on the human circulatory system. The results showed that pairs shared not only correct knowledge that was presented in the text, but also incorrect knowledge and/or knowledge that had to be inferred from the text. In addition, pairs who interacted more shared significantly more inferred knowledge than those who interacted less did. Taken together, these findings indicate that interaction enables dyads to construct new knowledge and their representations tend to converge after collaboration.

## Introduction

Traditional cognitive psychology has mainly focused on how information is processed within individuals' minds, that is, how individuals represent stimuli, learn new things, solve problems, make a discovery, etc. As a consequence, even when people learn collaboratively, learning has been mainly defined in terms of what individuals learn and not much attention has been paid to the collaborative aspect of knowledge construction that is shared by both partners. This study to be described below was an attempt to examine whether a shared activity such as collaborative learning would lead to the construction of shared knowledge.

Learning often occurs in the context of a group or community, and many researchers propose that learning, a *cognitive* activity, is a joint *social* activity (Lave & Wenger, 1991; Levine, Resnick, & Higgins, 1991; Resnick, Levine, & Teasley, 1991; Rogoff, 1998; Tudge & Rogoff, 1989; Vygotsky, 1978). To say that a cognitive activity is a social activity sounds contradictory at first, but the notion of "socially shared cognition" has been instantiated in two ways: It has been used to refer to shared cognitive activities such as group problem solving (e.g., Larson & Christensen, 1993) or shared representations such as a team mental model (e.g., Klimoski & Mohammed, 1994) or a community memory (e.g., Orr, 1992). Even if we operationalize socially shared cognition to be shared representations that all members of a group have in common, the question remains as to whether this shared representation can come about from a joint social activity such as collaborative learning.

In order to hypothesize whether a shared representation is constructed, we need to reconsider what individual learning

is. Learning requires people to process incoming material (such as an expository text) and to integrate it with their prior representations. Thus, we assume that when individuals can learn by themselves, and they do so by actively constructing new knowledge or skills and/or revising their incorrect understanding (Chi, in press). Although such active construction of knowledge is critical regardless of whether people learn alone or together (Jeong, under review), learning in a collaborative context gives rise to an additional question: Is each member of the dyad constructing and revising her own individual representation, or are they jointly constructing one representation, or is it a hybrid of the two?

If learning is the construction and revision of representation, then there are at least two hypotheses about what might be happening during collaborative learning. In the first case, collaborating partners may each be constructing and revising her own representation, taking the partner's comments and explanations simply as additional input or feedback. In this case, they would each be constructing their own representation, albeit simultaneously. So, partner A and B each would construct their own unique representations, A and B. Representations A and B may be totally distinct or they may overlap, but since partners are constructing and revising their own representations, their representations would not resemble one another. The overlap in their representations, if existed at all prior to collaboration, would not likely to change with collaboration either.

On the other hand, another possibility is that collaborating partners may be constructing and revising jointly a shared representation C. Regardless of whether the shared representation C is constructed *in addition to* or *instead of* their own representations A and B, the resulting representations would reflect the joint learning activity they engaged in during collaboration in that partner A's representation shares portions that are similar to partner B's representation. With collaboration, A and B share more and more parts in common, so that the common representation C gets larger with greater collaboration, whereas the representations unique to A or B would get smaller with collaboration (see Figure 1).<sup>1</sup>

---

<sup>1</sup> Although not examined in this study, a third possibility is that collaboration might encourage the two partners to construct a single representation that is either A or B (that is, they converged upon one of the partner's representation), or neither A nor B, but X.

Figure 1: Changes in the shared representation due to collaboration.

In this paper, we define “shared knowledge” as the knowledge that is common to both partners’ representations. The question that we need to address is whether this common knowledge is indeed constructed from collaboration. For example, if people knew that alcohol in moderation reduces the incidence of heart attack, then this is a piece of common knowledge. Such a piece of common knowledge is likely to arise from similar experiences with the environment, but not necessarily from collaborative construction in face-to-face interaction. Members of a group or a culture would possess a set of common knowledge as a result of exposure to the same news media (e.g., there was a fire in New York last month), textbooks (e.g.,  $e=mc^2$ ) or simply being in the same culture (e.g., it is okay to eat in a classroom).

Researchers from anthropology and linguistics have observed that various kinds of groups that have histories of interaction tend to share a set of common knowledge. For example, Orr (1990) reported that people who practice the same job (e.g., photocopier repair technicians) hold a community memory about machines and customers. Similarly, teams are reported to have a shared mental model about their task requirements, procedures, and their responsibilities, which in turn helps them to work more efficiently especially in emergencies (Cannon-Bowers, Salas, & Converse, 1993; Klimoski & Mohammed, 1994; see also Hazlehurst, 1994 and Sherif, 1936). Thus, it seems that there exists common knowledge, whether it is memory, team mental model, or a way to interpret an image, common to interacting group members in the real world.

However, these observations of common knowledge may arise because the group all experienced the same input, rather than because they co-constructed it. It is difficult to tease these two interpretations apart, because people often share input as well as co-construct during collaboration. Thus, to clearly differentiate the two, we need to examine and demonstrate that some new or incorrect knowledge, *knowledge that cannot be experienced directly from the environmental input* (such as incorrect knowledge or inferred knowledge) has been constructed and shared after collaboration and that construction of such knowledge is clearly linked to the extent of interaction.

Very few studies have even attempted to capture the existence of shared knowledge that resulted from collaboration rather than direct experience. Roschelle’s (1992) study did attempt to show a convergence of representation while one high school student pair was learning physics concepts of velocity and acceleration. The students’ representation became more similar to each other’s after collaboration. How-

ever, it was difficult to assess whether the resulting converged representation reflects knowledge that both experienced or was co-constructed, especially based on a single case.

In general, the evidence for socially shared cognition has relied on qualitative evidence based on a select few cases. One of the goals of this study was thus to provide quantitative evidence using clear operationalization of shared knowledge. In this study, college student pairs were asked to collaborate to learn a biology text about the human circulatory system. We were interested in exploring and identifying the role of several variables in collaborative learning, their collaboration was unstructured other than the instruction to collaborate and to talk. Students were individually pre-tested and only those who had inaccurate mental models about the circulatory system (see method section for what constitutes inaccurate models) were allowed to participate. After the pre-tests, students were paired with another student who was equally naive about the topic and collaborated to learn the text and then came back for an individual post-test. Students were given two tests before and after collaborative learning: Terms Task and Blood Path Drawing Task. The Terms Task was to assess what students knew about the topic, specifically about various terms important in understanding the circulatory system. The Blood Path Drawing Task was to assess what students knew about the blood flow in the human body.<sup>2</sup>

## Method

### Participants

Twenty (nine male and eleven female) pairs of undergraduate students at the University of Pittsburgh participated in the study for course credit. Students were asked to participate if they had not taken any college-level biology classes. Students were asked to stay in the study only if they had inaccurate models (see later coding section) at the pre-test, did not have relevant personal experiences (e.g., open heart surgery), and could be paired with another student of the same gender who could come in around the same time for collaborative learning session. The pairs did not interact with their partner prior to the study except in one pair.

### Materials

**Text** The text used in Chi et al. (1994) was used with a slight revision (the text was originally taken from the chapter on the human circulatory system in a high school biology text by Towle, 1989). The resulting text contained 73 sentences. They were presented in a binder with each sentence printed on a separate page.

<sup>2</sup> A set of Knowledge Questions was also given to students, but are not included in this paper. It was administered at the post-test (after Terms and Blood Path Drawing Tasks) and did not allow comparison between pre-test and test as to how much new common knowledge was constructed after collaboration.

**Terms Task** Students were given 19 terms about the human circulatory system (e.g., atrium), and asked to talk about everything they knew about each term, even if it seemed unimportant to them.

**Blood Path Drawing Task** Students were provided with an outline of a human body (with a heart in it) and asked to draw the blood path of the circulatory system. They were asked to talk about everything that came to their mind as they drew.

## Procedures

**Pre-test** Participants were tested individually on the Terms Task and the Blood Path Drawing Task. This session was audio-taped. The pre-test session took about 15 to 30 minutes. At the end of the session, they were asked not to do outside reading on this topic while the study was in progress.

**Collaborative Learning** About a week after the pre-test, students were paired with a partner to learn the text. Since most of them had never met each other, they were given some time to get to know each other before the session started: after the experimenter introduced them and initiated conversation (e.g., who were their psychology instructors), she left the room supposedly to check the equipment. The experimenter watched their interaction from a monitor in another room until they seemed to be comfortable with each other. Most students quickly established a rapport with each other (in about ten minutes), discovering a common friend or exchanging information about classes.

Students were asked to help and encourage each other to learn and understand the materials during the collaborative learning session. They were asked to read the text out loud at least once. Participants were informed that they would be tested after the learning was over (a few sample test questions were provided). The pairs shared the text binder, and were provided with paper and pens in case they wanted to take notes or draw. This session was audio- and videotaped. The experimenter was not present in the room during this session, but could hear and watch them from the control room. Participants knew that the experimenter could hear them, but not necessarily that she could watch them. They were allowed to take as much time as they needed to study the text. The actual learning session took about an hour on average, ranging from 40 minutes to one hour and 45 minutes.

**Post-test** Participants were tested individually on the Terms task and Blood Path Drawing Task about a week after the collaborative learning session. This session was audio-taped. Post-test sessions ranged from 45 minutes to 2 hours.

## Coding

All the sessions were transcribed. From the protocol, three measures were collected. First, individual knowledge pieces (KPs) students knew were coded using a template from the students' answers in the pre-test and post-test. Second, students' mental models about the human circulatory system

were analyzed. Third, turns the two students took during the collaborative learning session were coded in terms of whether the turn was relevant to their partner's previous contributions. A more detailed coding scheme is reported below along with the reliability measures. A second coder coded 20% of the data independently from the first coder. The coding of the first coder was used throughout.

**Template Scoring** A template was created to assess how much students knew about the topic presented in the learning text. The template was created based on the information presented in the text. The 73 sentences in the learning text were segmented and collapsed into individual knowledge pieces (KPs) that roughly corresponded to a proposition (e.g., "aorta is an artery"). The template contained a total of 173 KPs. There were two types of KPs: KPs that were explicitly stated in the text (Stated KPs) and KPs that could be inferred from the text (Inferred KPs). An example of a Stated KP is "atrium is the upper part of the heart" which is directly stated in sentence 20 "Each upper chamber is called an atrium." An example of an Inferred KP is "the heart has four chambers." This KP is not explicitly stated in the text but can be inferred by integrating sentence 17 "The septum divides the heart lengthwise into two sides" and sentence 19 "Each side of the heart is divided into an upper and a lower chamber." The template contained 115 Stated KPs and 58 Inferred KPs. The KPs were coded from the students' protocol during the Terms and the Blood Path Drawing Task. The agreement between the two coders was 87%.

**Mental Model Analysis** Students' initial and final mental models about the human circulatory system were coded to assess changes in how individual knowledge is integrated to form a coherent model of the circulatory system as a whole. Based on students' protocols during the Terms and the Blood Path Drawing task, each student's initial and final mental models were coded into one of the following models: (1) No Loop (NL) model, (2) Ebb and Flow (EF) model, (3) Single Loop (SL) model, (4) Multiple Loop (ML) model, (5) Single Loop with Lungs (SLL) model, (6) Double Loop-1 (DL1) model, and (7) Double Loop-2 (DL2) model. The seven models differ from each other in terms of the presence and the kind of incorrect conceptions (e.g., blood returns to the heart by way of the same blood vessels) and/or the correct conceptions (e.g., heart pumps blood to the lungs versus left ventricle pumps blood to the lungs). Both the Double Loop-1 and Double Loop-2 models represent the accurate flow of blood through the circulatory system with Double Loop-2 being the most complete model (see Chi et al., 1994 for more details on this analysis). The inter-rater agreement on mental model coding was 94%.

**Turn-taking** Each turn that a student took during collaboration was coded whether or not it was relevant to their partner's previous turn. A turn can be relevant in several different ways. A turn was coded as relevant, for example, if students answered questions that their partner asked, repeated and/or continued the statement and topic that their partner initiated, or acknowledged what their partner said. A turn

was defined in this study as a change of speaker in their learning dialogue. The transcript occasionally contained non-verbal (e.g., laughs, gestures) turns, but it was coded as a turn if it had information potentially relevant to the partner. Thus, turns that contain only “ok” or “umm” were coded as a separate turn when it could be answers or acknowledgements. Similarly, turns that contained only gestures were coded as a separate turns if it was communicative (e.g., nodding indicating “yes”). Based on this identification of turns, a second pass over the transcript was done to determine whether each turn was “relevant” to their partner’s previous turns. A turn was coded as relevant as long as the turn contained information relevant to their partner’s previous contribution in some way (see Jeong, under review, for more details). The reliability for this coding was 85%.

## Results

The process and outcome of knowledge construction were considered to be interdependent between the two members of the pair in this study. Thus, the unit of analysis in this study was pairs rather than individuals. Although students’ pre-test scores were mostly independent from each other’s (unless we start considering cultures), their post-test scores, although tests were individually administered, were partly dependent on their partner’s score due to their collaboration. Thus, we calculated common KPs as well as unique total KPs to deal with this dependency. In this section, we first describe how much learning occurred and how much common knowledge was constructed after collaborative learning. We then examine in more detail whether the increase in common knowledge was indeed co-constructed from interaction.

### Learning and Common Knowledge

Learning was assessed by addressing (1) the number of Knowledge Pieces (KPs) that were learned after collaborative learning and (2) improvement in the pairs’ mental model.

**Template Scoring: Knowledge Pieces (KPs)** Since template scoring gives scores for each partner, the amount of knowledge that the *pairs* knew as a whole was calculated by: (a) an average score of the two students in the pair and (b) a *unique total* score. These scores can be best understood by looking at Figure 1. Circle A represents what Partner A knows, Circle B represents what Partner B knows. *Common knowledge* is defined as the knowledge that both partners possess, represented by the area C, the overlap of the two circles. For example, if both partners know the KP that the heart has four chambers, then they are said to share that piece of common knowledge. On the other hand, *unique knowledge* is defined as the knowledge that only one member of the pair possesses. Learning for each individual is represented by an increase in the size of each circle (A, B) from the pre-test to the post-test. On the other hand, learning for the pair as a whole can be best represented by examining a *unique total* score that represents the number of distinctive KPs that the pair knew as a whole (see Table 1).

The average score of pairs increased significantly from 19.70 KPs at the pre-test to 47.70 KPs at the post-test,  $t(19)=10.08, p<.001$ , and the unique total score also increased significantly from 32.15 KPs at the pre-test to 72.85

Table 1: The relationship between various scores.

Scores	Areas in Figure 1
Common KPs	C
Unique KPs	(A-C) or (A-B)
Average KPs	(A+B)/2
Unique total KPs	(A+B-C)

KP at the post-test,  $t(19)=11.92, p<.001$ , indicating that students’ understanding of the human circulatory system increased significantly after collaborative learning. The amount of common knowledge also increased significantly from 7.25 KPs at the pre-test to 22.55 KPs in at post-test,  $t(19)=6.13, p<.001$ .

**Mental Models** Consistent with the overall gain in the KPs, there was an overall improvement in students’ individual mental models about the circulatory system after learning. Recall that none of the students had the correct Double Loop models at the pre-test, since students were selected that way for the study. The majority of them started with the Single Loop model (55%), followed by the Single Loop with Lungs model (25%). After learning, the majority of the students possessed the most accurate and complete Double Loop-2 model (52.25%), followed by the next most accurate Double Loop-1 model (37.5%). Thus, learning the text with a partner improved the accuracy of the students’ individual mental model as well as increasing the number of individual knowledge pieces that they knew, as in Chi et al. (1994).

To determine whether partners’ mental models converged onto the same model, each student’s mental model was compared to their partner’s. At pre-test, 10 pairs (50%) had different initial incorrect models. As stated earlier, none of the models was the correct Double Loop models. Six of these 10 pairs converged onto the same final mental models. However, five of the six pairs’ final models were the correct Double Loop-2 model, so we cannot rule out the interpretation that each partner’s model converged on the correct model, independent of interaction.

### Collaboration and Common Knowledge

Students were not coming up with arbitrary knowledge (e.g., how to name an ambiguous geometric figure) in this study. They were learning a science text that strongly constrains their interpretation and knowledge construction. Since they all learned the same text, the increase in common knowledge and the convergence toward the correct final model, could be the result of individuals learning the same materials from the text rather than their collaboration. In this section, we further examined whether there was any evidence that collaborative dyads co-constructed knowledge from interaction, rather than merely self-constructing their own knowledge, in the presence of an enabling partner.

**Common and Unique Knowledge** Although pairs had more common knowledge after collaborative learning, they also knew more after learning. Thus, just looking at the number of common KPs could give a false picture without taking into account the increase in total amount of knowledge due to learning. To address this problem, the percentage of common knowledge (over the unique total KPs) was calculated. The percentage of common knowledge increased after collaboration (from 23% to 31%), whereas the percentage of unique KPs decreased after collaboration (from 77% to 69%),  $F(1, 19)=11.05, p<.005$ . This significant interaction indicates that the increase in common knowledge was not a mere reflection of knowing more. In sum, after collaborative learning, pairs gained more KPs overall, but they learned proportionately more common knowledge than unique knowledge.

**Nominal Pair Analysis** If some parts of common knowledge is co-constructed (rather than learned individually by each partner), then collaborative pairs ought to learn more common knowledge than nominal pairs who did not collaborate. A hypothetical nominal pair was constructed by randomly pairing each member of the pair with a member of another pair. The results showed that there was an increase in common KPs in nominal pairs as in real pairs, but the increase was greater in real pairs (8% versus 4%). Although ANCOVA (controlling for their pre-test scores), did not reveal significant difference between the two conditions,  $F(1,36)=2.36, p<.14$ , the increase in the proportion of common knowledge from pre-test to post-test was significant in real pairs,  $t(19)=2.8, p<.01$ , but not in nominal pairs,  $t(19)=1.20, p>.10$ . Thus, although part of the common knowledge constructed during collaboration was due to learning from the same text (as can be seen in the small increase of shared knowledge in nominal pairs), it seems that part of the increase in common knowledge can be undoubtedly attributed to collaboration.

**Incorrect Knowledge Pieces** We also examined incorrect knowledge at the knowledge piece level from the pre-test and post-test answers. In total, pairs had 69.25 incorrect KPs at the pre-test and 91 KPs at the post-test. Out of these, the real pairs did not share any incorrect KPs at the pre-test, but shared a total of 4 at the post-test after collaboration. On the other hand, nominal pairs had a total of 3 common incorrect KPs at the pre-test, but 0 KP at the post-test. Although the numbers are small, the fact that pairs shared 4 incorrect KPs after collaboration suggest that these incorrect KPs must have been co-constructed with their partners during collaboration, rather than encoded and inferred from the text alone independently from their partner.

**Common Incorrect Mental Model** As mentioned earlier, six of the ten pairs of students who had different initial mental models converged onto the same final mental model. Of these six pairs, five pairs converged on the correct Double Loop-2 model, which could be attributed to having read a text that described such a correct model. One pair, however, converged on an incorrect model. Both of their models had

the same “error”: They both thought that blood from the lungs goes back to the heart through the ventricle, rather than through the atrium as in the correct model (see Figure 2). Thus, an incorrect model that both partners share strongly indicates that they somehow co-constructed it.

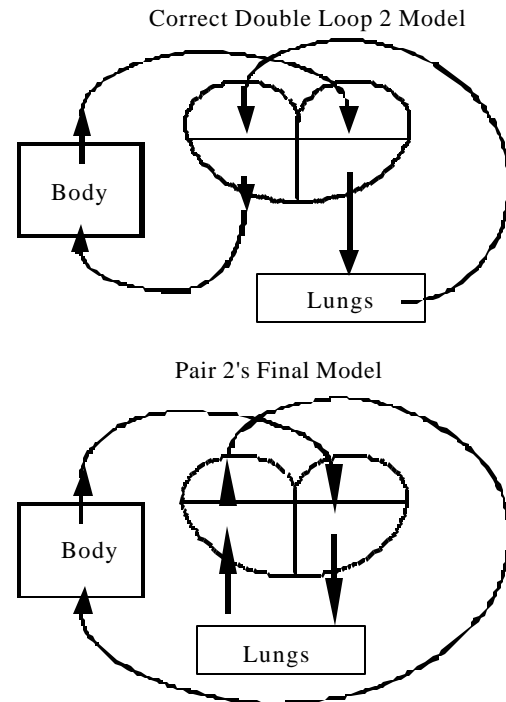

Figure 2: Pair 2's final mental model in comparison to Double Loop-2 model.

**Interaction and Common Knowledge** If dyads co-constructed common knowledge from interaction, rather than merely self-constructed their own knowledge, it would suggest that the more interaction they engaged in, the more common knowledge they would construct, especially the knowledge that cannot be obtained directly from the text, that is, knowledge that need to be inferred. To test this hypothesis, the pairs were grouped into high-interaction pairs (N=10) and low-interaction pairs (N=10) based on the amount (percentage) of relevant turns they took during collaborative learning.

As can be seen in Figure 3, high-interaction pairs shared more inferred knowledge than low-interaction pairs even after the pre-test difference was controlled,  $F(1, 17)=6.10, p<.05$ . On the other hand, high-interaction pairs did not necessarily shared more stated knowledge than low-interaction pairs,  $F(1, 17)=.107, p>.10$ . Thus, the more interaction pairs engaged in, the more likely they were to construct knowledge that was inferred (i.e., knowledge that was not given in the text). Since the knowledge was never presented in the text, it was more likely that dyads constructed them together through collaborative interaction.

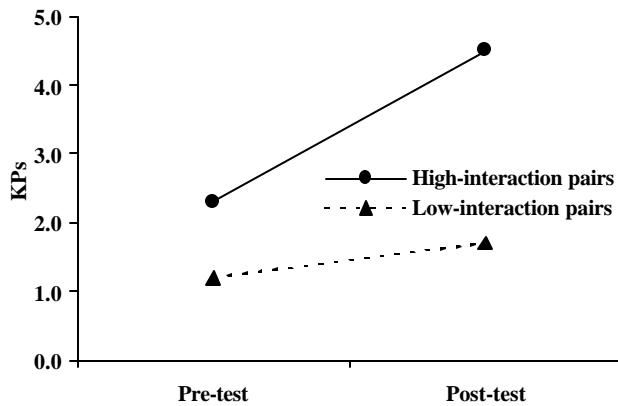

Figure 3: The increase in shared Stated KPs and shared Inferred KPs after collaborative learning in high-learning and low-learning pairs.

### Conclusions

In this study, we examined whether collaborative learning, a shared learning activity, leads to the construction of shared knowledge. Among the several potential representational outcomes of collaborative learning, one distinct possibility was that collaborating members of dyads (or groups) would construct common knowledge. To examine whether the common knowledge would really come from interaction rather than sharing the same environmental input, we examined whether students common knowledge when the knowledge cannot be obtained directly from the input. The results of this study showed that collaborating pairs shared more knowledge (correct and incorrect, stated and inferred) after collaboration. Since the incorrect knowledge and the correct but inferred knowledge was never presented in the text, it is more likely that they constructed it during collaboration. Above all, those who interacted more shared significantly more inferred knowledge than those who interacted less did. Even though each of these analyses produced a small effect and/or small amount of data, taken together, these findings indicate that participation in joint activity allows participants to construct a common knowledge.

There are several ways that the pairs went about constructing common knowledge in this study. In one scenario, the two pairs might have contributed to the construction of knowledge more or less equally, each generating part of inferences to complete the knowledge construction. In another scenario, one student might have made an inference, regardless of whether it is correct or incorrect, from the text by herself and tells her partner about it. At this point, the other partner had two choices: he or she could either accept it or reject it (Clark & Schaefer, 1989). It is only when the partner accepted the other's contribution that both of them get to possess the common knowledge. The partner who just heard the inference was more passive than the other person, but nonetheless participated in the construction process.

## Abstract

Workplaces are rapidly changing, placing increased cognitive demands upon workers. The use of computer workplace simulations has been proposed to help students successfully make the transition from school to work. In this study, we examined what kinds of learning occurred when students used a computer workplace simulation called Court Square Community Bank. We hypothesized that three types of learning would occur: (1) students would gain knowledge about the banking business in which the simulation is situated and (2) students would also learn general business knowledge and problem solving/decision making skills that they could apply in other work contexts. Thirteen pairs of high school students used a workplace simulation. The results showed that students knew significantly more knowledge about the banking business. Students also adopted a new perspective to organize their knowledge and their problem solving activities became more coordinate. Taken together, the results of this study showed that computer workplace simulation can serve as a useful tool to prepare students to make a better school-to-work transition.

## Introduction

There is a growing concern that many of today's high-school graduates are ill-prepared for succeeding in today's demanding and rapidly changing workplaces. The world of work is experiencing a dramatic transition: jobs increasingly require complex thinking skills and adaptive performance. As a consequence, there have been many calls for school-to-work transition programs such as youth apprenticeship or technical preparation. Recently, Ferrari, Taylor, and VanLehn (1999) advocated the use of computer simulations as a way to facilitate the school to work transition. They argued that computer simulations of workplace environments can help familiarize students with a particular workplace and assist them in developing the analytical/problem-solving skills needed to successfully participate in the workplace, while allowing them to remain safely situated in the classroom. The goal of this paper is to assess what kinds of learning opportunities are afforded and how much learning actually occurs when students use such a computer simulation.

For our study, we selected a workplace simulation called Court Square Community Bank (CSCB), one of the simulations recommended by Ferrari et al. (1999). CSCB is an episode-based simulation. Students play the role of vice president, engaging in activities such as interacting with

bank customers, consulting the opinions of other bank employees, and making business decisions. Each of the 14 episodes poses different kinds of problems that the vice president of a small community bank must deal with such as approving mortgages or selecting the best candidate for a position (see Ferrari et al., 1999 and McQuaide, Leinhardt, & Stainton, 1999 for more details on the program).

In assessing learning from CSCB,<sup>1</sup> we were less concerned with evaluating the specific workplace simulation and were more interested in understanding the learning issues involved in workplace simulations in general. We hypothesized that two types of learning can occur when students interact with a computer workplace simulation. Students could acquire (1) knowledge about the banking business in which the simulation is situated, and (2) general business knowledge and problem solving skills that are applicable to a wide variety of workplaces. Below, we describe these in more detail and speculate on how learning such knowledge/skills might occur.

## 1. Knowledge about the Banking Business

One of the most notable features of the computer workplace simulation in comparison to other medium of instructions (e.g., reading an expository text or listening to a lecture) is its contextualized nature. In the case of CSCB, the specific business context was a small town community bank. The contextualization was done by using the problems that arises from the banking business (e.g., when to approve a mortgage) and implementing interactions with simulated characters who are primarily bank personnel or customers. This means that much of the information about banking business is embedded in the problem descriptions and the students' interactions with the characters of the simulation. In addition to this contextualization, declarative banking knowledge is presented in the form of on-line dictionary and procedural manual. In sum, the simulation provides extensive amount of information about banking business, either implicitly or explicitly. Although this banking knowledge is never the focus of the simulation (e.g., the program never asks stu-

---

<sup>1</sup> The effect of the simulation is likely to be different when used in schools compared to when it was used in the laboratory as in this study. For example, in one of the schools that used the CSCB as part of their curriculum, it was augmented with instructional and teacher supports (see McQuaide et al., 1999 for more details).

dents to supply the definition of various financial terms), it seems reasonable to expect that students would at least learn some amount of banking knowledge as a result of using the simulation.

## 2. General Business Knowledge and Skills

Although learning about banking is meaningful and could be helpful in other contexts, we hope that students would also learn general knowledge or skills that can be used in contexts other than banking. When students go through the simulation episodes, they need to process episode-specific information (e.g., salary of the mortgage applicants) as well as banking specific knowledge (e.g., interview loan applicant before approving the loan). Such knowledge, although useful in making banking-related decisions required in the episode, is largely irrelevant in other contexts.

Concrete contexts can help initial learning because they can be elaborated and help students appreciate the relevancy of new information in problem solving. Context can also be helpful to learning by facilitating the construction of a more accurate representation in a manner similar to how context helps to disambiguate word meaning. On the other hand, context can also present a problem for abstracting general principles or features (e.g., category structure). Overly contextualized learning tasks could potentially impede the abstraction of general principles (Bransford & Schwartz, 1999). Despite its benefits for learning, learning in context could also present a challenge to students in that the contextualized nature of the simulation may impede learning general knowledge or skills that can be useful in other work contexts.

It should be noted that this problem is not unique to computer workplace simulations. The same issue is present in on-the-job or apprenticeship training. There is an abundance of context/job-specific information in the actual work context. Although people need to pay attention to this information, often the ideal learning goal can be met only when people go beyond this information and understand more general business issues (Pearlman, 1997). For example, students need to learn that one needs to consider all the available options before making the final decision or that the role of the vice president may be complicated due to potential conflicts of interest or concerns about nepotism.

According to the analysis of Ferrari et al. (1999), approximately two thirds of the information presented in the two simulations that they examined in detail were specific to the particular type of the industry simulated (i.e., banking and software development). Only one-third of the information was general work knowledge that dealt with issues such as decision making, information management or interpersonal relations that occur across many jobs. In other words, unlike textbooks that often present this decontextualized knowledge in the form of abstract principles or concepts, simulations like CSCB embed this general knowledge in a specific context. The question then is what the kinds of general knowledge or skills students could learn from their experience with the simulation that could be used in other work or business contexts. In this study, we examined the following two candidates.

**Perspective Taking** In the simulation, students are asked to play the role of bank's vice president and interact with various characters related to the business (e.g., customers, managers, etc.). Given that prior to using the simulation, almost all of the students' interactions with business would have occurred while they were in the role of a consumer (i.e. purchasing items from stores), one would expect students to answer banking terms to be answered from a similar perspective. For example, a banking term such as *interest* can be defined from the perspective of a consumer or a business. When students approach the term from a customer's perspective, *interest* is more likely to be defined as an expense paid to banks. On the other hand, when students approach the same term from a business perspective, *interest* is more likely to be defined as a means for earning profit. The ability of students to take multiple perspectives would reflect a richer understanding of the terms and principles under discussion. Thus, being given the opportunity to take on new roles might affect how students frame their experiences, allowing them to think about the same issue in multiple ways.

**Decision Making/Problem Solving Skills** Most of the episodes in CSCB require some kind of decision to be made. In each episode, students are first presented with basic descriptions of the problem (e.g., the treasurer announces that the downtown branch has a shrinking profit margin). Students attend a meeting to hear what managers think may be the cause of the problem, read newspaper article about how the community is reacting to the possible closing of the branch, and evaluate various options to address the problem of the branch. The simulation provides a set of alternatives regarding the closing of the branch and asks the students to choose and justify their choice.

Although the decisions in the simulation are simplified by using multiple choice format, they are still complex in nature, resembling the kinds of decision making that might occur in real workplaces. In general, the problems given in the simulation episodes are different from the problems commonly dealt in the classroom (e.g., algebra problems). First, they require an understanding of a both specific context (banking business in this case) and general problem solving skills (e.g., goal state). Second, there is no single right answer as is the case in typical problems taught at schools. There often exist multiple equally viable options that can solve the problem, and even the best solution can be flawed in some way. Third, the problems are complex in that the goals and solution options of the problem are often unclear. The problems also have multiple, interacting causes.

