Understanding the mechanisms of learning is one of the central questions of Cognitive Science. Recently Marcus et al. showed that seven-month-old infants can learn to recognize regularities in simple language-like stimuli. Marcus proposed that these results could not be modeled via existing connectionist systems, and that such learning requires infants to be constructing rules containing algebraic variables. This paper proposes a third possibility: that such learning can be explained via structural alignment processes operating over structured representations. We demonstrate the plausibility of this approach by describing a simulation, built out of previously tested models of symbolic similarity processing, that models the Marcus data. Unlike existing connectionist simulations, our model learns within the span of stimuli presented to the infants and does not require supervision. It can handle input with and without noise. Contrary to Marcus' proposal, our model does not require the introduction of variables. It incrementally abstracts structural regularities, which do not need to be fully abstract rules for the phenomenon to appear. Our model also proposes a processing explanation for why infants attend longer to the novel stimuli. We describe our model and the simulation results and discuss the role of structural alignment in the development of abstract patterns and rules.

## Introduction

Understanding the mechanisms of learning is one of the central questions of cognitive science. Recent studies (Gomez & Gerken, 1999; Marcus, Vijayan, Rao & Vishton, 1999) have shown that showed that infants as young as seven months can process simple language-like stimuli and build generalizations sufficient to distinguish familiar from unfamiliar patterns in novel test stimuli. In Marcus et al's study, the stimuli were simple 'sentences,' each consisting of three nonsense consonant-vowel 'words' (e.g., 'ba', 'go', 'ka'). All habituation stimuli had a shared grammar, either ABA or ABB. In ABA-type stimuli the first and the third word are the same: e.g., 'pa-ti-pa.' In ABB-type stimuli the second and the third word are identical: e.g., 'le-di-di'. The infants were habituated on 16 such sentences, with three repetitions for each sentence. The infants were then tested on a different

set of sentences that consisted of entirely new words. Half of the test stimuli followed the same grammar as in the habituation phase; the other half followed the non-trained grammar. Marcus et al. found that the infants dishabituated significantly more often to sentences in the non-trained pattern than to sentences in the trained pattern.

Based on these findings Marcus et al. proposed that infants had learned abstract algebraic rules. They noted that these results cannot be accounted for solely by statistical mechanisms that track transitional probabilities. They further argue that their results challenge connectionist models of human learning that use similar information, on two grounds: (1) the infants learn in many fewer trials than are typically needed by connectionist learning systems; (2) more importantly, the infants learn without feedback. In particular, Marcus et al. demonstrated that a simple recurrent network with the same input stimuli could not model this learning task.

In response, several connectionist models have attempted to simulate these findings. Unfortunately, all of them to date include extra assumptions that make them a relatively poor fit for the Marcus et al experiment. For example, Elman (1999; Seidenberg & Elman, 1999) use massive pre-training (50,000 trials) to teach the network the individual stimuli. More importantly, they turn the infants' unsupervised learning task into a supervised learning task by providing the network with external training signals. Other models tailored to capture the data of the study seem unlikely to be applicable to other similar cognitive tasks (Altmann & Dienes, 1999). Using a localist temporal binding scheme, Shastri and Chang (1999) model the infant results without pretraining and without supervision, but still require an order of magnitude more exposure to the stimuli than the infants received.

We propose a third alternative. There is evidence that structural alignment processes operating over symbolic structured representations participate in a number of cognitive processes, including analogy and similarity (Gentner, 1983), categorization (Markman & Gentner, 1993), detection of symmetry and regularity (Ferguson, 1994), and learn-

ing and transfer (Gentner & Medina, 1998). Although these representations and processes are symbolic, they do not need to be rule-like, nor need they involve variables. Instead, we view the notion of correspondence in structural alignment as an interesting cognitive precursor to the notion of variable binding<sup>1</sup>. Correspondences between structured representations can support the projection of inferences, as the analogy literature shows, and therefore a symbolic system can draw inferences about novel situations even without having constructed rules. Moreover, as discussed below, comparison can be used to construct conservative generalizations. Across a series of items with common structure such a process of progressive abstraction can eventually lead to abstract rule-like knowledge. The attainment of rules, in those cases where it occurs, is the result of a gradual process. As we will show, symbolic descriptions can be used with structural alignment to model learning that is initially conservative, but which occurs fast enough to be psychologically realistic.

We first describe our simulation model of the Marcus et al task, which uses a simple combination of preexisting simulation modules, i.e., SME, MAGI, and SEQL. All of these modules have been independently tested against psychological data and independently motivated in prior modeling work. With the exception of domain-specific encoding procedures, no new processing components were created for this task. We then describe the results of our simulation of the Marcus et al data, showing that our simulation can learn the concepts within the number of trials that the infants had, without supervision and without pre-learning. We also show that the simulation can exhibit the same results with noisy input data. Finally, we discuss some of the implications of the symbolic similarity approach for models of cognitive processing.

### Modeling infant learning via structural alignment

A psychological model of the infants' learning must include the kind of input, the way the infants are assumed to encode the individual sentences, and the processes by which they generalize across the sentences. The architecture of our simulation is shown in Figure 1. We first describe our assumptions concerning the infants' processing capacities. Then we describe each component in turn.

**Processing Assumptions:** We assume that infants can represent the temporal order within the sentences (Saffran, Aslin & Newport, 1996). We further assume that the infants notice and encode identities within the sentences: for example, the fact that the last two elements match in an ABB sentence. This assumption is consistent with evidence that human infants, as well as with studies of nonhuman primates (Oden *et al*, in press), can detect identities. We also assume that infants can detect similarities between sequentially presented stimuli, consistent with studies of infant habituation, which demonstrate that infants respond to sequential sameness (e.g., Baillargeon, 1994).

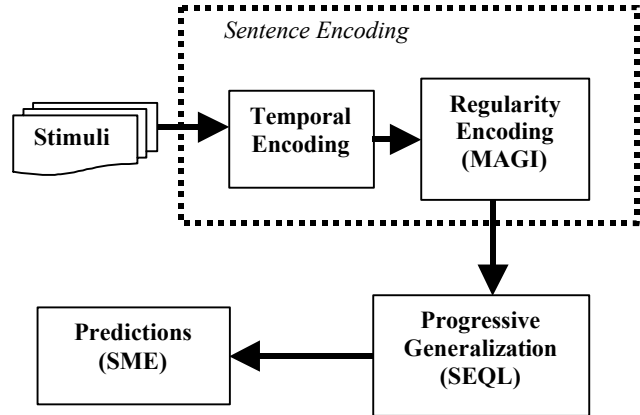

Figure 1: Simulation Architecture

**Input stimuli:** To make our simulation comparable with others, we use a representation similar to that of Elman (1999), namely, Plunkett & Marchman's (1993) distinctive feature notation. Each word has twelve phonetic features, which can be either present or absent. The presence or absence of each feature for each word is encoded by symbolic assertions. If feature  $n$  is present for word  $w$ , the assertion  $(Rn\ w)$  is included in the stimulus, and if absent, the assertion  $(Sn\ w)$  is included. Thus the acoustic features of each word are encoded as twelve attribute statements.

We modeled the Marcus et al experiment both without noise (Experiment 1) and with noise (Experiment 2). Marcus et al. used a speech synthesizer to control the pronunciation of the stimuli, but while this reduces variability, it cannot eliminate the possibility that the infant might encode something incorrectly.

**Temporal encoding:** We assume that the infant encodes the temporal sequence of the words in a sentence in two ways. First, each incoming word has an attribute associated with it, corresponding to the order in which it appears (i.e., FIRST, SECOND, or THIRD). We further assume that the infant encodes temporal relationships between the words in a sentence; to code this, an AFTER relation is added between pairs of words in the same sentence indicating their relative temporal ordering. The particular labels used in this encoding step are irrelevant – there are no rules in the system that operate on these specific predicates – the point is simply that infants are encoding the temporal order of words within sentences.

**Regularity Encoding:** We assume that the infants notice and encode identities within the sentences: for example, the fact that the last two elements match in an ABB sentence. Thus the simulation must incorporate a process that detects when words are the same. We use the MAGI model of symmetry and regularity detection (Ferguson, 1994) to automatically compute these relationships. MAGI treats symmetry as a kind of self-similarity, using a modified version of structure-mapping's constraints to guide the self-alignment process. MAGI has been successfully used with inputs ranging from stories to mathematical equations to visual stimuli,

<sup>1</sup> That structure-mapping algorithm neither subsumes, nor is subsumed by, traditional pattern matching such as unification is shown in Falkenhainer, Forbus, & Gentner (1988).

and it has done well at modeling certain aspects of visual symmetry, including making new predictions (Ferguson *et al* 1996). Here MAGI is used on the collection of words in a sentence. For any pair of words  $w1$  and  $w2$  that MAGI finds sufficiently similar, this module asserts (SIM  $w1$   $w2$ ), and a DIFF statement for every other pair of words in the sentence. (If MAGI does not find any pairs similar, DIFF statements are asserted for every pair of words.) This module also asserts (GROUP  $w1$   $w2$ ) for pairs of similar words, to mark that they form a substructure in the stimulus, and adds DIFF statements between groups and words not in the group. This use of MAGI is an example of what Ferguson (1994, in preparation) calls *analogical encoding*.

## SEQL

Once each sentence is encoded, we assume infants can detect the similarities between sequential pairs of sentences. The detection of structurally parallel patterns across a sequence of examples is modeled by SEQL (Skorstad, Gentner & Medin, 1988; Kuehne, Forbus, Gentner & Quinn, 2000), a model of the process of category learning from examples. SEQL constructs category descriptions via incremental abstraction. That is, the representation of a category is a structured description that has been generated by successive comparison with incoming exemplars. If the new exemplar and the category are sufficiently similar, the category description is modified to be their intersection -- i.e., the commonalities computed via structural alignment by a generalization algorithm. If the new exemplar is not sufficiently similar, it is stored separately and may later be used as the seed of a new category.

The structural alignment process is implemented via SME, (Falkenhainer *et al* 1988; Forbus *et al* 1994) a cognitive simulation of analogical matching. Here the base description is a category description, and the target description is the new exemplar. The structural alignments that SME computes are used in three ways by SEQL. First, the numerical structural evaluation score it computes<sup>2</sup> is used as a similarity metric, a numerical measure for deciding whether or not two descriptions are sufficiently similar. Second, the candidate inferences it computes serve as a model for category-based induction (c.f. Blok & Gentner, 2000; Forbus, Gentner, Everett, & Wu, 1997). Third, the correspondences in the best mapping SME produces serves as the basis for SEQL's generalization algorithm.

SEQL maintains a set of generalizations and a set of singular exemplars. When a new exemplar comes in, it is compared against existing generalizations to see if it can be assimilated into one of them. Otherwise, it is compared with the stored exemplars to see if a new generalization can be formed. If it is insufficiently similar to both the generalizations and the stored exemplars, it is stored as an exemplar itself.

SEQL begins with no generalizations; it simply stores its first exemplar. If the next exemplar is sufficiently close to the first, their overlap is stored as the first generalization. A

<sup>2</sup> Although SME can compute multiple mappings, we use the structural evaluation score of the best mapping, normalized by the size of the base description.

generalization consists of the overlap between the two input descriptions: that is, the shared structure found by alignment. Thus generalizations are structured descriptions of the same type as the input descriptions, although containing fewer specific features. If a new exemplar is sufficiently similar to a generalization (as determined comparing the structural evaluation score to a set threshold), then (a) the generalization is updated by retaining only the overlapping description that forms the alignment between the generalization and the exemplar; and (b) candidate inferences are projected from the generalization to the exemplar. Non-overlapping aspects of a description (e.g., phonetic features or relations that aren't shared) are thus "worn away" with each new assimilated description. (The threshold that determines when descriptions are sufficiently similar to be assimilated helps prevent descriptions from diminishing into vacuity.)

Returning now to the infant studies, we assume that babies are carrying out an ongoing process of comparing and aligning the incoming exemplars with an evolving generalization. We further assume that the relational candidate inferences from the general pattern to a new exemplar represent expectations on part of the infant.<sup>3</sup> When these expectations are violated by an incoming stimulus that does not fit the generalized pattern (e.g., an ABB test sentence after the ABA generalization has been formed), we assume the infant requires extra time to process the inconsistent stimulus.

## Simulation Experiments

In both experiments, we followed the procedure of Marcus *et al*. Each stimulus was a simple three-word sentence, encoded as described earlier. There were two sets of training stimuli, one following the ABA pattern and one following the ABB pattern. The training stimuli were (ABA) de-di-de, de-je-de, de-li-de, de-we-de, ji-di-ji, ji-je-ji, ji-li-ji, ji-we-ji, le-di-le, le-je-le, le-li-le, le-we-le, wi-di-wi, wi-je-wi, wi-li-wi, wi-we-wi and (ABB) de-di-di, de-je-je, de-li-li, de-we-we, ji-di-di, ji-je-je, ji-li-li, ji-we-we, le-di-di, le-je-je, le-li-li, le-we-we, wi-di-di, wi-je-je, wi-li-li, wi-we-we. The test stimuli in both experiments were four descriptions representing two novel ABA-type (ba-po-ba, ko-ga-ko) and two novel ABB-type sentences (ba-po-po, ko-ga-ga). The threshold value for SEQL was set to 0.85 in both experiments.

### Experiment 1

This experiment is most comparable to previous simulation models of the phenomena, in that we assume noise-free encoding of the stimuli. A simulation run consists of exposing SEQL to all of the stimuli from a particular training set (either ABA or ABB) once and then seeing the response given the four test sentences. To avoid possible biasing due to sequence effects (See Kuehne *et al.*, 2000), 20 simulation runs were made for each training set using different random

<sup>3</sup> SME can also produce attribute-level candidate inferences, and does so on these stimuli. We assume that, since these inferences concern directly perceivable features, testing them takes very little time.

orders. Identical match score and relational candidate inferences were produced for all sequences with a given stimulus set. In each case, SEQL produced a single generalization during the learning phase. For the test phase we used encodings of the corresponding stimuli used with infants, as noted above. Tables 1a and 1b show the results of this series for two generalizations paired against the four test sentences.

**Table 1a: ABA training stimuli**

Test Stimulus	Match Score	Candidate Inferences
<b>Ba-po-ba</b>	<b>0.658</b>	<b>None</b>
<b>Ko-ga-ko</b>	<b>0.689</b>	<b>None</b>
Ba-po-po	0.486	(DIFF po1 ba1) (DIFF po1 po2) (SIM ba1 po2)
Ko-ga-ga	0.455	(DIFF ga1 ko1) (DIFF ga1 ga2) (SIM ko1 ga1)

**Table 1b: ABB training stimuli**

Test Stimulus	Match Score	Candidate Inferences
Ba-po-ba	0.328	(SIM po1 ba2) (DIFF ba1 (GROUP po1 ba2))
Ko-ga-ko	0.350	(SIM ga1 ko2) (DIFF ko1 (GROUP ga1 ko2))
<b>Ba-po-po</b>	<b>0.776</b>	<b>None</b>
<b>Ko-ga-ga</b>	<b>0.753</b>	<b>None</b>

The in-grammar (bold) and out-of-grammar (plain text) matches show clear differences in their match scores. In-grammar matches are above 0.64 and do not generate relational candidate inferences. Out-of-grammar matches have match scores below 0.5, and lead to relational candidate inferences. Thus out-of-grammar test sentences lead to longer looking behavior, as predicted.

## Experiment 2

As noted earlier, we believe that noise-free stimulus encodings are unrealistic. Consequently, we used the same procedure as Experiment 1, but this time introducing noise into the representations for the training and test stimuli. For each sentence, one of the words was randomly picked, and one of its attributes (also chosen at random) was dropped or flipped, with the rest of its description being unchanged. Such changes can be significant: for example, flipping a single phonetic feature turns the word ‘de’ into the word ‘di’. Again, 20 simulation runs were made for each training set using different random orders. Naturally the match scores and, to a lesser degree, the generated candidate inferences, did vary across the individual runs. Tables 2a and 2b show the results. The scores were averaged over all 20 runs.

Although the noise affected the details of the computations, the overall pattern of results remains the same. The in-grammar (bold) match scores are far higher than the out-of-grammar (plain text) scores; and the out-of-grammar

stimuli produce relational candidate inferences while the in-grammar stimuli do not.

**Table 2a: ABA training stimuli**

Test Stimulus	Average Match Score	Candidate Inferences Min, Average, Max
<b>ba-po-ba</b>	<b>0.647</b>	<b>0, 0, 0</b>
<b>ko-ga-ko</b>	<b>0.682</b>	<b>0, 0, 0</b>
ba-po-po	0.435	2, 2.45, 3
ko-ga-ga	0.395	2, 2.55, 3

**Table 2b: ABB training stimuli**

Test Stimulus	Match Score	Candidate Inferences Min, Average, Max
ba-po-ba	0.339	2, 2, 2
ko-ga-ko	0.352	2, 2.05, 3
<b>ba-po-po</b>	<b>0.805</b>	<b>0, 0, 0</b>
<b>ko-ga-ga</b>	<b>0.783</b>	<b>0, 0, 0</b>

## Comparison with other models

The results of Marcus et al. (1999) have sparked an active debate focused on two issues: (1) Can current connectionist models (e.g., simple recurrent networks) model these results? (2) Do infants generate abstract rules that include variables?

Regarding the adequacy of simple recurrent networks, Marcus et al. state “Such networks can simulate knowledge of grammatical rules only by being consequently trained on all items to which they apply; consequently, such mechanisms cannot account for how humans generalize rules to new items that do not overlap with the items that appeared in the training.” Elman’s (1999) response describes his use of a simple recurrent network to model this task. Elman’s model requires tens of thousands of training trials on the individual syllables, and treats the problem as a supervised learning task, unlike the task facing the infants. By contrast, our simulation handles the learning task unsupervised, and produces human-like results with only exposure to stimuli equivalent to that given to the infants. Moreover, our model also continues to work with noisy data, something not true of any other published model of this phenomenon that we know of.

The learning in our model is due to the “wearing away” of non-identical phonetic attributes through subsequent comparisons. Although SEQL’s learning proceeds faster than connectionist models, it is still slower than systems that generate abstractions immediately (e.g., explanation-based learning (DeJong & Mooney, 1986)). In SEQL’s progressive alignment algorithm, the entities in the generalizations lose their concrete attributes across multiple comparisons, leaving the relational pattern of each grammar as the dominant force in the generalization only after a reasonable num-

ber of varied examples are seen.<sup>4</sup> There is considerable evidence for this kind of conservative learning (Forbus & Gentner, 1986; Medin & Ross, 1989).

Turning to the second issue, whether infants have variables and generate abstract rules, Marcus et al (1999) claims “[I]nfants extract abstract algebra-like rules that represents relationships between placeholders (variables), such as ‘the first item X is the same as the third item Y,’ or more generally that ‘item I is the same as item J.’” But our simulation does not introduce variables, in the sense commonly used in mathematics or logic. The generalizations constructed by SEQL do indeed include relational patterns that survive repeated comparisons because they are shared across the ingrammar exemplars. Furthermore, the entities (words) in the generalizations have many fewer features than the original words, as a result of the wearing away of features in successive comparisons. One could consider these patterns as a form of psychological rule, as proposed by Gentner and Medina (1998), with the proviso that the elements in the rule are not fully abstract variables, although they might asymptotically approach pure variables.

## Discussion

This paper proposes a third kind of explanation for the infant learning phenomena of Marcus et al (1999): incremental abstraction of symbolic descriptions via structural alignment. We believe our explanation is currently the best one for three reasons. First, it models the infant data with fewer extra concessions than previously published models (i.e., no pre-training, no supervision, and noisy data). Second, the processes we postulate are cognitively general; they apply to a large set of phenomena. Third, the abstraction processes we propose are consistent with research demonstrating that human learning is initially conservative (Brooks, 1987; Forbus & Gentner, 1986; Medin & Ross, 1989). Interestingly, there is ongoing research in developing symbolic connectionist models consistent with these processes (e.g., Holyoak & Hummel, 1997).

Many issues remain to be explored. For example, although our system does not introduce variables in its generalization process, there is a sense in which the entities in the generalization are on their way to becoming variables. Gentner and Medina (1998) have proposed that the process of progressive alignment can lead to rules. They further suggested that the application of rules to instances can be accomplished using the same general processes of structural alignment and projection that are used in analogy. The difference is that the base domain is an abstraction, the entities are ‘dummies’ with no features to either help or impede the match with the specific entities in the exemplar. Another issue concerns the incorporation of statistical notions in SEQL. Although SEQL is to a certain degree noise-resistant,

---

<sup>4</sup> SEQL learns with only one exposure to the 16 learning sentences, whereas Marcus’s infants received three exposures for each sentence. It is possible that the infants would have learned with only one pass; however it is also possible that the infants were less consistent in detecting the similarities than our simulation with its current parameters.

we suspect that to model large-scale learning, it will need to keep track of more statistical information than it does currently, so that properties wear away more slowly.

We note that it is common to conflate symbolic processing with rule-based behavior, and parallel processing with connectionist models. The model described here is symbolic, but it need not involve variables or rules. Further, it involves extensive parallel processing (most of SME and MAGI’s computations are parallel). Given the complexity of the phenomena, such confluations seem unwise.

The debates stirred by the Marcus et al. results bear on a critical issue in human learning and development: namely, what knowledge or mechanisms must be assumed to account for the rapid and powerful achievements demonstrated by infants in both cognition and language. Our results suggest that the general learning mechanism of structure-mapping theory may go a long way in accounting for these accomplishments.

## Abstract

Schemata are frequently used in cognitive science as a descriptive framework for explaining the units of knowledge. However, the specific properties which comprise a schema are not consistent across authors. In this paper we attempt to ground the concept of a schema based on constraints arising from issues of learning. To do this, we consider the different forms of schemata used in computational models of learning. We propose a framework for comparing forms of schemata which is based on the underlying representation used by each model, and the mechanisms used for learning and retrieving information from its memory. Based on these three characteristics, we compare examples from three classes of model, identified by their underlying representations, specifically: neural network, production-rule and symbolic network models.

## Introduction

One of the unifying themes in cognitive science is the use of *schemata* for explaining the units of knowledge within humans. However, the specific properties which comprise a schema usually vary between authors. Early work in the AI and cognitive traditions (e.g. Rumelhart, 1980) set the scene for the use of schemata in computational models of learning. It is now appropriate, with a number of successful models in the literature, to see what forms of schemata arise within a learning-based system. This question is especially interesting because computational models do not simply implement basic concepts such as schemata with an added learning mechanism. Instead, each computational model is based on some core representational structure and primitive learning mechanisms, from which structures such as schemata may be inferred.

The aim of this paper is to consider examples from a number of computational models and simply extract those elements which most relate to schemata. The difficulty here is that the models have not been tested on identical tasks, and so the comparison must be at a more qualitative level. Hence, we begin with some informal definitions of schemata to define our analytical framework.

## Learning and Using Schemata

Brewer (1999) defines schemata as “the psychological constructs that are postulated to account for the molar forms of human generic knowledge.” The idea is that knowledge of visual scenes or discourse structure may be considered in terms of basic units. For instance, house-scenes typically consist of rooms, each room containing certain basic properties, such as walls or furniture. The schema for a room will contain *slots* for the properties, and, in the absence of spe-

cific information, these slots will be filled with *default* values. So a room will, by default, be considered to have four walls, a ceiling, a door, lighting, probably a window, and so forth.

Less committal is the definition by Rumelhart (1980; italics in original): “A schema theory is basically a theory about knowledge. It is a theory about how knowledge is represented and about how that representation facilitates the *use* of the knowledge in particular ways.” Rumelhart therefore focuses on the form of the schema theory (representation and reuse), whereas Brewer (1999) defines the form of the schema (a molar form of knowledge). Rumelhart’s definition is also echoed in that of Sweller (1988), whose concern is with modelling problem-solving behaviour. According to Sweller (1988), a schema is simply a “structure which allows problem solvers to recognize a problem state as belonging to a particular category of problem states that normally require particular moves. ... certain problem states can be grouped, at least in part, by their similarity and the similarity of the moves that can be made from those states.” Each of these definitions stresses the functionality of the knowledge in the schema. Also worth noting is that the schema is a form of retrieval structure, identifying elements from earlier experience which can be reused in the current situation.

Our interest in this paper is in describing computational models of learning, and for this purpose, as will become evident later, a fairly loose definition of schemata is required to provide the basis of comparison between different models. Hence, we will use the following definition:

*A schema is a cognitive structure for representing and retrieving classes of typical situations for which a similar response is required of the learner.*

Our comparison looks at the variation in schema-form based on the different assumptions underlying each model. The greatest assumption made is the basic *representation* used by the model for storing learnt information in its memory. This representation may be highly structured, localised or distributed. The type of the representation affects the processes which the model can use to *learn*, where learning is the process of converting what has been experienced into an internal representation. In this context, some representations provide better support for incremental real-time learning, whereas others are better for complex rule induction. The type of representation also affects the *retrieval* of information from the model’s memory for use in novel situations. Some systems assume that every item of memory is compared to determine the closest match to the current situation, whereas others maintain a hierarchy for indexing

their memory and consequently only search a subset of the total memory.

These three characteristics, for representing, learning and retrieving a schema, provide a framework for analysing how different computational models address the questions of learning and using schemata. We use this framework in the next three sections, where we compare examples from three classes of model. The classes are distinguished by their underlying representations: neural network, production-rule and symbolic network models. The examples are selected to be representative (without attempting to be comprehensive).

### Neural network models

The ability of a PDP (Parallel Distributed Processing) model (otherwise known as a neural network) to learn schemata was addressed at an early stage by Rumelhart, Smolensky, McClelland and Hinton (1986), who described how such properties can arise within a class of PDP models. However, they did not address the question of learning. A better demonstration of these ideas within the context of a learning system is the Sentence Gestalt (SG) model of St. John and McClelland (1990). We also consider the CLARION system of Sun, Merrill and Peterson (in press), which is a hybrid model of skill learning.

#### Sentence comprehension

The aim of the SG model (St. John & McClelland, 1990) is to capture the process by which people fill out semantic information whilst reading a sentence. For example, given the sentence 'Bobby pounded the board together with nails', the inference "with a hammer" is made automatically. We can explain such behaviour by hypothesising that people recall (subconsciously) some schema for the sentence from which default information (the hammer) can be inferred. The SG model attempts to account for such phenomena. It consists of a two-stage recurrent neural network. The first stage learns a distributed representation for the sentence, called the sentence gestalt, from a temporal sequence of constituents. Each constituent is either a simple noun phrase, a prepositional phrase or a verb. The second stage acts as a probe for information contained in the sentence gestalt. Each probe is a role/filler pair, and the sentence gestalt is probed by presenting either a role or a filler, from which the network is to supply the complete pair. Requested information need not refer directly to words in the sentence. For example, after seeing 'Mary ate the spaghetti', the model should return the filler "fork" for the role "instrument".

The experiments performed by St. John and McClelland demonstrate that the SG model successfully assigns constituents to thematic roles based on syntactic and semantic constraints. Further, the model can disambiguate meanings and instantiate vague terms as appropriate to their context and the training data previously seen by the model. This behaviour fulfills the requirements for schemata as discussed previously: the model classifies sentences into various groups, and these groups can have variable or default information associated with them.

We can now consider the schemata used in SG against the three basic characteristics of our framework:

#### Representing a schema

All knowledge contained within a neural network is held implicitly across the weights within the network. Once activation is presented on the input, every weight and node within the network interact to generate an output. In this situation, specific schemata are not really *represented* within the network, in the sense of identifiable units, but instead *emerge* as a consequence of the specific set of inputs. Hence, the schemata used by the model cannot be extracted for use as explicit rules, but instead must be inferred from their effects on the network's output.

#### Learning a schema

Given the nature of distributed representations, it is not possible to learn about just one schema, because of the unpredictable effect on other information held in the weights. Indeed, the process by which the SG model (and most similar neural network models) is trained involves continuous passes of the entire training dataset whilst the weights in the network are gradually altered to approximate the mapping between the input data and its target output. This process means that the network captures generalisations true of the entire dataset, making it robust in novel situations.

#### Retrieving a schema

Again, the nature of the distributed representation within the model implies that the whole network is activated when obtaining a response to a novel input. Hence every piece of acquired information (every weight value) is used in generating a response. This process additionally ensures a robust response in novel but similar situations, because the retrieval process is based on the *similarity* between the novel input and the model's previous experience. For instance, if a large number of examples are presented to the network, and the responses analysed, it will be seen that those examples which are most similar tend to generate similar responses. Conversely, if a novel input is partly similar to one type of example in the training data, and partly similar to another type, the computed response will fall somewhere between that for the two items of training data. Note that the similarity in input to the network is heavily dependent on the form of encoding used for representing each item of data to the network on numeric input units.

#### Bottom-up skill learning

CLARION (Sun, Merrill & Peterson, in press) is a hybrid model for bottom-up skill learning. It is designed to model the process by which low-level perceptual-motor skills are converted into explicit rules, and also capture the interaction between these two levels of knowledge whilst carrying out a complex task. CLARION assumes that declarative knowledge is represented explicitly within a rule-based system, whereas procedural knowledge is represented implicitly within a neural network. CLARION has been tested in a perceptual-motor task involving navigation through a minefield, in which the model must learn to react to particular visual patterns of mines with appropriate navigation instructions to avoid the mines and reach a target. The dual use of knowledge is reflected in subjects' responses: mostly they

react instinctively, but after some experience in the domain some explicit planning is reported. CLARION's use of two knowledge levels is intended to capture this shift towards more explicit knowledge.

The novelty in CLARION is that the rules can either be pre-programmed (i.e. taught in the standard top-down manner) or learnt based on the low-level knowledge in the neural network. Specifically, if the neural network suggests an action which satisfies its criterion for success, then the current sensory state is turned into the condition part of a new production in the rule set, with its action part being the currently suggested action. Further learning processes on the rules update statistics and may refine and alter rules for efficiency. CLARION therefore contains two independent learning mechanisms, but the two can also work together with an interesting transfer of bottom-up (procedural) knowledge into the explicit rule-set. As with SG, schemata are evident in the similarity-based generalisations made by the model.