Engaging in such decision making is a complex task. Successful problem solving requires students to understand several factors and their relationships (e.g., governmental regulations or why the branch is losing money). Like in real workplaces, problems in the simulation often do not have a single right answer. Additionally, students often need to evaluate each option based on their own criteria. For example, students need to evaluate the relative merits of advanced technology (e.g., ATM) versus personal attention to cus-

tomers (e.g., human tellers). Due to such characteristics of the problem presented in the simulation, we postulated that students would learn how to solve such ill-defined problems better after using the simulation. According to the notion of "Preparation for Future Learning" proposed by Bransford and Schwartz (1999), the benefits of previous experience often do not reveal themselves immediately. Instead, the benefit takes the form of helping to prepare students to learn new information. Thus, we examined not only how the overall quality of their decision improved, but also whether they had a better understanding of the problem solving process after using the simulation.

In this study, to get a detailed picture of students' learning, we asked high school students to do eight (out of fourteen) CSCB episodes in the lab. We constructed three assessment tools to test and elaborate our hypotheses about potential learning outcomes from the workplace simulation. They were: (1) Definition Task, (2) Question Answering Task, and (3) two transfer problems.

## Method

### Participants

Twenty-six high school students (23 from public and 3 from parochial schools) participated in this study. The students were either juniors or seniors from local urban high schools. During recruitment, students were asked to bring a friend of the same gender to participate in the study, which resulted in four male and nine female pairs. On average, they had known their partner for about 4 years, having engaged in academic and after-school activities together. As compensation for participation in the study, students were provided with a base pay of \$75 and up to \$25 as a bonus if they kept their appointments. With regard to their familiarity with computers, about half of the 26 students (54%) reported that they had computers in their home. Almost all students (96%) reported that they used computers 1-15 hours per week and had experience with word processing or e-mail. A majority of the students (58%) reported that they used other computer simulations or games.

### Materials

**CSCB Episodes** A representative subset of CSCB episodes (8 out of 14) was selected so that diverse topics would be covered (e.g., ethical as well as financial issues) with minimum overlap.

**Definition Task** The aim of this task was to assess the context-specific knowledge that students might learn about the banking business. This task consisted of 13 terms relevant to banking (e.g., collateral) that were covered in the eight selected episodes. Students were asked to talk about everything they knew about these terms.

**Question Answering Task** This task was to assess general business knowledge that students might have abstracted from their experience with the simulation. This task

consisted of 12 questions that were constructed based on the propositional content of the simulation episodes. These were general questions about how business operates (e.g., name 3 ways that a business can stay competitive) or about a vice president's role (e.g., name three kinds of activities/jobs that a CEO or a vice president has to do in a company). We expected that students would find this task difficult due to the lack of specific contexts. We thus included in the instructions that they could use examples of specific businesses to help to answer these questions.

**Problem Solving Task** This task was to assess broad changes in students' problem solving. Two transfer problems called Fresh Food and Giant Gallery were constructed based on two episodes of the simulation (Episode 9 and 10, respectively). They were identical to the problems presented in the simulation episodes in terms of the underlying problem/goal, constraints, and options, but differed from the simulation problems in two respects.

First, instead of banking, the transfer problems used the supermarket business (also familiar to high school students) as the context. Thus, although the surface features were different, the underlying structures of the transfer problems were identical to the problems presented in the simulation.

Second, transfer problems were less structured than the problems presented in the simulation episodes. Unlike the simulation episodes that provide a set of alternative choices, in the transfer problems students were asked to generate their own solutions. A set of seven open-ended probes about various aspects of students' reasoning were included. Each transfer problem consisted of two general phases: information interpretation and probe answering. Students were first presented with a set of documents about the problem and then responded to a set of five probes. They were then provided with an additional set of documents and they responded to two more probes. The seven probes were the following:

- Probe 1: Could you please state the store's problems in your own words?
- Probe 2: If you could request more information about this supermarket's problem, what information would you request and how would you get this information?
- Probe 3: As vice president of this supermarket, how (or where) would you get this information?
- Probe 4: What factors do you have to take into account to solve the supermarket's problems?
- Probe 5: As vice president, how would you go about implementing your options?
- Probe 6: What do you think is the best way to solve the problem and why?
- Probe 7: What kind of information did you use to make your decision?

### Procedures

The study was carried out in the laboratories located in the Learning Research and Development Center at the University of Pittsburgh. Students visited the laboratory over four sessions: (1) pre-test, (2) simulation session I, (3) simulation session II, and (4) post-test. On average, each session

was separated by approximately four days. All sessions were audio-taped. In addition, the two simulation sessions were video-taped to provide a context for the interaction between the students.

**Pre- and Post-test** During the pre-test and post-test, students were given the three tasks described earlier. Students first generated answers to the terms in the Definition Task. They then solved the two transfer problems, Giant Gallery and Fresh Food. Lastly, they completed the Question Answering Task. The order of the two transfer problems was counterbalanced across pairs and pre/post-test sessions. Throughout the sessions, students were asked to think aloud and to talk about everything that came to their mind. To familiarize them with think-aloud procedure, students were given a short think-aloud practice at the beginning of the problem-solving during the pre-test. The pre-test and post-test sessions were individually administered. The pre-test took about two hours, and the post-test took about one and a half hours on average.

**Simulation Sessions** The first three episodes in each simulation session (Episode 1, 2, & 5 in the simulation session I, and Episode 9, 10, & 11 in the simulation session II) were done collaboratively by the pair, and the last episode in each session (Episode 7 in the simulation session I, and Episode 12 in the simulation session II) was done individually. In the collaborative simulation session, the pairs were instructed to work as a team, in discussing how to handle the problems and to reach a consensus before making a decision. After the collaborative learning session, students were led to separate rooms and completed an episode alone while thinking aloud. Students took approximately 40 minutes per episode, a total of five hours on the simulation over both sessions (excluding time spent on breaks).

## Results

Please note that only a subset of results was reported in this paper for the two types of learning examined: (1) learning about the banking business and (2) learning about general knowledge or problem solving skills. We presented two sets of results for the first type of learning and four sets of results for the second type of learning.<sup>2</sup>

### 1. Knowledge about the Banking Business

**Increase in Correct Knowledge and Decrease in Incorrect Knowledge** A Knowledge Piece (KP) roughly corresponds to an idea (e.g., ATM costs banks less than tellers). A template was constructed by identifying individual Knowledge Pieces (KPs) relevant to the 13 terms in the Definition Task. The template consisted of 113 KPs captured from the information presented in the simulation in various formats (e.g., on-line dictionaries or reports given to

the vice president). The template represented the maximum possible knowledge that students *could* learn from the eight episodes of the simulation. Based on their answers to the Definition Task, students received one point for every unique KP that they stated (partial credit was given if their answer was vague or they expressed uncertainty). Students knew on average 24 KPs at the pre-test and 27.98 KPs at the post-test,  $t(24)=3.79$ ,  $p<.01$ . In addition, we examined the terms in which students either provide no answer or provided incorrect (or irrelevant) answers (e.g. *principal* was a “person in school”) and found that such answers decreased significantly from 2.28 (18%) at the pre-test to .88 (7%) at the post-test,  $t(24)=4.09$ ,  $p<.001$ .

**Schema about Banking Business** A subset of questions in the Question Answering Task asked students to explain general business operations. The answers to these questions were analyzed in terms of the type of business schema used (e.g. manufacturing, retail, banking, etc.). For example, to the question “Please name three kinds of expenses that a business has,” one student answered: (1) rent, (2) expense to make the product, and (3) expense to get the products out to the public (e.g., shipping or mailing expenses). In this case, the first answer was an expense that was applicable to the banking business, whereas the second and the third answers were not. On average, students’ answers applicable to the banking business significantly increased after using the simulation (from 62% to 77%),  $t(25)=5.02$ ,  $p<.01$ , suggesting that students learned some rudimentary schema about the banking business.

### 2. General Business Knowledge and Problem Solving Skills

**From Customer to Business Perspectives** To assess the change in the perspectives, we examined the perspectives that students used in defining the terms in the Definition Task. We coded their answers to each term in the following two perspectives: (1) customer perspective, (2) business perspective. The results showed that there was a significant decrease in answers with customer perspective (3.44 to 2.44),  $t(24)=2.45$ ,  $p<.05$ , and a significant increase in answers with a business perspective (1.04 to 2.44),  $t(24)=3.03$ ,  $p<.005$ . Thus many students now demonstrated the ability to think about banking terms from additional framework (i.e. a business perspective in addition to their initial consumer perspective).

**Improvement in the quality of the students’ final decision** As mentioned before, due to the nature of the problem, it was often difficult to determine optimal solutions. What constituted the “best” solution was highly dependent on one’s beliefs and priorities (e.g., the importance of technology versus that of renovation in business). Nonetheless, we examined whether there were any improvements in the quality of students’ final decisions that they chose in the two transfer problems. This was done based on their response to Probe 6 (“What do you think is the best way to solve the problem and why?”). Based on the analysis of the

<sup>2</sup> Due to recording errors, the following data was lost: student 9B’s pre-test answers to the Definition Task and in the Giant Gallery problem and student 8B’s post-test answers to Question 3 in the Giant Gallery problem.

simulation episodes, we selected five constraints important to the decision-making and examined how many constraints each of their final decision satisfy. In the Giant Gallery problem, students' final decision met 3.20 constraints (out of 5) at the pre-test and 3.96 constraints at the post-test,  $t(24)=1.93$ ,  $p<.05$ . In the Fresh Food problem, there were no significant changes in the numbers of constraints (3.62 to 3.54).<sup>3</sup>

**Improved Understanding of the Problem Solving Component** We examined students' understanding of problem solving components, specifically, their understanding of solution option. At pre-tests, when asked to generate options to solve the store's problem in Probe 3, students were more likely to generate options that did not really *solve* the problems that the supermarket was facing. For example, students answered "look [at] every aspect of the store" or "get ideas from other stores." These answers may be steps to arrive at the final solution, but were not options that could *solve* the specific problems that the supermarkets had. Generation of such *non-options* decreased significantly both in the Fresh Food problem (1.31 to .52),  $t(25)=2.33$ ,  $p<.05$ , and in the Giant Gallery problem (.78 to .32),  $t(24)=1.83$ ,  $p<.05$ , suggesting that students understood better what a solution option was after using the simulation.

**Integrated Problem Solving** In addition, students' problem solving activities became more integrated and coherent. First, students became better at gathering the information. In Probe 2, students were asked to request information they need to understand and solve the problem and then specify how to get it. At pre-tests, they tended to specify the steps to gather information in general rather than the information they requested. For example, in the Fresh Food problem, one student requested three pieces of information: (a) how old the current machines at the checkout counter were, (b) whether customers use the machines properly, and (c) why the machines at the checkout counter was not connected to the main computer system. Then, she specified that she would get that information by (a) asking the company that made the checkout machines in the store about how to fix it, (b) talking to the competitor whether they had similar problems, and (c) talking to the bank about the compatibility of the card and the machine. In this example, none of her information gathering methods were about the information she requested, although they were valid ways of getting information. At post-tests, students were more likely to specify information gathering methods to get the information they requested. Although the increase was only significant in the Fresh Food problem (53% to 71%),  $t(25)=2.45$ ,  $p<.05$ , the trend was also present in the Giant Gallery problem (58% to 69%).

A similar finding was obtained when students were justifying their final decisions in Probe 6. We coded whether students actually considered the constraints that they listed in

their response to Probe 4 ("What factors do you have to take into account to solve the supermarket's problems?"). After students did the simulation, they were more likely to consider the constraints that they listed in Probe 4. In the Fresh Food problem, students used .81 reasons at the pre-test (out of 1.58 reasons they used to justify their final decision) that they had named and 1.17 reasons (out of 1.96) at the post-test,  $t(25)=1.74$ ,  $p<.05$ . In the Giant Gallery problem, students used .84 reasons at the pre-test (out of 2.04) that they had named and 1.24 reasons (out of 2.60) at the post-test,  $t(24)=1.79$ ,  $p<.05$ . Thus, it seemed that students' problem solving activities became more connected or coherent in that they generated ways to get the information they requested and used more of the constraints that they initially thought were important in solving the problems.

## Discussion

In this study, we attempted to identify and assess the learning outcomes of computer workplace simulations. We first speculated that students would learn about the work context of the simulation. The CSCB simulation uses banking as a context, but other simulations have used other businesses (e.g., hotel management or software development). We also speculate that students would learn general knowledge about business and how to solve complex real-world like problems.

First, the results showed that the simulation helped students to learn about the banking business. They knew more knowledge about banking, which was accompanied by a corresponding decrease of incorrect knowledge. Students also acquired a schema about banking business. Such results are interesting, considering the fact that (a) students were never asked to learn about banking explicitly and (b) they were not likely to have accessed all the relevant information about the banking business even though they were provided in the simulation.

Second, the results also showed that the simulation helped students to learn general business knowledge and problem solving skills. Students learned to take a business perspective, one that they would not have likely gained from their everyday experiences. As a result, students' answers to the banking terms became more organized from a business perspective rather than from a customer perspective. In addition, students understanding of the problem improved and became more coherent, which seems to be one of the reason why the quality of their final answer improved after the simulation. Considering the fact that the simulation never teaches these knowledge and skills didactically and embeds them in contexts, it is encouraging to discover that students can not only learn about the banking business in which the simulation is contextualized, but also some general knowledge and problem solving skills that they can use in other business and work contexts as well. These results of this study are consistent with the findings obtained with other instructional mediums that use contexts or cases, although they did not deal with workplace issues (e.g., mathematical problem solving as in Jasper Series; see Barron, Zech, Schwartz, Bransford, Goldman, Pelligrino, Morris, Garrison, Kantor, 1995). Taken together, it seems that workplace computer

---

<sup>3</sup> This seems to be due to the fact that students pre-test decisions were highly similar to the decisions that were reinforced in the simulation in the Fresh Food problem.

simulation could be useful in preparing students for the future workplaces.

## Abstract

The authors propose a dynamical model of memory retrieval that explains how people break an impasse or a memory block spontaneously without an external stimulus. We describe the process as “insightful memory retrieval”. First, an experiment was conducted in which 15 participants retrieved eight Chinese characters from memory space using figural pattern cues. The results indicated that the retrieval process was divided into three phases: (1) direct retrieval, (2) indirect retrieval, and (3) an impasse and insightful retrieval. Second, a dynamical model named DIMeC was developed from the results. The direct and indirect phases depend on constraint relaxation, and the insightful retrieval phase is simulated using a chaotic neural network. Third, the DIMeC model was implemented on a computer. The results of the simulation indicate that the model reflects the typical dynamic retrieval process of the participants.

## Introduction

Insight and memory block resolution are connected (e.g., Weisberg & Alba 1981; Bowers, Balthazard, & Parke 1990; Yaniv, Mayer, & Davidson 1995). Insight is characterized by spontaneity, suddenness, unexpectedness, and satisfaction (Seifelt et al. 1995), however, research into memory blocks, including the tip-of-the-tongue phenomenon, output interference, fixation, and priming effects has not shown a “spontaneous” mechanism (e.g., Smith 1995; Smith & Tindell 1997; Yaniv et al. 1995). These researchers have explained a memory block and its resolution mechanism by setting an external stimulus, such as priming. We assume that “insightful memory retrieval” expresses a spontaneous mechanism, which breaks a memory block or an impasse without an external stimulus.

An artificial neural network is one of the cognitive models that can explain the human memory system. Many models use a minimized energy function to retrieve a memory from an initial pattern, and cannot search for additional memories. Inevitably, they cannot express dynamical retrieval processes, such as retrieving one memory from another. However, Nara, Davis, & Totsuji (1993) developed a model that could travel among memories, using chaotic dynamics by controlling the number of connections among units. Tani (1996) developed the “chaotic steepest descent” model, which

could also travel among memories. Tani employed a non-linear resistance to control the chaotic transition. It is interesting to apply such dynamics to the memory retrieval process of actual psychological phenomena.

Therefore, our purposes were (1) to explore how people reach an impasse and break it by insight in the memory retrieval process, (2) to develop a dynamical model using a chaotic neural network from the results, and (3) to examine the model using computer simulations.

## Experiment

### Method

**Participants** The participants were 15 Japanese graduate students at the Tokyo Institute of Technology.

**Material** The problem they were given was to find all the Chinese characters (Kanji) that can be made by adding one straight line to “*I*” without rotation, where “*I*” denotes the initial character in Figure 1. Eight Chinese characters can be constructed from “*I*”. Figure 1 shows the initial character (*I*) and the target characters ( $C_1 \dots C_8$ ) and Table 1 shows the operations that must be made on the initial character to retrieve the targets. All Japanese people should have learned all these characters and the initial character in school between ages seven and fifteen years. We call the problem the ALIC (Add a Straight Line to the Initial Character) task.

**Procedure** Each participant was tested individually, and participants’ actions and speech were recorded using a VCR. The participants were told to write down their answers on a sheet. During the session, they were urged to speak their thoughts aloud and to write, regardless of incorrect answers. When the participants indicated that they could not think of any more targets, they were told the number of remaining targets. Each session lasted until all eight targets were retrieved.

### Results

**Retrieval Times and Targets** All the participants retrieved all the targets within 30 minutes. Figure 2 shows the retrieval patterns of the 15 participants. Each line represents the retrieval pattern of one participant. The horizontal axis indicates the cumulative number of retrieved targets and the vertical axis indicates the cumulative time. These patterns indicate that the retrieval processes were “insightful”. The participants routinely retrieved five to seven targets regularly in 0 to 120 seconds, however, they could not retrieve the remaining targets for a long time; they reached an impasse (a memory

Table 2: Retrieval times for targets

Target	$C_1$	$C_2$	$C_3$	$C_4$	$C_5$	$C_6$	$C_7$	$C_8$

Figure 1: Initial ( $I$ ) and target ( $C_1...C_8$ ) characters

Table 1: Targets and operations

Target	Operation on the initial character
$C_1$	Add a vertical line inside $I$
$C_2$	Add a horizontal line inside $I$
$C_3$	Add a vertical line on the left outside $I$
$C_4$	Add a horizontal line under $I$
$C_5$	Add a vertical line that goes through $I$ and protrudes from the bottom
$C_6$	Add a vertical line that goes through $I$ and protrudes from the top
$C_7$	Add a vertical line that goes through $I$ and protrudes from both the top and the bottom
$C_8$	Add a slanted line on the top of $I$

block developed). Then, they broke the impasse, and subsequently retrieved the remaining targets relatively quickly.

Table 2 shows the mean retrieval time and the standard deviation for the eight targets by the 15 participants. There was a relationship between the figural features of the targets and retrieval time. Targets  $C_1$  and  $C_2$ , which are made by adding a line inside the initial character, were retrieved quickly. Targets  $C_3$  and  $C_4$ , which are made by adding a line outside the initial character, were retrieved next. It took longer to retrieve targets  $C_5$ ,  $C_6$ , and  $C_7$ , which have same added feature, a protruding line. Figure 3 shows the cluster tree for the eight targets obtained by cluster analysis using the flexible  $\beta$  method, where  $\beta = 0.25$ . Each target was clustered by retrieval time, so that the distance between targets indicates the retrieval time interval. It is clear that  $C_3$  and  $C_4$  were retrieved within a short interval, and the same applies to  $C_1$  and  $C_2$ , and  $C_5$  and  $C_6$ . These results show that the participants retrieved the targets using figural cues.

**Protocol analysis** The protocol data revealed that the participants repeated the following processes: (1) drawing a straight line, (2) confirming whether the character was a target. Repeating the processes, they reached the following three phases. *Phase1* (direct retrieval): 14 out of 15 participants reached this phase, and retrieved some targets without failure. *Phase2* (indirect retrieval): All the participants reached this phase, and retrieved some targets with retrieval failures, repeated retrievals, or by making writing motions with the hand without producing a visible trace. *Phase3* (impasses and insightful retrieval): 13 out of 15 participants reached this phase, and were unable to retrieve the remaining targets for a long period (over 50 seconds). In this period, they drew curved lines, added two strokes and found a Chinese char-

Figure 2: Retrieval patterns ( $n = 15$ )

Figure 3: Cluster tree of the targets

acter formed by adding two lines to the initial character, or did nothing. They failed repeatedly and their mental state fluctuated. However, they then suddenly retrieved one of the remaining targets. Once they found the figural pattern of the retrieved target, the rest were retrieved.

Table 3 shows the frequency of retrieved targets and time spent in each phase for the 15 participants.  $C_1$  and  $C_2$  (add inside) were retrieved mainly in *Phase1*.  $C_3$  and  $C_4$  (add outside) were retrieved mainly in *Phase2*.  $C_4$ ,  $C_5$ , and  $C_6$  (add protruding line) were retrieved mainly in *Phase3*.  $C_8$  (add a slanted line) was retrieved in all phases. The duration time indicates that it took much longer to complete *Phase3* than *Phase1* or *Phase2*, so that the subjects smoothly retrieved some targets in *Phase1* and *Phase2*, with some failures, but were deadlocked for a long time in *Phase3*. This indicates that retrieving targets by adding a line inside “ $I$ ” was easy, adding a line outside was relatively easy, and adding a protruding line was difficult.

## Discussion

**Chinese Characters for Japanese People** Japanese people store Chinese characters as not only letters but also words, and they can understand their meanings from their shapes, and it is natural and routine for them. We regard the ALIC (Add a Straight Line to the Initial Character) task as similar for Japanese people to the Word Fragment Completion task (e.g., Smith & Tindell 1997) for English-speaking people in terms of making up deficiency to retrieve a word.

Table 3: Frequency of retrieved target and duration time in each phase

	Drawing Operation										Duration time*		
	Inside line			Outside line			Protruding line			Slanted line	Mean	S.D.	
	$C_1$	$C_2$	Subtotal	$C_3$	$C_4$	Subtotal	$C_5$	$C_6$	$C_7$	Subtotal			$C_8$
<i>Phase1</i>	9	12	11	2	4	6	4	4	5	13	5	23.2	15.2

<i>Phase3</i>	1	0	1	1	1	2	6	7	6	19	5	540.3	547.6

Note: n = 15, \*seconds

**Retrieval with Constraint Relaxation** It has been shown that there are constraints on insight problems and that insight arises when the constraints are relaxed (e.g., Hiraki & Suzuki 1998; Knoblich et al. 1999). In the ALIC task, there seemed to be stronger constraints to add lines inside and outside the initial character, and a weak constraint to add a protruding line. Their strength seemed to change with repeated failure as the retrieval process progressed. When the constraints were relaxed, the participants could retrieve the remaining targets by insight.

## Model

### Hypothesis of the Model

**Retrieval Process and Constraint Relaxation** Hiraki & Suzuki (1998) maintained that the problem can be expressed by three components (object, relation, and goal), where each component has a constraint, and that insight problems are solved by cooperation among the components and with relaxing their constraints, which triggers a representation change. We assume that memory retrieval processes in the direct and indirect phases depend on the relaxation of constraints (object and relation), evaluated by the goal constraint.

**Insightful Retrieval with Chaotic Process** Finke & Bettle (1996) maintained that insight is spontaneous, and occurs at levels of processing that lie below conscious awareness and control of the underlying process, which characterizes chaotic thinking, and that a chaotic process can often be employed when normal pathways are blocked. Then, we assume that chaotic dynamics explain the insight process.

**Conscious and Unconscious Layer** Since Finke & Bettle (1996) maintained that a chaotic process is employed without awareness when logical strategies fail, we developed a model including conscious and unconscious layers. The former characterizes direct and indirect retrieval and the latter characterizes an impasse and insightful retrieval. In the conscious layer, a strategic process generates an image by adding one straight line to the initial character “I”, and then the image is sent to the unconscious layer. In the unconscious layer, the memory space associates the image and the retrieved result is sent to the conscious layer, where it is evaluated. Strategic procedures fail with repeated retrieval failure, so a chaotic retrieval process is then employed in the unconscious layer. Consequently, the state of the memory space repeats the chaotic transition and retrieves the remaining targets by insight.

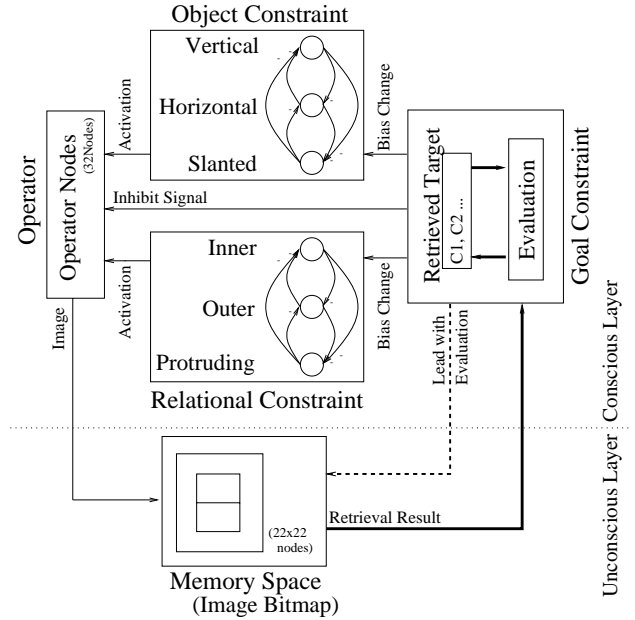

Figure 4: The DIMeC model

### Retrieval Process

Figure 4 illustrates the model. We named the model “DIMeC” (Dynamical model of Insightful Memory retrieval with Constraint relaxation). Narrow solid lines are enabled only when a strategic process is employed, the dashed line is enabled only when a chaotic process is employed, and bold solid lines are enabled all the time.

DIMeC repeats the following four steps: it generates an operator to draw a straight line; it generates an image by adding the line to the initial character; it associates the image with memory space and retrieves the result; and it evaluates the result. This process retrieves some targets and this period includes *Phase1* and *Phase2*.

After retrieving some targets, an impasse arises, with constraint relaxation because of repeated retrieval failure. Then, the chaotic process is employed and the remaining target is retrieved by insight. This period is *Phase3*.

### Definition of Memory Space

The image generated by the operator is associated with the memory space to be evaluated. The memory space is defined by learning Chinese characters with the Hebb rule, and representing their shape on a  $22 \times 22$  pixel image bitmap, where one unit represents one pixel. We employ a Hopfield network (Hopfield & Tank 1985) where the internal state of the  $i^{\text{th}}$  unit is defined as  $x_i$ ,

$$\frac{dx_i}{dt} = -\frac{x_i}{\tau} + \epsilon \left( \sum_k w_k u_i + \theta_i \right) \quad (1)$$

where  $\tau > 0, \epsilon > 0$  and  $\theta_i$  is the threshold of  $i^{\text{th}}$  unit. The output of the  $i^{\text{th}}$  unit is defined as  $u_i$ ,

$$u_i = \frac{2}{1 + e^{-\alpha x_i}} - 1 \quad (2)$$

where  $\alpha > 0$ . The energy function of the memory space is defined as  $E$ ,

$$E = - \sum w_{ij} u_i u_j \quad (3)$$

where  $w_{ij}$  is the connective weight between the  $i^{\text{th}}$  and  $j^{\text{th}}$  units. The weight is based on the one-year frequency data for Chinese characters in the daily *Asahi Shimbun* (Nozaki et al. 1996). Only the initial character and the eight targets are trained.

### Retrieval with Constraint Relaxation

As mentioned above, the retrieval process in the direct and indirect phases depends on constraint relaxation (object and relation). In the ALIC task, the object constraint consists of three elements (horizontal, vertical, and slanted) and the relational constraint consists of three elements (inside, outside, and protruding). Table 4 shows the relationship between constraints and targets. The goal constraint is not relaxed, but evaluates the result of retrieval and acts on the object and relational constraints.

**Relational and Object Constraints** A Hopfield network (Hopfield & Tank 1985) is employed to represent object and relational constraints, which are called object and relational constraint networks, respectively. One unit is introduced for each constraint element, and each inhibits the others within each network. The strength of each constraint is represented by its threshold. The initial state of the unit is set to zero, and the network repeats the transition, minimizing the energy function. After it stabilizes, an operator corresponding to the output of the constraint networks generates an image by adding a straight line to the initial character. The operator consists of 32 units, previously defined with the protocol data of the experiment. The output of operator  $\mathbf{q}$  is calculated by the transformation matrix  $\mathbf{W}$ ,

$$\mathbf{q} = \mathbf{W} \begin{bmatrix} \mathbf{Z} \\ \mathbf{R} \end{bmatrix} \quad (4)$$

where  $\mathbf{Z}$  is the output of the object constraint network and  $\mathbf{R}$  is the output of the relational constraint network. Then, the memory space associates the image and the result is retrieved.

**Goal Constraint** As mentioned above, the goal constraint evaluates the retrieval result and acts on object and relational constraints. There are five functions

(a) When a target is retrieved, the goal constraint sends an inhibitory signal  $\mathbf{G}$  to the units of the operator corresponding to the previous operation,

Table 4: Targets and constraints

Target	Constraint					
	Object			Relation		
	ver.	hor.	sla.	inn.	out.	pro.
$C_1$	+	-	-	+	-	-
$C_2$	-	+	-	+	-	-
$C_3$	+	-	-	-	+	-
$C_4$	-	+	-	-	+	-
$C_5$	+	-	-	+	-	+
$C_6$	+	-	-	+	-	+
$C_7$	+	-	-	+	-	+
$C_8$	-	-	+	-	-	+

Note: + indicates positive and - indicates negative

$$\mathbf{G} = -\mathbf{TA} \quad (5)$$

where  $\mathbf{A}$  is the retrieved target vector and  $\mathbf{T}$  is the transformation matrix from the target to the inhibitory signal. Consequently, in the next operation, a different operator with the same constraints generates an image.

(b) In the case of repeated retrieval of a target, the constraints corresponding to the previous operation are relaxed by,

$$\frac{\partial \Theta}{\partial t} = -\zeta_r \mathbf{s} \quad (6)$$

where  $\zeta_r > 0$ ,  $\Theta$  is the strength of the constraints (i.e., threshold vector of the object and relational constraint networks), and  $\mathbf{s}$  represents the relaxed unit.

(c) In the case of retrieval failure (i.e., finding no Chinese characters), the constraints corresponding to the previous operation are relaxed by using equation (6) and replacing  $\zeta_r$  with  $\zeta_f$  where  $\zeta_f > 0$ .

(d) In the case of an impasse, the state transition in the memory space is led by an evaluation function. Details are presented in the following section.

(e) In the case of an insightful retrieval, constraints corresponding to the figural pattern of the target are strengthened,

$$\frac{\partial \Theta}{\partial t} = \zeta_s \mathbf{VA} \quad (7)$$

where  $\zeta_s > 0$  and  $\mathbf{V}$  is the transformation matrix from the target vector to the figural pattern vector.

### Impasses and Insightful Retrieval

Impasses and insightful retrieval processes arising in the memory space are simulated using the ‘‘chaotic steepest descent’’ (CSD) model (Tani 1996) led by an evaluation function.