#### *Representing a schema*

CLARION uses a two-level representational structure: a rule-based system and a feed-forward neural network. As with SG, schemata are seen to emerge through the interaction of many elements in the model. Hence, the network and the rules can generalise robustly to novel situations based on partial similarity. The purpose of the rule-based system is to 'fix' the generalisations learnt by the neural network and prevent later experience 'blurring' them. These rules may in themselves represent broader classes of situation, because some of the attributes can have variables instead of specific values, rather akin to slots on a more generic template.

#### *Learning a schema*

The procedural knowledge in CLARION is learnt in a similar manner to the SG model described above, using a modified form of backpropagation: an additional reinforcement term is included in the training error because the correctness of a specific action is only known at the completion of the task. The rule-based declarative knowledge includes mechanisms for constructing new rules, or expanding or shrinking the conditions of existing rules. The mechanism for constructing a new rule is merely to include, for a successful action, the situation and action as the condition and action parts of a new rule. Expanding or shrinking a rule's conditions amounts to increasing or decreasing the likelihood of the rule matching future inputs by altering the range of possible values in one of its attributes. Before making any such changes to a rule's conditions, an information gain for each rule is computed to determine whether a modified version would do better than the current rule.

#### *Retrieving a schema*

As with SG, the whole of CLARION's memory is probed simultaneously to determine all information relating to the current situation. The possible actions suggested by the separate procedural and declarative levels are then chosen through a weighted competition, reflecting the degree of emphasis CLARION is placing on each type of knowledge. Note that in both levels CLARION relies on a similarity-

based metric to generalise to novel situations. This is natural in the chosen domain, where all inputs are visual scenes; the rules basically contain a localist representation of information similar to that in the neural network.

### **Summary**

The form of schemata possible in these neural network models is determined partly by their learning mechanisms and partly by their retrieval mechanisms. The basic neural network is capable of learning complex mappings from the input to output data, and inherent mechanisms within the neural network are used to retrieve information most similar to the current situation. In CLARION, situations may be learnt explicitly with specific rules consisting of core and variable information.

### **Production-rule models**

Production rules have been a popular representation for a number of computational models, two notable examples being Soar (Laird, Newell & Rosenbloom, 1987) and ACT-R (Anderson & Lebiere, 1998). However, such models are also difficult to discuss in our framework, as their inherent power makes them suitable for application in a wide range of domains and settings, as well as for testing various theories of learning: there are few architectural constraints which have a significant bearing on the forms of knowledge learnt. Here, we describe the generic learning and retrieval mechanisms in Soar.

#### **Soar: chunking of productions**

The Soar system integrates perceptual-motor behaviour with basic capabilities for learning and problem solving. All knowledge within Soar is held in the form of productions, with a working memory holding specific attributes and their values. Soar operates in a cycle, attempting to satisfy some goal within its working memory. This cycle takes the contents of working memory and matches it to productions in its knowledge-base. These matching productions place new goals or other elements into working memory (this is known as the *elaboration* phase, which proceeds until all eligible productions have fired, *quiescence*), and then a decision is made as to which of the new goals to pursue next.

#### *Representing a schema*

All behaviour within Soar is goal oriented, in the sense that the system is always trying to satisfy some goal or another. Each goal contains three slots: the current problem space, state and operator. The specific representations for information in these slots can vary across applications. A particular schema may not be represented specifically in a production, but instead, in a specific context, a number of similar rules will be matched, suggesting interrelated subgoals, and so yield the effect of a schema.

#### *Learning a schema*

Learning within Soar is based on a chunking process that creates new rules. Each rule recreates the results of subgoals in relevantly similar future situations (Laird, Rosenbloom &

Newell, 1986). Chunking relies on an analysis of the dependencies within the solution to a given subgoal to create new rules. A new rule is created for each independent result, with a condition relating to the dependency analysis of the subgoal, and an action relating to the specified subgoal. This chunking mechanism is a universal learning mechanism, similar to explanation-based learning (see Rosenbloom & Laird, 1986). The interesting facet of learning within Soar is its ability to focus on those aspects of the situation used for problem solving, and to use only these relevant aspects in chunking. This focus ensures that the chunks learnt by Soar will generalise to novel situations. In addition, Soar has a process of variabilisation, in which information is made as general as possible before it is stored as a chunk in a production.

#### *Retrieving a schema*

The retrieval mechanisms within Soar operate only in its elaboration phase, in which “all directly available knowledge relevant to the current situation is brought to bear” (Laird, Rosenbloom & Newell, 1987). In this phase, every production in its memory whose condition directly matches something in the working memory is activated, and its suggested subgoals and other information are added to memory. Matching productions against working memory is based on the similarity of the attributes and their values.

#### **Summary**

Just as with neural networks, no specific structure corresponding to a schema exists in Soar. However, the basic learning mechanism within Soar, chunking, does limit the form and content of learnt productions. Firstly, productions are retrieved based on their similarity to items in working memory. The features placed within a production are taken from the set of dependent relations in the attainment of a goal. In addition, some variabilisation can occur on the features.

### **Symbolic network models**

This section considers a pair of models which construct symbolic networks of symbol-level information within a hierarchy. Each of these lays some claims to universality of application, but have currently only demonstrated good results in one or two areas. The first is the CHREST model, which learns about chess patterns, and the second is EUREKA, which learns about physics problems.

#### **CHREST: storing chunks into templates**

The CHREST (Chunk Hierarchy and REtrieval STRucture) model of expertise (Gobet & Simon, in press) is a recent development of EPAM (Elementary Perceiver and Memoriser) (Feigenbaum & Simon, 1984). The learning processes in EPAM include mechanisms for constructing a discrimination network and incorporating information into it; the learnt information is known as *chunks*. CHREST includes extra mechanisms for learning *templates* (Gobet & Simon, in press); it is this template which is of interest to us here, as it possesses schema-like properties.

A template is created in the following manner. During training, CHREST (just like EPAM) builds a discrimination network of chunks of information. Specific to CHREST is the ability to create lateral links (Gobet, 1996): in this case, *similarity links*. These similarity links can be used whilst searching the network to suggest chunks not directly linked by the tests in the network. However, the novel aspect of this is that a node can reorganise information in similar chunks (satisfying an overlap criterion) into a template. This template contains a core pattern, based on the original chunk, and a set of slots, for the information which varied across the associated chunks.

#### *Representing a schema*

CHREST represents all information as chunks within nodes in a discrimination network: a chunk is a familiarised pattern. Nodes are linked by test links, which require some features to be matched on traversal. Some of the nodes in the network contain *templates*, where a template contains a core chunk and a number of slots. However, CHUMP (Gobet & Jansen, 1994) and CHREST+ (Lane, Cheng & Gobet, 2000) additionally allow nodes in the network to be associated with information about possible moves or problem solutions, allowing CHREST to learn to solve problems.

#### *Learning a schema*

The discrimination network within CHREST is learnt through four learning mechanisms. Beginning from the root node, CHREST sorts a novel pattern through the network until no further test links can be applied. At the node reached, two things can occur. First, the pattern may match the chunk, in which case more information can be added to the chunk from the pattern (familiarisation). Second, the pattern may mismatch the chunk, in which case a further test link and node are created based on the mismatching features (discrimination). The third learning mechanism constructs *similarity links* between two nodes when their chunks have at least 3 identical items. Finally, for a node with at least 5 similarity links satisfying an overlap criterion, the chunk may be replaced by a template. This template uses the existing chunk as its core, and the varying information across the other nodes as its slots.

#### *Retrieving a schema*

Retrieving knowledge within CHREST is achieved simply by following the test links from the root node, applying the tests to the target pattern until no further test applies. The chunk at the node reached is the retrieved schema.

#### **EUREKA: restructuring knowledge**

EUREKA (Elio & Sharf, 1990) demonstrates how an effective organisation for large amounts of domain-specific knowledge can support efficient recognition and application of relevant knowledge to the problem at hand. Secondly, the model demonstrates how the qualitative shift from novice to expert levels of knowledge and organisation can arise within a learning framework. EUREKA uses a discrimination network, rather like the CHREST model described above, but instead of simple chunks, the nodes in EUREKA's network

hold Memory Organization Packets (MOPs) (Schank, 1980). Each MOP represents a complex knowledge structure holding generalised knowledge extracted from a group of individual experiences. Differences between experiences are encoded in the tests between the links in the discrimination network, and so similar previous experiences are retrieved based on the features in the network which match the current experience.

EUREKA has been applied to physics problems, and is initialised with a set of MOPs containing basic knowledge about physics concepts, equations and inference rules. However, this knowledge does not contain any information about their usefulness or relevance in any particular type of problem. When EUREKA is given its first physics problems, it must use its basic knowledge in conjunction with a means-ends problem-solving strategy to construct a solution. Having done this, EUREKA then places the entire problem and its solution (features, inferences and solution steps) into a P-MOP (Problem MOP). This P-MOP is then stored in the P-MOP network, where some reorganisation of the network may occur. When solving later problems, EUREKA can use information in a P-MOP in preference to its means-ends analysis, which can lead to a shift in EUREKA's problem-solving strategy towards a greater use of important abstract physics concepts, such as force or energy, usually not present in the problem statement. Also, the use of a P-MOP instead of means-ends analysis means the model begins to solve problems working forwards from the given information instead of backwards from the target, in accordance with observed differences between novice and expert problem solvers (cf. Koedinger & Anderson, 1990; Larkin, McDermott, Simon & Simon, 1980).

#### *Representing a schema*

EUREKA stores information in a network of P-MOPs. At the root of the network is a P-MOP representing a "generic physics problem". Each P-MOP contains several elements: firstly, a set of *norms* represent the features which a problem must satisfy for this P-MOP to apply; secondly, a set of *indices* (links) to other P-MOPs, with the index specifying the feature(s) which distinguish between them; thirdly, the P-MOP includes a general inference rule; fourthly, the P-MOP includes a specific solution method for carrying out the inference rule; and fifthly, the P-MOP includes a count for the number of problem-solving experiences which it organises (i.e. has matched in the past). The P-MOP representation is a clear example of an explicit schema, with the norms indicating the class of similar problems to which its inference rules will apply.

#### *Learning a schema*

EUREKA's learning mechanisms operate through a process of *reorganisation*. Once a problem has been solved, everything about the problem and its solution is collected into a problem-solving experience. This experience is then compared with the existing P-MOP retrieved from the network. If any of the norms differ between the P-MOP and the experience, these are removed from the P-MOP and used as indices to new organisation beneath this P-MOP; any inference rules referring to these differing norms are also removed

from the P-MOP and included in the new organisation. This process has the side-effect that partial solution methods may reside on P-MOPs. A further reorganisation can occur in cases where a descendant P-MOP covers most of the problem-solving experiences of its parent P-MOP; in such situations the organisation of the network is not efficient, and one of the discriminating features might be better seen as a commonality.

These two learning mechanisms can lead the network to focus on abstract features in the following way. A property such as a force may not be represented within the problem statement, however, it will be referred to in the problem solution. As problem-solving experiences are gathered, a number will be seen to include force within their solution, and so this feature will become a norm within the P-MOP. From there, the feature may be used to discriminate between different P-MOPs, because it has been derived as a feature of a number of problem-solving experiences.

#### *Retrieving a schema*

Each P-MOP in EUREKA's memory is a separate schema, and each is indexed through the P-MOP network. Any of the features in the initial problem representation can serve as indices into the P-MOP network. Whenever the feature appears as a difference in the P-MOP, the corresponding index is traversed. If a number of indices may be traversed, then EUREKA prefers the index leading to the P-MOP that organises the most problem-solving experiences. Hence, EUREKA is directed preferentially to patterns that recur most often. During the traversal, EUREKA will apply the inference rules of any P-MOPs that match the current situation; this process will alter the current situation (the set of equations and unknowns) and so affect the further traversal of the P-MOP network. Note that EUREKA's bias towards P-MOPs which organise larger numbers of problem-solving experiences means that P-MOPs arising from reorganisation of the network will be preferred during problem solving. It is this bias which ensures EUREKA will preferentially use P-MOPs emphasising the presence of forces or abstract entities: as discussed above, such P-MOPs are formed from the aggregate of several more concrete P-MOPs, and so organise a larger number of problem-solving experiences.

### **Summary**

The symbolic network models are closer to the spirit of traditional schemata theories. In particular, there is a close correspondence between the information in a P-MOP or the pairing of problem and solution nodes within CHREST, and the schemata discussed in Koedinger and Anderson (1990). Both models can use information to partially match a current situation. However, different learning mechanisms encode different kinds of information in their nodes; CHREST restricting itself to perceptual similarity, with EUREKA inferring more abstract quantities for use in discrimination.

### **Conclusion**

This paper has taken an inductive approach to the question of how to learn schemata by applying an analytical framework to a number of computational models, and describing

the ways in which these models represent, learn and retrieve schemata. Our aim has been to uncover, from existing models, the origins of constraints on the possible forms of schemata. From our analysis we can see some similarities across all the models. Firstly, all use a distributed form of representation, in the sense that schemata for novel situations will usually arise from a number of partial matches, although the symbolic network models possess more explicit schema-like structures. Secondly, all use a similarity-based form of retrieval, differing in the features which may be used for discrimination. In particular, EUREKA allows abstract features (not perceptually obvious) to become significant.

However, the differences in behaviour of the various models are largely down to their specific learning mechanisms. As stated in the introduction, the motivation for these models has not been to learn schemata, as such, but instead to learn effectively in general situations. We therefore conclude that, for the purposes of developing a more meaningful definition of schemata, we should begin by analysing the available range of learning mechanisms in models such as those referred to here. These learning mechanisms should be explored in their cognitive implications. For instance, the use of seriality or resource bounds, the malleability of learnt features and how wide-ranging any changes to previous knowledge may be. Most of these properties will come directly from the learning mechanisms, whereas others will be imposed by the interaction of the learning mechanisms with the other properties of the system, such as its use of perceptual-motor stimuli. Once these properties have been understood, the use of schemata for describing the units of knowledge within humans will become grounded in the processes by which that knowledge has been learnt.

## Abstract

The phenomenon of retrospective revaluation has been a challenge to many associative learning theories as it involves a change in the associative strength of a cue on trials on which that cue is absent. The present experiment combines several retrospective learning contingencies in a single, within-subjects experiment, allowing for valid comparisons between contingencies. One of the most popular models of retrospective revaluation, Dickinson & Burke's (1996) modification of Wagner's (1981) SOP theory, fails to explain the full pattern of results. A connectionist model that explains retrospective revaluation in terms of changes in retrievability in memory, rather than as new learning about absent cues, is shown to provide a better account of the results.

## Introduction

Perhaps the biggest challenge to traditional theories of associative learning in recent years has come from studies of retrospective effects in cue competition. Such effects have overturned the central tenet of many of the most influential learning theories (e.g. Rescorla & Wagner, 1972; Wagner, 1981) – that only cues present on a given trial may engage the learning process.

Consider a typical retrospective revaluation study, as shown in Table 1. Stage 1 involves training of the cue compounds AB and CD to predict some outcome. In Stage 2 one of the cues (the competing cue) from each compound is selected for either further training (in what is known as the backward blocking condition) or extinction (unovershadowing). The typical result of such studies is that, following stage 2 training, when the cues that have not received any further training in stage 2 (the target cues) are tested, D is now rated as a better predictor of the outcome than B. Thus the perceived predictive validity of a cue can be altered after initial compound training with that cue, either by training the other cue of the compound pair as a valid predictor of the outcome (as in backward blocking) or by extinguishing it (as in unovershadowing). The inference from this is that the associative strength of the target cue representation (B or D above) to outcome representation association can change on trials in which that cue is not presented (A+ and C-).

Retrospective revaluation has now been reliably demonstrated in a number of experiments with humans, using causal judgments of a cue→outcome relationship as indicators of the strength of the association between their representations (e.g. Chapman, 1991; Dickinson & Burke,

1996; Shanks, 1985). We will consider in some detail here one of the more popular theories of associative learning; Wagner's (1981) SOP model, and Dickinson & Burke's (1998) modification allowing it to explain retrospective effects.

SOP proposes that stimuli are represented by nodes in an associative memory that are composed of a number of elements. These elements can be in one of three states at any instant; one inactive state (I) and two active states (A1 and A2). Presentation of a stimulus excites the elements representing that stimulus into A1. These elements then decay back to I via A2. Exciting a node via an associative connection, however, causes a transition from I directly to A2. Changes in the associative connection between two nodes depend on temporal overlap of the states of their elements. Whenever the elements of two nodes are in A1, there is an increment in the excitatory strength between them. When the elements for one node are in A1 and those of another are in A2, there is an increment in the strength of an inhibitory connection. Critically, SOP states that only cue elements in A1 will engage the learning process (i.e. learning will only accrue to cues that are physically present on a trial). Hence, as there can be no learning about absent cues, SOP is unable to explain the results of retrospective revaluation studies.

Dickinson & Burke (1996) proposed a modification to SOP to allow it to explain retrospective revaluation (Table 2). They suggested that CS elements in A2 could engage learning, with an increment in excitatory strength whenever there was an overlap in activation states (be this in A1 or in A2) and an increment in inhibitory strength whenever elements were in different states. Thus they specified the sign with which learning occurs to be a symmetrical function of elemental activation states.

Consider now the contingencies shown in Table 1. During the first stage both target and competing cues, and the US, are presented, and so all will have elements in A1. Hence target and competing cue elements will form excitatory connections to US elements, and within-compound associations will form between target and competing cues. In the unovershadowing contingency cue C is now presented, and will retrieve D elements into A2 via the within-compound link. The US will also have elements in

Table 1: A typical retrospective revaluation design.

Condition	Stage 1	Stage 2	Test
Backward Blocking	AB+	A+	B?
Unovershadowing	CD+	C-	D?

Table 2: Modified SOP.

		US Element	
		A1	A2

	A2	<b>I</b>	<b>E</b>

E : Excitatory connection strengthened

I : Inhibitory connection strengthened

A2 (retrieved via the C→US connection). As both D and the US have elements in the A2 state, modified SOP predicts an increment in the excitatory strength between them. Hence D's rating is predicted to increase as a result of the C- trials, even though it is absent.

The case for the backward blocking contingency is less clear. Presentation of A in stage 2 will retrieve B elements into A2. The outcome is presented, so some of its elements will be in A1, but it is also predicted by virtue of the A→US connection, so it will also have elements in A2 (these elements cannot go straight from A2 to A1 when the US is presented; they must pass through the I state first). Thus any inhibitory A2-A1 learning between B and the US will be offset to some extent by excitatory A2-A2 learning. Whether the model predicts a net increase or decrease in the rating of B depends on which of the processes engaged by congruent and incongruent elemental states is stronger.

The overall result, though, is that after training D will be rated higher than B. According to modified SOP, then, the driving force behind retrospective revaluation is unovershadowing; backward blocking has a smaller role. This is supported by Larkin, Aitken & Dickinson (1998), who tried to measure the effects of unovershadowing and backward blocking separately by comparing each to a control contingency, EF+ X+ (for which neither target cue nor competing cue is trained in Stage 2). As predicted by modified SOP, they found evidence for a significant effect of unovershadowing, but the evidence for backward blocking was weaker and fell short of significance.

Backward blocking and unovershadowing are not the only retrospective effects that have been found in human causal learning. It has long been known that following A+, AB- training, B will typically become established as an inhibitor of the US, able to counteract the excitatory potential of A. Chapman (1991) reversed this procedure, to give an AB-, A+ design. This procedure was sufficient to establish B as an inhibitor of the US (i.e. it received a lower rating on test than C or D from a CD-, X- control contingency). The inhibitory properties of B must have been assumed in retrospect, as A was only established as a good predictor of the US following AB- trials.

Note that the phenomenon of backward-conditioned inhibition is in line with the predictions of modified SOP. During the first stage a within-compound association is learnt between A and B. A then retrieves B elements into A2 in stage 2. The outcome is presented, and so has elements in A1. The resulting A2-A1 activity will result in formation of an inhibitory link between B and the US.

Thus modified SOP is well equipped to deal with some of the major findings of retrospective learning studies with humans. In the present experiment we use these retrospective effects as a benchmark from which to provide a more critical assessment of the mechanism for retrospective revaluation proposed by modified SOP.

The design of the experiment is shown in Table 3. We used an allergy prediction paradigm, as employed by Dickinson & Burke (1996) and Larkin et al. (1998). Participants play the role of a food allergist trying to judge the likelihood that various foods will cause an allergic reaction in a hypothetical patient (Mr. X). The foods, then, constitute the cues, and the allergic reaction is the outcome. Following training, subjects rated how strongly each of the foods predicted the occurrence of an allergic reaction.

Table 3: Design of the experiment.

Condition	Pre-exp	Cond 1	Cond 2
B. Block		AB+	A+
Unover		CD+	C-
L,A&D Control		EF+	G+
PR Control		HI+	H+/H-
BCI		JK-	J+
BCI Control 1		LM-	L-
BCI Control 2		NO-	P-
BB Pre-exp	QR		Q+
BB Pre-exp Control 1	ST		S-
BB Pre-exp Control 2	UV		
Fillers		WX-	

These ratings were taken as a measure of the associative strength of a connection from cue to outcome.

We also follow Dickinson & Burke (1996) and Larkin et al. (1998) in using a large number of cues. This creates a large memory load, hopefully preventing subjects from basing their ratings on inferences made from explicit episodic memories of the various trial types. Instead subjects should have to rely on associative processes to provide an "automatic" measure of the causal efficacy of each cue.

The first two rows of Table 3 (B. Block and Unover) are the contingencies of a standard retrospective revaluation experiment, as shown in Table 1. Retrospective revaluation is demonstrated if D is rated higher than B on test.

The "L,A&D" contingency is a control of the kind used by Larkin et al. (1998). Following compound training in Cond 1, neither cue is presented in Cond 2, and so no revaluation will occur. Thus backward blocking and unovershadowing can be assessed independently relative to this control. Backward blocking would be evidenced by a lower rating of B than E or F; unovershadowing by a higher rating of D than E or F.

The "PR Control" is a second control that might allow us to dissect out the effects of backward blocking and unovershadowing. Following compound training in Cond 1, the competing cue receives partial reinforcement. Thus there are an equal number of H+ and H- trials. Suppose that unovershadowing is much stronger than backward blocking. On each H- trial in stage 2 there would be an unovershadowing effect, with I's association to the US becoming stronger. On each H+ trial there would be little effect, as backward blocking is weak. The contingency becomes, in effect, HI+ H-, i.e. unovershadowing, and so we expect I's rating to be similar to D (from an actual CD+ C- contingency). The opposite would be true if backward blocking were stronger than unovershadowing. In general, the PR Control target cue will receive a rating closer to the target cue of the retrospective revaluation contingency having the stronger effect.

The next three rows show a backward-conditioned inhibition contingency and two controls respectively. As described earlier, backward-conditioned inhibition will be demonstrated if K is rated lower on test than M (from Control 1) and N or O (from Control 2).

"BB Pre-exp" is short for backward blocking pre-exposure. This involves compound pre-exposure during the first stage (cf. compound training for backward blocking), followed by excitatory training of the competing cue in Cond 2. Modified SOP predicts that unovershadowing will have a larger effect than backward blocking in retrospective revaluation, because in a backward blocking con-

tingency the US is strongly predicted in the second stage, such that it has elements in A2. The excitatory A2-A2 learning then offsets the effect of inhibitory A2-A1 learning. As a result of using compound pre-exposure in the "BB Pre-exp" contingency, though, the US will not be expected on Cond 2 trials. Hence when it is presented all of its elements should be free to enter A1. R will be retrieved into A2 by Q via the Q-R association developed during pre-exposure. The resulting A2-A1 overlap should produce strong inhibitory conditioning. Modified SOP thus makes the clear prediction that R will be rated lower than T (from Control 1) and U or V (from Control 2).

The Filler trial was used so that there were an equal number of positive and negative trials during Cond 1.

## Method

**Participants** Twenty-four Cambridge University students (14 female, 10 male; age 19-23) took part in the experiment.

**Apparatus** The experiment was run on a Power PC Macintosh with a 14" monitor.

The foods used were: Oranges, Tomato, Cheese, Lobster, Rice, Peaches, Banana, Grapes, Yoghurt, Melon, Broccoli, Aubergine, Eggs, Potatoes, Carrots, Lentils, Sardines, Gammon, Dates, Mushrooms, Raspberries, Jam, Onion, Steak. These foods were randomly assigned to the letters A to X in the experimental design for each subject.

**Procedure** At the start of the experiment each subject was given a sheet of instructions presenting the "allergy prediction" cover story for the experiment. They were told that in the first block they would be looking over records of foods eaten at the clinic by Mr. X, but would not be told whether or not allergic reactions occurred, while in the second and third blocks they would be asked to make predictions based on the foods eaten. They were also told that at the end of the experi-

ment they would be asked to rate each of the foods according to how strongly it predicted allergic reactions.

On each pre-exposure trial, the words "Meal [meal number] contains the following foods:" followed by the two foods appeared on the screen. Subjects were then cued to enter the initial two letters of each of the foods. This was to ensure that they paid attention to the pairings of foods when no allergy prediction was required. There were three trial types in this stage: the order of trials was randomized over each set of three with the constraint that there were no immediate repetitions across sets. Participants saw each pair of foods eight times in this stage. The order of presentation on the screen (first/second) within each compound pair was randomized.

The same message appeared on the screen on Cond 1 and Cond 2 trials. However, now the subjects were asked to predict whether or not eating the foods would cause Mr. X to have an allergic reaction, using the "x" and "." keys (counterbalanced). The screen then cleared, and immediate feedback was provided. On positive trials the message "ALLERGIC REACTION!" appeared on the screen; on negative trials the message "No Reaction" appeared. If an incorrect prediction was made, the computer beeped. There was an explicit break between Cond 1 and Cond 2, when subjects were told that they would now see a new set of meals, some of which contained foods they had seen earlier and some of which didn't. There were eight trial types in Cond 1, and nine in Cond 2. The order of trials was randomized over each set of eight or nine. Participants saw each meal eight times in Cond 1 and Cond 2. Four of the eight H trials in Cond 2 were positive, and the other four were negative, in random order.

In the final rating stage subjects were asked to rate their opinions of the effect of eating each of the foods on a scale from -10 to +10. They were to use +10 if the food was very likely to cause an allergic reaction in Mr. X, -10 if eating the food was very likely to prevent the occurrence of allergic reactions which other foods were capable of causing, and 0 if eating the food had no effect on Mr. X (i.e. it neither caused nor prevented allergic reactions).

All of the foods seen in training were then presented in random order for rating. For clarification, participants also had access to a card on which the instructions on how to use the rating scale were printed. Once a food had been rated it disappeared from the screen and the next appeared, so that participants could not revise their opinions upon seeing later foods.

## Results

Figure 1 illustrates the percentage of trials on which subjects thought an allergic reaction would be caused by the food(s) shown in each of the 8 trial sets of Cond 1 and 2. Subjects' responses were clearly appropriate to the relevant underlying contingencies by the end of each stage, with all of the positive trial types eliciting more "Allergic Reaction" responses, negative trial types receiving more "No Reaction" responses, and the H+/H- trials receiving about 50% positive and negative responses.

Of more interest are the ratings of the causal efficacy of each of the foods. The mean rating given to each of the 24 foods is shown in Figure 2. A one-way, repeated measures ANOVA was carried out on these ratings as a preliminary to assessing the effects of interest by means of planned comparisons. There was a significant main effect of food [ $F(23,529) = 22.46, p < 0.001$ ]. Retrospective reevaluation was seen, in that the target cue of the backward blocking contingency (B) was rated significantly lower than that of the unovershadowing contingency (D) [ $F(1,23) = 7.24, p < 0.01$ ]. Hence it appears that our experimental paradigm is sensitive to changes in the perceived causal efficacy of cues on trials on which those cues are not present.

Figure 1. Acquisition of discriminations in (A) Stage 1 and (B) Stage 2.

Figure 2. Mean ratings given to the 24 foods.

The result for the L,A&D Control contingency is given by the average of cues E and F, which are equivalent. This does not differ significantly from B or D [ $F(1,23)=2.78$  and  $1.23$  respectively,  $ps > 0.05$ ]. Given this failure to reach significance, our results neither confirm nor contradict those of Larkin et al. (1998).

We now turn to the results of the PR Control contingency. The rating of the target cue from this contingency (I) is very similar to that of the backward blocking contingency, but quite different from that of the unovershadowing contingency. This is supported statistically: B and I do not differ significantly [ $F < 1$ ], whereas the difference between D and I is highly significant [ $F(1,23) = 7.44$ ,  $p < 0.01$ ]. It was stated earlier that the rating of the target cue of the PR Control contingency should be more similar to the target cue of whichever retrospective revaluation process (backward blocking or unovershadowing) is stronger. Hence, given that the rating of I is more similar to B than D, the PR Control contingency indicates that backward blocking is a stronger process than unovershadowing.

We also have evidence for backward-conditioned inhibition in this experiment. Cue K is rated lower than its equivalents in the two control contingencies (M, and the average of N and O, none of which differs significantly from each of the others). These differences are significant [ $F(1,23) = 7.45$ ,  $p < 0.01$  and  $F(1,23) = 6.98$ ,  $p < 0.01$  respectively]. There is no evidence for any retrospective learning in the BB Pre-exp contingency, however. The target cue of this contingency is R. The two controls here are T and the average of U and V (none of which differ from one another). In the former case, the means are identical; in the latter the difference is not significant [ $F < 1$ ].

## Discussion

Looking at the results above, we can see that modified SOP is successful in explaining some aspects of this experiment (the occurrence of retrospective revaluation and backward-conditioned inhibition). However, it also has important failures.

The fact that the PR Control indicates a stronger role of backward blocking than unovershadowing in this experiment is a great problem for modified SOP. It implies that the simplistic approach taken to the associative processes occurring in these contingencies is insufficient to provide a full account of human behaviour with respect to learning about absent cues, as the model predicts that unovershadowing will be more influential than backward blocking.

Note that this result also argues against subjects' using a rational, Bayesian approach to the contingencies seen. According to this idea, subjects would integrate the information experienced in the two stages to derive the most likely cause of the US. For example, A- trials following AB+ trials (unovershadowing) indicate that it *must* have been B that caused the US on the AB+ trials. Hence B's rating will increase as a result of A- trials. Less information is given by A+ trials following AB+, though: B *could* still be a cause of the US on AB+ trials. Hence this rational approach predicts that unovershadowing will be stronger than backward blocking, whereas the results of the PR Control indicate the opposite.