**Chaotic Transition** Tani (1996) developed the CSD model with a neural network employing a nonlinear resistant  $f_i$  for the  $i^{\text{th}}$  unit.

$$m\ddot{x}_i + f_i(\dot{x}_i, t) = -\epsilon \frac{\partial E}{\partial u_i} \quad (8)$$

$$f_i(\dot{x}_i, t) = (d_0 \sin \omega t + d_1)\dot{x}_i + d_2 \dot{x}_i^2 \text{sgn}(\dot{x}_i)$$

where  $m > 0, \epsilon > 0, d_0 > 0, d_1 > 0, d_2 > 0, \omega > 0$ ,  $u_i$  is the output of the  $i^{\text{th}}$  unit,  $x_i$  is the internal state of the  $i^{\text{th}}$  unit,  $\ddot{x}$  is the acceleration of  $x$ , and  $\dot{x}$  is the velocity of  $x$ . With this model, Tani showed that the state of the network travels from one energy basin to another

Figure 5: Retrieval patterns simulation 1 (left); simulation 2 (center); simulation 3 (right)

with chaotic dynamics as the resistance characteristics change from positive to negative, and the transition pattern corresponds to the cluster tree of the memory pattern. We employ the CSD model to simulate traveling among memories in an insightful retrieval process.

**Transition by Evaluation Function** Smith (1995) maintained that metacognitive monitoring towards a goal was often predictive of impending success. We have developed a metacognitive evaluation mechanism, similar to that which Nakagawa (1987) used to explain avoidance behavior by maximizing the evaluation of a psychological measure,

$$E_v = \sum_k \gamma_k \log \|\mathbf{u}_k - \mathbf{u}\|^2 \quad (9)$$

where  $\gamma_k > 0$ ,  $\mathbf{u}_k$  is an already retrieved target vector, and  $\mathbf{u}$  is the internal state vector in memory space. The value of the evaluation gets larger as the state in the memory space gets further from targets already retrieved.

As a result, we obtain the dynamics of the insightful retrieval, which can go from one memory to others as maximizing the evaluation,

$$\begin{aligned} m\ddot{x}_i + g_i(\dot{x}_i, x_i, t) &= -\epsilon \frac{\partial E}{\partial u_i} \\ g_i(\dot{x}_i, x_i, t) &= f_i(\dot{x}_i, t) + \beta \frac{\partial E_v}{\partial x_i} \end{aligned} \quad (10)$$

where  $\beta > 0$ .

## Simulation

### Method

The threshold vectors that represent the object and relational constraints at  $t$  are expressed as:

$$\Theta(t) = [\theta_v \ \theta_h \ \theta_s \ \theta_i \ \theta_o \ \theta_p]^T \quad (11)$$

where  $\theta\{v|h|s|i|o|p\}$  represents the strength of vertical, horizontal, slanted, inner, outer, or protruding constraints, and the notation “ $T$ ” indicates transposed.

**Simulation 1** The default constraint  $\Theta(0)$  was set as:

$$\Theta(0) = [2.0 \ 2.0 \ 1.0 \ 1.5 \ 1.0 \ 0.5]^T \quad (12)$$

In this condition, the vertical and horizontal constraints were stronger than the slanted constraint; the inner constraint was stronger than the outer constraint; and the outer constraint was stronger than the protruding constraint. The other parameters were as follows:  $\tau = 1.0$ ,

$\epsilon = 1.0 \times 10^{-3}$ ,  $\alpha = 3.0$ ,  $\zeta_f = 0.2$ ,  $\zeta_r = 0.8$ ,  $\zeta_s = 1.0$ ,  $m = 1.0$ ,  $\omega = \pi/20$ ,  $d_0 = 4.0$ ,  $d_1 = -4.0$ ,  $d_2 = 4.95 \times 10^1$ ,  $\beta = 1.0 \times 10^{-3}$ ,  $\gamma = 1.2 \times 10^1$ .

**Simulation 2** The default constraint  $\Theta(0)$  was set as:

$$\Theta(0) = [2.0 \ 0.5 \ 0.5 \ 1.5 \ 0.0 \ 3.0]^T \quad (13)$$

In this condition, the vertical constraint was stronger than the horizontal and slanted constraints; the protruding constraint was stronger than the inner constraint; and the inner constraint was stronger than the outer constraint. The other parameters were the same as in simulation 1.

**Simulation 3**  $d_2$  was set to 4.0, and the other conditions were the same as in simulation 1.

## Results and Discussion

Figure 5 shows retrieval patterns of simulations 1, 2, and 3. The horizontal axis indicates the retrieved target, the vertical axis indicates cumulative time,  $R(C_n)$  ( $n = 1, 2 \dots 8$ ) denotes the repeated retrieval of  $C_n$  ( $n = 1, 2 \dots 8$ ),  $F$  denotes retrieval failure, and  $I$  denotes the initial character. These patterns are similar to Figure 2. The retrieval patterns of the simulation reflected the typical retrieval patterns of the participants, because (1) each result could be divided into three phases, (2) targets with a figural pattern corresponding to strong constraints were retrieved first and weak ones were retrieved later, (3) targets with the same figural patterns were retrieved within a short interval, and (4) the retrieval process reached an impasse, and broke it insightfully by chaotic transition.

**Simulation 1**  $C_2$  (add inside) was retrieved at  $t = 14.3$  and  $C_1$  (add inside) was retrieved at  $t = 24.7$  because of the strong inner constraint. This period represents *Phase1* (direct retrieval).

$C_2$  was retrieved again at  $t = 35.2$  and  $C_1$  was retrieved again at  $t = 45.6$ , so the vertical, horizontal, and inner constraint were relaxed (i.e., the outer constraint became relatively stronger). As a result,  $C_3$  (add outside) was retrieved at  $t = 45.7$  and  $C_4$  (add outside) was retrieved at  $t = 45.8$ . Retrieval failed at  $t = 57.7$  and  $C_4$  was retrieved again at  $t = 57.8$ , so the horizontal, vertical, and outer constraints were relaxed. Since the protruding and slanted constraints became relatively stronger,  $C_8$  (add slanted) was retrieved at  $t = 68.8$ . This period represents *Phase2* (indirect retrieval with

repeated retrieval of some targets and retrieval failures).

After a retrieval failure at  $t = 78.9$ ,  $C_8$  was retrieved again at  $t = 79.5$ , so the slanted and protruding constraints were relaxed. Then, the strategic process failed, and the chaotic process was employed. The state in the memory space traversed  $C_4$ ,  $I$ ,  $C_1$ , and  $C_4$ . Traveling among memories,  $C_6$  (add protruding) was retrieved at  $t = 162.3$ . Having retrieved  $C_6$ , the protruding constraint became stronger. Therefore, the chaotic transition stopped and strategic process was employed again. Consequently,  $C_5$  (add protruding) was retrieved at  $t = 172.7$  and  $C_7$  (add protruding) was retrieved at  $t = 182.8$  because of the stronger protruding constraint. Retrieving all targets, the retrieval process ended. This period represents *Phase3* (impasses and insightful retrieval).

**Simulation 2**  $C_7$ ,  $C_6$ , and  $C_5$  (add protruding) were retrieved first because of the strong protruding constraint, then  $C_2$  and  $C_1$  (add inside) were retrieved. Because the outside constraint was weak,  $C_4$  and  $C_3$  were not retrieved by the strategic process in *Phase1* or *Phase2*, but were retrieved by the chaotic process in *Phase3*.

**Simulation 3** In *Phase1* and *Phase2*, the retrieval process was the same as in simulation 1, but  $C_7$ ,  $C_6$ , and  $C_5$  were retrieved earlier than in simulation 1 by the chaotic process in *Phase3*, because the retrieval process traveled among memories more often. This was caused by the smaller value of the nonlinear resistant coefficient  $d_2$ , which corresponds to the result of Tani (1996).

## General Discussion

Research into memory blocks has shown its process by setting an external stimulus (e.g., Smith 1995; Smith & Tindell 1997; Yaniv et al. 1995). We examined the dynamic spontaneous process of its resolution, and showed that the retrieval processes are similar to insight with constraint relaxation. We think that insight and memory block resolution can be explained by the same mechanism, even though representational change or information retrieval can explain the process of insight. The DIMeC (Dynamical model of Insightful Memory retrieval with Constraint relaxation) was developed, depending on constraint relaxation and a chaotic neural network. Therefore, we consider that the DIMeC architecture can be applied to the dynamic insight process.

Human memory has been explained using a neural network model based on its parallelism and distributive representation. Too much interest in this has prevented the development of a dynamical model of memory retrieval, although the human cognition process essentially consists of both parallel and sequential processes. The DIMeC model is a hybrid system that has both parallel and sequential mechanisms, enabling it to explain dynamical processes. It also refers to the conscious and un-

conscious, and can explain the priming effect, TOT phenomenon, output interference, and other memory block phenomena.

## Abstract

This paper presents three experiments that study declarative and procedural learning in alphabetic retrieval. It is based on the view that speed-up during skill acquisition can result from acquiring either new procedural knowledge or new declarative knowledge, followed by speed up of both types of knowledge. In addition, both lead to different predictions of transfer due to the different retrieval characteristics of declarative and procedural knowledge. Specifically the paper uses three forms of alphabet arithmetic problems: 1)  $A + 3 = ?$ , 2)  $D - 3 = ?$ , and 3)  $? + 3 = D$ , to further examine the acquisition and use of declarative and procedural knowledge. The first two forms replicate experiments conducted by Rabinowitz and Goldberg (1995), whereas the third experiment attempts to maximally discriminate between declarative and procedural skill acquisition. The results provide further support for the hypothesis that speed-up can result from either declarative or procedural acquisition and strengthening.

## Introduction

The alphabet is a long and well-learned list. How such lists are structured in memory and how they are accessed is certainly one of the fascinating inquiries in cognitive science.

Different from the traditional serial memory tasks, where subjects are to recall a newly-learned list of items in a specified order, in alphabetic retrieval, the content retrieval is trivial. The central interest in alphabetic retrieval research is to study how the sequence information is maintained and accessed in human memory.

The techniques often used to study alphabetic retrieval can be roughly classified into two categories based on whether letters are to be actually retrieved or not. In the first category, no letters need to be retrieved. In Lovelace and Snodgrass (1971), for example, subjects were presented two letters in a pair, and had to judge if the two are in the correct alphabetic order. In the second category, one or more letters have to be retrieved. An example is the experiment by Lovelace, Powell, and Brooks (1973), in which subjects were presented a pair of letters and were

instructed to retrieve (recite) the letters between the two (see also Browman and O'Connell, 1976).

A more elegant technique in the second category is the so-called *alphabet arithmetic* task. In an alphabet arithmetic task, subjects are presented a letter, *letter1*, and a *number*. The goal is to retrieve the letter, *letter2*, that is *number* letters after (or before) *letter1*. Reaction Time (RT) is usually measured. This technique can either take the form of questions like “what comes three letters after K” (e.g., Lovelace & Spence, 1972; Hovancik, 1975; Klahr, Chase, & Lovelace, 1983), or appear in the pure algebraic form (e.g., Rabinowitz & Goldberg, 1995; Johnson, Wang, & Zhang, 1998). An example of the latter is “ $K+3=?$ ”. Subjects have to provide *N* as the answer, because *N* is 3 letters after *K*.

Various alphabet arithmetic studies all produce a more or less consistent result pattern. When RTs are plotted as a function of the serial positions of *letter1* (the stimulus), the curve ascends non-monotonically at the aggregated level, with local peaks and valleys. However, there is no general agreement upon the theoretical explanation.

Klahr, Chase, and Lovelace (1983) proposed a theory of the cognitive structure and process involved in alphabetic retrieval. According to this theory, the alphabet is represented hierarchically. At the top level, the whole list is represented as a set of groups. At the second level, each group is represented as a set of letters. Alphabetic retrieval is a search process that occurred sequentially on both levels. First, the correct group that the to-be-retrieved letter is in has to be found. Second, the letter then has to be found within that group. Both processes are conducted by self-terminating, serial searches, starting with the initial item at each level.

Obviously, based on this theory, the gradually ascending pattern of alphabetic retrieval results from this self-terminating, serial search process: it takes longer to retrieve later letters in the alphabet. In addition, since the search occurs on two levels, a sawtooth-shaped RT curve with local peaks and valleys is evident: valleys and peaks appear at the beginning (with minimum second-level search) and the end (with maximum second-level search) of each group, respectively.

---

<sup>1</sup> Portions of this research were conducted when the authors were at The Ohio State University, Departments of Pathology (Dr. Johnson) and Psychology (Drs. Wang and Zhang).

Although the idea that serial lists are represented hierarchically in memory is quite popular (e.g., Anderson & Bower, 1973; Estes, 1972; Johnson, 1991; Shiffrin & Cook, 1978; Slamecka, 1967), some researchers argue that such a structural speculation is unjustified and a simple associative model is at least equally plausible (e.g. Scharroo, Leeuwenberg, stalmeier, & Vos, 1994). According to this association idea, the alphabet is not represented hierarchically but as a single-level associative chain. In addition, alphabetic retrieval is often a direct access rather than a serial search from the very beginning. RTs in an alphabet arithmetic task are determined by the association strengths between the stimulus and the answer. The difference in association strengths is a function of past experience of how the alphabet is learned and practiced. In this view, therefore, the increasing RT curve across the alphabet is a result of the overall decreasing association strength across the alphabet. The concept of group (or chunk), which is critical in the hierarchical view and is assumed to be responsible for the fine structure of the RT curve, is nothing more a series of letters with strong associations.

Both views explain the data reasonably well (see Scharroo, Leeuwenberg, Stalmeier, & Vos, 1994). As a result, the debate continues. Fortunately, recent progress in cognitive architectures and distinction between declarative and procedural knowledge (e.g., Anderson, 1993; Anderson & Lebiere, 1998) shed new light on how alphabetic retrieval might work. Instead of treating alphabetic retrieval as either serial searching or direct associative access, it is now possible to incorporate the two views in a unified framework of declarative/procedural distinction. Specifically, the knowledge of alphabet arithmetic can be represented either declaratively (e.g., “N is 3 letters after K”) or procedurally (e.g., “To find out the letter that is 3 letters after K, count from K three times, and output the result”). While procedural knowledge is universally applicable and supports more general problem solving, such as searching, it is time consuming. On the contrary, declarative knowledge supports direct memory retrieval thus is fast, but it is conditioned on the availability of the specific declarative knowledge. As a result, when a certain problem can be solved based on stored declarative knowledge, direct retrieval is applied – no serial counting is necessary. On the other hand, when the specific knowledge necessary to solve the problem is not readily retrievable, some problem solving methods based on generally-purposed procedural knowledge, such as serial counting, have to be used. This declarative/procedural approach incorporate the hierarchical searching view and the direct association view in the sense that strong association strengths are represented by retrievable declarative knowledge, and when retrievable declarative knowledge is not available, active searching with the aid of procedural knowledge starts.

Whether alphabetic knowledge is represented declaratively or procedurally is determined by, among other things, past experience. Repeatedly solving a problem procedurally may eventually result in declarative knowledge of that problem. Rabinowitz and Goldberg (1995)

nicely illustrated this phenomenon. In one of their experiments, they asked subjects to solve 432 alphabet arithmetic problems and measured their RTs. For one group of subjects, the 432 problems include a set of 12 different problems, each repeated 36 times. For another group of subjects, the problem set consists of a set of 72 different problems, each repeated 6 times. They found that although the two groups had the same RTs at the beginning of training, the first group solved the problems much faster than the second group in the later stage of training. The reason, they argued, is that both groups solved problems procedurally (i.e., by counting) at the beginning. Since the first group solved the same set of problems over and over again, they acquired declarative knowledge about these problems and began direct retrieval in the later stage. The second group did not get enough practice for any problem, thus they kept procedurally searching in the entire session.

The idea that people solve problems by applying both declarative and procedural knowledge, whichever is appropriate, has received much support (e.g., Anderson & Lebiere, 1998; Reder & Ritter, 1992; Siegler, 1988). However, how well this framework can be applied to account for various alphabetic retrieval tasks remain unexplored. It is the purpose of this paper to report a study that empirically investigates the declarative/procedural distinctions in alphabet arithmetic.

## Experiment

For any specific alphabet arithmetic fact (e.g., C is 2 letters after A), we distinguish three different evaluation forms (see Figure 1). The first one is the standard *addition* form, in which subjects are presented “A + 2 = ?” and required to produce “C”. The second form is a *subtraction* form, in which subjects are asked to produce “A” with respect to the problem “C – 2 = ?”. The third form is called *match*. In a match form, subjects are presented “? + 2 = C”, and have to report “A” as the answer.

Addition:	A + 2 = ?
Subtraction:	C – 2 = ?
Match:	? + 2 = C

**Figure 1.** Three forms of alphabet arithmetic

Solving the three problems in Figure 1 essentially requires the same alphabet arithmetic fact. However, due to the different evaluation forms, different declarative and/or procedural representations might be applied. More specifically, if it is available and retrievable, a single piece of declarative knowledge, “C is 2 letters after A”, can be used to quickly solve both the addition and match problems. However, a different piece of declarative knowledge, “A is 2 letters before C”, has to be available and retrievable to quickly solve the subtraction problem. On the other hand, when relevant declarative knowledge is not retrievable, these problems have to be solved procedurally. Specifically, while the addition problem requires

a count forward procedure (i.e., “A, B, C..”), both the subtraction and match problems require a count backward procedure (i.e., “..C, B, A”). In addition, due to the addition format in the match problem, an extra step may be needed to convert it to a recognizable subtraction format so that the count backward procedure can be applied.

118 subjects from The Ohio State University participated in the experiment. They were divided into three groups, with at least 30 subjects in each group. A learning-transfer paradigm was adopted. In the learning phase, all three groups of subjects learned to solve alphabet arithmetic problems in the addition form. In the transfer phase, each group of subjects was instructed to solve only one type of problems, either addition, subtraction, or match.

One critical manipulation in the experiment is that each subject group was further divided into two subgroups, with each having different learning experience. Specifically, in the *consistent* subgroup, subjects solved a set of 12 problems over and over again, with each problem presented 36 times. In the *varied* subgroup, subjects solved a set of 72 problems, with each only presented 6 times. It is hypothesized that subjects in the consistent subgroups gradually developed declarative knowledge about the problems that they solved repeatedly, while subjects in the varied subgroups did not due to insufficient practice.

The experimental design is shown in Table 1. It is clear that in the transfer phase, subjects in the addition group were presented new problems that they had not seen in the learning phase, although they were in the same addition form. On the contrary, subjects in the subtraction and match groups were presented a subset of the problems they had seen in the learning phase, but in different forms. It is important to note that a portion of the experiment is essentially a replication of Rabinowitz and Goldberg (1995)’s experiment.

**Table 1.** Experimental Design\*

	Learn- ing	Transfer		
		addition “A+2=?” [30]	subtraction “C-2=?” [36]	match “?+2=C” [39]
consis- tent	$\alpha$ (36)	$\beta_2$	$\alpha$	$\alpha$
varied	$\alpha+\beta_1$ (6)	(2)	(3)	(3)

\*An alphabet arithmetic problem takes the form of letter1 +/- number = letter2. In the experiments, letter1, letter2  $\in \{A, B, \dots, Z\}$ , number  $\in \{1, 2, \dots, 6\}$ . With the constraint that the problem must be valid, we have a total of 135 problems. Let  $\alpha$  be a set of 12 such problems, where each possible number appears twice. Let  $\beta$  be a set of 96 such problems, and  $\alpha \cap \beta = \emptyset$ . In addition,  $\beta_1$  contains 60 problems of  $\beta$ , and  $\beta_2$  contains the other 36 problems. Each possible number appears in  $\beta_1$  10 times, and in  $\beta_2$  6 times. The numbers in parentheses are the number of times each problem was presented. The numbers in brackets are the numbers of subjects.

The results show that subjects could solve these alphabet arithmetic problems quite accurately. The overall error rate is 8%. There were 13 subjects who either did not follow the instruction (e.g., writing down the alphabet on a piece of paper) or had more than 20% errors. They are excluded in further analysis. More detailed error rate information, conditioned on subject groups and experimental phases, is shown in Table 2. It is clear that subjects made significantly more errors in the transfer phase, especially when they tried to solve problems in different evaluation forms.

**Table 2.** Error Rate

%	Addition	Subtraction	Match	Overall
Learning	6.0	7.8	6.4	6.8
Transfer	7.5	30.2	25.9	18.9
Overall	6.3	9.5	7.9	8.0

The RT results are presented separately for the learning performance and the transfer performance.

Since all three groups of subjects were trained in the same evaluation forms, the learning data is combined across the three groups. Following the practice of Rabinowitz and Goldberg (1995), to show the trend, we divided the total number of trials (432) into 36 blocks, with 12 trials in each. For each subject, we calculated the median RT of each block. Then the mean of these medians was computed across the subjects. The results are shown in Figure 2, separately for the consistent and varied conditions. It indicates that although subjects showed the same level of performance at the beginning of learning, the subjects in the consistent condition solved problems much faster toward the later stage of learning than those in the varied condition. Statistics confirmed the result. A non-linear mixed-effect exponential model was nicely fitted to the data in each condition, and the fitting curve is also shown in Figure 2. Examining the parameter estimations, it is shown that the two conditions differ significantly in terms of both the decay rate ( $z=-2.07$ ,  $p<0.05$ ) and the asymptote ( $z=14.15$ ,  $p<0.01$ ). The effect size of the asymptote difference, about 1457ms, is a strong support for the argument that different problem solving strategies were adopted in the later stage of training.

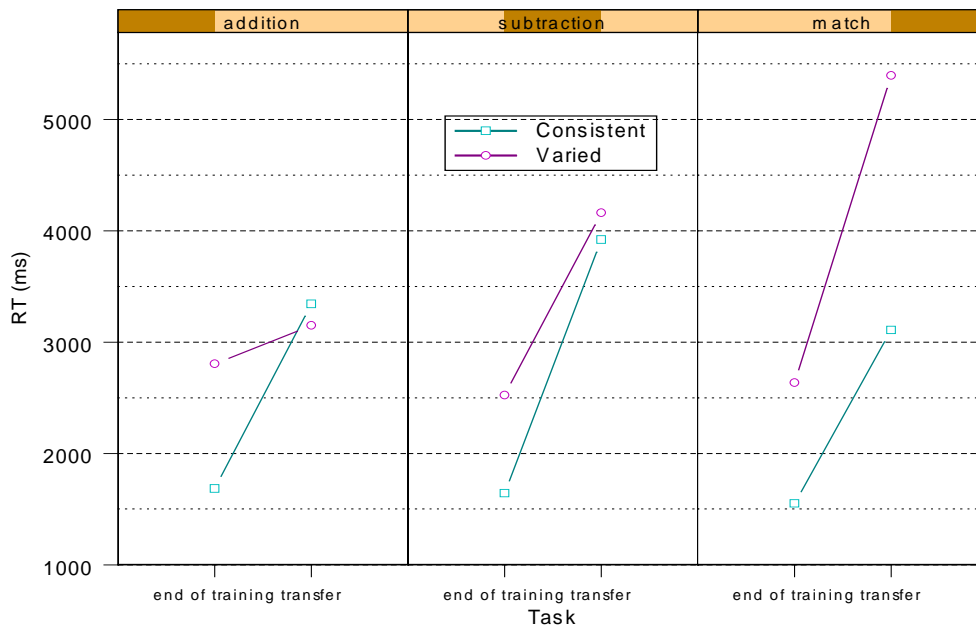

The transfer performance, conditioned on three groups of subjects and two learning conditions, is shown in Figure 3. It is easy to observe that the transfer effect (i.e., the difference between the end-of-training performance and the transfer performance) is quite different across the experimental manipulations. An overall three-way MANOVA shows that the three-way interaction among the transfer condition (addition, subtraction, or match), the learning condition (consistent or varied), and the transfer itself (the end of training performance vs the transfer performance) is significant ( $F(2,99)=6.23$ ,  $p<0.01$ ). Further analyses show that, 1) while the interaction between the learning condition and the transfer effect is significant in both the addition and match groups ( $F(1,28)=34.20$ ,  $p<0.01$ ;  $F(1,37)=5.15$ ,  $p<0.05$ , respec-

tively), it is not significant in the subtraction group; 2) In the consistent learning condition, the transfer effect is significant in all three groups ( $F(1,13)=82.63$ ,  $p<0.01$ ;  $F(1,19)=33.46$ ;  $p<0.01$ ;  $F(1,20)=64.58$ ,  $p<0.01$ ; for the addition, subtraction, and match groups, respectively). In addition, both the end-of-training performance and the transfer performance are not significantly different across the three groups; 3) In the varied learning condition, the interaction between the transfer effect and the transfer condition is significant ( $F(2,47)=7.39$ ,  $p<0.01$ ): the trans-

fer effects in the three transfer conditions are 345.3ms, 1637.7ms, and 2759.1ms, respectively; and 4) while in both the addition and subtraction transfer conditions, the performance in the transfer stage is not different between the consistent and varied learning conditions (3150ms vs 3343ms, and 4162ms vs 3922ms, respectively), in the match transfer condition, variedly-trained subjects performed much worse (i.e., longer RTs) than those consistently-trained (5396ms vs 3109ms,  $F(1,37)=23.12$ ,  $p<0.01$ ).

**Figure 2.** The Learning Performance.

**Figure 3.** The Transfer Performance.

## Conclusions and General Discussions

Overall the results are consistent with our hypothesis about declarative/procedural distinction and interaction. First, in the addition-transfer condition, it is assumed that consistent training leads to declarative knowledge about the 12 over-learned problems, and varied training results in the counting procedure being well practiced though no declarative knowledge has been acquired. In the transfer stage, since different and new addition problems were presented, no relevant declarative knowledge was available, which left the counting procedure the only appropriate means. As a result, subjects with varied training benefited and showed a transfer effect because they had practiced and speeded up their counting procedure during their extensive training. On the contrary, subjects with consistent training showed no transfer to the new addition problems, presumably because the declarative knowledge they gained was specific to the training problems thus not useful and meanwhile they did not practice enough their counting procedure in the training.

Second, in the subtraction-transfer condition, both consistently-trained and variedly-trained subjects basically faced the same new challenge – counting down the alphabet. For those with consistent training, although the transfer problems were essentially equivalent to the training problems, due to different evaluation forms, declarative knowledge about these problems was not applicable in the transfer stage. In other words, it seems likely that most subjects did not realize that they could use their memory of addition results to solve subtraction problems. As a result, they had to join those variedly-trained subjects to try to adopt the brand new counting-back procedure to solve those transfer problems. Both groups showed no transfer.

Finally, the match problem serves an excellent condition to maximally discriminate between procedural and declarative learning. According to the model of alphabet arithmetic described above, to solve a match problem, subjects could use either declarative knowledge or procedural knowledge. To solve a match problem declaratively, one need only match the problem with their declarative knowledge in order to find an answer, which would suggest a perfect transfer when the corresponding declarative knowledge is available. To solve a match problem procedurally, normally one would need to first recognize that the problem is actually a subtraction problem by doing an algebraic transformation, then adopt a procedure to count back through the alphabet, which would suggest very little transfer from the previous training.

In the current match condition, subjects with varied training in fact had no choice: they had to solve the match problems procedurally, simply because they had not acquired the relevant declarative knowledge. This explains the worst transfer performance in the varied match condition. On the contrary, for those subjects with consistent training, they actually had a choice. They could solve the match problems by either using their newly acquired de-

clarative knowledge, thus producing perfect transfer, or, they could adopt the similar converting-and-counting-back procedure, thus producing much worse transfer. The current data seems to indicate that subjects adopted neither one. In the consistent match condition, the transfer is neither perfect nor as bad as that in the varied match condition. It seems that subjects somehow combined the two approaches to solve the transfer problems. One possible scenario is that subjects used declarative knowledge to fetch the possible answer and then used a counting procedure to verify the solution. Another possibility is that some subjects used a declarative strategy and some subjects used a procedural strategy, which, when aggregated, produces the resultant pattern.

Johnson, Wang, and Zhang (1998) described an Act-R model of alphabet arithmetic that accounted for the results of the two experiments conducted by Rabinowitz and Goldberg. How this model can be applied to the match condition is of great importance to further clarify the declarative and procedural learning and application issues in alphabetic retrieval. Such a model is currently under development.

# A Process Model of Children's Early Verb Use

Gary Jones (gaj@Psychology.Nottingham.AC.UK)  
Fernand Gobet (frg@Psychology.Nottingham.AC.UK)

## Abstract

The verb-island hypothesis (Tomasello, 1992) states that children's early grammars consist of sets of lexically-specific predicate structures (or verb-islands). However, Pine, Lieven and Rowland (1998) have found that children's early language can also be built around lexical items other than verbs, such as pronouns (this contradicts a strict version of the verb-island hypothesis). This paper presents a computational model (called MOSAIC), which constructs a network of nodes and links based on a performance-limited distributional analysis of the input (mother's speech). The results show that utterances generated from MOSAIC: (1) more closely resemble the child's data than the child's mother's data on which MOSAIC is trained; and (2) can readily simulate both the verb-island and other-island phenomena which exist in the child's data.

## Introduction

One of the most influential recent constructivist accounts of early grammatical development is Tomasello's (1992) verb-island hypothesis. According to this view children start producing multi-word speech without knowledge of syntactic categories, such as noun and verb. Instead, children's early language use is based on a "functionally based distributional analysis" (Tomasello, 1992, p.28) of the language they hear. This analysis assigns predicate<sup>1</sup> status to specific words based on their function in sentences. For example, in the sentence "Adam kicks the ball", the roles of Adam and the ball are centred around "kicks", such that Adam is someone who can kick things, and the ball is something that can be kicked. The lexical item "kick" is therefore assigned a predicate role which takes as arguments a "kicker" (Adam) and a "kickee" (the ball).

The notion of "verb-island" arises because most predicates are verbs in adult language and the arguments the predicate takes are specific to that predicate (e.g., "kickers" and "kickees"). Based on this idea, children's early grammar will consist of inventories of verb-specific predicate structures (i.e., verb-islands). For example, the child will use any object which it knows has performed kicking as the antecedent to "kick". Verb-general marking (e.g., knowing that someone who *kicks* can also be someone who *hits*) does not occur until the formation of a verb category.

---

<sup>1</sup> For Tomasello, a predicate is a lexical item (typically a verb) which forms the main relational structure of a sentence. Arguments are the lexical items to which the predicate relates. Therefore in the sentence "John walks the dog", "walks" is the predicate and "John" and "dog" are the arguments.

In agreement with Ninio (1988), Tomasello argues that children will only start to construct word categories such as noun and verb when they begin to use instances of these categories as the arguments of predicates (e.g., using "ball" as an argument to the predicate "kick"). As verb-islands often use nouns as their arguments, children should form noun categories relatively early in their language development. Verb categories will only be formed later when children begin to use verbs as the arguments of other predicates (e.g., in double-verb constructions such as "Want to + V" or "Can't + V").

The verb-island hypothesis can account for a number of phenomena in children's early multi-word speech. First, it can explain the lexically-specific patterning of children's early verb use. For example, Tomasello (1992) has shown that in the early stages of grammatical development his daughter's ability to generate longer sentences built up piecemeal around particular verbs, and failed to generalise to new verbs which typically entered her speech in very simple structures. Second, it can explain the restricted nature of children's early word order rules. For example, Akhtar and Tomasello (1997) have shown that young children not only fail to generalise Subject-Verb-Object (SVO) word order knowledge from one verb to another, but are also unable to use it as a cue for sentence comprehension with novel verbs. Third, it can explain differences in the flexibility with which children use nouns and verbs in their early multi-word speech. For example, Tomasello and his colleagues have shown that young children will readily use novel *nouns* as arguments in familiar verb structures but tend to restrict their use of novel *verbs* to the structures in which they have heard those same verbs modelled in the input (Akhtar & Tomasello, 1997; Olguin & Tomasello, 1993; Tomasello & Olguin, 1993).