In addition, modified SOP predicts a large difference between the target cue of the BB Pre-exp group and its controls, but no difference is seen. The BB Pre-exp contingency should be the situation in which the inhibitory A2-A1 process, proposed to underlie backward blocking, should be most prominent, and yet no effect was seen. This is particularly noticeable as the BCI contingency, which on the surface appears very similar, did show an effect. The failure to find an effect in one of the two contingencies is hard to reconcile with modified SOP.

In summary, then, it seems that modified SOP is able to explain the existence of retrospective revaluation and associated phenomena, but that the mechanics of the explanation offered do not agree with our empirical findings. We now offer an alternative class of model which seems better able to cover the known facts with respect to human studies of retrospective revaluation.

## APECS: A model of associative learning

It is possible to explain the results of the above experiments using a version of McLaren's (1993) APECS model. The mechanics for learning in APECS are similar to standard backpropagation (Rumelhart, Hinton, & Williams, 1986), but differ in that once the weights appropriate to a mapping have developed, the learning represented in those weights is protected. This is achieved by reducing the learning rate parameters for the hidden unit carrying the mapping. The effect is to "freeze" the weights to and from a certain configural unit at the value they hold immediately following experience of that configuration. Crucially, this freezing of weights to and from a hidden unit occurs only if that hidden unit has a negative error value, i.e. *if it is part of a mapping that predicts an incorrect outcome for the current input*. This reduces the interference arising as a result of subsequent experience of similar (but not identical) input patterns. Indeed APECS was originally designed as a solution to the problem of catastrophic interference in learning (McCloskey & Cohen, 1989).

Specifically, APECS has different learning rate parameters for input-hidden and bias-hidden connections. The former are frozen to prevent interference; the latter remain high. Hence extinction (suppression of inappropriate responses) is achieved by an increase in the negative bias on the hidden unit carrying the inappropriate mapping, rather than by reduction of weights (which would cause the original mapping to be lost from the network). Given appropriate input cues, the negative bias on the hidden unit can be overcome and the original mapping retrieved.

In addition, in our instantiation of APECS each different pattern of stimulation is represented by its own hidden unit, similar to Pearce (1987).

Consider what happens in the network on AB+ training. It will learn a mapping from A and B input units to the US output unit, mediated by a hidden unit that can be thought of as representing the configuration of A and B ( $AB_{\text{hidden}}$ ). On each AB+ trial the excitatory connections to and from  $AB_{\text{hidden}}$  will grow stronger. Now consider the gap between AB+ trials, when no inputs are presented. According to the logistic activation function employed with APECS, when no inputs are presented the hidden units will have an activation of 0.5 (see Rumelhart et al., 1986). This activation will feed along the  $AB_{\text{hidden}} \rightarrow \text{US}$  connection learnt on the preceding trial, and activate the US unit. This is obviously inappropriate when no inputs are presented. The US unit will take on a negative error, which is propagated back to  $AB_{\text{hidden}}$ . As explained earlier, a negative error means that the weights to and from the hidden unit are frozen. In order to suppress the expression of the US on gaps between the AB+ trials, the  $AB_{\text{hidden}}$  unit will therefore develop a negative bias.

In a backward blocking contingency we now train on A+ trials. As explained above, in this instantiation of APECS, each different input  $\rightarrow$  output mapping is assigned a new hidden unit. Hence a new unit is recruited to carry the A+ mapping. As the previous excitatory connection from A to the US (via the AB configural unit) is still useful in reducing the output error (i.e. there is a positive output error on A+ trials, which is propagated back to the  $AB_{\text{hidden}}$  unit), the learning rate for the  $A \rightarrow AB_{\text{hidden}} \rightarrow \text{US}$  connections will also remain high. Given the negative bias on the  $AB_{\text{hidden}}$  unit, and the fact that training was with A and B in stage 1, A alone will not succeed in fully activating the US at the start of A+ training. Hence the connections from A to both hidden layer units, and from the hidden layer units to the US node, will strengthen.

Now, when no stimuli are applied (during inter-trial interval) the hidden units will deliver some positive activation to the output unit. Thus the  $A_{\text{hidden}}$  unit will assume a negative bias. More importantly, the negative bias on the  $AB_{\text{hidden}}$  unit will also become increasingly negative to counter the extra positive activation feeding to the US.

What now happens when B is presented on test? B will provide  $AB_{\text{hidden}}$  with positive activation, but this may not effectively counter the unit's large negative bias, and hence the US will receive little activation. This, of course, assumes that  $AB_{\text{hidden}}$ 's gain in negative bias outweighs the strengthened  $AB_{\text{hidden}} \rightarrow \text{US}$  connection. This is guaranteed, as the two bias changes must together counter the increased  $A \rightarrow \text{hidden}$  and  $\text{hidden} \rightarrow \text{US}$  weights of *both* routes to the US, whereas only the increased  $AB_{\text{hidden}} \rightarrow \text{US}$  connection will facilitate B's ability to retrieve the US.

Hence APECS is able to explain backward blocking: as a result of A+ trials following AB+ training, B becomes less able to retrieve the US. Note that, unlike modified SOP, this is not as a result of new learning about B (the  $B \rightarrow \text{hidden}$  connection is unchanged on A+ trials), but rather as a result of changes in the retrievability of a previously-learned association.

Consider now the A- trials of the second stage of an unovershadowing contingency. Once again a new hidden unit is recruited to carry this mapping. In this case, however, the  $AB_{\text{hidden}}$  unit is not reused: it carries an inappropriate excitatory mapping and so will have a negative error. Hence its weights are frozen, and it takes on an increased negative bias. In addition, an inhibitory mapping from A to US will develop via the  $A_{\text{hidden}}$  unit in

order to counter the positive activation flowing to the US via the original mapping.

Between A- trials, when no inputs are presented, the US will receive excess negative input as a result of this new, un-suppressed inhibitory mapping. The network counters this problem in two ways. One is for the  $A_{\text{hidden}}$  unit to develop a negative bias. The other is for the negative bias on the  $AB_{\text{hidden}}$  unit to reduce, allowing through more positive activation.

The upshot of the decrease in negative bias on the  $AB_{\text{hidden}}$  unit is that presentation on B will now excite the US more effectively than following initial AB+ training: this is the standard unovershadowing effect.

Thus the features of APECS that prevent it from suffering from catastrophic interference also allow it to explain retrospective revaluation. Indeed, a backward blocking contingency can be seen as an interference design, where two different pathways (via  $A_{\text{hidden}}$  and  $AB_{\text{hidden}}$ ) compete to activate the same outcome. Hence A+ trials interfere with memory of the AB+ mapping, causing this pathway to be suppressed. In unovershadowing the situation is reversed: the two pathways have opposite outcomes (AB+ and A-), and so on A- trials the AB+ pathway need not be suppressed, and can even become stronger to counter the influence of the new negative pathway.

On performing initial simulations of retrospective revaluation using APECS it was found that unovershadowing consistently showed a larger effect than backward blocking. This sits well with the results of Larkin et al.'s (1998) study. But how then could this model explain the PR Control, which indicates that backward blocking has the greater effect?

The answer lies in the nature of the AB+ A+/A- design used. It was mentioned earlier that each new input  $\rightarrow$  output mapping recruits a new hidden unit. Hence the occurrence of A+ and A- trials in stage 2 will lead to the recruitment of two new hidden units, one carrying an excitatory mapping, the other an inhibitory mapping. Thus there are now two excitatory pathways to the US (via the  $AB_{\text{hidden}}$  and  $A_{\text{hidden}}$  units) as opposed to only one inhibitory pathway (via the  $A_{\text{hidden}}$ ). This means that any influence of the inhibitory pathway on each excitatory pathway (i.e. unovershadowing) will be relatively slight, as the effect is shared between, and countered by, both excitatory pathways. The effect of one excitatory pathway on the other (backward blocking), though, is relatively unaffected, as it is still a one versus one situation. Hence backward blocking is relatively preserved in this contingency, whereas unovershadowing is greatly reduced.

Figure 3 shows simulation results for the retrospective revaluation contingencies of our experiment, along with the empirical results. The simulation results are the average of 24 simulations run with APECS, each representing one subject, with exactly the same trial order as experienced by the real subjects. Each trial involved 1000 learning cycles. A hidden unit is defined as being "active" when it receives positive activation from the input layer. Thus if cue A is presented to the network, any hidden unit representing a configuration that includes cue A will be active. Activity extends into the period immediately following each trial, when no inputs are presented (again for 1000 learning cycles). The learning rate parameters for input-hidden and hidden-output units are both 0.85 when a hidden unit is active and has a positive error, and 0.001 when it is not. The parameter for bias-hidden changes is 0.25

Figure 3. Empirical and simulated data for the retrospective revaluation contingencies.

when a hidden unit is active, 0.001 when it is not. Thus we make the reasonable assumption that changes due to learning take place faster than changes in memory, i.e. learning represents rapid acquisition, and memory represents a more gradual decline in retrievability.

What predictions does APECS make for other contingencies used in our experiment? Easiest to understand is the BB Pre-exp contingency. On the pre-exposure trials, there is no error on the output unit (whether or not the outcome occurs is not known). Given that it is output error that drives learning in error-correcting networks, this lack of error means that there is no drive to form associations. Hence the cues involved in these trials remain unconnected to the US following pre-exposure. As these cues have no connections to the output, their associative status cannot change on any subsequent trials on which they are not presented, and so no differences will be seen amongst these groups (as observed empirically).

The situation is slightly more complex for the BCI contingency. Typically a context in which outcomes occur will become a weak excitator of the outcome itself. Thus cues presented on negative trials in this context will become weak inhibitors in order to overcome this excitation (demonstrated by the negative ratings given to cues W and X). Hence J and K will develop an inhibitory link to the US via a  $JK_{\text{hidden}}$  unit. This unit will take on a slight negative bias to prevent its expression when no inputs are presented. The network is now presented with J+ trials. A new hidden unit will be recruited to carry this excitatory mapping. There will be a slight increase in the negative bias on the  $JK_{\text{hidden}}$  unit, but given that the inhibitory influence of this pathway is slight, the drive to suppress it will also be slight. On the gap between J+ trials, the US will receive excess positive input. One way to decrease this is for the  $J_{\text{hidden}}$  unit to develop a negative bias to suppress the excitatory mapping just learnt. A second way to reduce the activation of the US is to decrease the suppression of the  $JK_{\text{hidden}}$  unit, allowing more activity to flow through the inhibitory pathway. This release in suppression between trials (driven by the strong excitatory pathway) more than compensates for the increase in suppression on J+ trials (driven by the weak inhibitory pathway), and so overall the suppression of the  $JK_{\text{hidden}}$  unit (which carries the inhibitory mapping) decreases over J+ trials. Hence the ability of K to retrieve the US decreases as a result of J+ training following JK- trials: backward-conditioned inhibition is seen.

This is again confirmed by simulation. Figure 4 shows the results for the relevant contingencies from the simulation of this experiment described above.

Figure 4. Empirical and simulated data for the backward-conditioned inhibition contingencies.

In conclusion then, it seems that modified SOP is able to explain certain retrospective effects in human causality learning on a coarse scale, but that the explanation offered for these effects (novel learning about absent cues following retrieval via within-compound associations) does not stand up to closer scrutiny. A memory-based explanation, with retrospective effects manifest as changes in retrievability rather than new learning about absent cues, shows better agreement with empirical data, and may prove a more fruitful approach for future investigation.

## Abstract

We present a new architecture for robot control rooted in notions from Brooks' subsumption architecture and extended to include an internal representation which matures as it experiences the world. Our architecture is based on the Copycat program of Mitchell and Hofstadter, a model of fluid representation whose details we discuss. We show how our architecture develops a representation of its environment through a continuing interaction with it. The architecture is founded on a dynamical systems interpretation of representation and demonstrates the importance of the use of "embodiment". It reflects a constructivist epistemology, with the robot designed to utilize its environment in its exploration.

## Introduction

We present an architecture for robot control based on the constructivist insight that representation occurs as a product of the active interpretation of perception-based experience. This architecture supports the control program for a robot whose task is to move about, explore, and map its world. The robot generates a representation of its environment by converting sequences of sensory data into perceived "objects". We believe that our approach will allow the robot to behave more robustly than does the use of the more traditional "preinterpreted" (McGonigle 1998) representations of its world.

In this paper, we describe the details of the model and then show its capacity to construct interactively a representation of surfaces and gaps (discovering the "objects") in its environment. The preliminary results demonstrate the use of this emergent architecture to solve simple robotics problems and to generate emergent structures that represent persistent features of the changing data from the environment. We also discuss work currently underway to allow the robot's behavior to be improved by the emergent representations.

Our work builds on research from several disciplines. These include: behavior-based robotics (Brooks and Stein 1994), the "dynamical nature" of representation and intelligence (Steels 1995, 1996), and the philosophical insights of Maturana and Varela (1980) and Clark (1997), on the self-organizing nature of living systems and their "coupling" with their environments. Further support for our approach comes from Holland's (1986, 1998) ideas on emergence in the context of classifier systems, and work on "fluid representations" in software architectures, for example Copycat, proposed by Mitchell and Hofstadter (Mitchell 1993). We continue the focus on "situating"

cognitive behavior in its environment originating with (Winograd and Flores 1986).

Traditional cognitive science and artificial intelligence have focused on building the (supposedly static) structures involved in representational processes. The peculiar fluid quality of actual structures that support complex problem solving in changing environments has resisted elucidation. More recently a shift of focus, generated in part from the study of complex adaptive systems, has driven research to attempt to characterize the dynamical processes underlying these representational structures. Architectures whose representations are implicit in behavior, supported by dynamical constraints and triggers from the environment, have begun to validate the constructivist claim that "refinement of an interpretive framework is usually driven by the tension between the pattern of interpretation and the demands of successful interaction." (Luger 1994). These models also provide suitable tests for the assertion that representations only have meaning in the context of embedding experiences.

Our control architecture implicitly defines intelligence with the four characteristics of evolving complex adaptive systems proposed by Steels (1996). The first of these criteria is *self-maintenance* (we prefer the term *autopoiesis* from Maturana and Varela (1980) who also describe a "mutual maintenance" relationship among system components). The remaining criteria for describing intelligence are *adaptivity*, *information preservation*, and, in response to the demands of a complex environment, a *spontaneous increase in complexity*.

We also follow Steels (1996) suggestions that there are two ways that intelligent systems can achieve these four criteria. The first is through the use of a general purpose dynamical architecture. The second is through the capture of the emergent properties of interactive behavior, enabling the formation of concepts about and representations of the environment. We feel that the emergence of structures evolved through "coupling with" an environment is a defining feature of intelligence, and call this *behaviorally coupled representation*. Furthermore, this "embodiment" is so critical to the study of intelligence that at least at the present state of our understanding, building and testing robots is an insightful necessity.

## A New Architecture for Robot Control

Most early approaches to robotics subscribe to an implicit *sense-model-plan-act* framework (Brooks 1991b). In the

1980s, concern arose about the performance and complexity entailed by this framework when applied to adaptive autonomous agents functioning in actual environments. This concern motivated a shift in thinking about the design of robotic systems as well as conjectures about the organization and use of intelligence itself.