One weakness of the hypothesis is that there are aspects of children's early multi-word speech that do not fit a strict version of the verb-island hypothesis. For example, Pine, Lieven and Rowland (1998) have shown that many children acquire structures based around high frequency items which Tomasello would not define as predicates (e.g., case-marked pronouns such as "I" and "He" and proper-nouns such as "Mummy" and the child's name). Moreover, these pronoun and proper-noun islands not only seem to be functioning as structuring elements in children's speech, but as structuring elements which accept verbs as slot fillers. These data suggest that the lexical specificity of children's early multi-word speech is not always "verb-specificity" or even "predicate-specificity" (because verbs can be slot fillers of other structures). Verb-island effects may simply be a

special case of more general frequency effects on children's acquisition of lexically-specific structures.

This paper presents a computational model called MOSAIC (Model of Syntax Acquisition in Children), which combines naturalistic input (mother's speech) and a performance-limited distributional learning mechanism in order to produce child-like utterances as output. The results will show that MOSAIC is able to: 1) simulate verb-island phenomena that are consistent with children's early multi-word speech; 2) simulate other-island phenomena which exist in children's early multi-word speech but which are problematic for a strict version of the verb-island hypothesis; and hence 3) provide a process-based explanation of why some lexical items come to function as "islands" in the child's grammar and others do not.

### The MOSAIC model

MOSAIC is a variant of EPAM/CHREST (De Groot & Gobet, 1996; Gobet, 1996; Gobet & Simon, in press) which creates a discrimination network (a hierarchical structure of nodes which are linked together) based on a given input. Discrimination networks have a root node at the top of the hierarchy, with all other nodes cascading from the root node (see Figure 1 for an example). Nodes are connected to each other by links. This section will describe the basic working of MOSAIC, and then give an example of MOSAIC's learning mechanisms using mother's speech as input.

#### A general overview of MOSAIC

MOSAIC's discrimination network begins with a root node (which always contains no information). As in other models of the EPAM family (Feigenbaum & Simon, 1984), learning occurs in two steps. The first step involves traversing the network as far as possible with the given input, taking one feature of the input at a time. This is done by starting at the root node and examining all the test links from the root node, selecting the first test link whose test is fulfilled by the first feature in the input (when beginning learning, only the root node will exist and therefore no tests can be fulfilled). The node at the end of the test link now becomes the current node and the next feature of the input is applied to all the test links immediately below this node. The traversal continues until a node is reached where no further traversing can be done (either because the current input feature fulfilled none of the tests of the node's test links, or the current node has no test links below it). Traversing the network in this way is also how information can be output from the network (this will be explained later).

The second step involves adding new information, nodes, and test links. The full input is compared to the information at the final node that was reached by traversal. Based on this comparison, learning can arise in two ways:

1. *Discrimination*. When the input information mismatches the information given at the node (the *image*), a new test link and node are added to the tree below the node that has just been reached. The new test

will relate to the next immediate mismatched feature in the input.

2. *Familiarisation*. When the input information is under-represented by the image (the information given at the node), additional feature(s) from the input are added to the image. The information in the node will contain all information that led to the node during traversal, plus any additional feature(s).

Discrimination therefore creates nodes and test links, and familiarisation creates or modifies the information contained in nodes. The amount of information stored at nodes increases with their distance from the root, because each node contains the accumulation of information of all the nodes that were accessed in traversing to the node.

There are two constraints that are imposed when learning by discrimination and familiarisation. First, before creating a node containing more than one input feature (i.e., a sequence of features), the individual features in the sequence must have been learnt (each input element is said to be a *primitive*). Second, all nodes containing just one input feature are linked to the root node (i.e., all primitives are immediately below the root node; in this way all sequences of input features are below the node which represents the initial feature in the sequence).

Learning can also occur *whilst* traversing the network. MOSAIC compares each node traversed with other nodes in the network to see if they have a similar usage. Similar usage means that there are common test links below each of the two nodes. When this is the case, a lateral link is created between the nodes (this is explained further in the following section).

#### An example of MOSAIC learning an utterance

The input given to MOSAIC consists of a set of mother's utterances. Each line of input corresponds to a single utterance (delimited by an END marker which signifies the end of the utterance), and each word in the utterance is an input feature. The example utterance "Who came to see you on the train?" will be used as input to illustrate how MOSAIC learns.

The first input feature ("who") is applied to all of the root node's test links in the network. As the network is empty, there are no test links. At this point MOSAIC must discriminate because the input feature "who" mismatches the information at the root node (the root node information is null). The discrimination process creates a new node, and a test link from the root node to the new node with the test "who" (see Figure 1). MOSAIC must then familiarise itself with the input feature, in order to create the "who" information in the image of the node.

When encountering the same input for a second time, the test link "who" can be taken, and the input can move to the next feature, "came". As the node "who" does not have any test links below it, then under normal circumstances discrimination would occur below the "who" node. However, MOSAIC has not yet learnt the input feature

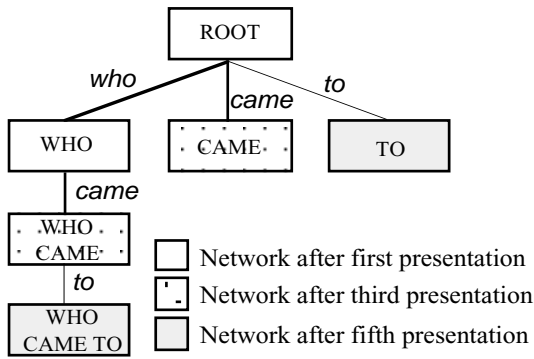

Figure 1: Structure of the MOSAIC net after five presentations of the input “Who came to see you on the train”.

“came”, and so discrimination occurs below the root node. Familiarisation will then fill the image of the new node with “came”. The third time the input is seen, the “who” test link can be taken, and the input can move onto the next feature (“came”). No further test links are available, but the input “who came” mismatches the information at node “who” and so discrimination occurs. A new node “who came” is created (see Figure 1). Familiarisation will fill in the image of the new node.

After a total of five presentations of “Who came to see you on the train?”, the network will have learnt the phrase “Who came to” (see Figure 1). This simple example serves to illustrate how MOSAIC works; in the actual learning phase each utterance is only used once, encouraging a diverse network of nodes to be built.

During traversal of the network, lateral links can be created. A lateral link is a link between any two nodes in a MOSAIC network (excepting the root node). Lateral links are designed to link together nodes which are used in the same manner. Usage is based on the test links that are immediately below a particular node. The way that MOSAIC creates nodes and test links means that all the test links that are below a particular node will consist of the word or words that follow that node in the input (as shown in the previous section). For example, in Figure 2, the words “moves”, “sits”, “walks”, and “chases” must have followed “cat” in the input, meaning sentences such as “cat sits down” have been seen in the input.

When there is a significant amount of overlap between words or phrases that follow a particular word in the input (i.e., there is significant overlap between the test links that are below two particular nodes) then the two nodes can be linked by a lateral link. The minimum number of test links which must overlap for a lateral link to be created is determined by an *overlap parameter*. Using the network in Figure 2 as an example, “cat” and “dog” will have a lateral link between them when the overlap parameter is set to 3 because at least 3 of the test links below “cat” and “dog” are shared. The next section shows how lateral links are used when generating output from MOSAIC.

### Generating utterances from a MOSAIC network

Utterances can be generated from MOSAIC by beginning at the root node and traversing down until encountering a node which contains an END marker (i.e., the last word in the utterance must be one which ended an utterance in the input). Whilst traversing down the network, both test links and lateral links can be taken. To help explain how utterances are generated from the network, test links will be called *rote links* hereafter, and lateral links will be called *generative links*. This is because test links are created from rote learning, and lateral links are created from overlap in node use. When traversing the network, if only rote links are taken then the resulting utterance must have been present in the input (because of the dynamics of the creation of the discrimination network, traversing down from the root node will always produce a phrase that existed as a full utterance or part of an utterance in the input). However, when a generative link is taken, the resulting utterance may never have been seen before in the input.

When generative links exist, MOSAIC can take these links as part of the traversal of the network. For example, in the network shown in Figure 2, the generated utterance could begin with “cat”, take the generative link across to “dog”, and then continue the utterance with any phrase that follows “dog” (i.e., the remainder of the phrase is built up by traversing the nodes below “dog”). This produces novel utterances that were not seen before in the input, such as “cat runs” and “dog moves”. Currently, only one generative link is taken per traversal of the network in order to limit the number of generated utterances (the next section

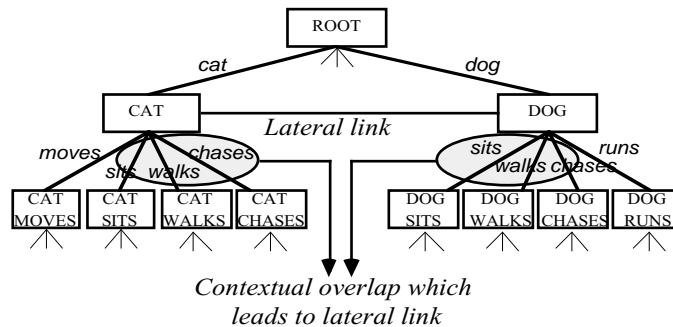

Figure 2: Example of how lateral links are created.

shows that taking only one generative link enables the network to produce over seven generated utterances to every one rote learned utterance).

### Modelling verb-island phenomena

The verb-island hypothesis states that children’s early language consists of lexical items (typically verbs) existing as predicates, which take other lexical items as arguments. As lexical items such as pronouns cannot, in Tomasello’s terms, be predicates, then for flexibility the terms frame and slot filler will be used in place of predicate and argument. A frame is therefore a relational structure of a sentence and the slot fillers to the frame are the lexical items which relate to the frame. For example, the sentence “Daddy moves the chair” has “moves” as the frame and “Daddy” and “chair” as the slot fillers.

The verb-island hypothesis can be confirmed if the language data contain verbs which exist as frames (i.e., verbs which take several different lexical items as slot fillers), and contain *very few other lexical items* which exist as frames. To examine this, the language data will be analysed by extracting verb+common-noun and common-noun+verb sequences. Common-nouns, rather than all lexical items, are examined because: 1) they are the most common category in children’s speech; 2) Tomasello (1992) predicts that children form noun categories earlier than verb categories based on their use as slot fillers (i.e., they should be used often as the slot fillers of verb frames); and 3) the analysis is more tractable with only two types of lexical item.

To investigate whether other-island phenomena exists, pronoun+verb and proper-noun+verb combinations will be extracted and analysed. Pronouns are used because a strict version of the verb-island hypothesis does not allow pronouns to act as islands. Also, pronouns occur with high frequency in the child’s data and are often followed by a verb (i.e., they may show verbs being used as slot fillers to other frames). Proper-nouns are used for an additional test of other-islands.

### Method

#### Subject data

Three sets of data are compared for the verb-island phenomena: the utterances from one child, Anne; the utterances from Anne’s mother; and the utterances from

Table 1: Sample of the utterances generated from MOSAIC.

MOSAIC utterance
I forgotten
That’s my toes again
Where’s the magic bag
And she like them
Baby put the sheep in the farmyard
What about the camel
All on the settee
Who can you see on here
He didn’t catch me

MOSAIC when trained using Anne’s mother’s utterances as input. The utterances for Anne and her mother were taken from the Manchester corpus (Theakston, Lieven, Pine & Rowland, in press) of the CHILDES database (MacWhinney & Snow, 1990). The corpus consists of transcripts of the mother-child interactions of twelve children over a period of twelve months. The transcripts contain both the utterances and the syntactic categories (e.g., noun, verb) of all words in the utterances. The child focused on here, Anne, began at age 1;10.7 and completed the study at age 2;9.10. Her starting MLU (Mean Length of Utterance) was 1.62 with a vocabulary size of 180.

For Anne there were 17,967 utterances (i.e., utterance tokens), of which 8,257 utterances were unique (i.e., utterance types). There were 7,331 multi-word utterance types. For Anne’s mother, there were 33,390 utterance tokens, 19,358 utterance types, and 18,684 multi-word utterance types. A random sample of 7,331 of Anne’s mother’s multi-word utterance types were taken to match Anne for quantity of data.

#### MOSAIC data

MOSAIC was trained on the full 33,390 utterance tokens of Anne’s mother in chronological order, one utterance at a time (as a list of words). MOSAIC’s overlap parameter was set to 15. The input to MOSAIC did *not* contain any coding information. This means that MOSAIC was not presented with any information about the categories of words (e.g., that “dog” was a noun or “go” was a verb) or about noun or verb morphology (e.g., “going” was seen rather than the morpheme “-ing” attached to the root form of the verb “go”).

After MOSAIC had seen all of the input utterances, every possible utterance that could be generated was output. This resulted in 178,068 utterance types (21,510 produced by rote and 156,558 produced by generation). Examples of the utterances generated from MOSAIC are shown in Table 1. The analyses of the data from MOSAIC are based on a random sample of 7,331 (i.e., matching Anne for quantity) of the multi-word utterance types produced by *generation*, because these are the novel utterances that will not have existed as part of the mother’s input.

#### Procedure

The utterances for both the child and mother included the syntactic category for each word in an utterance. The codings for the child’s utterances were used to determine the categories of words in the utterances of the child; the codings for the mother’s utterances were used to determine the categories of words in the utterances of the mother. Some words (such as “fire”) belong to more than one category. In these cases, a category was only assigned if the word was used as that category in at least 80% of the instances in which the word was used. For MOSAIC’s utterances, the categories were calculated based on the codings from the mother’s utterances.

The three sets of data were analysed in the same way. The method of extracting verb+common-noun combinations is detailed here but the method is the same

Table 2: Percentage of the 7,331 multi-word utterances from Anne, Anne’s mother, and MOSAIC that contain nominal+verb or verb+nominal combinations. The nominals are broken down into pronoun, proper-noun, and common-noun combinations.

Pair distribution	Anne		Anne’s mother		MOSAIC	
	Nominal+ Verb	Verb+ Nominal	Nominal+ Verb	Verb+ Nominal	Nominal+ Verb	Verb+ Nominal
<b>Pronouns</b>	4.73%	4.60%	8.83%	6.15%	5.16%	2.58%
<b>Proper-nouns</b>	1.31%	0.61%	1.94%	1.49%	0.55%	0.64%
<b>Common-nouns</b>	1.91%	7.41%	5.65%	10.42%	1.16%	5.18%

for the extraction of common-noun+verb, pronoun+verb, and proper-noun+verb combinations.

Each utterance was searched for a word which was categorised as a verb. The two words following the verb-category word were examined to see if either occurred as a common-noun. If so, the verb+common-noun pair was stored for analysis. Verbs were then converted to their root form (e.g., “going” and “goes” both become “go”) and common-nouns to their singular form (e.g., “dogs” becomes “dog”), and any duplicate pairs were removed. Analysis was therefore conducted on types, not tokens. The number of slot fillers for a verb is the number of different common-noun types that were paired with that verb.

### How well does the output of MOSAIC match the subject data?

Table 2 shows the percentage of each set of 7,331 multi-word utterances from Anne, Anne’s mother, and MOSAIC that contained verb+nominal and nominal+verb combinations (the label “nominal” refers to the group of all pronouns, proper-nouns, and common-nouns).

The data show that the utterances from MOSAIC match

Anne much more closely than they do Anne’s mother (on whose utterances MOSAIC was trained). For example, 5.16% of MOSAIC’s utterances and 4.73% of Anne’s utterances contain pronoun+verb combinations, compared with 8.83% for Anne’s mother. In fact, despite all three datasets having been matched for overall sample size, Anne’s mother produces many more instances of *every* combination shown in Table 2 (e.g., producing over twice as many different nominal+verb combinations [16.42%] as Anne [7.95%] and MOSAIC [6.87%]).

### Verb-islands exist in the data

As explained earlier, the data are expected to show that verbs act as frames (taking lots of different common-nouns as slot fillers) whereas common-nouns are not expected to act as frames. Whether this is true can be examined by looking at the number of common-noun types that follow verb types, and vice versa. We operationalise the concept of an “island” as a lexical item which acts as a frame for at least ten different slot fillers (e.g., a verb type would have to have ten different common-noun types as slot fillers). For example, for Anne, the verb “Find” is an island because it

Table 3: Verb-island data for Anne, Anne’s mother, and MOSAIC (mean=mean number of slot fillers for each frame type; islands=number of frames that have 10 or more slot fillers).

Data source	Mean	Islands	Islands having the most slot fillers
<b>VERB+COMMON-NOUN (frame=verb; slot filler=common-noun)</b>			
Anne	6.24	10	Get, Put, Want, Go, Need, Make
Mother	5.97	13	Get, Put, Want, Need, Have, Find
MOSAIC	9.74	10	Get, Put, Eat, Think, Want, Find
<b>COMMON-NOUN+VERB (frame=common-noun; slot filler=verb)</b>			
Anne	1.51	1	Baby
Mother	2.08	4	Baby, Animal, Dolly, Penguin
MOSAIC	1.57	1	Baby
<b>PRONOUN+VERB (frame=pronoun; slot filler=verb)</b>			
Anne	21.69	10	I, You, He, It, That, They, We
Mother	27.65	11	You, I, He, We, She, They, It
MOSAIC	25.20	12	You, It, That, I, He, We, She
<b>PROPER-NOUN+VERB (frame=proper-noun; slot filler=verb)</b>			
Anne	5.65	3	Anne, Mummy, Daddy
Mother	3.23	3	Anne, Mummy, Daddy
MOSAIC	6.67	2	Anne, Mummy

is followed by ten common-noun types (“Dolly”, “Plate”, “Seat”, “Welly-boot”, “Baby”, “Ribbon”, “Hat”, “Duck”, “Pen”, and “Bird”). Table 3 shows these data for Anne, Anne’s mother, and MOSAIC. This shows that there are many verb-islands for all three sources of data, but very few common-noun islands. In both cases, MOSAIC provides an identical match to Anne for number of islands.

#### **Other-islands exist in the data**

Table 3 shows that both pronoun-islands and proper-noun islands exist for Anne, Anne’s mother, and MOSAIC. The pronoun-islands are particularly strong (the mean number of slot fillers for pronouns is more than 20 for all three sets of data) and because pronouns take verbs as slot fillers, these islands are problematic for a strict version of the verb-island hypothesis which predicts that only verbs are initially used as frames. The other-islands, as Table 3 shows, are readily simulated by MOSAIC.

#### **Discussion**

The output from MOSAIC more closely resembles the child than the child’s mother, demonstrating that MOSAIC is doing more than just a straightforward distributional analysis of its input. In fact, it is a combination of the performance-limitations imposed on the model (e.g., learning one word at a time), and the frequency of occurrence of items in the input, that enable MOSAIC to match the child data. MOSAIC seeks to maximise the information held at nodes in the network, but can only do so for input sequences that occur frequently (e.g., due to limitations in only learning one item at a time). MOSAIC therefore offers a process-based explanation of why some lexical items come to function as “islands” in children’s grammar and others do not: children are maximally sensitive to the high frequency lexical items that exist in their input.

The results presented here show that when combined with naturalistic input, a simple distributional learning mechanism is able to provide an effective simulation of child language data. The simulations show that first, it is possible to model verb-island phenomena as the product of a frequency-sensitive distributional analysis of the child’s input, and, second, that the same mechanism can also simulate other-island patterns which are problematic for a strict version of the verb-island hypothesis.

## Abstract

Outside of cognitive neuropsychology, it is often assumed that differences among individuals in cognitive activity may be adequately represented theoretically in terms only of quantitative variation across a population. A possible exception to the presumption of homogeneity within cognitive processing is explored here. It is shown that left-handed and right-handed populations exhibit consistent, qualitative differences in their remembering of orientational information. It is concluded that the subject matter of cognitive science may be more heterogeneous than is commonly assumed.

## Assumption of Homogeneity

A widespread implicit assumption in cognitive science is that its subject matter is homogeneous, in the sense that differences in cognitive processing among individuals may generally be expressed in terms of merely quantitative variation. A major exception to this assumption is commonly recognised in the field of cognitive neuropsychology, where the cognitive processes of individuals have been shown to exhibit a range of idiosyncrasies associated with different forms of physical damage to the brain (e.g., Jones & MacAndrew, 1990). For this field, the occurrence of a double dissociation of function is generally held to indicate heterogeneity of population (e.g., Jones, 1983), although the validity even of this inference has been challenged within cognitive science (e.g., Juola & Plunkett, 1998). But for those without brain damage, differences among individuals are often viewed within cognitive science as essentially random, with variation in cognitive activity among individuals represented theoretically in terms of dispersion around a central tendency. If this is a correct characterisation of much of cognitive science,

then it raises the question of whether the assumption, outside cognitive neuropsychology, of homogeneity among individuals is justified in particular circumstances.

Where may qualitative differences in cognitive processes among individuals be manifested? A classical area of investigation is that of personality (e.g., Martin, 1985). However, the domain of handedness is also an appropriate area to consider. Can the models and descriptions of cognitive science be applied indifferently, as is generally assumed, to the right-handed majority and to the left-handed minority? Or do fields of heterogeneity exist in which people's handedness influences their cognitive performance? Empirical evidence that allows these questions to be addressed is considered here. First, however, it is appropriate to consider briefly the distinctive characteristics of handedness itself.

## Handedness Populations

Most human beings exhibit a preference for the use of one or other hand. This preference is not evenly distributed between left and right, as it is for most animals. Instead, the predominant pattern of limb preference is for use of the right hand.

Although hand preference can be influenced by social pressures (e.g., Harris, 1990), it has a number of features which suggest that it is also under genetic influence (e.g., Corballis, 1997; Laval, Dann, Butler, Loftus, Rue, Leask, Bass, Comazzi, Vita, Nanko, Shaw, Peterson, Shields, Smith, Stewart, DeLisi, & Crow, 1998). For example, Klar (1996) has reported that the likelihood of a person being left-handed is increased if one of the parents of the person, although right-handed, in turn had two left-handed parents. We have shown (Jones & Martin, 2000) that a genetic model for

Figure 1. Orientation responses

handedness may be formulated which accounts satisfactorily for this and a number of other similar effects.

It has frequently been suggested (e.g., Day & MacNeilage, 1996) that asymmetry in limb use, via an accompanying specialisation of function in the cerebral hemispheres, played a decisive role in the evolution of language. Similarly, the degree of lateralization of language function between the hemispheres is known to differ between left-handed and right-handed populations (e.g., McManus, 1999). However, it is less clear that cognitively based performance itself differs between the left-handed and right-handed populations. Thus, despite considerable research, it has proven difficult to establish reliable associations between handedness and either developmental reading disorder (e.g., Bishop, 1990) or a variety of symptoms linked to immune disorders (cf. Geschwind & Galaburda, 1987; Bryden, McManus, & Bulman-Fleming, 1994). Indeed, until recently there has been suggestive evidence of a heterogeneity in cognitive function between left-handed and right-handed populations in only one field, that of chimeric perception.

### Heterogeneity for Cognitive Function

Chimeric faces may be constructed by artificially pairing their left and right halves. If people are asked to match a control face to either a chimeric face composed only of the left half (and its mirror image) or a chimeric face composed only of the right half (and its mirror image), it has been reliably demonstrated (e.g., Levy, Heller, Banich, & Burton, 1983; Luh, Redl, & Levy, 1994) that right-handed people, but not left-handed people, have a significant tendency to select the left half (plus its mirror image) face as the better match.

The chimeric finding appears to represent a genuinely cognitive, not hemispheric, effect since it occurs with unrestricted fixation and therefore is not related to visual field (and hence hemisphericity). However, it may also be noted that the effect is a relatively narrow one. If the assumption of homogeneity of cognitive processing broke down only in this limited field, then the case for a wider consideration of heterogeneity in cognitive science would be relatively weak. It is now becoming apparent, however, that heterogeneity is demonstrable in the wider area of memory for orientation (e.g., McKelvie & Aikins, 1993; Martin & Jones, 1998). Two further studies of memory for orientation, which are described next, confirm this finding. The first also investigates whether the heterogeneity extends

Figure 2. Name responses

to memory for other types of information, and the second also investigates whether it resides genuinely in memory or alternatively in strategic behavior.

### Extent of Heterogeneity

Are differences between left-handed and right-handed populations in cognitive functioning confined to memory for orientation, or do they extend to memory for abstract information? This question was investigated by examining people's memory for Comet Hale-Bopp, selected as subject because of the long history of popular interest in cometary appearances (see Schechner Genuth, 1997).

Approximately equal numbers of left-handed and right-handed participants were tested (N = 401). Testing occurred approximately six months after the comet's visit. Participants were tested on a series of items "about the comet which was visible to the naked eye over the Easter period." Questions probed both abstract and concrete knowledge. Binary handedness classifications were made on the basis of the hand which the participant used for drawing.

Figure 1 shows memory for orientation for left-handed and for right-handed participants. Recall of the direction of the head of the comet was classified into eight different sectors,

defined by the combination of it pointing leftwards, centrally, or rightwards; and downwards, level, or upwards. There was a significant difference between the frequency distributions of responses for left-handed and right-handed participants,  $\chi^2(7) = 20.29$ ,  $p < .01$ . In particular, right-handed participants produced a significantly greater number than left-handed participants of responses with the comet facing down to the left (the orientation most frequently encountered),  $\chi^2(1) = 7.86$ ,  $p < .01$ . Similarly, considering downward and level responses overall, it can be seen from Figure 1 that there was a contralateral tendency which associated right-handed participants with left-facing responses, and vice versa; this tendency also was significant,  $\chi^2(1) = 12.97$ ,  $p < .001$ . Similar results were found with recognition rather than recall responses.

Figure 2 shows the distributions of written name responses which were made by left-handed and by right-handed participants. Recall was classified as either (a) completely accurate (both Hale and Bopp), (b) partially accurate (incomplete or misspelled), (c) Halley (either a semantic error or an approximation to Hale), (d) unrelated name, or (e) no response. There was no significant difference between the two frequency distributions,  $\chi^2(4) = 3.08$ . Similar results were found for the recall of other

Figure 3. Contralateral handedness effect in recognition

abstract information, such as the length of time since the comet's last visit to Earth (about four thousand years).

The present findings suggest therefore that the assumption of homogeneity, which breaks down in the case of memory for orientation, continues to hold in the case of memory for more abstract information.

### Heterogeneity for Memory or for Strategy?

Although overt responses concerning memory for information have been shown to differ for left-handed and right-handed populations, it is possible in principle that the underlying difference between these populations relates not to their memory processing but instead to their strategic behavior. That is, it is possible that left-handed and right-handed populations differ not in their likelihoods of retrieving information about orientation, but instead in their strategies of producing responses when memory fails. To investigate this possibility, the confidence with which responses are produced can be examined. If heterogeneity is confined to strategic behavior, then differences between populations should arise only for responses that are made with relatively low confidence. But if heterogeneity applies to memory itself, then differences should be observed in those responses which are made with high confidence.

Approximately equal numbers of left-handed and right-handed participants were tested ( $N = 230$ ). Each participant was shown a sequence of

40 different black-and-white photographs for 3 sec each. In half of the photographs a person faced to the left of the viewer and in half a person faced to the right. Subsequently, each photograph was shown alongside its mirror image (reflected in a vertical plane) in a two-alternative forced-choice recognition task. In addition, for each recognition response the participant assigned a confidence level on a scale between 1 (guess) and 5 (certain).

Figure 3 shows the overall levels of recognition. There was a significant interaction between the effects of the direction in which the stimulus faced and the handedness of the participant,  $F(1, 228) = 9.18, p < .01$ . It can be seen that the effect was a contralateral one, in that left-facing stimuli were recognised better by right-handed than by left-handed participants, whereas right-facing stimuli were recognised better by left-handed than by right-handed participants.

To examine the possible influence of confidence, further analyses were carried out on the recognition responses that were made with the lowest level of confidence (1) and those made with the highest confidence (4 or 5). Confidence level was found to modify the two-way interaction, yielding a significant three-way interaction,  $F(1, 174) = 4.19, p < .05$ . Decomposing the three-way interaction, it was found that for those responses made with high confidence there was again a significant interaction between the effects of stimulus direction and of handedness,  $F(1, 201) = 5.06, p < .05$ . In contrast, for those responses made

with low confidence, there was no significant interaction.

Thus it is in memory processing itself, rather than in strategic behavior, that the assumption of homogeneity appears to break down. Left-handed and right-handed populations differ in how they remember orientation, not in how they guess.

### **Origin of Population Effect for Memory**

It is important to note that the results do not suggest that either left-handed or right-handed populations enjoy a general advantage in memory. Rather, the finding is one of contralaterality, in that left-handed people were more accurate than right-handed people when recalling right-facing stimuli, but less accurate when recalling left-facing stimuli. This zero-sum finding of contralaterality presents a problem for any theorists (e.g., Luh, Redl, & Levy, 1994; McKelvie & Aikins, 1993) who attempt to explain the influence of handedness upon cognition in terms of possible correlated differences in hemispheric specialization of function, because such a theory would predict that either left-handed or right-handed people should show a consistent advantage in performance.

In contrast, we have recently proposed (Martin & Jones, 1999) that the consistent differences among people in patterns of overt motor activity which categorise them as either left-handed or right-handed are accompanied by correlated differences in motor imagery. It is well established that extensive motor activation occurs in the cortex in the absence of physical movement (e.g., Decety, Grezes, Costes, Perani, Jeannerod, Procyk, Grassi, & Fazio, 1997; Jeannerod, 1994; Logie, 1995). Characteristic patterns of motor activation for left-handed people differ from those for right-handed people, partly in response to the asymmetric nature of the everyday environment (e.g., left-to-right writing). The present results suggest that, depending upon the precise details of a cognitive task, either left-handed or right-handed motor imagery may prove to be the more effective in assisting memory for orientation.

### **Conclusions**

Outside of cognitive neuropsychology, it is often assumed that differences in cognitive activity between individuals may be adequately represented theoretically in terms of random variation around a central tendency. One

exception to the implicit assumption of homogeneity within cognitive science has been characterised here. Subtle differences can be detected in the remembering of orientation by left-handed and right-handed populations. It remains to be investigated, however, how widespread is the occurrence of such heterogeneity.

## Abstract

In this paper we evaluate the utility of a referential communication paradigm to study the content and use of mental models. In this task pairs of people collaborate to determine which of a set of infra-red images depicts a physically possible situation. We demonstrate that the referential communication task provides insight into the interaction between the content and use of naive theories of physics in a problem-solving domain.

## Introduction

Causal explanation is critical for our daily existence. Causal connections support our perception of the world as coherent, and they give us a sense of mechanism,- a sense of how things work. Our control of the physical world is to a great extent dependent on the accuracy of our understanding of the mechanics of the world.

A prominent suggestion is that causal knowledge is organized into theories that people use to reason about the world. The term "theory" has been used in a number of different ways by psychologists (see e.g., Gopnik & Meltzoff, 1997, for a discussion). One view assumes that theories are large bodies of knowledge that are coherently organized according to a few well-defined principles, so that all explanations can be deductively derived (e.g., Kuhn, 1991). A more local view of theories is presented by Murphy and Medin (1985), who define theories as "any host of mental explanations, rather than a complete organized scientific account" (p.290). Schemas and scripts contain implicit theories of causality that allow us to explicate the world, although may not possess properties of coherence and consistency.

One area where theories have received extensive attention is in naive physics, which is concerned with understanding how knowledge and experience are integrated to create an understanding of the mechanics of the world. Despite the fact that physical principles describe properties of objects with which we interact daily, people have serious difficulties understanding formal principles of physics. People's understanding of fundamental physical principles has been described as incoherent and full of misconceptions (diSessa, 1993; McCloskey et al., 1980; Clement, 1982; Cooke and Breedin, 1994).

Various theories have been proposed to account for these difficulties. Some researchers have suggested that these misconceptions arise from basic misunderstandings of physical systems that are formed prior to any formal training in physics (Caramazza and Green, 1980; McCloskey, 1983a, 1983b). The systematic nature of some errors has led researchers to suggest that certain misconceptions are not idiosyncratic, but instead are based on a more general system of beliefs or a naive theory (Clement 1982; McCloskey, 1983a, b). These theories are described as systematic, general, coherent, well-developed and well articulated conceptions that conflict with basic principles of physics, but that nonetheless adequately explain observed events in the world (McCloskey, 1983b).

An alternative view contends that people's understanding of physical phenomena is a collection of fragmented and loosely connected ideas about the world that can be used to generate situation specific explanations (diSessa, 1988, 1993). In his view, naive theories are nothing more than ad hoc explanations that are invented for particular situations. Ueno (1993) in his re-interpretation of diSessa's theory points out that these explanations are socially formed and shared. They are maintained through communication and are to a great extent guided by conversational pragmatics. For example it would be anomalous to cast a simple sentence like "Susie slapped Tom" in it's Newtonian physics equivalent of "Tom's face slaps the palm of Susie's hand, while the force of Susie's slapping is the same as the force of Tom's slapping". In everyday discourse the latter sentence would be judged nonsensical.

This reinterpretation is in line with current research on the role of communication in category acquisition. Category representations are structured in a manner that facilitates communication. People typically learn categories in the process of communicating with others. Further, people are constrained to form categories that are shared by other members of their culture if they are to use them effectively (Garrod & Doherty, 1994; Malt, 1995). In this view naive theories of physics are pragmatically motivated explanations of complex phenomena that are socially constructed to support our simplistic categorizations of the physical world.

Ultimately, of course, we would like to understand the structure of people's naive theories. In the present paper,

we begin to address this issue by examining a novel method that can elicit people's naive theories of the physical world and to explore the causal relationships that make up those theories. This methodology draws on recent findings on the role of communication in category acquisition, and attempts to elicit and explore naive theories in a communicative setting.

A popular method of eliciting people's theories of physical phenomena is to ask people to explain their predictions or decisions in interviews or other verbal protocols. These verbal protocols permit a systematic examination of explanations people generate for their own errors in reasoning. Chi and her colleagues have successfully used this method to study learning in a variety of problem-solving tasks (Chi, 1989, 1983). The method we propose is novel in that it incorporates a referential communication design into the study of naive theories. In this task, pairs of people are presented with four infra-red pictures that show the heat emanating from objects. One of the pictures is an actual infra-red image, and the other three are doctored images that have been altered to contain systematic errors. Pairs of people are shown these images and are asked to determine which image is correct.

In order to perform this task, dyads must talk about the heat pictured in the image. In this way, they must use their naive understanding of thermodynamics. Because the task involves two people, many aspects of people's beliefs about heat are stated explicitly in the conversations. People have extensive experience with heat and have a naive theory of heat-flow.

Referential communication tasks are quite data-intensive, as full transcripts of conversations are developed and must be coded. In this paper, we limit our focus to three issues. First, does communicating about this task improve performance? This question is useful for understanding whether theory development occurs through communication. If the performance of dyads improves with communication, then it is plausible to think that theories develop when people communicate. Second, we are interested in whether people use correct theories when discussing thermodynamics. Finally, we will address the relationship between theories and topics of discussion, as well as the qualitative change in discussions over time.

## Method

**Participants:** Participants were 70 members of the Columbia University community (50 in the dyad task and 20 in the control task). Six dyads involved two male participants, five involved two female participants, and the rest were mixed sex dyads. All participants were native speakers of English who did not know each other before the session. Data from one dyad had to be eliminated due to mechanical failure leaving a total of 24 dyads for analysis.

**Materials and Procedure:** The stimuli were 12 sets of false-color infra-red images of familiar objects and scenes such as plants, kitchen appliances, and street scenes. Each

set consisted of one actual image and three variants of it. The actual image was a picture of the infra-red (i.e., thermal) energy at the surfaces of the image. The color scheme involved 10 colors that were each assigned to a range of temperatures. The resulting image is called a false-color image, because it appears in colors that differ from the colors of those objects in visible light. To complete each set three additional versions of each picture were created using Adobe Photoshop by changing some of the colors in the image to create thermal inconsistencies that are highly unlikely to occur naturally. For example, the nose of a dog might be made to appear cooler than the fur-covered skin, or the pattern of heat diffusion from a heat source might be changed so that temperature did not decrease monotonically with distance.

During the experiment the sets were presented in a random order. Each pair of participants was instructed to collaborate to figure out which image in the set was the actual thermal image. Both subjects had to agree on their response before the trial was completed. To encourage discussion rather than pointing, a divider was placed between the subjects, and each subject was given an identical set of 4 images. Thus, subjects were free to refer to pictures verbally but could not point to pictures or their elements to establish reference. The discussions were videotaped and later transcribed. All subjects were aware of being videotaped. The control group consisted of 20 subjects who performed the same picture selection task alone and without verbalizing their reasons.

**General Coding:** Each utterance from the transcript was coded along six dimensions. An utterance was defined as a turn each subject took when speaking. Thus, an utterance could contain as little as a sentence fragment or as much as a paragraph. Because of space limitations, we will focus on two codes: 1). the correctness of the theory and action taken by the dyad and 2). the topic of the discussion. To assess the reliability of the coding, ten of the transcripts were scored by both coders. Correlations ranging between .9 and .98 were obtained for all codes.

The correctness of the theory and action code focused on utterances where the dyad took an action (either selecting a particular picture as the correct one or rejecting a picture). First, the action was coded as correct or incorrect. A correct action was either rejecting a picture that was not an actual thermal image, or selecting the valid image. An incorrect action was either rejecting the correct image or accepting an incorrect one. Actions were typically justified in some way, and the theory part of the code assessed whether the justification was in accord with basic principles of physics. Thus, this code had four levels:

1. Correct action considered on the basis of incorrect theory
2. Correct action considered on the basis of correct theory.
3. Incorrect action considered on the basis of incorrect theory.
4. Incorrect action considered on the basis of correct theory.

The discussion topic code distinguished between five different topics including discussions of abstract physical principles, discussions of the thermal conductivity of materials, and discussions of the internal mechanics of an object depicted. Of these codes only two yielded enough observations to warrant further analysis: 1). discussion of temperature and 2). discussion of heat diffusion. Temperature referred to explicit discussions of the temperature at particular points in the image or to relative temperatures at neighboring points. Discussions of heat diffusion were cases in which people talked about the flow of heat from one location to another or to the dissipation of heat. Because naive theories often treat temperature as a physical quantity (rather than a measure of mean molecular kinetic energy), discussions of temperature are likely to be associated with poor reasoning about thermal images (Wiser & Carey, 1983). In contrast, discussions of heat flow and thermodynamics are more likely to be related to an accurate theory of thermodynamics, and so they should be associated with good reasoning about thermal images.

### Predictions

In this paper, we focus on four aspects of the present task:

1. Communication: The first question to be explored is whether communication influences performance accuracy on this task. To address this issue, we test to see if dyads have higher accuracy than do people who perform the task alone. In addition to examining overall accuracy, we look at performance curves over the course of the experiment. Related to this issue, we can explore how the performance of dyads changes over time.
2. Correctness of theories: Expertise is typically characterized by the presence of a fully integrated representation of the domain of expertise. Experts in domains like physics reason better than novices, because they are able to focus on deep relational aspects of the situation rather than being derailed by surface aspects of the task (e.g., Chi, Feltovich, & Glaser, 1981). In the present task, we expect that subjects who exhibit evidence of having a correct theory of thermodynamics will perform the picture selection task more accurately than those with fragmentary knowledge of this domain.
3. Considered actions: When discussing an image, a dyad could decide to classify it as one of the transformed images or to retain the picture in the set that could be classified as the unaltered thermal image. Considering a particular action in relation to a particular picture singles that picture out and temporarily makes it more salient than others. It may be that mere consideration of an action, be it based on a correct or incorrect theory, affects the decision by anchoring people on a particular picture. That is, if a dyad starts out considering a particular picture and spends extensive time and energy discussing it, that investment alone may be sufficient to influence the final choice.
4. Topics of discussion: As discussed above, temperature and heat differ in their relationship to a correct theory of

thermodynamics. We will explore the relationship between the topics discussed and people's accuracy in classifying the pictures to see whether talking about terms that are more relevant to correct theories is related to accurate performance.

### Analysis and Results

**Communication:** A key part of the present task was that dyads worked together to find the correct thermal image. As a way of exploring accuracy on this task, we explore differences between the dyads and the control group on their accuracy in selecting the actual thermal image. This analysis addressed the following questions: 1. Are dyads performing better than singles? 2. Are there differences in performance during the experiment? and 3. How does performance of dyads change over time? An examination of overall accuracy revealed that dyads were significantly more accurate ( $M=7.3$  (out of 12)) than were the people in the control group who worked alone ( $M=5.3$ ),  $t=3.1$ ,  $p<.05$ . Chance performance would be 3 correct out of 12. Both groups performed reliably above chance.

To explore how the dyads differed from the control group more carefully, we broke down the performance data into four blocks of three trials. The accuracy for each block for both conditions is shown in Figure 1.

Figure 1: Accuracy by Blocks of Three Trials

As we would expect if the people in each condition were approximately equivalent in their expertise, performance in the first block of trials is about the same in each group. The groups diverge after the first block. By the second block, the dyads are significantly more accurate ( $M=1.96$ ) than the singles ( $M=1.2$ ),  $t= -2.66$ ,  $p<.05$ . The performance of singles does improve with practice, but this does not occur until after the last block ( $M=1.65$ ).

**Theories and Actions:** We now turn to the relationship between type of action, correctness of theory and overall accuracy. For this analysis, we first converted the frequency of each combination of accuracy and theory correctness for each dyad to a proportion. This conversion allowed us to control for individual differences in the length and content of dyads' discussions. We expected that correctness of

theories would be the major factor that determined accuracy. However, this prediction was not borne out. As expected, consideration of a correct action was positively related to accuracy ( $r = .58, p < .01$ ). However, in contrast to our expectations, consideration of an incorrect action was negatively correlated with accuracy regardless of whether the statement was accompanied by a correct or an incorrect theory ( $r(\text{incorrect action/incorrect theory, accuracy}) = -.67$ ;  $r(\text{incorrect action/correct theory, accuracy}) = -.47$ , both  $p < .05$ ). If we examine correctness of action and correctness of theory separately, we also find that correct actions are a better predictor of accuracy than correct theories ( $r = .74, p < .001$  and  $r = .48, p < .05$  respectively).<sup>1</sup>

The changes in performance during the experiment may be related to the consideration of correct actions and theories over the course of the study. Figure 2 shows the frequency with which correct actions and theories are considered as a function of four performance blocks, each consisting of three trials.

Figure 2 Correct Theories and Actions by Blocks of Three Trials

As shown in the graph, the pattern of change in the consideration of correct actions and theories closely follows that of the accuracy improvement pattern. The greatest increase in the frequency of correct actions and theories occurs between the first and the second quarters, followed by a plateau thereafter. Looking at the proportional frequency of correct actions considered on the basis of correct theories and incorrect actions on the basis of incorrect theories we see a similar separation.

**Topics of Discussion:** Finally, we can examine the relationship between accuracy and topics discussed. As described above, we are most interested in discussions of temperature and heat flow. The relationship between the use of these topics and accuracy is shown in Figure 3. As expected, discussion of temperature is negatively related to accuracy ( $r = -.43, p < .05$ ) and discussion of diffusion of heat is positively related to accuracy ( $r = .68, p < .05$ ). This finding reflects that temperature is a static quality of an image that

may signal an incorrect theory, while heat flow is a property that is central to a correct theory of thermodynamics.

Figure 3: Topics of Discussion and Accuracy

We can also look at the relationship between discussion topic and the use of correct actions and correct theories. We expect the discussion of temperature to be negatively related to the use of the correct theory and to the selection of correct actions. Consistent with this prediction, there is a relationship between the frequency of discussion of temperature and the use of incorrect theories ( $r = .56, p < .05$ ). There is also a positive relationship between the frequency of discussion of temperature and the consideration of incorrect actions ( $r = .59, p < .05$ ). In contrast, the frequency of discussions of heat diffusion are related to the consideration of correct actions ( $r = .52, p < .01$ ). Contrary to our expectation, no significant relationship was observed between the frequency of discussion of heat diffusion and the use of correct theories. This unexpected finding will be discussed in more detail below.

Finally, the use of these topics was explored across the four blocks of the experiment. While the frequency of discussion of temperatures did not change over the course of the experiment, there was an increase in the frequency of discussion of diffusion of heat during the experiment.

## Discussion

This research is the beginning of a line of research aimed at exploring the development and use of mental models. In order to get a view of people's mental models (in this case mental models of heat flow), we examined their interactions in a task in which they selected an actual thermal image from a set of doctored images of the same object. The dyadic design allows us to get people to talk about their mental models without having to resort to an unnatural task like a concurrent verbal protocol.

Any study involving transcripts of communication creates a large amount of data, and we have necessarily covered only a small fraction of what could be extracted from this work. We have focused on four main issues here: 1) the

<sup>1</sup> Correct action/incorrect theory code is not represented here because it yielded very low frequencies as compared to frequencies of other codes, and while the results are in the right direction, they were not significant.

influence of causal theories on performance accuracy in a problem solving task; 2) the relationship of considered actions to causal theories, and their influence on accuracy in a problem solving task; 3) the relationship between topics of conversation and causal theories; 4) the qualitative change in discussions and theories over time.

**Theories and Actions:** What sort of theories do people tend to have about thermodynamics? The mean accuracy in this task was 60.8%, which was well above chance. Thus, people who had probably never seen a thermal image before were pretty good at identifying actual images. While this performance must have been based on some knowledge of thermodynamics, it was not based on an accurate physical theory. The data suggest that correct performance in the task was influenced far more strongly by whether the dyad considered correct actions (properly accepting or rejecting a picture) than it was by the presence of accurate discussions of physical principles.

There are (at least) two important reasons for this finding. First, we defined the use of a correct theory as a discussion that was internally consistent and did not contradict basic principles of physics. It is quite likely, however, that this definition is too restrictive. Many people's naive physical models are successful at predicting performance in the world without necessarily embodying principles from the science of physics. McCloskey (1983b) points out that people's naive theories are well-developed conceptions that are useful for predicting the behavior of objects in the world. However, these theories often conflict with basic principles of physics. Further research must explore ways of characterizing people's naive theories of thermodynamics. One task that we have begun to use that has some promise is to give people a blank picture of a scene (such as an outdoor scene during the winter at night) and ask people to color the scene as if they were looking at the heat coming off surfaces. Pilot research with this technique suggests that it is capable of uncovering situations where people's mental model of heat differs from scientifically accepted principles.

A second reason why the presence of a correct model of heat did not always lead to correct performance is that people may have a correct model of thermodynamics, but may have some difficulty translating that model to thermal images. For example, people often correctly recognize that heat will escape from an open window if the room is warmer than the surrounding area. However, they may mistakenly expect the room to look cold in a thermal image, because it would feel cold to be standing in this room with the open window. In fact, such a room would look warm, as an infra-change in the frequency of discussions of diffusion of heat followed the same pattern.

One factor that may account for the difference in the learning curves has to do with the learning benefit associated with constantly verbalizing one's thoughts in a collaborative process. Chi and her colleagues have successfully used talk

red camera would be seeing the heat energy escaping from the room. Thus, people may understand principles of thermodynamics but have difficulty transferring this knowledge to thermal images.

**Topics of Discussion:** Another way to explore people's mental models is to look at the topics that get considered for discussion. A key distinction involves differences between discussions of temperature and discussions of heat flow. Discussions of temperature were associated with lower accuracy and less use of correct theories in this study. There are two reasons why this relationship makes sense. First, to the extent that people are treating temperature as a property of objects rather than as a measure of heat energy, they are subscribing to a mental model that is not in accord with physical principles (Wiser & Carey, 1983). Second, even if they recognize that temperature is a measure of mean molecular kinetic energy, they are still focusing on an attribute of an object. Reasoning about physical principles also requires consideration of relational properties (e.g., Gentner, et al., 1997). Discussions of heat flow, in contrast, reflect a discussion of relational properties of the domain. An important aspect of heat is that it flows from high temperature regions to low temperature regions. Focusing on these relations is often useful for understanding how thermal images are in error. In many cases, errors in thermal images reflect situations in which heat is flowing in an impossible way. The relations between locations are critical for finding errors in images.

Heat flow should also generally be related to the use of a correct theory of thermodynamics. Contrary to this expectation, there was no significant relationship between discussions of heat flow in our data. This discrepancy probably reflects the same problem raised above that our coding scheme focused on theories that were both internally consistent and in accord with physical principles. It is possible that people's models are fragmentary, and thus prone to exhibit inconsistencies. Further work must address this issue.

**Communication:** Another striking aspect of the data was that dyads were significantly more accurate than were people who performed the task alone. This difference in accuracy manifested itself in a difference in performance across blocks. The dyads showed the greatest improvement in performance accuracy in the shift from the first block of three trials to the next. In contrast, singles did improve until the final block of three trials. The frequency of correct actions and theories for dyads closely followed the pattern of the performance curve. Similarly, the pattern of out-loud protocols to study problem solving strategies in a variety of tasks. One finding that emerged from this methodology is the learning benefit of self-generated explanations (Chi, 1989; 1993). Chi argues that learning requires integration of existing knowledge with new information and that the process of self-explanations

facilitates this integration. Self-explanations derived from talk out-loud protocols have been shown to improve understanding and to enhance learning (Chi, 1989, 1994; Webb, 1989). High self-explainers display deeper understanding and more complete mental models than low self-explainers as assessed by ability to answer complex questions. Chi argues that the beneficial effect of self-explanations is partly due to the fact that self-explaining is essentially a constructive activity. Self explanations provide an opportunity to construct new declarative knowledge and to generate new rules that can subsequently be used to solve complex problems. In our study, dyads are forced by the nature of the task to engage in explanatory activity from the very outset. Since the task itself is novel, there is a strong demand to integrate and adopt an existing knowledge and to construct new rules appropriate for the task at hand. To the extent that self-explanation is a constructive activity, the construction of the new knowledge structure needed to succeed on the task is started from the very onset of the task through self-explanations and explanations designed for the partner. No similar demand was placed on the singles performing the task. They were not required to verbalize their strategies, although it is interesting to note that a few subjects had spontaneously attempted to think out-loud in the course of the study, and had to be stopped by the experimenter. Thus, while the same mental process of self-explaining may be going on in the minds of the singles, there is no experimental constraint to facilitate it. This may account for the delay in improvement among singles. The learning benefit of self-explanations and explanations generated for the partner has not been explored in the context of referential communication design. We believe that it offers a potent medium to explore these issues.

## Abstract

We present the results of an experiment involving a curriculum designed to foster conceptual changes, generative understandings, and coherent evolutionary explanations. This middle school curriculum highlights dinosaur knowledge due to its intrinsic interest to students and its compatibility with the objectives of integrating several concepts (e.g., variation and heredity) into a coherent natural selection schema. The domain also allows one to communicate an understanding of the process of evolutionary change across geologic time. Students in a class that received the curriculum exhibited significantly greater gains than did a control class, across a range of problem types. Further, the subjects in the conceptual change classroom appear to be less prone to generating the kinds of explanations that directly conflict with Darwinian patterns of reasoning.

## Introduction

Transfer is one of the most widely investigated phenomena in both cognitive science and science education. Arguably, the most important goal of education is to foster the transfer of knowledge and skills. Similarly, any learning theory worth its salt must include mechanisms of transfer. From some perspectives, studies of transfer have often yielded dismal results (Detterman, 1993). However, as one might expect, increasing any salient similarity between training and the transfer materials increases the probability that transfer will occur (Bassok & Holyoak, 1993) as does selecting a source domain in which the subjects have substantial prior knowledge (Kaufman, Patel, & Magder, 1996).

Evolution is a central unifying theory in modern biology, contributes to a foundation for learning across biological sciences, and provides a basis for understanding the interrelationships among all organisms. However, evolution remains a polarizingly controversial and poorly understood subject that typically receives a minimal amount of class time (Working Group on Teaching Evolution, 1998). In addition, evolutionary concepts are often taught as a set of discrete ideas, rather than as a central integrative topic (Sharman, 1994). Several recent studies have documented a range of misconceptions and erroneous beliefs in students' understandings of evolutionary concepts and their resistance

to instructional effects. Many individuals regard evolution as a need-driven, adaptive teleological process, whereby organisms change traits in response to some environmental pressure (Bishop & Anderson, 1990). Some see evolution as Lamarckian, in which an organism passes on to its offspring characteristics that are acquired during its lifetime (Samarapungavan & Wiers, 1997). These teleological and Lamarckian beliefs conflict with Darwinian theory of evolution by natural selection theory, an essential component of modern biological understanding.

Why is evolution such a difficult topic for students to master? In our view, the development of evolutionary competence is predicated on the following four factors (Kaufman, Ranney, Thanukos, & Brem, 1999). 1) Conceptual Knowledge: evolutionary knowledge involves the complex integration of concepts from several biological disciplines, including genetics, ecology, and paleontology. 2) Reasoning and argumentation: evolutionary reasoning makes formidable demands on the process of coordinating evidence and hypotheses; part of the problem concerns the unique nature of evolutionary explanation, which often requires reasoning about historical narratives rather than proximate (Kaufman, et al, 1998). 3) Epistemological commitments: students' views concerning the nature of science and of the biological world affect their understandings of evolution (Rudolph & Stewart, 1998). 4) Discourse practices: as in all sciences, there are ways of constructing explanations and using communication that are sanctioned or eschewed by the domain; students have considerable difficulty mastering mechanistic causal explanations and often use scientific terms, such as adaptation, inappropriately.

What are the ultimate objectives of an introductory evolutionary curriculum designed for middle school students? As with other sciences, the goals are to promote robust conceptual understanding and durable transfer. That is, we do not want students to learn merely about the evolution of dinosaurs, insects or other sets of organisms. We want students to begin to "own" Darwinian patterns of reasoning and apply them flexibly in multiple contexts. Ohlsson's (1993) notion of an abstract schema allows us to sharpen our intuitions about transfer. Such a schema encodes the structure of an explanation, rather than its content. The

following schema, adapted from Ohlsson, illustrates the notion of a Darwinian explanation pattern:

- There exists a species that varies randomly on a set of heritable characteristics.
- An environmental pressure (from imperceptible to catastrophic) will favor individuals (regarding survival) with certain traits.
- The selection mechanism operates such that these individuals are more likely to reproduce and pass on their traits to offspring.
- Therefore, more individuals in the next generation will possess the favored trait and the relative distribution of the trait will increase.
- Over many generations (i.e., hundreds or thousands), these small changes in traits accumulate and may eventually substantially modify the characteristics of the species.

This natural selection schema is potentially applicable to any organism and can be articulated by instantiating the appropriate slots (e.g., favored traits, and environmental pressure). The schema embodies both core conceptual knowledge and the relational argument structure that constitutes natural selection. Mastery of this explanation form across several domains would constitute strong evidence for transfer. Of course, a mere syntactic mapping is not all that is required; the use of this abstract schema requires substantial biological knowledge and development of the aforementioned factors that comprise evolutionary competency.

We sought to develop a curriculum that (a) specifically targets conceptual knowledge and reasoning/argumentation, and (b) engages students' prior knowledge in a domain of student interest. Chi and colleagues (Gobbo & Chi, 1986; Chi, Hutchinson, & Robbins, 1989) demonstrated that young children have substantial dinosaur knowledge and can employ this knowledge to make inferences about the organisms' diets, habitats, and locomotion. In addition, many middle school students have a basic mastery of the concepts required to learn natural selection (e.g., inheritance, biodiversity, variation, and prey/predation), but they lack an organizing schema for understanding evolution (Ash & Brown, 1996). It was hypothesized that knowledge of dinosaurs would represent a generative source domain in order to impart a robust understanding of evolution. Further, the study of dinosaurs exemplifies the historical/narrative dimension of evolutionary reasoning and the process of evidence gathering from the fossil record. In general, greater subject matter knowledge increases the likelihood of transfer since both entities (i.e., dinosaurs) and ecological processes (e.g., predator/prey relations) are familiar in this context. There is less need for negotiating new terminology and other unfamiliar surface features. This domain may also serve to foster epistemological commitments regarding the transitional state of knowledge, since new fossil finds and concomitant hypotheses are regularly brought to the public's attention.

## Method

### Participants

Two seventh grade classes from an urban, ethnically diverse, public school participated. The experimental and control classes included 21 and 27 students, respectively.

### Procedure

**Pretest:** In the first of the study's three phases, each class was given a dinosaur knowledge test followed by two evolutionary knowledge tests. The dinosaur test consisted of 39 questions that evaluated students' abilities to identify dinosaurs from pictures, draw inferences about the dinosaurs' diets from both pictures and dinosaur names, match dinosaur names to descriptions of dinosaurs, order events on a timeline, and, respond to Likert items about dinosaurs. The evolution tests assessed students' understandings of related concepts. The two tests respectively consisted of seven Likert items, followed by eight short essay questions (/problems). The evolution tests assessed students' knowledge of heredity, variation, selection pressure, survival advantage, and mutation. The test questions involved a variety of animal contexts including birds, humans, and dinosaurs. There were three types of essay questions, involving natural selection, conditions of adaptational change, and common ancestry. An example of an essay problem addressing natural selection is "Apatosaurus was a dinosaur that had a long neck (longer than modern giraffes). The ancestors of all Apatosaurs had short necks (similar to necks of horses). Please explain how Apatosaurs came to have long necks." The conditions of adaptational change questions can best be answered by discussing functional adaptation and the time scale for such adaptations to appear. An example of this type of problem is: "If there were a sudden drought that killed off most edible plants, could a cow start to eat other animals instead of plants? Explain why or why not." The common ancestry questions addressed the salient similarity and differences among ancestral and contemporary species. The following problem is an example: Ostriches are large birds that cannot fly. The Rhea and the Emu are in the same family of birds – they are very closely related genetically. Interestingly, Ostriches are found in Africa, the Rhea live in South America, and the Emu live in Australia. How can you explain that these birds, which cannot fly, are found on different continents? "

**Instruction:** In the next phase of the study, the two classes participated in divergent eight-day evolution units. In the experimental class, hands-on activities, illustrations, and lectures were constructed to illustrate scientists' conceptions of dinosaur life. (Each lesson included at least one hands-on activity, an interactive discussion, and independent thinking assignments.) The curriculum addressed a range of topics: heredity, variation in the environment, mutation, extinction, and variation among individuals in a population. Explicit examples were provided to model how students could transfer evolution concepts to other animal species. This curriculum was created and taught by the teacher-researcher, a Masters

student who had prior experience teaching the students in this classroom (Lewis, 1999). This instructor used a constructivist pedagogy, largely modeled after Minstrell's instructional approach (van Zee & Minstrell, 1997). Minstrell is noted for introducing a new topic with a "benchmark lesson." He attempts to discover what students know about a topic, and tries to evaluate which of the different facets of the larger concept are understood or misunderstood.

The control class was taught by its regular teacher. He had over 25 years of teaching experience and taught in a traditional didactic manner while relying on the textbook. Students were responsible for taking accurate notes and answering the questions that appeared in the text. The control class drew on a range of organisms to illustrate the process of how life changes over time and evidence for these changes.

**Posttest:** The final phase of the study measured what students learned by again assessing dinosaur and evolution knowledge. The dinosaur test was essentially identical to the original test except for the order of questions. The evolution posttest used analogous (structurally isomorphic) and questions that were identical to those on the pretest. The evolution posttest was thus designed to assess the students' basic learning and their ability to transfer evolutionary knowledge to novel contexts.

**Analyses:** The Likert questions were initially scored on a seven point scale, based on the "correctness" of answers, and then scaled to fractions of a single point. The essay questions were scored and weighted for difficulty, according to a modified version of a rubric created by Kaufman, et al (1999). The coding criteria are similar to those used by Ferrari and Chi (1997) and Ohlsson (1990). For example, on the natural selection questions, explanations were coded for clear expressions (i.e., not merely jargon usage) of 1) variation, 2) selection pressure (environmental contingencies), 3) survival advantage (adaptive characteristics) and 4) heredity. A subset of the 16 questions was rescored by a second reader, resulting in an interrater reliability of 94%.

## Results

The results indicate that both control and experimental classes exhibited various gains. A multivariate repeated measures analysis of variance was performed, with the three tests serving as the dependant variables and class as the independent variable. The analysis revealed a main effect for class ( $F(1,46)=6.24$ ,  $p<.05$ ) with the experimental class performing better than the control class. There was also a significant temporal effect, indicating that subjects performed better on the posttests ( $F(1,46)=100.79$ ,  $p<.001$ ). In addition, there was a significant time by class interaction ( $F(1,46)=19.46$ ,  $p<.001$ ) with the experimental class exhibiting a larger gain.

The overall results, presented in Table 1, reveal that both classes had considerable and comparable prior dinosaur knowledge, averaging 70% ( $F(1,46)=1.19$ , n.s.) on the

dinosaur pretest. The evolutionary knowledge pretest indicated even more similarity between the experimental and control classes, averaging 67% ( $F(1,46)=.28$ , n.s.) over the Likert questions and 23% ( $F(1,46)=.002$ , n.s.) over the essay questions. Both classes improved on the evolution posttests, averaging 77% of the Likert questions' points ( $F(1,46)=37.26$ ,  $p<.001$ ) and 39% of the essay questions' points ( $F(1,46)=67.70$ ,  $p<.001$ )

Not surprisingly, the experimental class demonstrated a significantly greater increase on the dinosaur posttest than the control group ( $F(1,46)=9.660$ ,  $p<.005$ ). More importantly, the experimental class showed a greater gain on both the Likert ( $F(1,46)=7.60$ ;  $p<.01$ ) and the essay ( $F(1,46)=6.43$ ;  $p<.02$ ) evolution tests. In concert with the view of dinosaur knowledge as an anchor for learning, an exploratory regression analysis to determine the predictors of the evolution essay posttest showed the dinosaur pretest to be the best predictor, accounting for over 30% of the variance.