The subsumption architecture (Brooks 1991a) marked the beginning of *behavior-based robotics*. Behavior-based robotics emphasizes the integration of semi-independent layers that produce behaviors directly from input rather than each contributing to a stage of the sense-model-plan-act framework. The focus is on interaction with the environment as a trigger for behavior rather than use of explicit representation. The ability to react to dynamic features of an unpredictable environment and to generate robust behavior despite sensor uncertainty is a signature of this behavior-based approach. Testing physically constructed robots interacting with complex worlds bears much weight in this new paradigm of robotics research. The behavior-based approach is a useful framework for organizing our understanding of intelligence (Brooks 1991b).

Brooks was right to criticize AI for the use of representational schemes with fixed and predetermined interpretations. As a result of moving away from the use of explicit representations, however, too little emphasis has been placed on the "appropriate" role of representation in intelligent problem solving. We want to pair Brooks' insights with a flexible representation that evolves with its interactions within an environment. A new dynamical model of representation, focusing on the role of emergent structure in behaviorally coupled systems, will accompany our new framework for robotics. McGonigle, referring to the polarity between representational stances, claims "we have the concept of a co-evolving agent and environment leading to a mutual specification..." (McGonigle 1998). To explore this new notion of representation, we must develop models that are both dynamical and embodied. Then we must seek mechanisms in those models for the emergence of structures coupled through system behavior to the environment.

Maturana identifies a hallmark of living systems which he calls *structural coupling* (Maturana and Varela 1980). Structural coupling means that the environment triggers changes in the internal structures of a system; but the nature of those changes is dictated by the dynamics of the system rather than being specified by the environment. An "embodied" model is one which participates in the dynamics of its world and which undergoes changes in its internal processes triggered by events in the environment. Representation for a robot control system can be achieved by providing a sufficiently rich dynamical system inside the robot to enable structural coupling to take place between the robot control architecture and the environment.

In spite of admonitions against representation, the use of partial world models may actually increase the ability of dynamical systems to meet the real-time demands of their environments. Clark discusses this in connection with

Kawato's work on proprioception (Clark 1997). Partial models devoted to the improvement of specific behavior are called *niche models* (Clark 1997). Representations can be partial because they derive their meaning from the context of interactions within an environment.

## "Fluid Representation" and Copycat

Copycat (Mitchell 1993) is one of the first computer programs to attempt to capture the dynamical processes from which symbolic or representation-based behavior can emerge. Copycat solves analogy problems such as, if "abc" becomes "abd" what does "ijk" become? Such seemingly simple analogies involve evolving, context-dependent processes of integration and differentiation that are at the core of intelligent problem solving.

In addition to its novel mechanisms for parallelism and flexible adaptation, one of Copycat's most important components is the *slipnet*. The slipnet is a semantic network organized with spreading activation and multiple kinds of links among its nodes, some of which can change in length. The processes which evolve representational structure impact the topology of the slipnet, making the program's own behavior part of the adaptive control. For example, if several interacting processes have successfully built structures about *opposite* relationships among the input, the node for *opposite* in the slipnet becomes more active. Furthermore, *opposite* links become shorter and more likely to be traversed, and further processes to explore *opposite* are generated. Figure 1 shows the lengths of links between two nodes, *successor* and *predecessor*, as 85. This value shrinks as the label node for those links, namely *opposite*, gets an increase in activation (shown inside the ovals), making substitutions of one for the other more likely. In addition to spreading activation, this is the method by which slipnet evolves its meanings in response to events in its environment.

Figure 1: The Evolving Slipnet

Interacting with the slipnet in Copycat are the *coderack* and the *workspace*. The interactions of these three components of Copycat are mediated by the system's *temperature*, which measures the cohesion of the workspace structures. The workspace is a global arena for creating structures that the other components of the

system can inspect. In this sense it is much like a Blackboard (Luger and Stubblefield 1998) or the message area in Holland's (1986) classifier system. Copycat's coderack is a priority biased probabilistic queue containing codelets. Codelets are small pieces of executable code designed to interact with the objects in the workspace, exploring different facets of the problem space and attempting to further some small part of the evolving solution. The codelets are very much like the individual classifiers in Holland's (1986) original system.

Copycat is a unique hybrid between serial and parallel execution, between goal-driven and data-driven search, and in particular between the symbolic and connectionist paradigms. The Copycat architecture models the fluid representation of concepts and their adaptive application to the active construction of features from perceived data.

One limitation of the Copycat program is that it has only one point of interaction with its environment (the initial exposure to the letter-string analogy problem). There are no means for continuing interaction with the external environment, only an ongoing maturation of the internal structures of the program guided by its own context-sensitive semantic network.

A second limitation of Copycat is the program's restricted domain. The domain structure in Copycat, which facilitates exploration of fluid concepts in high-level perceptual processes, also restricts the interpretations available to the program of its developing representation. For example, the relationships possible between structures in Copycat, like *predecessor*, *successor*, and *opposite*, are derived from abstract ordering relationships in the alphabet. We have extended the program to include richer semantic relationships whose application can continue to evolve throughout the program's interaction with its environment. Related issues, for example, the ability to interactively discern new rules and interpretations from observed behavior, are addressed in the Metacat project (Marshall 1999). By using the ideas from Copycat and Metacat in our own embodied world of the robot, we have begun to address these limitations.

## The Madcat Architecture

The Madcat project explores how an architecture similar to Copycat can be used to detect abstract features of sensory data obtained from an ongoing dialog with the environment. With its three mutually self-maintaining components, the slipnet, workspace and the coderack, the Copycat architecture is an autopoietic system and a starting point for a general model of embodied intelligence. Copycat exhibits the characteristics of an evolving complex adaptive system relying on a subsymbolic dynamical system whose structural coupling supports its representation of a domain. In Madcat the emergence of representational structures is coupled to the environment through system behavior.

The Madcat project extends the Copycat architecture to the control system for a robot, producing a control

architecture capable of ongoing interaction with a dynamic environment. The Madcat robot is a Nomad Super Scout II capable of translational and rotational motion with 6 bump sensors, 16 sonar sensors, and a color vision camera (not incorporated into the current model; see Further Research). This collaboration between Copycat and the Nomad robot produced the project name *Madcat*. The ultimate goal of our research is to construct a robot architecture that, from its emergent exploratory behavior, can build a flexible representation of its environment that improves its real-time performance.

In our research we look for behaviors that can be made more effective by niche models (Clark 1997). We build the individual components of the architecture and their rules to interact with data from the sensors and relationships among that data. The resulting emergent structures are correlated with the events in the environment, such as the passing of a corner. The internal "representations" of these events interact with the control system to produce behavior that is based on that "representation".

For example, we overcome certain sensor limitations in the robot using this emergent representation scheme. The maturation of the representation through interaction with the environment is what makes this feasible for a robot whose motion creates constant change in its sensory data. This evolving representation in the behavior-based framework is an important feature of this model.

Figure 2: The Madcat Architecture

Figure 2 shows the components of the architecture and their relationships. Simple reflex-like behaviors, such as obstacle-avoidance and wall-following, are achieved by instantiations of four basic rules for a given set of readings (called a *snapshot*). These rules are expressed in codelets with high priorities. The coderack is a stochastic priority queue where the choice of the next codelet is made probabilistically with a bias toward the higher urgency codelets. This provides the flexibility to discover alternate possibilities. For further discussion of the importance of randomness in the coderack and elsewhere see (Mitchell

1993). A codelet is just a C++ object containing only one method that is executed when that codelet object is selected from the coderack. The method may initiate robot movement as in reflex behavior, or it may take a new snapshot and launch further codelets to build emergent structures and generate behavior from them.

The workspace serves as the locus of structure-building activity of the codelets from the coderack. Activity in the workspace biases codelet choices in the coderack. The slipnet contains nodes and links that dictate the data to which the codelets respond and the kinds of structures they build. The slipnet topology changes in response to activity in the workspace but its nodes and links remain fixed. The *entropy* reflects how well emergent structures fit into the data the robot encounters and affects the biases of the system. A high entropy inclines the system toward random behavior and perception of different patterns in the data. With low entropy the system gravitates toward the established structures.

The control functions for the robot are made available as C functions that can be linked into developed software. The Madcat architecture itself is implemented in C++. Besides the C-based interface of the robot, the choice of C++ was dictated by the need for real-time behavior. We are building in Java an interface to the architecture that will be used as a development and testing tool.

## The Behavior of Madcat

The first goal of the Madcat architecture was to demonstrate that certain basic competencies, roughly those of Brooks (1991a), could be implemented using this emergent architecture. The chosen behaviors are obstacle avoidance, wandering, and wall-following. Obstacle avoidance is defined as the behavior of moving to avoid a collision. Wandering is defined as the behavior of choosing a random direction of motion when no other particular movement is required. We define wall-following as the behavior of moving approximately parallel to the nearest surface, without necessarily moving nearer to that surface to do so.

In the behavior-based approach of Brooks (1991a) these behaviors would be supported by individual interacting layers, each capable of a particular behavior. In an emergent architecture, such as Madcat, a few simple rules interacting among all the data readings give rise to the appropriate behavior. Instead of layers, an emergent architecture relies on competition between peer behaviors to generate coherent global behavior.

There are four basic rules for responding to the data readings. These have been determined empirically by considering immediate needs of particular elements, as is done in cellular automata for instance. Genetic algorithms, reinforcement learning, or other methods might also be used. For readings that come from the sonar sensors above either wheel the robot should move forward to follow the surfaces which reflected the signals from those sensors. For readings that come from sonar sensors clockwise from

either wheel but not beyond the forward or rear sensors the robot should rotate clockwise to become parallel with the surfaces that reflected the signals from those sensors. An analogous rule holds for readings from those sonar sensors counterclockwise from the wheels. If the robot senses contact from one of the six regions of the bump sensor, then it should back up a small amount and turn away from the region to avoid further contact. When each of these rules is given a priority proportional to the proximity of the readings, the desired three behaviors emerge as a result of the moment by moment interactions of the rules, readings, and features of the environment.

Wall-following can be seen in Figure 3 where the robot moves counterclockwise, turning corners to remain on a course parallel to the nearest wall. Obstacle-avoidance is also demonstrated, as the robot turns in response to surfaces detected in its path. Wandering is subordinate to these first two behaviors and so only appears at the end of the path in the upper left corner.

Figure 3: Obstacle Avoidance, Wandering, and Wall-Following

The second goal of the Madcat architecture is to generate emergent structures correlated with environmental features. These support more effective real-time behavior. For example, the direction choice for wandering can be made more useful if the system has a rough model of what it has already encountered. Random directions can be chosen from among those not yet explored. As another example, consider that the sonar sensors produce the same measurement for all readings below 6 inches, preventing the distinction of a corner from a continuation of a nearby wall. If the system contains structures representing a wall located directly ahead, it may use this information to turn away from the wall with which it would otherwise collide.

At the top of Figure 4 the robot passes a convex corner. *Single Surface Element (SSE)* structures, corresponding to each of the sonar readings taken while traversing this path, are built in the workspace. Bonds can be built between these SSEs according to the relationships in the data. For instance, *Adjacent Equivalence Bonds (AEB)* may be built between SSEs from adjacent sonar sensors if their values are within a certain percentage of each other. *Candidate Surface Bonds (CSB)* tend to be built linking a sequence of AEBs, which might possibly constitute a surface. Bonds built from a single snapshot are only tentative. As the data from successive snapshots continue to bear certain

relationships, bonds based on those become strengthened. The *Maximum Difference Bond (MDB)* identifies the apexes in curved surfaces. These only occur after many snapshots have produced well-established structures. Figure 4 illustrates this process. There is no attempt to maintain a direct spatiotemporal correlation between internal structures and external features; rather the relative importance of the structures dictates the ones to which the robot's behavior responds.

Figure 4: Emergent Structures Form in Response to Environmental Features

Figure 5 shows the robot approaching a wall to which its sensors are blind. The wall to its left is closer than six inches, below which distance the sonar system is unable to make any distinctions. This makes the approaching wall look like a continuation of the wall to the left. However, during the approach, structures will form which reflect the sonar readings of the forward wall. If a CSB is built in time, the robot will notice it when scanning its internal surfaces for discrepancies with the environment. At that point it can choose to turn and avoid the wall based on its internal niche model of the world. This will demonstrate the use of emergent representation to improve real-time behavior. We expect many similar improvements to be possible based on the emergent representation.

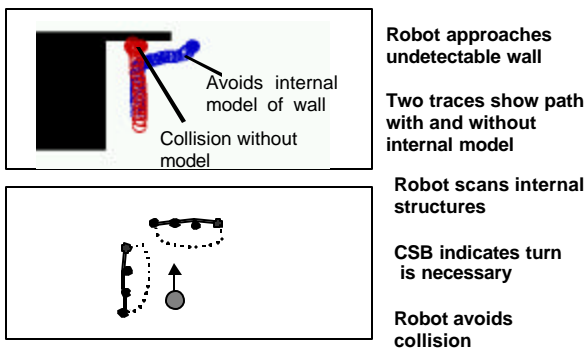

Figure 5: Emergent Structures Aid in Navigation

The role of the slipnet is to provide context-dependence to the competing behaviors in Madcat. For example, consider the creation of an AEB, proposed by some codelet. The comparison of values between adjacent SSEs uses information from the slipnet concerning relative

distances of objects in the current environment to discern how precisely the comparison should be made. When the objects detected are at a greater distance from the robot both trigonometric considerations and reliability of the sensors dictate that a greater difference in readings may still correspond to a single surface. Alternatively, when the robot is near its targets, a small difference between surfaces by adjacent sensors more likely indicates distinct surfaces. As another example, the SSEs between which the AEB will be built are themselves chosen probabilistically with a bias coming from the slipnet's indications of which objects have greatest relevance at that moment. Indeed every time a codelet must choose an object on which to perform an operations (e.g. build a structure around it) the bias for the probabilistic choice is made based on the activation level of the nodes in the slipnet associated with the object and the action of the codelet.

Occasionally, the parallel nature of the architecture will give rise to the proposed construction of an object that conflicts in some way with an existing object (e.g., duplication, overlap, and opposition). As in the Copycat architecture, the choice of whether to veto the construction or destroy the conflicting object and continue is made probabilistically with a bias that comes from information in the slipnet about which kinds of objects are currently more useful to build. This information comes from the context to which the slipnet has been exposed in the preceding moments of the robot's behavior. Indeed at times the priorities implicit in the current arrangement of the slipnet will bias the probabilistic codelet executions so that the system explores otherwise unnoticeable options.

The entropy measure, like the temperature in Copycat, is used as a feedback mechanism for the entire architecture. When entropy of the workspace is calculated, values are obtained from the workspace objects that indicate their relative importance and degree of incorporation into larger structures. The calculation of these values includes the level of activation of the node in the slipnet corresponding to that type of object. So an object whose node in the slipnet has high activation is likely to have greater importance and higher expectation for structure-inclusion. Thus, even the self-organizing feedback in the system is mediated by the context-driven relevance of the concepts in the system. Information in the slipnet about relative priorities of certain kinds of structures and actions can be used to select or restrict entire classes of behavior.