Further exploration (Table 2) of the three essay questions that most involved natural selection reveal very modest pretest performance; the mean score for the experimental class was 12% (SD = 9%), while that for the control class was 16% (SD = 10%). However, during the posttest, the mean for the experimental class grew to 35% (SD = 16%), while the mean for the control class was 22% (SD = 19%). Table 2 also illustrates the breakdown of these three essay responses into the four natural selection criteria. The results indicate that students generated responses that accounted for selection pressures 36% of the time, whereas students only discussed the role of heredity in natural selection 8% of the time. The experimental class demonstrated several notable gains regarding the criteria (particularly, mutation/variation, which grew from 11% to 54%), whereas the gains of the control class were generally more modest. Consider the following student responses, regarding why apatosaurs/giraffes had longer necks than their ancestors:

### A7 Pretest

They need to reach the food at the top of trees and they evolved with longer and longer necks.

### A7 Posttest

"There was a random mutation and one baby had a long neck some of its baby will have long neck too. Then soemthing in there environment or surrounds change i.e. Food is higher in the trees making it good to have a long neck because food is harder to get the ones with the short necks die leving only ones with long necks. They mate and then there are more long neck and this keeps happing."

### A13 Pretest

I think that apatosaurs came to have longer necks by evolution. Over time, they got bigger and bigger.

### A13 Posttest

RANDOM MUTATION! Giraffes may have had offspring that, purely by luck, had long necks. Maybe food on the floor of the forest was

diminishing and the long necked giraffes got food from high up. The short neck giraffes probably died of starvation. Then when only long necks were left, long necks had to reproduce. If longnecks mated they'd produce other long necks, until present day giraffes were known for their long necks.

The pretest responses often invoked the notion of "need" with no real sense of mechanisms. On the posttest, the subjects expressed more sophisticated understandings of

evolutionary concepts and at least rudimentary mastery of the appropriate form of a natural selection explanation. In spite of the differential learning successes exhibited by the experimental class, their explanations were still rather modest or inconsistent, as evidenced by their evolution posttest essays and their natural selection question responses. These results are consistent with other studies (e.g., Ohlsson, 1990; Bishop & Anderson, 1990) that documented persistent difficulties in students' (from middle school to college) reasoning about natural selection.

**Table 1.** Mean percentages and standard deviations (parentheses) for all tests and classes.

**Table 3.** Percentages of some non-Darwinian essay responses.

	<b>Experimental</b>		<b>Control</b>	
	Pretest	Posttest	Pretest	Posttest
Lamarckian	4	3	4	7
Teleological	10	7	10	18
Amechanistic	24	14	21	24
<i>Total</i>	<i>38</i>	<i>24</i>	<i>35</i>	<i>49</i>

Students often exhibit patterns of reasoning that are inconsistent with Darwinian explanations. When possible, non-Darwinian response patterns were classified as Lamarckian, Teleological, or Amechanistic (absence of mechanism), as shown in Table 3. Note that there were many responses that were not fully consonant with a Darwinian explanation, yet were not classifiable according to

this coding scheme. Lamarckian explanations implying the passing of acquired traits to progeny. For example, a student from the experimental class explained, "I think that maybe the cheetahs hunted animals that started to get fast and run away. The cheetahs had to adapt and run faster to catch their food. As their prey began to lead them on chases, their speed increased. Over time, their muscles probably just got bigger

and stronger (because they worked them so much). Now, cheetahs run very fast, and can catch gazelles and impalas and zebras and antelope." Teleological explanations suggest that need causes evolutionary change. A control class student envisioned changes in the eating habits of a cow if there were suddenly no grass to eat: "I think that they would just get so hungry they would start with insects and move their way up to fish." Another student, during the control class's posttest, explained that giraffe necks are so long "Because the giraffes had to stretch their necks to reach the trees for food." A mechanistic explanation indicates that evolution simply happens. In explaining why cheetahs became faster, one control class student stated "they had adapted to the prey getting faster. Through evolution." While some non-Darwinian explanations merely reflect an inability to express ideas maturely or the absence of specific biological knowledge, they may also indicate an inability to construct reasonable Darwinian arguments with their existing knowledge of evolution.

Table 3 also illustrates ways in which the two classes, while performing rather similarly on the pretest, differ when it comes to posttest response patterns. The experimental class's non-Darwinian responding went from 38% to 24%, while the control class's non-Darwinian responding moved in the opposite direction, from 35% to 49%. One of the central goals of the experimental curriculum was to foster effective Darwinian reasoning, and the results suggest modest success in that regard. Further, the results suggest that instruction may even foster more problematic patterns of reasoning.

## Discussion

Recently, innovative curricula have targeted different facets of student difficulty regarding understanding evolution. The present study suggests that a conceptual change evolution curriculum anchored in the domain of dinosaur knowledge can promote the integration of core concepts and foster more effective Darwinian reasoning. Dinosaurs seem to be a good choice as an anchor for a contextualized curriculum. Dinosaur knowledge has been established to be relatively high among middle school students, and the results of this study suggest that having dinosaur knowledge may provide students with an advantage in learning about evolution.

Although the results of this curriculum are promising, the gains are still modest. Further research is needed to exclude the possibility that the differences between groups are not the result of extraneous factors. For example, the gains may be explained by the novelty of dinosaurs, the experimental teacher's enthusiasm, or the relative advantage of constructivist teaching methods over conventional didactic instruction. Nevertheless, this study suggests that employing an intrinsically motivating curricular source domain that engages a student's prior knowledge can facilitate the development of evolutionary competence. The dinosaur curriculum was designed to foster generative conceptual knowledge and coherent evolutionary reasoning. The other two pieces of the evolutionary competence puzzle,

epistemological commitments and discourse practices, were less central in the curriculum. These core features of evolutionary competence are clearly interdependent. For example, a student who appreciates the "correct form" of a natural selection explanation, but lacks a suitable descriptive vocabulary (i.e., one who can't "talk the talk") is unlikely to generate a coherent explanation. The standards of coherence for evolutionary explanations are particularly exacting, and coherence-building interventions are worthy pursuits in fostering critical thinking (Ranney & Schank, 1998).

Teleological reasoning was noted in many of the students' explanations. Teleological causation in explanations is hardly unique to evolution. It may underlie intuitive theories of biology in children as well as adults (Carey, 1995). Biological processes can be thought about in mechanistic or teleological terms. While it is advantageous for students to have a principled, mechanistic, understanding of scientific concepts, teleological or goal-oriented explanations are often presented in textbooks and lectures to orient students to the functions of a particular bodily mechanism. Teleological explanations are also commonplace in everyday discourse. Considerable research indicates that young children develop rudimentary theories in which biological functions are often expressed in intentionalist terms, such as striving to fulfill "wants" and "needs" (Hatano & Inagaki, 1996; Carey, 1995). This phenomenon is not unique to children. Medical students sometimes generate teleological explanations in reasoning about the function of the heart and circulatory system (Kaufman, Patel, & Magder, 1996).

Teleological thought is rooted in productive forms of knowledge and provide coherent explanations for nonintuitive phenomena that surrounds us. It is a challenge is to effectively exploit this knowledge in formal education in order to develop mechanistic understandings of biological processes. For example, teleological reasoning may promote an understanding of structure-function relations in young children; Ash and Brown (1996) developed a curriculum that fosters transitions from more rudimentary forms of teleological thought towards adaptationist reasoning that approximates mature natural selection explanations.

Our results suggest that some students began to demonstrate proficient Darwinian explanation patterns. However, most students continued to experience difficulties incorporating notions of variation and heredity into their responses—and subjects were somewhat inconsistent across problems. Anchoring in a given domain represents a starting point, but experience applying the schema in different domains is likely a prerequisite to mastery.

Learning about evolution in a familiar domain can certainly facilitate the development of disciplinary discourse, though more needs to be done to foster proficient "evolution speak". Tabak and Reiser (1999), using BGUILLE (the Biology Guided Inquiry Learning Environment) and working with middle school teachers, also try to advance productive discourse strategies in learning about natural selection, striving to scaffold students so that they can progress from lay explanations to increasingly sophisticated scientific explanations. The process involved establishing scientific norms, providing specific prompts (e.g., to elaborate incomplete explanations) and reshaping response patterns in

a manner that approximates scientific discourse. Fostering effective disciplinary discourse practices is essential in the development of evolutionary competence.

The concept of biological evolution represents a critical challenge for students to master, and given that it is a foundational concept in the biological sciences, it warrants special attention. A growing body of empirical work has systematically diagnosed a range of student difficulties pertaining to evolution, and researchers will certainly continue to develop ever more promising instructional strategies to support coherent evolutionary reasoning and argumentation.

### Acknowledgments

We thank the participants in the Evolution and Biology Education research groups. We are especially grateful to Anli Liu, Jennifer Schindel, and Franz Cheng for their comments and assistance in the data analyses.

# Evaluating Competition-based Models of Word Order

Frank Keller

keller@cogsci.ed.ac.uk

Institute for Communicating and Collaborative Systems

Division of Informatics, University of Edinburgh

2 Buccleuch Place, Edinburgh EH8 9LW, UK

## Abstract

The ordering of constituents in semi-free word order languages has attracted considerable attention in theoretical linguistics. Three types of models have been proposed to explain word order preferences, based on (a) weighted constraints, (b) Optimality Theory (c) syntactic weight. All three models use grammatical competition to explain the interaction of word order constraints. They rely on intuitive judgments or corpus studies, but have not been evaluated against experimental data. This is the purpose of the present paper. We report the results of a magnitude estimation experiment investigating word order in German, focusing on the interaction of verb position, case marking, pronominalization, and information structure. The experimental data are compatible with models (a) and (b), indicating that relativized (ranked or weighted) constraints are essential in explaining word order preferences. Model (c), on the other hand, is not compatible with the data.

## Introduction

The languages of the world differ substantially in the degree of word order variation they allow. On the one end of the spectrum, we find languages like English, which exhibit a relatively fixed word order. On the other end, there are languages like Warlpiri (an Australian language), which allow a large degree of word order variation. Many languages exhibit a semi-free word order, i.e., the word order is fixed in some respects, but variable in others.

Word order variation typically manifests itself not in binary acceptability judgments, but in the form of word order preferences, to which a diverse set of factors contribute, including syntactic, pragmatic, and phonological factors. This poses an interesting challenge for linguistic theory, which is equipped to deal with binary ungrammaticality resulting from the violation of individual linguistic constraints, rather than with preferences (degrees of acceptability) that emerge from the interaction of a diverse set of factors.

A number of approaches have been developed to deal with this challenge, all of which diverge from conventional linguistic frameworks in assuming a relative (weighted or ranked) rather than an absolute (binary) notion of linguistic constraints. Three main types of models have been proposed, based on (a) weighted constraints (Jacobs, 1988; Uszkoreit, 1987), (b) Optimality Theory (Choi, 1996; Müller, 1999), (c) syntactic weight (Hawkins, 1992). All of these models use a notion of grammatical competition to explain the interaction of the factors that influence word order.

Models (a)–(c) rely on informal, intuitive acceptability judgments (and on corpus data in the case of (c)). It is safe

to assume that such judgments allow to determine binary acceptability reliably. However, their reliability is much less obvious with respect to degrees of acceptability like the ones that occur in word order data (Bard, Robertson, & Sorace, 1996; Cowart, 1997; Schütze, 1996). This makes it desirable to evaluate linguistic models of word order against experimentally collected acceptability data.

The purpose of the present paper is to provide a first step towards such an experimental evaluation.<sup>1</sup> The methodology we use is magnitude estimation, which has been shown to yield reliable, yet maximally delicate judgments of linguistic acceptability (Bard et al., 1996). The empirical domain of our investigation is the variation in the order of verb complements in German, a semi-free word order language. We outline the necessary linguistic background in the following section.

## Word Order in German

German has a fixed verb order. Subordinate clauses are verb final, while yes/no questions require verb initial order, and declarative main clauses have the verb in second position. In the generative literature, the subordinate clause order is generally considered the basic order from which the main clause and question orders are derived by movement (e.g., Haider, 1993). The present experiment will focus on subordinate clauses (which is also customary in the processing literature on German, e.g., Bader & Meng, 1999). Using subordinate clauses avoids potential confounds from topicalization and other phenomena that can occur in verb second clauses.

While verb order is fixed in German, the order of the complements of the verb is variable, and a number of factors have been claimed to influence complement order. These factors include case marking, thematic roles, pronominalization, information structure, intonation, definiteness, and animacy (Choi, 1996; Jacobs, 1988; Müller, 1999; Uszkoreit, 1987; Scheepers, 1997). The present study focuses on the effect of case marking, pronominalization, and information structure on word order.

We elicited acceptability judgments for four subordinate clause orders, illustrated by the examples in (1). As mentioned above, subordinate clauses in German require verb final order (see (1a), (1b)). Verb initial orders (see (1c), (1d)) give rise to strong unacceptability.

---

<sup>1</sup>Previous experimental work on word order preferences in German (Pechmann, Uszkoreit, Engelkamp, & Zerbst, 1994; Scheepers, 1997) only dealt with isolated stimuli, i.e., failed to address contextual effects on order, one of the topics of the present paper

- (1) a. **SOV:**  
 Maria glaubt, dass der Vater den Wagen kauft.  
 M.-NOM believes that the father-NOM the car-ACC buys  
 ‘Maria believes that the father will buy the car.’  
 b. **OSV:** Maria glaubt, dass den Wagen der Vater kauft.  
 c. **VSO:** Maria glaubt, dass kauft der Vater den Wagen.  
 d. **VOS:** Maria glaubt, dass kauft den Wagen der Vater.

We also examined the influence of pronominalization on word order. The experiment included sentences where none of the NPs was pronominalized (see (1)), but also sentences where the subject, object, or both the subject and the object were pronominalized (see (2)).<sup>2</sup>

- (2) a. Maria glaubt, dass er den Wagen kauft.  
 Maria-NOM believes that he-NOM the car-ACC buys  
 ‘Maria believes that he will buy the car.’  
 b. Maria glaubt, dass der Vater ihn kauft.  
 Maria-NOM believes that the father-NOM it-ACC buys  
 ‘Maria believes that the father will buy it.’  
 c. Maria glaubt, dass er ihn kauft.  
 Maria-NOM believes that he-NOM it-ACC buys  
 ‘Maria believes that he will buy it.’

Information structure figures as a determinant of complement order in the accounts of Choi (1996), Jacobs (1988), Müller (1999), and Uszkoreit (1987). Information structural effects can be studied by embedding the sentence in a question context: the *wh*-phrase marks the focussed constituent, while the other constituents are non-focussed, or ground (Vallduví, 1992). The following contexts were used in the experiment:

- (3) a. **All Focus:** Was gibt’s neues?  
 ‘What’s new?’  
 b. **S Focus:** Wer kauft den Wagen?  
 ‘Who will buy the car?’  
 c. **O Focus:** Was kauft der Vater?  
 ‘What will the father buy?’

A null context condition was included as a control, allowing us to study how subjects react in the absence of any contextual information.

## Models of Word Order

### Weighted Constraints

Uszkoreit (1987) models word order preferences using weighted constraints. In such a setting, linguistic constraints are annotated with a numeric weight that reflects their importance in determining grammaticality (for a similar proposal, see Jacobs, 1988). Uszkoreit assumes constraint competition, i.e., not all constraints are necessarily satisfiable in a given linguistic structure. This entails that grammaticality is a gradient notion; the degree of grammaticality of a linguistic structure is computed as the sum of the weights of the constraint violations the structure incurs.

Uszkoreit (1987, p. 114) proposes the following constraints on word order in German (constraints irrelevant to the data under consideration are omitted and constraint names are provided):

<sup>2</sup>Note that only masculine NPs were used, as these are unambiguous in their case marking, both as full NPs and as pronouns (while the case morphology of feminine and neuter NPs exhibits syncretism).

- (4) a. VERB:  $X \prec V[-MC]$   
 b. NOM:  $[+NOM] \prec [+ACC]$   
 c. FOC:  $[-FOCUS] \prec [+FOCUS]$   
 d. PRO:  $[+PRO] \prec [-PRO]$

These constraints are constituent order constraints, with ‘ $\prec$ ’ denoting linear precedence. The constraint VERB relies on the feature MC (main clause) to specify verb order; if this feature is negative (i.e., in a subordinate clause), then the verb has to succeed any other constituent. The constraint NOM requires that nominative precedes accusative. The information structural requirement FOC specifies that ground constituents (marked  $[-FOCUS]$ ) precede focused constituents. The constraint PRO requires pronouns to precede full NPs.

Uszkoreit does not provide weights for the constraints in (4).<sup>3</sup> Intuitively, however, we expect a violation of VERB to lead to serious unacceptability, i.e., VERB should receive a higher weight than the other constraints.

### Optimality Theory

Standard Optimality Theory (OT; Prince & Smolensky, 1993) assumes a binary notion of grammaticality; a linguistic structure is either optimal (and thus grammatical) or suboptimal (and thus ungrammatical). However, OT can be extended to model gradient grammaticality; Müller (1999) puts forward a modified version of OT based on the distinction between grammaticality (manifested in binary judgments) and markedness (associated with word order preferences). Grammaticality is handled in terms of conventional OT-style constraint competition. This competition can yield several grammatical candidates, among which further competition takes place based on markedness constraints. The markedness competition then induces a preference order on the candidates that predicts their relative acceptability. (Note that the grammaticality/markedness dichotomy is reminiscent of the distinction of hard and soft constraints proposed by Keller (1998).)

In Müller’s account, the constraints on pronoun order belong to the realm of grammaticality, while the constraints on case order and focus-ground order (among others) belong to the realm of markedness. We omit technical details and only state constraints relevant to the present data set:

- (5) a. NOM:  $[+NOM] \prec [-NOM]$   
 b. FOC:  $[-FOCUS] \prec [+FOCUS]$   
 c. AN:  $[+ANIMATE] \prec [-ANIMATE]$

Note that the constraints NOM and FOC are similar to Uszkoreit’s constraints in (4). AN is an additional constraint that requires animate NPs to precede inanimate ones. In contrast to Uszkoreit, Müller postulates an explicit constraint ranking:

- (6)  $NOM \gg AN \gg FOC$

In addition to the markedness constraints in (5), a set of grammaticality constraints is postulated (omitted here). These constraints deal with pronoun order and ensure that pronouns occur at the left periphery of the clause. All candidates that fail to meet this requirement are predicted to be (categorically) ungrammatical. In contrast to Uszkoreit, Müller does not include constraints on verb order.

<sup>3</sup>Pechmann et al. (1994) tentatively assume that all constraints have equal weights, which entails that the degree of unacceptability only depends on the number of violations.

## Syntactic Weight

Hawkins (1992) proposes an approach to word order preferences that also relies on grammatical competition, but makes very different assumptions concerning the source of this competition. Hawkins assumes that constituent order is determined by the syntactic weight of the constituents, a notion that is supposed to reflect how easily the constituents can be recognized by the human parser. According to Hawkins (1992, p. 200), relative syntactic weight explains word orders frequencies in corpora, as well as the relative acceptability of different orders in native speaker's judgments.

Hawkins proposes Immediate Constituent to Word Ratio (ICR) as a metric for syntactic weight. Intuitively, ICR measures the length of a constituent relative to its position in the clause (see Hawkins, 1992, for details). If two sentences differ in average ICR, the one with the higher average ICR is predicted to be more acceptable. The ICR for a given word is calculated as  $n/m$ , where  $n$  is the number of the constituent, while  $m$  is the number the word, counted from left to right. The average ICR for a sentence is obtained by averaging the ICRs of its words. As an example, consider the ICRs for the sentences in (1):

- (7) a. M. glaubt, dass [[der Vater] [den Wagen] kauft.] ICR  
1/1 1/2 2/3 2/4 3/5 .65  
b. M. glaubt, dass [kauft [der Vater] [den Wagen].] ICR  
1/1 2/2 2/3 3/4 .86

Provided that subject and object have the same length, SO and OS orders receive the same ICR, i.e., examples (1a) and (1b) both have an ICR of .65 (see (7a)), while examples (1c) and (1d) both receive an ICR of .86 (see (7b)). For pronominalized NPs, the following ICRs are predicted:

- (8) a. Maria glaubt, dass [[er] [den Wagen] kauft.] ICR  
1/1 2/2 2/3 3/4 .86  
b. Maria glaubt, dass [[der Vater] [ihn] kauft.] ICR  
1/1 1/2 2/3 3/4 .73  
c. Maria glaubt, dass [[er] [ihn] kauft.] ICR  
1/1 2/2 3/3 1.0

This means that Hawkins's account predicts that pronouns have to precede full NPs (if they are longer than a single word). However, if both the subject and the object are pronouns, then both SO and OS receive an ICR of 1.0, i.e., they should be equally acceptable.

Note that Hawkins predicts that information structure (focus and ground) should not play a role in determining word order preferences, contrary to claims by Müller (1999) and Uszkoreit (1987), among others.

## Experiment

### Method

**Subjects** Fifty-one native speakers of German participated in the experiment. All participants were naive to syntactic theory.

**Materials** A factorial design was used that crossed the factors verb order (*Vord*), complement order (*Cord*), pronominalization (*Pro*), and context (*Con*). The factor *Con* had four levels: null context, all focus, S focus, and O focus, as illustrated in (3). The factor *Vord* had four two levels: verb final

(see (1a), (1b)) and verb initial (see (1c), (1d)). The two levels of *Cord* were subject before object and object before subject, as in (1a), (1c) and (1b), (1d). In the null context condition, the factor *Pro* had four levels, viz., both S and O full NPs, S pronoun and O full NP, S full NP and O pronoun, and both S and O pronouns (see (2)). In the context condition, *Pro* only had two levels, viz., no pronoun and pronoun. In the all focus and S focus contexts, the object was pronominalized, while in the O focus context, the subject was pronominalized. This design ensures that the pronoun is interpreted as ground and hence is unstressed (as the sentential stress has to fall on the focussed constituent). We are only interested in the syntactic behavior of weak (i.e., unstressed) pronouns; strong (i.e., stressed) pronouns are subject to different syntactic constraints.

This yielded a total of  $Vord \times Cord \times Pro = 2 \times 2 \times 4 = 16$  cells for the null context condition, and  $Vord \times Cord \times Pro \times Con = 2 \times 2 \times 2 \times 3 = 24$  cells for the context condition. Eight lexicalizations per cell were used, which resulted in a total of 320 stimuli. A set of 24 fillers was used in the null context condition; 16 fillers were employed in the context condition. The fillers were designed to cover the whole acceptability range.

To control for possible effects from lexical frequency, the lexicalizations for subject, object, and verb were matched for frequency. Frequency counts for the verbs and the head nouns were obtained from a lemmatized version of the Frankfurter Rundschau corpus (40 million words of newspaper text) and the average frequencies were computed for subject, object, and verb lexicalizations. An ANOVA confirmed that these average frequencies were not significantly different from each other.

**Procedure** The method used was magnitude estimation as proposed by Stevens (1975) for psychophysics and extended to linguistic stimuli by Bard et al. (1996) and Cowart (1997).

Subjects first saw a set of instructions that explained the concept of numerical magnitude estimation using line length. Subjects were instructed to make length estimates relative to the first line they would see, the reference line. They were told to give the reference line an arbitrary number, and then assign a number to each following line so that it represented how long the line was in proportion to the reference line. Several example lines and corresponding numerical estimates were provided to illustrate the concept of proportionality. Then subjects were told that linguistic acceptability could be judged in the same way as line length. The concept of linguistic acceptability was not defined, but examples of acceptable and unacceptable sentences were provided.

The experiment started with a training phase designed to familiarize subjects with the magnitude estimation task. Subjects had to estimate the length of a set of lines. Then, a set of practice items (similar to the experimental items) were administered to familiarize subjects with applying magnitude estimation to linguistic stimuli. Finally, subjects had to judge the experimental items. A between subjects design was used to administer the factor *CON*: subjects in Group A judged non-contextualized stimuli, while subjects in Group B judged contextualized stimuli. The factors *Vord*, *Cord*, and *Pro* were administered within subjects. Using a Latin square design, eight lexicalizations were created for each group. The lexi-

Figure 1: Interaction for word order and pronominalization, null context

calizations for Group A contained 16 items, while the ones for Group B contained 24 items.

Each subject saw one lexicalization and 24 fillers in Group A or one lexicalization and 16 fillers in Group B, i.e., a total of 40 items per group. Each subject was randomly assigned to a group and a lexicalization: 20 subjects were assigned to Group A, and 31 to Group B. Instructions, examples, training items, and fillers were adapted for Group B to take context into account.

## Results

The data were normalized by dividing each numerical judgment by the modulus value that the subject had assigned to the reference sentence. This operation creates a common scale for all subjects. All analyses were carried out on the geometric means of the normalized judgments, as is standard for magnitude estimation data (Bard et al., 1996; Cowart, 1997).

In discussing the results, we make use of the following abbreviations: SO for subject before object, OS for object before subject, XV for verb final, VX for verb initial. The indices ‘pro’ and ‘full’ indicate pronouns and full NPs, respectively. For instance,  $VS_{full}O_{pro}$  stands for an VSO order where the subject is a full NP and the object is a pronoun.

**Null Context Condition** Figure 1 graphs the average judgments for each word order. An ANOVA for the null context condition revealed a highly significant main effect of *Vord* (verb order) ( $F_1(1, 19) = 56.911, p < .0005; F_2(1, 7) = 621.924, p < .0005$ ): XV orders (mean = .1879) were more acceptable than VX orders (mean = -.2129). A highly significant main effect of *Cord* (complement order) was also obtained ( $F_1(1, 19) = 26.966, p < .0005; F_2(1, 7) = 72.610, p < .0005$ ): SO orders (mean = .0659) were more acceptable than OS orders (mean = -.0909). The main effect of *Pro* (pronominalization) was significant by subjects only ( $F_1(3, 57) = 5.150, p = .003; F_2(3, 21) = 0.647, p = .593$ ).

The ANOVA also revealed a significant interaction of *Cord* and *Pro* ( $F_1(3, 57) = 13.026, p < .0005; F_2(3, 21) = 4.663, p = .012$ ). This indicates that pronominalization has an influence on complement order preference. We also found interactions of *Cord* and *Vord* ( $F_1(1, 19) = 47.437, p < .0005; F_2(1, 7) = 17.148, p = .004$ ) and of *Vord* and *Pro* (significant

Figure 2: Interaction for word order and pronominalization, all focus context

Figure 3: Interaction for word order and pronominalization, subject focus context

by subjects only,  $F_1(3, 57) = 4.223, p = .009; F_2(3, 21) = 1.107, p = .368$ ). A three-way interaction *Vord/Cord/Pro* was also present (significant by subjects only,  $F_1(3, 57) = 7.415, p = .009; F_2(3, 21) = 1.900, p = .161$ ).

The meaning of the interactions involving *Vord* becomes clear from Figure 1: the effect of pronominalization on complement order is limited to verb final orders; all verb initial orders are equally unacceptable, independent of complement order and pronominalization.

**Context Condition** Figures 2–4 graph the average judgments for each context. An ANOVA for the context condition confirmed the main effect of verb order found in the null context condition ( $F_1(1, 30) = 121.507, p < .0005; F_2(1, 7) = 225.903, p < .0005$ ): XV orders (mean = .2519) were more acceptable than VX orders (mean = -.1973). The main effect of complement order could also be replicated ( $F_1(1, 30) = 40.275, p < .0005; F_2(1, 7) = 15.359, p = .006$ ): SO orders (mean = .0785) were more acceptable than OS orders (mean = -.0239). A highly significant main effect of *Con* (context) was also present ( $F_1(2, 60) = 28.953, p < .0005; F_2(2, 14) = 54.056, p < .0005$ ), as well as a weak effect of *Pro* ( $F_1(2, 60) = 5.564, p = .025; F_2(2, 14) = 1.511, p = .259$ ).

The ANOVA uncovered an interaction of *Cord* and context,

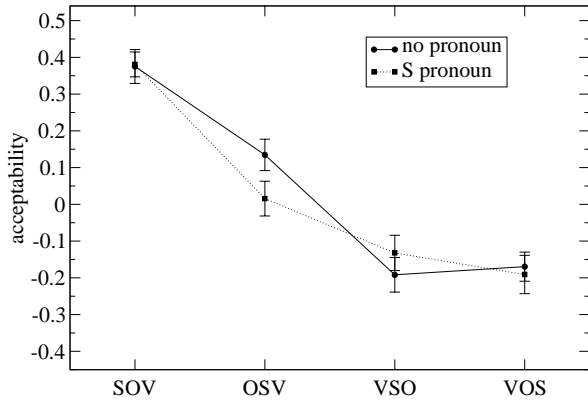

Figure 4: Interaction for word order and pronominalization, object focus context

significant by subjects and marginal by items ( $F_1(2, 60) = 6.016, p = .004; F_2(2, 14) = 3.076, p = .078$ ), which confirms that information structure (manipulated by context) has an influence on complement order preferences. We also found a marginal interaction of *Cord* and *Pro* ( $F_1(1, 30) = 4.025, p = .054; F_2(1, 7) = 3.634, p = .098$ ) and a highly significant interaction of *Pro* and context ( $F_1(2, 60) = 11.864, p < .0005; F_2(2, 14) = 16.07, p < .0005$ ). Recall that our materials were designed such that in all focus and S focus contexts, the object was pronominalized, while in an O focus context, the subject was pronominalized. This means that the *Cord/Pro* and *Pro/Con* interactions are only meaningful with respect to the three-way interaction *Cord/Pro/Con* which was also significant ( $F_1(2, 60) = 19.718, p < .0005; F_2(2, 14) = 7.73, p = .005$ ). This interaction demonstrates that the ordering of pronouns is subject to contextual effects (which will be discussed in the next section). The ANOVA also showed an interaction of *Vord* and *Cord* ( $F_1(1, 30) = 50.960, p < .0005; F_2(1, 7) = 7.221, p = .031$ ) and of *Vord* and context ( $F_1(2, 60) = 10.589, p < .0005; F_2(2, 14) = 11.945, p = .001$ ). The meaning of these interactions becomes clear from Figures 2–4: the interaction between complement order and context is limited to verb final orders; all verb initial orders are equally unacceptable, independent of context.

## Discussion

All differences referred to in the following were significant according to post-hoc Tukey tests (space limitations prevent the inclusion of the full set of Tukey results).

**Weighted Constraints** The experimental findings for the null context condition provided broad support for the ordering constraints in (4), initially proposed by Uszkoreit (1987). There was a clear preference for XV over VX, in line with the predictions of the verb ordering constraint VERB. The NOM constraint, which requires nominative to precede accusative, received support from the fact that SO orders were more acceptable than OS orders. Finally, the constraint PRO, which requires that pronouns precede full NPs, explains why  $S_{full}O_{pro}$  is less acceptable than  $S_{pro}O_{full}$ , while  $O_{full}S_{pro}$  is less acceptable than both  $O_{full}S_{full}$  and  $O_{pro}S_{full}$  (see Figure 1).

The interactions involving the factor *Vord* demonstrated that the effects of NOM and PRO disappear if the constraint VERB is violated. This indicates that a violation of VERB is more serious than violations of PRO or NOM, which in Uszkoreit’s framework means that VERB receives a higher weight than both PRO and NOM.

The behavior of VERB was replicated in the context condition. VERB leads to serious unacceptability in all contexts and blocks out all other constraint effects. Note, however, that we found an interaction of PRO and context that does not readily follow from Uszkoreit’s account. The prediction that pronouns have to precede full NPs is only born out in the all focus context. In the S focus and O focus contexts, the effect of PRO disappears, which might indicate that PRO is only valid if the context fails to provide an antecedent for the pronoun.

S focus and O focus contexts showed evidence for FOC, the constraint that requires ground elements to precede focus elements. In both contexts, SO was the preferred order, even though it violates FOC in the S focus context; in both contexts, the acceptability of OS was reduced compared to SO. However, this reduction was significantly higher in the O focus context, where OS violates FOC. The overall SO preference (even if it is disfavored by the context) indicates that the effect of FOC is weak compared to the influence of NOM, i.e., NOM should receive a higher weight than FOC. Only for OS orders, i.e., when NOM is violated, the influence of FOC becomes visible. No effects of context were found for VX orders, which indicates that FOC has a lower weight than VERB, just like NOM and PRO.

Overall, we have established the following facts about constraint weights: VERB has a higher weight than PRO, NOM, and FOC. NOM, on the other hand, has a greater weight than FOC. This is compatible with the following weight assignments:

$$(9) w(\text{VERB}) = 3, \quad w(\text{PRO}) = w(\text{NOM}) = 2, \quad w(\text{FOC}) = 1$$

To conclude, our results provide support for Uszkoreit set of word order constraints and show that his weighted constraint model is able to account for the experimental data.

**Optimality Theory** Note that the weights in (9) can also be interpreted as a set of OT-style constraint ranks:

$$(10) \text{VERB} \gg \{\text{PRO}, \text{NOM}\} \gg \text{FOC}$$

This ranking is compatible with Müller’s ranking in (6). Note that the effect of the AN (animacy) could not be tested in the present experiment: all nominative NPs were animate, while all accusative NPs were inanimate, hence a violation of NOM also entails a violation of AN.

Müller distinguishes between grammaticality and markedness, and predicts that ungrammatical candidates are categorically unacceptable, while marked structures are only dispreferred. PRO is a classified as a grammatical constraint, and hence should induce categorical unacceptability. Our data provides counterevidence to this prediction: in the null context,  $S_{full}O_{pro}V$  and  $O_{pro}S_{full}V$  are equally acceptable (see Figure 1), even though  $S_{full}O_{pro}V$  violates PRO while  $O_{pro}S_{full}V$  does not (the same pattern occurs in the all focus and S focus contexts). This is unexpected under the assumption that PRO is grammatical constraint; the data suggest that it should be reclassified as a markedness constraints.

On the other hand, VERB seems to be a genuine grammatical constraint. Its violation leads to strong ungrammaticality in all contexts, independently of which other constraints are violated (see Figures 1–4). This indicates that VERB (not explicitly dealt with by Müller) is a grammatical constraint.

Hence our data provides counterevidence for some aspects of Müller's particular account of word order in German. However, the main feature of his model, viz., the distinction between grammaticality and markedness, is supported by our experimental results.

**Syntactic Weight** Several of the order preferences found in this experiment are incompatible with Hawkins's account in terms of ICR. Most strikingly, we found that  $S_{full}O_{full}V$  is more acceptable than  $O_{full}S_{full}V$  (see Figures 1–4), even though both have the same ICR (see (7)).

As far as pronominalization is concerned, we found that in the null context,  $S_{pro}O_{full}V$  is more acceptable than  $S_{full}O_{pro}V$  and  $O_{pro}S_{full}V$  is more acceptable than  $O_{full}S_{pro}V$  (see Figure 1), consistent with the ICR predictions (see (8)). However, the predictions with respect to double pronouns were not born out: these receive the maximum ICR score of 1.0, but we found that the orders  $S_{pro}O_{pro}V$  and  $O_{pro}S_{pro}V$  are as unacceptable as  $S_{full}O_{pro}V$  and  $O_{full}S_{pro}V$ , respectively, even though these orders only have an ICR of .73 (see (8)). Also, the fact that  $S_{full}O_{pro}V$  and  $O_{pro}S_{full}V$  are equally acceptable is unexpected as these orders differ in ICR (see (8)). This observation holds across contexts, see Figures 1–4.

Also the focus effects we found are unexpected under a syntactic weight account: the acceptability of OSV is increased in an O focus context (compared to an S focus context, see Figures 3, 4), even though the ICR remains constant.<sup>4</sup> Finally, the fact that VX structures are severely unacceptable across the board does not follow from syntactic weight—in fact VX orders have a higher ICR than XV orders (see (7)).<sup>5</sup>

To summarize, while corpus data seems to support a syntactic weight account (see Hawkins, 1992, for details), the acceptability judgments in our experiment are largely incompatible with Hawkins's predictions.

## Conclusions

We reported the results of a study of word order variation in German that investigated the interaction of syntactic (complement order and verb order) and information structural constraints (pronominalization and focus). The data were used to evaluate a set of competition-based models of word order, including (a) Uszkoreit's (1987) weighted constraint model, (b) Müller's (1999) optimality theoretic account, and (c) Hawkins's (1992) syntactic weight model.

The experimental data are broadly compatible with models (a) and (b), indicating that a relativized (ranked or weighted) notion of linguistic constraints is essential for explaining word order preferences. Model (c), however, was not

<sup>4</sup>Note that Hawkins (1992, p. 196) concedes that informational concepts like focus play a limited role in 'structures for which syntactic weight makes either no predictions or weak predictions'.

<sup>5</sup>However, Hawkins argues that languages can grammaticalize word orders, which then are no longer subject to syntactic weight. This would explain the general unacceptability of VX in subordinate clauses in German.

well-supported by the data. While this model may be suitable for describing word order distributions in corpora, it does not seem to be directly applicable to contextualized acceptability judgments such as the ones reported in the present paper.

On the other hand, we found that some of the individual linguistic assumptions made by Uszkoreit and Müller were not born out in our data. This highlights the fact that informal acceptability judgments are not sufficient to clarify the intricate preference patterns that emerge from the interaction of syntactic, pragmatic, and phonological constraints on word order. Experimentally collected judgments are necessary to obtain reliable, delicate data that can inform detailed models of word order preferences.

The results of the present study have been replicated for a free word order language (Greek) and for spoken stimuli (Keller & Alexopoulou, 2000).

## Abstract

Project Nemo examines the cognitive processes and representational structures used by submarine Commanders while attempting to locate an enemy submarine hiding in deep water. In phase 2 we collected performance and protocol data from junior, mid-career, and senior submarine officers. The data support the conclusions from phase 1 (Gray, Kirschenbaum, & Ehret, 1997) that most AO actions can be characterized as a sequence of small, steps in a shallow goal hierarchy (rather than as following a detailed master plan). The nature of these successive choices vary as a function of the officer's expertise. The results are congruent with an interpretation in which the process of schema instantiation provides the control of cognition.

## Introduction

In phase 1 of Project Nemo (Gray et al., 1997) we analyzed six hours of verbal and action protocols from expert submarine Approach Officers (AOs) as they detected and localized (i.e., determined the course, speed, and range) a hostile submarine hiding in deep water.

The results of phase 1 support a description of the cognitive control structure that orchestrates the AOs' behavior as *schema-directed problem solving with shallow and adaptive subgoaling* (Ehret, Gray, & Kirschenbaum, in press). The schema is the task-relevant knowledge accumulated in over 20 years of experience as a submariner (half of it at sea). It is a set of declarative as well as procedural knowledge structures. An implication of shallow subgoaling is that the knowledge available to AOs is so rich that steps to supplement this knowledge can be shallow.

A second implication is that the AO solves a series of problems, one every 30 to 300 s. The problem is always the same; namely, "what is the state of the world – NOW." The AO is trying to find a quiet target hiding in a noisy environment while remaining undetected himself. The protocol analysis revealed that he takes a series of short steps that either (a) assess the noise from the environment or signal from the target – NOW, or (b) attempt to reduce the noise or increase the signal from the target by maneuvering ownship. As shown in Figure 1, these short steps result in shallow subgoaling. When a

subgoal pops, the schema is reassessed. The result of this reassessment directs the next step (i.e., selects the next subgoal). This step is accomplished, it returns information to the schema, the schema is reassessed, and so on.

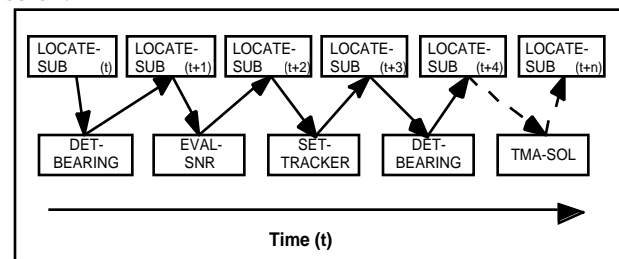

Figure 1: Schema-directed problem solving with shallow and adaptive subgoaling

The process of subgoaling is adaptive in two senses. First, the subgoal that is chosen next reflects the current reassessment of the schema. Second, this choice is sensitive to both the long-term importance of the subgoal as well as its recent history of success or failure. Regardless of a goal's long-term importance, AOs will not continue to attempt a goal if successive tries fail. Instead, they will choose another goal and return to the more important goal later.

The dynamic aspect of the AO's task plays an important role in this view of schema-directed problem solving. First, the state of the AO's world is continually changing – both ownship and target are moving at a given depth, direction, and speed. For ownship the value of these attributes can be changed, but the problem cannot be stopped. Consequently, time is an important part of the picture. Second, subgoals are not accomplished once and then discarded. In the AO's world, subgoals bring in certain types of information or accomplish certain changes to ownship. As the world changes, any given subgoal may be revisited not only to acquire the current value, but also to acquire information about the rate and direction of change (e.g., DET-BEARING in Figure 1).

Phase 1 ran 10 senior officers on a high fidelity simulation located at the Naval Undersea Warfare Center

in Newport, RI. For phase 2, we built the Ned<sup>1</sup> scaled world in Macintosh Common Lisp to run on a portable computer. (A description of the simulation can be found in Ehret et al., in press.) This portability enabled us to take Ned to U. S. Navy submarine bases in Bangor, WA and Pearl Harbor, HI. Consequently, we were able to collect data from 36 active-duty submarine officers.

In this paper we present a brief overview of the phase 1 empirical data. (More details can be found in Gray et al., 1997; and Kirschenbaum, Gray, & Ehret, 1997.) Our focus is on the data collected using the Ned scaled world, its similarities to the phase 1 data, and the variations among levels of expertise.

### **The Submariner's Task and Tools**

The job of the Approach Officer is to respond to hostile targets. He<sup>2</sup> heads the team that must detect, track, classify, localize, and if ordered, attack the target. He performs this task with the support of many special-purpose systems run by skilled operators, but is ultimately responsible for the success of the encounter.

Two features of the problem make it an especially challenging one. First, this is a dynamic problem. Both ownship and the contacts are moving, and, perhaps, changing course, etc. during the encounter. Second, there are only sparse and highly uncertain data about the contacts. The AO's expertise lies in using his knowledge of the relationships among the cues to guide information gathering over the course of the scenario and instantiate a generic "contact" schema for each contact.

Special tools are used for controlling own ship, listening to the contact, and localizing. As sound transmission is distorted, reflected and bent in the ocean by temperature, salinity, pressure, detecting, tracking, and locating the source of a passive sonar contact is highly very difficult and impacted by uncertainty. Because passive sonar only provides bearing (direction) data, target-motion-analysis (TMA) tools for localizing the targets employ statistical methods to estimate the target's course, speed, and range. As this is a mathematically under-constrained problem, submariners call this process "finding a solution."

## **Review of Phase 1**

### **Method**

All of the participants in phase 1 were highly experienced submarine officers who had served as Commanding Officers (COs) or Executive Officers (XOs) aboard U. S. Navy Submarines. The officers were presented with scenarios that required localizing an enemy submarine hiding in deep water. The scenarios were presented on the CSEAL (Combat Systems Engineering and Analysis Laboratory) high fidelity simulation. CSEAL is a submarine command-center-in-a-box. It has generic

versions of all of the essential submarine tools. As CSEAL is a developer's tool, it was run by an operator. The AOs requested information and ordered actions to be carried out by the operator. Videotapes and verbal protocols were the primary data. These were supplemented by computer-logged action protocols.

In both phases we investigated the situation assessment part of the AO's mission. Situation assessment begins with detection of the contact and ends when the AO is sufficiently confident of the solution to declare that he is ready to move to the engagement phase. Each scenario began with a status report such as an AO might receive when first taking his turn on watch. The status report provided scenario specific information including ownship course, speed, and depth as well as information on any contacts. All scenarios began with a single contact, classified as a merchant.

### **Review of Phase 1: Results**

During phase 1 we developed an encoding scheme (Gray & Kirschenbaum, in press) that included nine operators and a three-level goal structure (for detailed information, see Kirschenbaum et al., 1997). Most of the AOs' time and effort was spent in service of two top-level goals: LOCATE-MERCHANT (LOC-MERC) and LOCATE-SUBMARINE (LOC-SUB). Given that localizing the sub is clearly the higher priority, we were puzzled to find that the two goals were used with approximately equal frequency (see the left side of Figure 2). However, as the middle of Figure 2 shows, this equal frequency of use masked a large difference in the number of subgoals per LOC-MERC versus LOC-SUB.

More interesting, this disparity in number of subgoals per goal was not reflected in the number of operators per subgoal. As shown by the right-side of Figure 2, the mean number of operators per subgoal was constant. The same number of operators were used in a subgoal regardless of whether its supergoal was LOC-MERC or LOC-SUB.

Along with other analyses that we conducted, this analysis suggested that the basic unit of action was the subgoal. Formalized plans or established methods with fixed number of steps, exist at the subgoal level. At the level of LOC-MERC or LOC-SUB, each subgoal returns a discrete piece of knowledge that is added to the schema. The schema is reevaluated to determine what piece of knowledge to select next. When there is little new information to be gained by continuing working on the current goal, the goal is popped and a new top-level goal is pushed.

The question pursued below is whether the phase 2 data support the phase 1 interpretation of expert performance and in which ways intermediate and novice behavior conforms or differs from the experts.

<sup>1</sup> Ned Land was an able seaman and trusted assistant to Prof. Aronax aboard the Nautilus.

<sup>2</sup> In the current US Navy all submariners are men.

Figure 2: Phase 1. Data for the two main top-level goals, LOCALIZE-MERC and LOCALIZE-SUB. Left -- mean number of level-1 goals per AO-Trial. Middle -- mean subgoals per goal. Right -- mean number of operators per subgoal. [Error bars show the 95-percent confidence intervals for the standard error of the mean (SEM).]

### The Ned Experiment: Replication and Expansion

Table 1: Demographic data on participants.

Means for	CO/XO	DH	JO
n	15	11	10
Years at sea	8.7	6.4	3.2
Years in Navy	17.8	13.4	7.3
Age	38.9	34.4	28.3

### Participants

Three groups of current submarine officers participated in the study: Junior Officers (JOs), Department Heads (DHs), and Commanding Officers or Executive Officers (CO/XOs). The average number of years spent at sea, years in the navy, and ages can be found in Table 1. The expert participants in this study had slightly less experience than those in phase 1. This was most likely because, unlike the phase 1 AOs, all were active duty and none were post-command. (The phase 1 COs had a mean of 10.8 years at sea and 20.3 years in the Navy.)

### Ned Simulation

The Ned simulation was designed to overcome problems encountered in collecting and encoding data from CSEAL. (These problems and their solution are detailed in Ehret et al., in press.) For the current discussion, the two most relevant improvements in Ned over CSEAL were the elimination of redundant information and the control that Ned provided over access to information.

With minor exceptions, Ned's displays were specialized so that each type of information was available from one display only. For example, when an AO went to the display for the broadband spherical sonar sensor, we could be sure that he wanted one of the 10 types of information

that was available only from that display. Once an AO selected a display, all information fields for the display were covered by black boxes (as in the bottom display of Figure 3). Clicking on the field removed the black box and revealed the data until the mouse was moved from the field. (Ned consists of 10 specialized displays.)

Ned captured all AO interactions, including display navigation and viewing information (enter and exit times and information content). It also recorded truth every 20 seconds. In addition, the AOs were encouraged to think aloud and all sessions were video recorded.

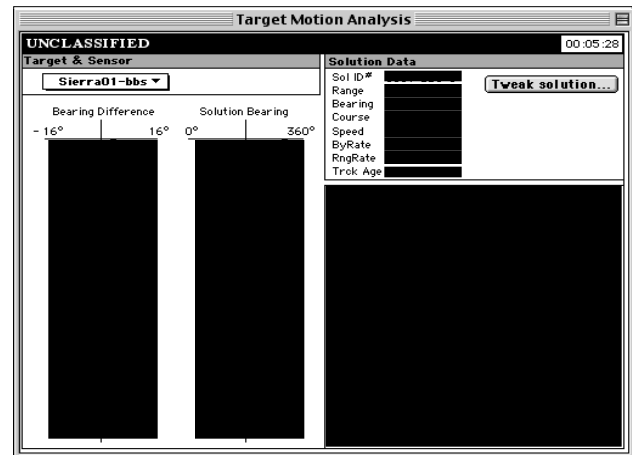

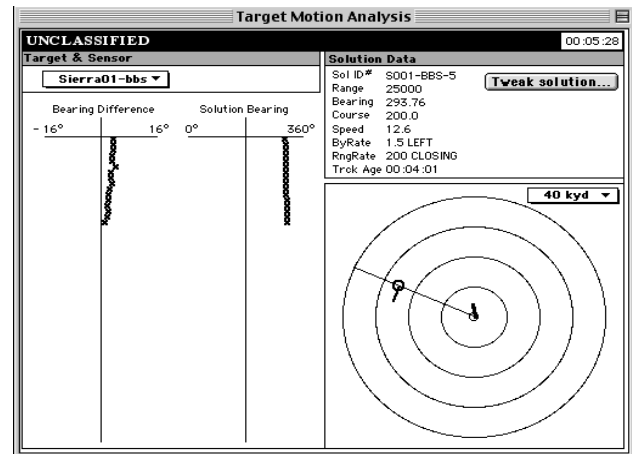

Figure 3: The Ned Target Motion Analysis screen without (above) and with (below) black boxes covering data fields.

### Scenarios

Four scenarios were used. Two were identical to those used in phase 1 and two were slightly modified versions of the phase 1 scenarios. At the beginning of each scenario the AO had ownship position (course, speed, and depth) and confirmed contact and bearing (direction from ownship) for a merchant. He also had intelligence that a "hostile" submarine was in the region.

### Procedures

Each session began with training on Ned and training in talking aloud while problem solving. Each AO solved two

scenarios. Sessions lasted approximately 2 hours.

### Protocol Encodings

Five CO/XO's were unable to complete two scenarios due to interruptions for other responsibilities. From the remaining 31 AOs, data from six AOs at each experience level (18 in all) were selected for detailed encoding. In each case, the second scenario was encoded. Protocols were selected on the basis of completeness, the lack of technical glitches, and the clarity of the recorded protocols.

### Semi-Automatic Protocol Encoding

Each click of the mouse on a menu item or a black box was saved to a log file. This enabled us to write code that encoded each action protocol and segmented groups of related actions. For example, if the AO clicked on the black box covering the range information in Figure 3 (see upper right part of the display), he was credited with two operators one for querying and one for receiving range information from the target motion analysis system.

### Operators

Operators are the lowest level encoding and represent the AO's direct interaction with the Ned simulation. Unlike phase 1, the majority of operators (approximately 99%) were encoded automatically from the computer outputted action protocols. All encodings were confirmed and/or modified by comparison with the video-taped verbal protocols. Across the three groups a total of 9,073 operators were encoded as belonging to one of nine operator categories.

Table 2: Example of goal and operator encodings.

GOAL	OP	INFO-SOURCE	SHIP	ATTR	VALUE	DUR
DETERMINE-BEARING						
	QUERY	NBT-BY-FIELD	SUB	BY		
	RECEIVE	NBT-BY-FIELD	SUB	BY	316 or 244	1.15
POP						

An example of the result of the automatic encoding of operators is provided in Table 2. Prior to this point in the scenario, the AO has called up the narrowband towed display (NBT). Here he queries the bearing (BY) information for the SUB by clicking on the black box that covers the field. The black box disappears, enabling the AO to receive the information that the narrowband towed sensor gives the ambiguous information that the hostile submarine's bearing from ownship is either 316 or 244 degrees. The bearing information is uncovered for 1.15 sec before the AO moves the cursor out of the bearing field.

Details of the operator types and categories used in phase 1 are available from Kirschenbaum, et al. (1997).. The phase 2 operator types and categories differed minimally from those used in phase 1; however, their similarity and differences from the phase 1 operators are beyond the scope of the current report.

### Goals and Subgoals<sup>3</sup>

The AO's mission, as given in the instructions, is to destroy the hostile submarine. Therefore his primary goal is to detect and localize the sub. However, these are not his only goals. He must also keep track of the merchant, avoid collision, evaluate the environment, and keep track of ownship.

Under Ned we have a precise record of the AO's information access. This record, linked by time to the verbal protocol, permitted a more detailed encoding of goals than was possible for phase 1. Hence, the goal and subgoals used in phase 2 differed from those discussed in Kirschenbaum et. al, (1997). However, the discussion of these differences will have to await a fuller report.

Of the 18 scenarios studied in phase 2, six were used to train the three encoders. These are referred to as "consensus encodings." The operators for each of the remaining 12 scenarios were encoded into goals by two independent encoders. Cohen's Kappa for interrater reliability averaged 0.84 and ranged from a low of 0.54 to a high of 0.96. All correlations are significant ( $p < .001$ ). The discrepancies between encodings were resolved by the third encoder.

### Goals and Schema

The schema instantiation process that we hypothesize controls cognition during situation assessment proceeds by pushing and popping a series of largely independent subgoals (see Figure 1). When a goal pops, information is returned to the schema being instantiated. The amended instantiation selects the next goal to push. For example, a typical sequence of goals, subgoals, and operators might read like that in Table 3

<sup>3</sup> For ease of exposition, level-1 goals will be referred to simply as *goals*; level-2 and level-3 subgoals collectively as *subgoals*.

In this sequence the AO first evaluates the sonar trace. This may return information to his schema regarding the target's bearing and bearing rate. He then switches to the display shown in Figure 3 and examines the TMA solution, alternately evaluating and tweaking the values of different parameters. As the values are returned to his schema he can compare them with his knowledge of how targets and the TMA algorithms work to derive better values to test. At the end of the sequence, he determines the solution quality by examining how closely the dots in the bottom-left section of the TMA screen (Figure 3a) stack on the central line.

### Summary

Ned records AO actions with greater specificity and accuracy than permitted by CSEAL. Consequently, we revised the goal types and categories to take advantage of this greater detail. However, the phase 2 revisions are elaborations on the goal categories and types used in phase 1. Thus, the phase 1 goal structure, with minor modifications, can support the detailed analysis of Ned data.

### Data Analysis and Results

The 9,073 operators collected in phase 2 can be aggregated and examined for many different purposes. In the current paper we limit our purposes to three. First we generally compare the goal and subgoal structure used in phase 2 with that of phase 1. For our second and third purpose, we limit ourselves to the three measures used in Figure 2: LOC-MERC and LOC-SUB goals per scenario, number of subgoals per LOC-MERC and LOC-SUB, and number of operators per subgoal. We begin by using these measures to compare the experts in phase 2 (i.e., the CO/XO's) to those in phase 1. We then use these same measures to look across levels of expertise for phase 2.

Figure 4: Phase 2 : Data for the two main top-level goals, LOCALIZE-MERC and LOCALIZE-SUB. Left -- mean number of level-1 goals per AO-Trial. Middle -- mean subgoals per goal. Right -- mean number of operators per subgoal. (Error bars show the 95% CI for SEM.) Compare with Figure 2.

### Comparison with CSEAL Data

The Ned data replicated all of the major findings reported in phase 1. In phase 1 we reported a relatively flat goal

hierarchy of 2-3 levels. This is confirmed by the more precise Ned data. Level-3 goals were confined to three level-2 goals, and the large majority 62.1% of all level 3 goals, were subgoals of a single, high-frequency level-2 goal, TMA-SOLUTION.

Secondly, in phase 1 we were able to encode the protocols using only 9 operators. Nine operators worked well for phase 2. The only notable difference in operator sets was exchanging the N/A category from the verbal protocol encodings of phase 1 for a display-manipulation category (i.e., clicking on menu item or black-box) in phase 2. Also, as in phase 1, we found relatively few operators per goal with a mean of 6.0 operators per Level 2 subgoal and 3.4 operators per Level 3 subgoal (though this varied by subgoal).

### CO/XO: Phase 1 versus Phase 2 Comparisons of Expert Level Performers

Comparing the three frames of Figure 2 with those of Figure 4 yields a qualitatively similar picture. In both phases, although the differences in numbers are small, the CO/XOs push more LOC-SUB than LOC-MERC goals. However, these small differences at the goal level are countered by large differences at the subgoals level (middle frame of Figure 4). As in phase 1, for phase 2 the number of operators per terminal subgoal (right frame of Figure 4) does not differ as a function of the top-level goal.

These comparisons are consistent with our phase 1 conclusions that the subgoal level captures a basic unit of AO expertise. The goal level, LOC-MERC and LOC-SUB, divides the world into episodes. An episode requires a varying number of subgoals. The exact number depends on features of the current scenario. Merchants are noisy and easy to localize. Hence, most LOC-MERC episodes occur between attempts to detect the submarine and most end with the AO obtaining a good solution on the merchant.

Figure 5: Mean frequency of LOC-MERC and LOC-SUB goals as a percentage of total Level-1 goal usage for three experience levels.

In contrast, enemy submarines are quiet and trying to avoid detection. Hence they are difficult to localize. Most LOC-SUB episodes end after the AO concludes that the current data are not very good and will not get better unless he can take some action to reduce noise or to collect data that will disambiguate data already collected. This decision to halt the current attempt to localize the submarine is never cut-and-dried.

These characterizations of the differences between LOC-MERC and LOC-SUB provide an explanation for the large differences in variance (see the error bars in the middle frame of Figure 2 and Figure 4) in number of subgoals per level 1 goal. For LOC-MERC, localizing is routine. In contrast, LOC-SUB requires flexibility to determine either that the current data are inadequate to enable the target to be localized or that the current best solution is such-and-such.

Figure 6: Mean total time spent in LOC-MERC and LOC-SUB goals for the three levels of expertise.

### Expertise Effects

All expertise groups pushed LOC-MERC and LOC-SUB goals with approximately the same frequency (see Figure 5). For all groups, within-group variability overshadows the apparent difference between the goal frequencies. Despite the approximately equal number of LOC-MERC and LOC-SUB goals, across expertise levels there were large differences in the amount of time spent trying to localize the merchant as opposed to the submarine (see Figure 6). The inequality in total time spent pursuing the two goals increases with inexperience.

Figure 7: Mean number of subgoals for LOC-MERC and LOC-SUB goals.

As suggested by Figure 7, this difference in time as a function of expertise can be largely accounted for by differences in the number of subgoals. The Junior Officers use almost twice as many subgoals as the most experienced officers. Analyses not reported show that the number of operators per subgoal does not vary with expertise.

### Summary and Conclusions

The similarity between the CO/XO's in the two phases of Project Nemo support our characterization of performance

as schema-directed problem solving with shallow and adaptive subgoaling. The top-level goals, LOC-MERC and LOC-SUB, do not involve a fixed number of steps; rather, progress on a goal continues until a reevaluation of the schema determines that further effort would be wasted. What is fixed are the number of steps (operators) required for the terminal subgoals.

The phase 2 differences in expertise enrich our hypotheses. The most junior officers use the same building blocks as the most senior officers; that is, the same terminal subgoals are used with the same number of operators per subgoal. In contrast to the typical study of expertise, our "novices" were experienced (see Table 1). Very few officers switch branches of the Navy. Hence, our novices had spent 7.3 years in the Navy with 3.2 years at sea. All of their sea time was spent in submarines.

Where our novices differ from our experts is in their facility at schema-directed problem-solving. Simply put, the less experienced officers pursue bad data longer than the more experienced ones. The experienced ones know when it is time to give up on the current data set and do something to obtain more or better data.

### Acknowledgments

Susan S. Kirschenbaum's work has been jointly sponsored by Office of Naval Research (ONR) (Program element 61153N) and by Naval Undersea Warfare Center's Independent Research Program, as Project A10328. The work at George Mason University was supported by a grant from ONR (#N00014-95-1-0175) to Wayne D. Gray.

We thank Brian Ehret for his knowledgeable encoding, for his programming skills, and for his development of the Ned simulation. We also thank LT David Soldow for collecting the data for the Ned phase of the project and the officers of the U.S. Navy Submarine force for their participation, both as AOs and as consultants.

## Abstract

Psychologists have argued that visual imagery plays a vital role in human reasoning. If so, then reasoning with materials that are easy to visualize should be better than reasoning with materials that are hard to visualize. The literature, however, reports inconsistent results. Our starting point was that the inconsistencies arise from confounding imageability with the spatial nature of the materials. Hence, we manipulated the ease of envisaging the materials as visual images and also as spatial layouts. An experiment showed that materials that are easy to visualize impair reasoning unless they are also easy to envisage spatially.

## Introduction

“I am by the sea and I have a picture. This is a picture of a picture. I am – ” She screwed up her face and scowled – “thinking.” . . . She paused, frustrated by the vivid detail of her picture, not knowing how to extract from it the significance she felt was there.

– *The Inheritors*, William Golding, 1955, p. 62

Speculations about the role of visual imagery in human reasoning have a long history, and have recently surfaced again in the claims of computer scientists that reasoning based on diagrams has advantages from a computational point of view (Glasgow, Narayanan, & Chandrasekaran, 1995). Yet, the situation is not so clear as it should be from either a psychological or computational standpoint. In psychology, Kosslyn (e.g. 1994) and his colleagues have no doubt that visual imagery plays a key role in reasoning. The origins of this idea are the pioneering studies of DeSoto, London, & Handel (1965) and Huttenlocher (1968), who investigated so-called three-term series problems, such as:

Ann is taller than Beth.

Cath is shorter than Beth.

Who is tallest?

DeSoto et al. argued that reasoners imagine the three individuals on the vertical axis of a visual image, and then read off the answer by inspecting the image. Various sorts of

evidence support this hypothesis, including the well-known effects of mental rotation (Shepard & Cooper, 1982) and mental scanning (Kosslyn, 1980). Indeed, metrical information, which is often posited as the main characteristic of mental images, affects reasoning performance (Kelter & Kaup, 1995; Rinck, Hähnel, Bower, & Glowalla, 1997). Likewise, Pearson, Logie, & Gillhooly (1999) studied mental synthesis tasks, which elicit reasoning, and detected interference from visual secondary tasks.

In contrast, several studies have failed to find any effect of imageability on reasoning (Mynatt & Smith, 1977; Sternberg, 1980; Newstead, Pollard, & Griggs, 1986; Richardson, 1987; Johnson-Laird, Byrne, & Tabossi, 1989). Furthermore, Sternberg (1980) did not find a reliable correlation between reasoning ability and scores on imageability items of IQ-tests (Sternberg, 1980). Knauff and his colleagues found interference between relational reasoning and spatial secondary tasks but no such effects of visual secondary tasks (Knauff, Rauh, Schlieder, & Jola, 1999; Knauff, Jola, Strube, Rauh, & Schlieder, 2000).