The slipnet captures this context information through its interactions with the workspace and the codelets. When a codelet successfully builds a structure in the workspace, the slipnet node which originated that codelet gets a boost of activation. That activation spreads to neighboring nodes in the slipnet as a function of the length of the link between them. Thus, related nodes also get some additional activation. As the activation of a node goes up, so does its chances of emitting codelets designed to explore the possibility of building structures in the workspace based on the concept represented by that node. Activation decays in the slipnet so that over time, if no new

objects of a given type are being built, then codelets stop being produced to look for them. Of course there is a certain low probability for generating any type of codelet so the system never stops discovering new possibilities. The mechanisms of the slipnet capture the priorities indicated from the context of recent interaction of the environment and drive the decisions in the entire system.

### Further Research

There are two specific areas of further development. The first is to use the internal models of environmental features to augment visual decomposition algorithms used with the color vision camera. The worm algorithm (McGonigle 1998) is commonly used, but it is easily misled. The presence of sonar edges in the internal model can help to corroborate edges found by a variant of the worm algorithm. This kind of synthesis is important in the intelligence of living organisms. We would like to build models with this capacity.

The second extension to our research is related to the idea that events in the environment enable certain behavior sets and disable others. We would like to model the sudden shift of priorities and behaviors in a system in response to events in the environment. Certain colors detected by the camera act as triggers for the system. When these occur, changes in the links in the slipnet and the priorities of codelets occur which override the bias to explore and complete internal models in favor of seeking out a resource or avoiding danger.

### Conclusion

We offer both a definition and an instantiation of intelligent problem solving in robotics based in evolving complex adaptive systems. We refine the behavior-based approach to robotics by requiring that representation, redefined as the emergence of structures coupled to the environment through behavior, be given greater focus. We believe that the four issues of embodiment, emergence, symbolic behavior, and representation will be very important in the challenging task of understanding intelligent activity in changing problem domains.

We have demonstrated the feasibility of an emergent architecture in solving simple robotics problems. We have demonstrated that emergent structures in an embodied architecture can be behaviorally correlated to features of the environment, producing niche models useful for generating adaptive behavior. Work is underway using this architecture for improved visual decomposition algorithms and environmentally triggered behavior shifts.

## Abstract

The present studies explored children's representations of motion verbs first, in an elicited production study using point-light displays (lights attached to the joints of the human body) and then in a language comprehension task using the Intermodal Preferential Looking Paradigm (IPLP). Results indicated that children indeed ascribe meanings to the portrayals of actions in point-light displays. When children could not spontaneously produce the actual verb for an action, they used either a more specific or a more general familiar verb that was considered appropriate by adults. These findings suggest that even by the age of 3, children's representations of the actions that verbs label are amazingly abstract. This is the first set of studies to probe the nature of children's verb representations under circumstances where the portrayal of the action is stripped of an apparent agent, a location, instruments, or in some cases, the objects ordinarily required in transitive actions (e.g., a shovel in shoveling). Using point-light displays provides the field with a methodological tool for exploring the components of verb representation in both children and adults and for investigating children's verb acquisition.

## Introduction

The purpose of this paper is to take a closer look at verb representations and to examine the question of how 3-year-olds, who already know many verbs, extend familiar verbs to novel events depicted in point-light displays. To extend a verb to a point-light action, children must activate their action representations and map the patterns of light sequences to their verb representations. The use of point-light stimuli provides a stringent test of children's motion verb representations due to the removal of context.

Considering that the semantic structure of verbs provides a kind of conceptual frame for constructing larger linguistic units such as phrases and sentences, verb learning is of central importance for young language learners. Since motion words are among children's first words (e.g., Bloom, 1993; Smith & Sachs, 1990), two essential questions are

whether children can successfully form word-action mappings and how they extend an action verb.

Research has found that infants are keenly aware of movement and can use movement to individuate objects and actions (Sharon & Wynn, 1997; Spelke, Katz, Purcell, Ehrlich, 1994). There is also evidence that 18-month-olds can distinguish the causal actions of push and pull and map novel words to these actions after limited exposure to the word-action pairs (Casasola & Cohen, in press). However, it is not clear what perceptual cues children use to form word-action mappings and how they decontextualize the use of verbs to successfully extend verb labels to the actions they witness. For example, how do children understand that the word "jump" refers to a category of jumping motions that include different kinds of jumps made by the same actor (e.g., Elmo jumping off tables and chairs), and the same action performed by different actors (e.g., Elmo or Lala jumping off the chair)?

One line of research suggests that children use lexical principles to narrow down the possible meanings of words (Golinkoff, Mervis, & Hirsh-Pasek, 1994). According to Golinkoff, Mervis, Hirsh-Pasek, Frawley, and Parillo (1995), lexical principles guide children to learn not only object nouns but also action verbs. For example, the "principle of extendibility" posits that nouns not only label the original exemplar but a category of objects of "like kind." When transferred to the acquisition of action verbs, this principle states that an action verb, like a label learned for an object, can be extended to more than just the original action. Yet, what is the basis for verb extension?

Golinkoff et al. (1995) suggested that shape, or the overall motion configuration of the action, may provide a basis for children's verb extension. The shape of an action can be primarily affected by the path of motion (horizontal vs. vertical such as walking versus jumping), the involvement of arms and/or legs, and the type of instruments, if any, involved in the action. With respect to nouns, shape provides important information about the function and categorical membership of an object and serves as an

important basis for object noun extension (Landau, Smith, & Jones, 1998). It is quite likely that, when no other information is accessible, the shape of an action will provide defining information about the event, as “many verbs of motion have ... a typical appearance, a physiognomy” (Marconi, p. 159). This typical appearance of action may represent what Pinker (1989) labeled the “shape” of an event, and provide the basis of children’s verb extension. In fact, certain semantic factors such as MANNER, PATH, and CONVEYANCE, seem to be embedded in the “shape” of an event (Talmy, 1985). By attending to the overall shape or configuration of an action, children may ignore the context details of the individual event and construe the semantic invariant that a verb encodes. This would result in a more abstract and flexible representation of the action to which a particular verb can be mapped. For example, while the particular individual or object is not necessarily a part of the meaning of the verb FALL, the so-called shape of downward trajectory does represent the core, typical appearance of the action “falling.”

The claim that shape serves as an important basis for verb extension is in accord with Gibson’s (1966) view that in perceiving events we detect the “invariants” that persist from one event to another of the same type. The overall configuration of an action may be an invariant of the event. This claim is equally in line with Mandler (1992) who argues that events are stored as “image schemas” or “dynamic analog representations” abstracted from children’s interpretations of the spatial relations between objects. These meaningful image schemas help reduce the infinitely varying perceptual displays into a limited number of meaningful concepts that can be described by words.

Here we argue that children may use the “shape” of an action that loosely represents the invariant cues from one action to another as a basis for verb extension. It should be noted, however, that in using terms such as “invariant,” we are not assuming that the representations themselves are fixed and rigid. On the contrary, we posit that the shape of an action is a prototypical representation that is flexible enough to include actions that are similar to, but do not exactly match the original exemplar in terms of, say, the agent and location.

Point-light displays were first used to study adults' event perception and biomechanical motion by attaching small lights to the head and main joints of an individual’s body and filming the person performing different actions against a dark background (Johansson, 1973). Because point-light displays are deprived of detailed contextual information such as the agent and location of an event, the information about an action given in such displays is expressed in the overall shapes of the light sequences. Previous studies using these moving light displays with infants and adults demonstrate the significance of prior knowledge in the perception of biomechanical point-light images (Bertenthal, 1993). For example, while 5-month-old infants can discriminate between a point-light walker shown in an

upright versus upside-down orientation, 3-month-olds do not demonstrate this sensitivity (Bertenthal, 1993). Thus, whether children can identify the actions depicted in point-light displays based on their previous experience provides a strong test of the hypothesis that toddlers use abstract, shape-based event representations to extend familiar motion verb labels. Research has found that 3-year-olds use many motion verbs, we therefore first investigated 3-year-olds' ability to identify point-light depictions of human actions.

## Experiment 1

This study explored 3-year-olds' ability to spontaneously produce a label for an action depicted in point-light displays. Since children do not encounter point-light displays in everyday life, to successfully complete this task, children must perceive the patterns of lights as meaningful action sequences, activate their verb representations for these actions, and ascribe meanings to these point-light sequences.

### Method

#### Participants

Thirty-eight children participated in the study. The final sample had 29 children, 16 boys and 13 girls, mean age = 3 years 7 months. Nine children were excluded from the data because 3 failed to produce a description for more than 3 of the actions and 6 either refused to talk to did not finish the study.

**Stimulus Videotapes** Biomechanical displays of motion verbs were created by videotaping a person in action with light-emitting diodes (LEDs) affixed to the major joints of the body (ankles, knees, hips, wrists, elbows, shoulders). These displays consisted only of a collection of white dots moving across a black screen. Figure 1 provides an example of a person walking, translated into frozen still images of point lights.

Figure 1: Canonical Point-light Walker

Each of the 8 actions was performed continuously for 3 seconds and repeated 4 times so that each action was

displayed for 12 seconds, followed by 5-second blank tape (Table 1). The actions were randomly ordered into two different sequences. To familiarize subjects with point-light displays, a point-light depicted cat walking from right to left on the screen was presented first.

### Procedure

The child sat on the parent's lap in front of a 32" TV. The parent was told not to say anything. Then the experimenter told the child they were about to see a fun videotape and would be asked to tell what they saw. After the cat display, the experimenter paused the VCR and prompted the child three times for a label for the action. If the child only produced an object label, such as "a cat" or "a doggie," the experimenter would probe again, "What was the cat/doggie doing?" If the child produced an unrelated answer such as "dots" or "snow," the experimenter would label the cat for the child and encourage the child to label the action. If the child did not produce an action label after being probed twice, the experimenter would produce the label, "Was the cat walking?" The same procedure was then repeated for each of the human actions except that the experimenter did NOT produce any description for the human action. If the child failed to produce a description for a human action after being probed twice, the experimenter went on to the next action. The experimenter made neutral comments as a response.

Table 1: Descriptions of the Actions in Point-light Displays

- \*Walking: Person walking.
- \*Dancing: Person twisting in place.
- Shoveling: Person bending at the waist and standing back up (without moving legs) as if shoveling snow.
- Picking flowers: Person bending at the waist and standing back up (without moving legs) as if picking up flowers from the ground and then putting them back in a handheld basket.
- \*Rolling: Person performing a somersault.
- \*Running: Person running.
- \*Skipping: Person skipping.
- \*Hopping: Person hopping on one foot.

\* Person moves diagonally from top left corner to bottom right corner across the screen.

**Data coding** Children's productions were divided into two groups: relevant vs. irrelevant. Words or phrases that did not indicate any motion were considered irrelevant, such as "have no feet." The rest were considered relevant. A group of college students (n = 15) were asked to rank the appropriateness of each relevant response on a 1-7 Likert scale after seeing each action in the point-light displays in the same way as children did.

Children produced a total of 110 different descriptions for the 8 actions. After eliminating 7 irrelevant answers and

combining 25 relevant answers by ignoring verb objects (i.e., "picking up snowballs" and "picking up stuff" were considered the same), there were 78 responses left. Each action had a range of 4-15 responses from children. These were listed on the ranking sheet. To examine the consistency of adults' ranking, 77 responses were used as foils for each other (the response "moving" was excluded as too general). The foils were distributed in ranking sheet for each action such that if adults were consistent in their ranking, these foils would receive on average lower rankings than the non-foils. The proportion of actual responses and foils for each action was 1:1, resulting in a total number of 154 responses for the 8 actions on the ranking sheet.

Table 2. Number of Children Who Gave Highly Appropriate Responses (standard deviation in parentheses)

Action	# of Children <sup>1</sup> /Total <sup>2</sup>	Mean Rating (>=5) <sup>3</sup>	Mean Rating (all responses)
rolling	10 / 25	6.33 (.70)	3.87 (2.00)
dancing	15 / 28	6.91 (.57)	3.17 (2.14)
picking flowers	10 / 25	6.41 (.68)	4.31 (2.22)
running	18 / 27	6.74 (.07)	4.65 (2.56)
walking	26 / 29	6.97 (.28)	4.77 (2.63)
hopping	16 / 27	6.78 (.70)	4.10 (2.42)
skipping	6 / 25	6.74 (.42)	3.46 (1.72)
shoveling	3 / 19	5.80 (.58)	2.69 (2.13)

1. Number of children who gave highly appropriate responses.
2. Total number of children who gave responses. Note that some children did not give responses for some actions.
3. Average rating for the highly appropriately responses.

### Results

Overall, most children produced labels for all actions after one prompt. Adults' rating for children's actual responses (M = 3.80, SD = 2.10) were significantly lower than for the foils (M = 1.45, SD = .84),  $F(1, 155) = 84, p < .001$ . Based on the adults' ratings, on average children's responses for most of the actions were considered appropriate (Table 2). Furthermore, 58% of children's responses were considered very appropriate (M = 6.73, SD = .58. All ratings greater than or equal to 5 were considered very appropriate). There was a significant correlation between the number of children who produced highly appropriate responses and adults' appropriateness rating of those responses,  $r = .36, p = .001$ , suggesting that the more appropriate a response was, the more children gave that response. However, few appropriate answers were given for the actions SKIPPING

and SHOVELING. Ten children were unable to produce a label for SHOVELING and 4 failed to produce a label for SKIPPING. The majority of others described SHOVELING as “dancing” or “exercising;” and SKIPPING as “running,” “jumping” and “walking.”

## Discussion

Findings of this study suggest that 3-year-olds can indeed perceive the abstract images depicted in point-light displays as meaningful actions based on the patterns of light sequences. Overall, 77% of the children produced responses for all actions. Given that these children had never been exposed to point-light displays, they must access abstract verb representations in order to identify these contextually bare actions. However, omission of objects in point-light displays might have increased the difficulty of identifying actions involving instruments, such as SHOVELING. In addition, some children's descriptions of SKIPPING overlapped with their description of WALKING and RUNNING, the overall shape of which are similar but for the differences in the movement of arms and legs. This interestingly indicates children's reliance on the overall configurations of these actions. Perhaps this problem, too, was caused by the nature of spontaneous production, a demanding task. Additional data of action labeling from 5 adults (100% correct) suggest that correct verbs can be produced for these abstract point-light displays. If children indeed possess abstract, shape-based verb representations and point-light displays can capture the properties of these actions, children should be able to map a familiar verb to these actions in a less demanding task.

## Experiment 2

The purpose of this study was to determine whether 3-year-old children could correctly extend familiar verbs to actions depicted in point-light displays in a comprehension task.

## Method

### Participants

Children's comprehension of at least 7 out of the 8 action verbs was confirmed with parents on phone calls. Out of the final sample of 32 subjects (44 were tested), 15 did not understand “skipping” and 3 did not understand “shoveling.” The age selected for testing was determined empirically from these phone. The final sample had 19 boys and 13 girls, age range from 2;11 to 3;2, mean age = 3;1.

**Stimulus videotapes** Two separate tapes were created, each containing half of the actions, paired in length and number of frames. The pairs of actions were created such that the lights appearing in the displays were balanced for size, number, brightness, and movement to ensure that each pair of actions was equally salient to children (Table 3). A female speaker recorded the linguistic stimuli in infant-

directed speech for all trials, as well as between the trials, on one track of the videotape.