From a computational point of view, the situation is similar. Researchers into diagrammatic reasoning have argued that diagrams are useful in solving problems, ranging from the analysis of molecular structure (Glasgow & Papadias, 1992) to the navigation of robots (Stein, 1995). Reasoning based on such analog representations can be more powerful than traditional propositionally based reasoning (Glasgow *et al.*, 1995). This approach, however, appears to conflict with theories of qualitative spatial reasoning. Their proponents argue that abstract representations of spatial relations together with an appropriate reasoning engine are a better way to enable computers to make predictions, diagnoses, and plans, when quantitative knowledge is unavailable or leads to computationally intractable inferences (Hernández, 1994; Cohn, 1997).

The aim of our research was to clarify the role of mental images in human reasoning. Our basic assumption is that the inconsistent psychological effects of imageability arise from

a failure to distinguish between visual characteristics and spatial characteristics of mental representations. On the one hand, if reasoning relies on mental images, then the easier it is to visualize the information in the premises, the better performance should be. On the other hand, if reasoning relies on spatial models, then the easier it is to envisage a spatial array, the better performance should be. We carried out a preliminary study of various relational terms to assess the ease of imagining assertions based on them as visual images and as spatial arrays. We then carried out an experiment to investigate the effects of both these factors on relational reasoning.

### A preliminary study

In order to generate the materials for our main experiment, 10 students at Princeton University, who were native speakers of English, filled out a questionnaire about the ease of forming visual images and spatial arrays for a set of thirty relational assertions, such as:

The cat was above the dog.

The assertions were based on such relations as *cleaner-dirtier*, *uglier-prettier*, *heavier-lighter*, *smarter-dumber*, and *above-below*. The participants rated the ease of forming visual images and of forming spatial arrays of the assertions on separate seven-point scales ranging from “very easy” to “very difficult”. The frequencies of usage of the relational terms were controlled word frequencies were controlled (Francis & Kucera, 1982), and the order of the assertions was counter-balanced across the participants.

Table 1: Three sorts of relational terms from the preliminary study and their mean ratings for ease of forming a visual image and a spatial array. The scales ranged from 7 (very easy) to 1 (very difficult)

	Visual image ratings	Spatial ratings
<u>Spatio-visual relations</u>		
above-below	5.3	5.4
front-back	5.2	5.3
<u>Visual relations</u>		
cleaner-dirtier	5.1	1.6
fatter-thinner	4.8	2.0
<u>Control relations</u>		
better-worse	2.1	1.1
smarter-dumber	2.8	1.2

The ratings of assertions based on a relation and its converse did not differ reliably, and so we pooled the results. The ratings enabled us to select three sorts of pairs of relations from the set as a whole. These pairs and their mean ratings are shown in Table 1. The three sorts of relations are: 1. relations such as *above-below* that were easy to envisage spatially and visually, which we henceforth

refer to as spatio-visual relations; 2. relations such as *cleaner-dirtier* that were hard to envisage spatially but easy to envisage visually, which we henceforth refer to as visual relations; and pairs such as *better-worse* that were hard to envisage either spatially or visually, which we henceforth refer to as control relations.

The differences between the three groups were statistically reliable, whereas there were no significant differences within the groups. None of the relations in the preliminary study were easy to envisage spatially but difficult to envisage visually.

### The Experiment

**Design.** The aim of the experiment was to investigate the effects of the three sorts of relational terms (visuo-spatial, visual, and controls) on relational reasoning. The participants acted as their own controls and evaluated inferences of all three sorts in 12 three-term series problems and 12 four-term series problems. The relations in these problems were those in Table 1. There were two valid and two invalid problems of each of the three sorts in both the three-term and four-term series problems, making a total of 24 problems. The problems were presented in a counterbalanced order over the set of participants.

**Participants.** We tested 22 undergraduate students of Princeton University (mean age 19.5; 12 female, 10 male), who received a course credit for their participation.

**Materials.** The three-term and four-term series problems all concerned the same terms (*dog, cat, ape* and *bird*). Here is an example of a problem with a valid conclusion:

The dog is cleaner than the cat.

The ape is dirtier than the cat.

Does it follow:

The dog is cleaner than the ape?

**Procedure.** The participants were tested individually in a quiet room, and they sat at a laptop computer that administered the experiment in separate stages (Potts & Scholz, 1977). The premises were presented one at a time on a sequence of screens (in black letters) followed by a putative conclusion (in red letters). The participants were told to evaluate whether or not the conclusion followed necessarily from the premises. They made their response by pressing the appropriate key on the keyboard, and the computer recorded their response and latency. Prior to the experiment, there were eight practice trials.

**Results.** The problems were easy, and 89 percent of the responses were correct. Furthermore, there were no significant differences in error rates for the three sorts of problems. Figure 1 shows the mean latencies for the correct responses to the three sorts of relational problems. As there was no reliable difference between the three-term and four-term series, we have pooled the results. The participants responded faster to the visuo-spatial problems (2200 ms) than to the control problems (2384 ms), though this difference was not significant, but slower to the visual problems (2654 ms) than to the control problems (Wilcoxon test  $z = 3.07$ ;  $p < .002$ ). Overall, the difference over the three groups was reliable (Friedman analysis of variance,  $F = 8.08$ ;  $p < .02$ ).

Figure 1: Mean reaction latencies [in milliseconds] and standard errors in the relational reasoning with the three sorts of relation: visual relations, control relations and visuo-spatial relations.

The differences are also reflected in the premise reading times. Because for all three premises we obtained a similar pattern of results, we pooled together all three premises. The mean reading times were 6.6s for the visual premises, 6.2s for the control premises, and 6.0s for the visuo-spatial tasks. The trend over the three groups was reliable (Page's  $L = 284$ ;  $p < .05$ ). Likewise, the difference between the visual and visuo-spatial premises was reliable (Wilcoxon test  $z = 2.07$ ;  $p < .05$ ).

## General Discussion

Our starting point was the conjecture that the conflicting results in the literature on imagery and relational reasoning arose from a failure to distinguish between visual images and spatial representations. Our preliminary study enabled us to identify (a) visuo-spatial relations, such as *above-below*, which are easy to envisage both visually and spatially, (b) visual relations, such as *cleaner-dirtier*, which are easy to envisage visually but hard to envisage spatially, and (c) control relations, such as *better-worse*, which are hard to envisage both visually and spatially. Unfortunately, we were unable to identify relations that were easy to envisage spatially but hard to imagine visually; and some colleagues doubt the existence of such relations. Nevertheless, the results of our experiment established the importance of distinguishing between visual and spatial representations. Visual relations such as *fatter* and *thinner*

significantly impede the process of reasoning in comparison with control relations such as *smarter* and *dumber*. In contrast, visuo-spatial relations, such as *front* and *back*, which are easy to envisage visually and spatially, speed up the process of reasoning in comparison with control relations (though the difference did not reach significance).

What causes the trend in our results? One possible explanation is suggested by the theory of mental models (Johnson-Laird, 1983; Johnson-Laird & Byrne, 1991). It postulates that people make transitive inferences by constructing models of the situations that the premises describe. They possess neither axioms nor rules of inference for transitivity, but merely construct an appropriate model. For example, given the premises:

The cat is above the ape.

The dog is below the ape.

they construct a spatial model representing the relative positions of the three individuals:

cat

ape

dog

They evaluate a putative conclusion by checking whether it holds in the model. If it does, they search for a counterexample, i.e., a model that satisfies the premises but refutes the conclusion. Given that no such counterexample exists, the conclusion is valid (see Byrne and Johnson-Laird, 1989). Perhaps the ability to envisage spatial models is a precursor to many forms of abstract reasoning (Johnson-Laird, 1996). Likewise, relational terms that lead naturally to spatial models should speed up the process of reasoning. In contrast, a visual relation, such as *dirtier*, may elicit irrelevant visual detail. One imagines, say, a cat caked with mud, but such a representation is irrelevant to the transitive inference. It takes additional time to replace this vivid image with one in which dirtiness is represented in degrees. In other words, the visual relations, which are hard to envisage spatially, lead to a mental picture. But, the vivid details in this picture interfere with the process of thinking – much as they did for the character in our epigraph from William Golding's novel.

This interpretation is consistent with Logie's (1995) distinction between the visual and spatial subsystems in Baddeley's conception of working memory (Baddeley & Hitch, 1974; Baddeley, 1986). One subsystem (the visual cache) is linked to visual perception and the "visual buffer" (Kosslyn, 1994), and the other subsystem (the inner scribe) is amodal and handles spatial information for use by different cognitive and motor systems (Logie, 1995). Knauff and his colleagues have carried out a series of experiments in which the participants evaluated three-term series inferences as primary tasks together with visual and spatial secondary tasks (Knauff et al., 1999, 2000). The results showed that the spatial tasks interfered with reasoning, whereas the visual tasks did not interfere with reasoning.

A theoretical argument corroborating our hypothesis comes from a comparison of computational accounts of spatial reasoning. Schlieder (1999) compared two computational models of empirical data from Knauff and his colleagues (Knauff et al., 1995, 1998). One model was based on visual images with metrical information (Berendt,

1996), and the other model was based on diagrams that represent only the characteristic points of objects with no metrical information (Schleider's own model). This second spatial account yielded a better account of the empirical results.

An alternative account of our results, however, makes no appeal to the nature of mental representations. It is conceivable that the critical difference between the three sorts of relations is that they differ in the extent to which they suggest transitive relations over the individuals in our problems. Spatial relations among them are unequivocal, whereas the visual relations are more dubious. Given, say, the following premises:

The cat is fatter than the ape.

The ape is fatter than the dog.

reasoners may wonder whether the *fatness* of cats, apes, and dogs, is commensurate. Thus, when one asserts that an elephant is thin, the claim is relative, and so it is perfectly sensible to assert that a thin elephant is fatter than a fat dog. Hence, the criteria of fatness shift from one animal to another. This factor might have confused reasoners in our experiment momentarily, and accordingly lead to longer latencies with the visual relations. One strong argument against this account, however, is that the reading times for the individual premises also showed an advantage for visuospatial relations over visual relations. There remains one other possibility: the visuospatial relations were expressed by prepositions whereas the other relations in our experiment were expressed by comparative adjectives. It is conceivable that this factor, or some other unknown confound, might be responsible for our experimental results. Our next task is to examine in more detail our explanation in terms of irrelevant visual data.

## Abstract

One consequence of the embodiment of cognition is that a single cognitive system may use fast internal mechanisms to coordinate conflicting actions in real time performance. In contrast, two different cognitive systems engaged in joint action have to resolve similar conflicts via the environment. A tracking paradigm was used to investigate the coordination of conflicting actions in individuals and groups. The main question was whether and how persons engaged in joint action would exploit the perceivable environmental outcomes of their partner's actions to adjust their own actions with respect to a jointly desired state. Groups performed worse than individuals, initially, but they achieved the same level of performance after some training. Groups improved because conflicting results of the partner's actions were taken into account when members of the pair produced their own actions. This led to the emergence of an agreed-upon environmental location, around which, group members coordinated their action effects. The results are consistent with the view that the special requirements of social interaction may have fostered the development of higher cognitive functions.

## Varieties of Embodiment

During the past decade, more and more researchers have become interested in the notion of embodied cognition (A. Clark, 1997; Port & van Gelder, 1995; Varela, Thompson, & Rosch, 1991). This approach has arisen largely out of dissatisfaction with the earlier notion of a central, disembodied symbol-manipulation system that is buffered from the environment via sensorimotor systems. In contrast, the Embodied approach stresses both, the importance of sensorimotor processes in cognitive functioning, and the close, dynamically supportive couplings that exist at all times between organisms and their environments.

Despite their common ground, different versions of the Embodied approach take issue with different aspects of the symbolic approach. In its most radical form, which is advocated by proponents of Dynamical Systems Theory (Port & van Gelder, 1995; Thelen & Smith, 1994), embodied cognition constitutes a rejection of representationalism as a whole, and conceptualizes cognition in terms of dynamic organism-environment couplings, exclusively. Less radical versions also stress the dynamic, organism-environment couplings, yet retain the notion of internal representation in order to account for the fact that certain biological systems

are able to produce actions that are directed toward objects not currently present in the immediate environment (Ballard, Hayhoe, Pook, & Rao, 1997; A. Clark, 1997). Given that these representing systems are assumed to have emerged due to the possibilities they afforded action production, proponents of this version often claim cognitive functioning to be constrained in one way or another, by the functioning of the sensorimotor system (e.g. the formation of concepts, (Barsalou, 1999; Lakoff & Johnson, 1999)).

The present research takes this notion as its starting point, and addresses its implications for action coordination. This is because, to date, embodiment has focused primarily on the individual cognitive system and its continuous environmental couplings. Members of many species, however, especially humans, often engage in joint action with other members of their species. Though some may consider social interaction just another example of environmental interaction, it may be the case that special requirements of joint action placed certain constraints on action production. Such constraints may have served, historically, to shape the structures and processes that came to be embodied in evolving cognitive systems (Mead, 1934; Vygotsky, 1978). The present research addresses these constraints.

## Individual and Joint Coordination of Conflicting Actions

A major function of action control in an individual organism is to select proper actions to obtain a desired impact on the environment (Prinz, 1997). If there are conflicting action alternatives, some internal mechanism may resolve the conflict (Anderson, 1990) and the motor system can be adjusted according to the action selected.

The situation is quite different when the action alternatives are distributed across two different cognitive systems that are engaged in joint action. Following a definition by H. H. Clark (1996), by a joint action we denote an action "that is carried out by an ensemble of people acting in coordination with each other" (p. 3). This implies that the individuals in the ensemble try to achieve a common goal. However, the intention to achieve a common goal does not protect the ensemble from encountering conflicts, especially when each system has only one of many action alternatives at its disposal.

To illustrate, imagine a situation in which two people drive a car together on a straight road. They can neither see

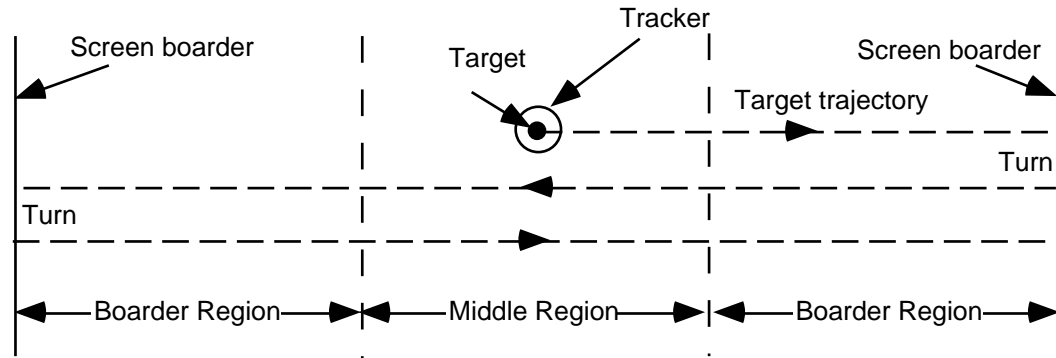

Figure 1: Illustration of experimental paradigm (vertical positions of target and tracker do not change in the actual task).

nor speak to one another. Person G controls the gas and person B, the brakes. As long as the car does not need to stop, there is no conflict, G acts and B does nothing. Now imagine a situation in which the ensemble encounters a traffic light. If the traffic light is green, no change is needed. If the traffic light is red, G has to stop acting and B has to start acting. Hence, this situation requires G and B to coordinate their actions according to an anticipated point at which they want to bring the car to a full stop. Conflicts may arise with respect to the point in time at which G stops and B starts acting, and as a consequence the ensemble may give gas and brake at the same time during a certain time interval. Hence, the car may well stop at a point that was intended neither by G, nor by B.

It is very unlikely that an individual in the same situation would carry out both actions at the same time even if different feet were used for giving gas and braking. An internal mechanism would select between the action alternatives in advance, instead of carrying out two conflicting actions at the same time. In the joint action example, conflict resolution is necessarily linked to noticeable changes in the environment, at least initially. Hence, if the situation requires braking, and B decides to start braking early, G will only know of that decision after perceiving that B has started to brake.

The aim of our research is to investigate how individuals and groups optimize their performance when conflicts arise in real time action coordination. Our main hypothesis is that persons engaged in joint action will use perceivable outcomes of the other's actions to dynamically adjust their own actions with respect to a commonly desired future state. Individual performance can be used as baseline to determine how the same conflict is dealt with within a single cognitive system.

### Experimental paradigm

We use a tracking paradigm for our studies. Generally, in tracking tasks one has to control a tracker so as to minimize the distance between the tracker and the target. The tracker is controlled by means of simple and clearly defined actions, e.g. hand movements or keypresses. The standard task requires minimal anticipation of future events and no conflict arises between alternative actions. For our study, we developed a different type of tracking task. In this task, an-

tipication of future events is crucial, and conflicts between two different action alternatives arise in a clearly defined manner. Figure 1 illustrates this task.

A target moves across the computer screen horizontally with constant velocity. As soon as it reaches a border of the screen, it changes its direction abruptly and moves back towards the other border, changes its direction again, and so on. The task is to keep a tracker on the target by controlling its velocity with two keys. When the tracker is moving to the right, hitting the right key accelerates it by a constant amount and hitting the left key decelerates it by the same amount. When the tracker is moving to the left, hitting the left key accelerates it and hitting the right key decelerates it. To illustrate, if the right key has been pressed five times, the left key will have to be pressed five times to bring the tracker to a full stop. Within the middle region, tracking performance can be optimized by decreasing the immediate error, as in most tracking paradigms. For instance, if the target is moving to the right and the tracker is left of the target, accelerating the tracker by a right keypress is the only reasonable action to be carried out (see panel a, in Figure 2).

The situation is different within the border regions. In these regions, a conflict arises between two alternative strategies. The first alternative, i.e., trying to stay on target as long as possible, will minimize the immediate error up until the point at which the target changes its direction. Afterwards, a large error will arise because tracker velocity can only be changed gradually. Several keypresses will be needed to stop the tracker and more will be needed to gain velocity in the opposite direction. During this interval, the target will continue moving in the opposite direction, constantly increasing the distance between itself and the tracker. Thus, trying to minimize immediate error will create an extremely large future error.

The second alternative is to slow down the tracker before the target turns. In this case, the immediate error will be *increased* to prevent future error. This is the case because the target continues to move toward the border as the tracker decelerates with each keypress. Using the latter strategy is the only way to improve performance within the border region, especially when the target moves fast and the impact of each keypress on the velocity of the tracker is low. Within this context, we refer to keypresses that decrease immediate error as compensatory presses, and those that that

increase immediate error in order to reduce future error, as anticipatory brakes (see panel a, and b, in Figure 2).

a) Effect of a compensatory button press.

b) Effect of an anticipatory button press.

Figure 2: Illustration of the effects of compensatory and anticipatory keypresses (in the actual task target and tracker are horizontally aligned).

To investigate conflict resolution in individuals and groups we used two versions of the task that differed in one single aspect. In the individual condition each person controlled both keys, in the group condition each person controlled only one key. Hence, in the individual condition, the conflict between minimizing immediate vs. future error arises within *one* cognitive system, while in the group condition it arises between *two* cognitive systems. As a consequence, individuals may solve the conflict by use of fast internal mechanisms, while groups have to use certain aspects of the environment to act out the conflict overtly. Thus, in the group condition, the only way to better coordinate conflicting actions and thereby improve performance is to focus on changes in certain aspects of the environment that result from the other person's actions. Regularities in these changes can then be used to adjust one's own actions with respect to the commonly desired future state.

### Predictions

The nature of the present paradigm affords the measurement of several dependent variables that characterize performance, the extent and timing of the anticipatory strategy, and certain environmental anchors to which coordination can be linked. In the following, we will describe the rationale for using each of these variables, and derive predictions for the individual and group condition, in turn.

### Performance

To characterize performance, we use the absolute distance

between tracker and target at the time of each button press as an error measure. Our prediction is that the error should be lower for individuals, initially, because individuals coordinate conflicting actions by using fast internal mechanisms, whereas groups can only use perceivable changes in the environment, in their attempt to coordinate conflicting actions. Hence, groups should need more time to coordinate, which in turn should deteriorate real time performance, initially. However, if persons in a group are able to integrate some aspect of the environment that characterizes their partner's actions into their individual planning, the difference in error between individuals and groups should largely decrease.

### Extent and timing of anticipatory strategy

**Anticipatory brakes.** The extent to which the anticipatory strategy is employed within the boundary regions can be defined as the proportion of anticipatory brakes (see Figure 2, panel b) occurring in that region. We predict that the anticipatory brake rate will be greater for individuals than for groups, because once individuals have decided to prevent future error, they will be less likely to switch back to the conflicting action that reduces immediate error. In contrast, coordination requires overt action within groups. Therefore, the person who is responsible for reducing immediate error will quite likely produce actions that interfere with the anticipatory actions of the other person. The anticipatory brake rate should increase in both, individuals and groups, as they become more familiar with the task, because employing an anticipatory strategy is the only way to reduce overall error.

**Decision point.** One way in which the person responsible for anticipatory braking in a group can compensate for conflicting actions of the other is to take them into account, when timing her or his own actions. This should lead to earlier initiation of anticipatory braking in the group condition. The decision point, by which we denote the position of the tracker at the time of the first anticipatory brake, can be used to test this hypothesis. It should be further removed from the border in the group condition than in the individual condition.

### Environmental anchors

**Location of turn-around points.** By the turn-around point we denote the most extreme tracker location during each run of the target from one side of the screen to the other. If the target turns at the right border, the turn-around point is the maximal screen position of the tracker, if the target turns at the left border the turn-around point is the minimal screen position of the tracker (see Figure 1). To make turn-around points on both sides of the screen comparable they are expressed in terms of the absolute distance to the respective border. At the turn-around point the tracker comes to a full stop and is accelerated towards the other direction by the following keypresses. The turn-around point is functionally important because it can be used as an environmental anchor to which the goal of minimizing overall error can be tied. The reason is that, given a certain velocity of the target and a certain impact of each keypress, the optimal turn-around point will be relatively invariant.

If, as predicted, groups pick a decision point that is further removed from the boarder, groups may achieve a turn-around

point that is as equally removed from the border as the one achieved by individuals. Otherwise, it should be less removed from the border in the group condition. In the individual and the group condition as well, the turn-around point should become further removed from the border in later trials because overall error can be decreased by turning the tracker earlier.

**Homogeneity of turn-around points.** In the individual condition the turn-around points at the left and the right border are the result of actions taken by the same person. The situation is different in the group condition. Whenever the target approaches the right border, the person who is in charge of the left key is responsible for anticipatory braking and the person who is in charge of the right key is responsible for compensating immediate error. Whenever the target approaches the left border, each group member must assume the opposite role (the compensator becomes the anticipatory braker, the anticipatory braker becomes the compensator).

Hence, the prediction for individuals is that they will pick similar turn-around points at both borders. Therefore, the absolute difference between the left and the right turn-around point in a trial should be relatively small and not change substantially across consecutive blocks. In contrast, two persons in a group should pick more heterogeneous turn-around points initially. However, in later trials they may coordinate their actions by „agreeing“ on a certain turn-around point. Therefore, we predict a huge initial difference that substantially decreases in later blocks.

## Method

**Participants** Forty-five paid participants took part in the experiment. Fifteen participants were assigned to the individual condition. Thirty participants were assigned to the group condition.

**Material and Procedure** Upon entering the lab, participants were informed of the nature of the task. They were instructed individually in the group condition. Afterwards, they were seated in front of a computer monitor at a distance of 80 cm and were asked to put on a set of headphones. Participants in the group condition were divided by a partition. They could neither see one nor talk to one another. However, each was provided with a separate computer monitor, and all events taking place during the experiment (e.g. the movements of the tracker and the movements of the target) were presented simultaneously on both monitors. Thus, the only information shared was the task display and the acoustic feedback accompanying each keypress.

At the beginning of each trial target and tracker were displayed in the middle of the screen for 500 ms, the tracker being superimposed on the target. Thereafter, the target started moving either to the left or to the right with constant velocity. After reaching the border, it abruptly began traveling back in the opposite direction. There were three such target turns during each trial. The initial velocity of the tracker was zero. Each left keypress accelerated the tracker to the left and each right keypress accelerated it to the right. Right presses triggered a 600 Hz tone and left presses triggered a 200 Hz tone. Participants in the individual condition controlled both keys. In the group condition, each member

was given an individual control panel consisting of one key. Keypresses of the individual on the left side of the partition resulted in tracker acceleration to the left, while those of the other individual produced tracker-acceleration to the right. The experiment consisted of 3 blocks of 40 trials each.

## Results and Discussion

### Performance

Figure 3: Individual and group performance across consecutive blocks

As can be seen in Figure 3, error decreased for individuals and groups across consecutive blocks. Hence, performance improved in individuals and groups. As expected, the error was much larger in the group condition during the first block. After the second block, group performance reached the level of individual performance. A 2 x 3 ANOVA with the factors Experimental Group (Individuals and Groups, between) and Block (1, 2, and 3, within) revealed a significant main effect for the Block factor,  $F(2, 56) = 24.2, p < .001$ , and a significant interaction between Experimental Group and Block,  $F(2, 56) = 3.5, p < .05$

### Anticipatory brakes

The anticipatory brake rate was computed as the number of anticipatory brakes in a border region divided by the overall number of button presses in that region. Figure 4 shows the results. The anticipatory brake rate increased over consecutive blocks for individuals and groups. As expected, the anticipatory brake rate was constantly lower in the group condition than in the individual condition.

A 2 x 3 ANOVA with the factors Experimental Group (Individuals and Groups, between) and Block (1, 2, and 3,

within) revealed significant main effects for the Group factor,  $F(1, 28) = 9.4, p < .01$ , and the Block factor,  $F(2, 56) = 26.1, p < .001$ . There was no significant interaction.

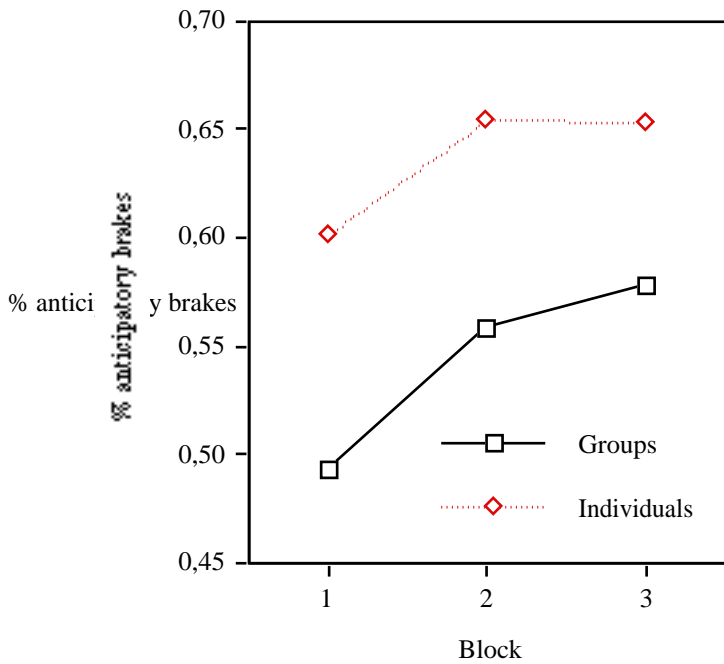

Figure 4: Anticipatory brake rate in individuals and groups across consecutive blocks

### Decision points

Figure 5: Decision point in individuals and groups across consecutive blocks.

Figure 5 shows the result of the analysis of decision points, i.e., the distance of the tracker from the border at the time of the first anticipatory brake.

As they became more familiar with the task, individuals and groups moved the tracker closer to the border before they initiated the first anticipatory brake. This result indicates that resolving the action conflict took less time in later trials. As expected, in the Group condition the tracker was always further from the border, when the first anticipatory brake occurred. A 2 x 3 ANOVA with the factors Experimental Group (Individuals and Groups, between) and Block (1, 2, and 3) revealed a significant main effect for the Group factor,  $F(1, 28) = 4.6, p < .05$ , and the Block factor,  $F(2, 56) = 11.2, p < .001$ . There was no significant interaction.

### Location of turn-around points

Figure 6 illustrates the results of the analysis of turn-around points, i.e., the absolute distance between the border and the point at which the tracker stopped before changing its direction.

Figure 6: Turn-around point chosen by individuals and groups across consecutive blocks.

As expected, in later blocks, the turn-around point became further removed from the border in both experimental conditions. Individuals produced a sharper increase than groups from the first to the second block. A 2 x 3 ANOVA with the factors Experimental Group (Individuals and Groups, between) and Block (1, 2, and 3) revealed a significant main effect for the Block factor,  $F(2, 56) = 11.6, p < .001$ , and a marginally significant interaction,  $F(2, 56) = 2.62, p = .08$ . The difference between individuals and groups was highly significant during the second block,  $t = 4.21, p < .001$ . The main effect of experimental group was not significant.

## Homogeneity of turn-around points.

Figure 7 depicts the results of the analysis of the homogeneity of turn-around points.

Figure 7. Homogeneity of turn-around points in individuals and groups across consecutive blocks.

Individuals turned the tracker at roughly the same point on both sides of the screen, i.e., there was only a small difference of about 30 pixels. The homogeneity of turn-around points increased only slightly across consecutive blocks. In contrast, persons in a group picked heterogeneous turn-around points, initially. In later trials, the selected turn-around points which were almost as homogeneous as those chosen by individuals. A 2 x 3 ANOVA with the factors Experimental Group (Individuals and Groups, between) and Block (1, 2, and 3) revealed a significant main effect for the Block factor,  $F(2, 56) = 8.25, p < .001$ , and a significant interaction,  $F(2, 56) = 3.30, p < .05$ . There was no significant main effect of experimental condition.

## Discussion

Individuals as well as groups are able to learn to coordinate conflicting actions with respect to a common goal, in real time, but groups clearly perform worse initially. The results illustrate robustly the different constraints that groups must deal with as they attempt to coordinate conflicting actions. To be sure, both groups and individuals improve by employing the advantageous anticipatory strategy. This is reflected in the fact that both gave rise to increases in anticipatory braking, as well as increases in the distance of the turn-around point from the border. Within groups however, this anticipatory strategy had to be worked out via the environment. Thus, it seems that group members take into account the potentially interfering actions of their partner by starting to brake at a further distance from the border. In addition, they seem to "agree" on a certain point in space at

which to turn the tracker, as is evidenced by increased homogeneity of the turn-around point. As soon as such an agreement has been reached, both the homogeneity of the turn-around points and the degree of error become almost indistinguishable from that produced by individuals.

The additional constraints on action coordination that arise within groups, as opposed to within an individual, are due to the fact that embodied cognitive systems have to make use of the environment to coordinate conflicting actions. This need to "lean" on the environment in group action, may constitute a selective pressure responsible for the phylogenetic emergence of cognitive systems capable of integrating the anticipated effects of another system's actions, into the planning of their own. This capability, in turn, may have afforded the emergence of the ability to produce environmental effects whose intended outcome was not solely entailed in the effect itself, but rather, in the impact that effect was anticipated to have upon the planning abilities of other cognitive systems. In short, the group need to collaborate through the environment may have driven the embodiment and environmental projection of symbol systems. This is consistent with Clarks (1996) assertion that the essence of language is joint action.