### Procedure

Children were tested in the Intermodal Preferential Looking Paradigm (Hirsh-Pasek & Golinkoff, 1996). The child sat on the parent's lap in front of two 19" TV monitors. The videotapes were played in complete synchrony, accompanied by the linguistic stimuli which emanated from the center of the two monitors.

**Familiarization trial** The study began with a brief, 6-second trial during which a point-light display of a cat walking across the screen appeared simultaneously on both monitors for 6 seconds. The cat and its action (i.e., “See the cat walking!”) were labeled to give children some familiarity with interpreting the contents of these motion-specified stimuli.

**Salience trials** Two salience trials followed during which a pair of actions appeared simultaneously on both screens, one action on the left monitor and another on the right. Salience trials had three purposes: First, they showed children that contrasting events could appear on both screens at the same time. Second, they were used to calculate stimulus salience. Finally, they provided exposure to the names of the actions without telling children which screen either action was on, e.g., “Hey, one is walking and one is dancing!” Thus, children were directed to watch both screens.

**Test trials** Two test trials followed to see if the child could distinguish between the displays and successfully choose the action that matched the linguistic stimulus. Now the child was exhorted to watch the screen containing the labeled verb, e.g., “Look at dancing! See dancing?” The target action appeared on the same screen side for both test trials in a block, the same side as the two preceding salience trials.

**Intertrial intervals** Each trial was separated by a 3-second intertrial interval during which both screens went blank. A red light mounted centrally between the two televisions lit up during this time to attract children's attention to the center, off the screens. This practice ensured that children would not just remain on one screen for long periods of time, but would have to choose which screen to look at for each trial. The appropriate linguistic stimulus for the trial to follow was first heard during the intertrial interval, so that prior to each test trial, the child was directed to find the matching screen (e.g., “Can you find dancing?”).

**Apparatus and Data Coding** All equipment – except for the two 19" color monitors – was shielded from the child's view. The videotapes were shown on 3/4" video decks. A 1 KHz tone was recorded for the duration of each trial on the

second, inaudible channel of the videotape and was “read” by a specially designed tone decoder which functioned in two ways: 1) it turned the centrally-mounted red light on during the intertrial intervals, and off during the trials; and 2) it signalled the beginning and end of each trial to the computer (a PC computer).

**Dependent and Counterbalanced Variables** The dependent variable was the mean visual fixation time to the named action (the match) versus to the foil (the non-match) during each pair of the test trials. For each test trial, visual fixation time was collected starting during the intertrial interval from the point at which a child watched the center light for .3 seconds or more. Coding began during the intertrial interval because if a child failed to reach the .3 second intertrial interval criterion on a trial, that trial was not included in the data analysis (this occurred on only 5 trials, or 2% of the time). When a child missed a trial, his or her overall visual fixation mean to the match and non-match across the remaining test trials was substituted in that cell. Thus, each child contributed 8 data points to the analysis: the mean visual fixation time to the match and to the non-match for each of 4 pairs of test trials.

Four factors relating to order of stimulus presentation were counterbalanced across subjects: 1) the number of matches on a screen side; 2) the order of the matches; 3) the order of the two actions mentioned during the salience trial; and 4) the member of a verb pair labeled as the match.

## Results

Comparison of mean visual fixation times during the salience trials in the three-way mixed ANOVA (sex (2) X verb pair (4) X match versus non-match (2)) suggested that there were no a priori preferences for one action or another in any pair (Table 3). However, a significant difference was found between the mean visual fixation time to the match ( $M = 3.36$ ,  $SD = 1.85$ ) vs. the nonmatch ( $M = 2.29$ ,  $SD = 1.44$ ) during the test trials,  $F(1,3) = 48.81$ ,  $p < .01$ . This effect was carried by the vast majority of children. Out of 32 subjects, 29 or 91% had mean visual fixation times in favor of the match for all of the four verb pairs.

## Discussion

When the motion-specified point-light images were presented in the IPLP (Hirsh-Pasek & Golinkoff, 1996), children who were 6 months younger than those in Experiment 1 demonstrated extension of all familiar verbs by watching the screen that matched the requested verb more than the nonmatch screen. Apparently, children could attend to the differences between the actions depicted in point-light displays in a comprehension task. Children could even map verbs to actions with which they were not familiar, such as SKIPPING. Perhaps their recognition of the unfamiliar verb was due to their successful mapping of a familiar verb to a familiar action presented as a comparison

in the IPLP. These results provided evidence that the combination of point-light displays and IPLP could be a powerful and sensitive tool to investigate children’s motion verb representations.

Table 3 Mean visual fixation times (in seconds) to the four stimulus pairs during salience and test trials (M = Match; NM = Non-match)

Verb pairs*	Saliency Trials	Test Trials**
	M (SD)	M (SD)
	NM (SD)	NM (SD)
Walking vs. Dancing	2.74 (1.46)	3.67 (2.29)
	2.82 (1.55)	2.22 (1.20)
Picking flowers vs. Shoveling	2.49 (1.15)	3.31 (1.69)
	2.84 (1.29)	2.37 (1.50)
Running vs. Rolling	2.39 (1.05)	3.40 (1.87)
	2.71 (1.18)	2.17 (1.37)
Skipping vs. Hopping	2.73 (1.49)	3.16 (1.56)
	2.53 (1.46)	2.05 (1.71)

\*The verb requested in each pair (i.e. match) was counterbalanced.

\*\* The match was watched more than the non-match for all test trials,  $p < .05$ .

## General Discussion

The purpose of these studies was to determine whether 3-year-olds could correctly extend familiar verbs to actions depicted in point-light displays. Experiment 1 found a majority of 3-year-olds could accurately identify the actions depicted in point-light displays. When children could not produce an accurate label for the point-light actions, they often used familiar verbs for actions that had similar overall shape to the target action. More than half of children’s responses (58%) were considered very appropriate by adults. Experiment 2 found that children who had just turned 3 could recognize all of the actions in the Intermodal Preferential Looking Paradigm (Hirsh-Pasek & Golinkoff, 1996), suggesting that the overall shape of an action could be a reliable basis for motion verb extension.

This is the first set of studies to suggest that young children can identify dynamic, complex events depicted in point-light displays and extend familiar verbs to the actions embedded in these events. Previous research focused on infants’ discrimination of familiar and unfamiliar biomechanical images (Bertenthal, 1993), and adults’ recognition of the familiarity and gender of a point-light walker (Kozlowski & Cutting, 1977). No work, however, had assessed the utility of these displays with young

children, let alone combining the stimuli with a language task. Point-light displays, which permit the use of dynamic events and contain so little contextual information, could serve as a critical tool to probe children's verb representations. Since the only available information in such abstract images was the "shape" of events, or an action's overall motion configuration, children's success in identifying these actions suggests that shape may be an important component of children's motion verb representations that guides motion verb extension.

We are not implying that children rely only on shape for motion verb extension. However, without disputing children's use of other complex verb learning processes (e.g., syntactic analysis), we underscore the flexibility of children's motion verb representations and the demonstration of their productive reliance on shape as one cue for the extension and categorization of motion verbs.

It is also important to note not all verb types can be illustrated through point-light displays. Verbs such as "see" or "think," for example, cannot be easily depicted through movie sequences, while motion verbs are ideal. Nonetheless, since motion verbs are generally among the first verbs acquired, future research employing these images may help uncover how early verb categories develop. Given that these contextually deprived displays can make contact with motion representations held by infants as young as 5 months, and that the children in this study could map a verb correctly to one of two choices, it appears that these stimuli could be used with older infants and children as well. Investigators could examine at what point young language learners are able to attach verb labels to these abstract images, and more specifically, when "shape" becomes a meaningful cue for extending novel verbs and forming motion verb categories. These types of research efforts can bring the critical study of verbs to the foreground, and help advance the understanding of fundamental verb learning processes that have for too long been neglected.

# Learning at Different Levels of Abstraction

Bradley C. Love

## Abstract

Previous category learning research and the SUSTAIN (Supervised and Unsupervised STRatified Adaptive Incremental Network) model of category learning suggest that preferred category level (in a hierarchy of categories) shifts towards lower-level (i.e., more specific) categories when stimuli are perceived to be more distinctive. This shift is in accord with work in expertise. In their domain of expertise, experts excel (relative to novices) at classifying stimuli at lower category levels, but their advantage is attenuated with higher-level categories. The work described here directly tests (within a single study) this predicted interaction between category level and stimulus distinctiveness using well controlled artificial stimuli. The results are consistent with prior work utilizing natural stimuli. The results are also informative for evaluating whether attention is dimension-wide (i.e., all items are represented in a common multi-dimensional space of the same extent) or cluster specific (i.e., different conceptual clusters can stress different stimulus dimensions so that different aspects of different stimuli are stressed). The results suggest that attention is not dimension-wide. Instead, attention can stress different aspects of different stimuli. The implications of these findings for models of category learning are discussed.

## Introduction

Humans frequently utilize and acquire category knowledge at multiple levels of abstraction. For example, the same object can be classified as a vehicle, as a car, or as a 1978 Lincoln Continental. Rosch, Mervis, Gray, Johnson, and Boyes-Braem (1976) argue that objects are most easily classified at the intermediate category level which most effectively partitions the world into informative clusters. However, Tanaka and Taylor (1991) have found that different groups of people tend to prefer different levels of abstraction with experts preferring lower-level categories (i.e., narrower or finer grained categories) compared to novices who prefer higher-level categories (i.e., broader or more abstract categories).

One domain in which all adult humans are experts is the domain of face perception. Medin, Dewey, and Murphy (1983) found that people are faster to associate unique names to photographs of nine female faces than they are to categorize the photographs into two categories. The logical structure of the two categories is shown in Table 1. One possible explanation for the relative ease of identification learning is that the stimuli used in Medin et al. (1983) were rich and distinct, varying along many dimensions not listed in Table 1, such as the shape of the face, the type of nose, etc.. This *idiosyncratic* information makes each stimulus item more dis-

Table 1: The logical structure of the two categories used in the category learning condition. The four dimensions were hair color, smile type, hair length, and shirt color.

tinct. Experts may be more sensitive to idiosyncratic information than novices. In the absence of idiosyncratic information, common wisdom holds that identification learning should be harder than category learning. In other words, the ease of category acquisition interacts with the nature of the stimuli such that learning at lower levels of abstraction (with identification learning being the lowest level of abstraction) becomes easier relative to learning at higher levels of abstraction as stimuli become more distinct.

Results from the category learning literature support this conclusion. Shepard, Hovland, and Jenkins (1961) trained subjects on the six category learning problems listed in Table 2 and found that Type I was the easiest to master, followed by Type II, followed by Types III-V, followed by Type VI. The Type IV problem has a family resemblance structure that resembles the category structure used in Medin et al. (1983). In the Type IV problem, each category consists of an underlying prototype (111 for category “A” and 222 for category “B”) and any item that matches a prototype on two out of three dimensions is a member of the corresponding category. The more difficult to master Type VI problem, while not an identification learning problem, requires subjects to memorize all eight stimulus items because no regularities exist across any pair of dimensions. This data, along with Medin et al.’s (1983) data, suggest that preferred category level and stimulus distinctiveness interact with learning being facilitated more at lower category levels with distinctive stimuli.

One category learning model can capture this interaction. SUSTAIN (Supervised and Unsupervised STRatified Adaptive Incremental Network) has successfully fit Shepard et al.’s (1961) and Medin et al.’s (1983) data using the same set of

Table 2: The logical structure of the six classification problems tested in Shepard et al. (1961). The three binary valued dimensions correspond to size (small or large), shape (triangle or square), and color (light or dark)

Input	I	II	III	IV	V	VI
111	A	A	B	A	B	B
112	A	A	B	A	B	A
121	A	B	B	A	B	A
122	A	B	A	B	A	B
211	B	B	A	A	A	A
212	B	B	B	B	A	B

222	B	A	A	B	B	A

parameters (Love & Medin, 1998a; Love & Medin, 1998b).<sup>1</sup> SUSTAIN is a connectionist model that clusters similar items together. When items are clustered together inappropriately (i.e., similar items from incompatible categories are placed in the same cluster), SUSTAIN adds a new cluster in memory to encode the misclassified item. For example, if SUSTAIN is applied to stimulus items and classifies them as members of the category mammals or the category birds it will develop one or more clusters (i.e., prototypes) for the bird category and one or more clusters for the mammal category. When SUSTAIN classifies a bat for the first time, the bat item will strongly activate a bird cluster because bats are similar to birds (both bats and birds are small, have wings, and fly). After incorrectly classifying the bat as a bird, SUSTAIN will create a new cluster to encode the misclassified bat item. The next time SUSTAIN classifies a bat, this new cluster will compete with the other clusters and will be the most strongly activated cluster (i.e., it will be more similar to the current stimulus than any other cluster), leading SUSTAIN to correctly classify the novel bat as a mammal and not as a bird. The new cluster would then become a bat prototype (a subcategory of mammal). The primary difference between SUSTAIN and exemplar models is that SUSTAIN can cluster examples together in memory (like a prototype model). Unlike a prototype model, SUSTAIN can form multiple clusters (i.e., prototypes) per category.

When applied to Shepard et al.’s data, SUSTAIN recruits fewer clusters for the simpler problems. For the simplest problem, the Type I problem, SUSTAIN only recruits two clusters (one for each category). For the most difficult problem, the Type VI problem, SUSTAIN resorts to recruiting eight clusters (one for each item; each stimulus is memorized). When applied to Medin et al.’s (1983) data, SUSTAIN recruits more clusters (nine clusters; one for each stimulus item) in identification learning condition than in the category learning condition (the modal solution involves seven clusters). It is important to note that abstraction does not occur in the identification learning condition (i.e., each cluster

responds to only one item), but does occur in the category learning condition. What is interesting about these data fits is that in one case memorizing more items (acquiring more fine grained clusters or subcategories) led to more efficient learning, while in the other case it led to less efficient learning. The critical difference between these two data sets is the distinctiveness of the stimuli.

Two factors conspire to cause SUSTAIN’s performance to interact with the nature of the stimuli. As the stimuli become more distinctive, clusters that respond to multiple items (i.e., prototypes) are not as strongly activated. In other words, the benefit of abstraction is diminished with distinctive stimuli. This occurs because distinctive items sharing a cluster are not very similar to each other (i.e., within cluster similarity is low). Notice that the diminished benefit of abstraction negatively impacts performance in the Medin et al.’s (1983) category learning condition, but does not affect identification learning. In identification learning, each item forms its own cluster (within cluster similarity is maximal). When SUSTAIN is altered so that it does not form abstractions in either condition, but instead recruits a subcategory unit for each item, SUSTAIN fails to predict the interaction or the identification learning advantage, suggesting that abstraction is critical for capturing this effect. Without abstraction, the inferred category structures (i.e., the clusters recruited) are identical for both conditions.

The second factor that leads SUSTAIN to predict that distinctiveness and category level should interact is that the effects of cluster competition are attenuated with distinctive stimuli. As items become more distinctive, the clusters that are recruited tend to be further separated in representational space (i.e., the clusters match on fewer dimensions and mismatch on more dimensions). In other words, the clusters become more orthogonal to one another. The more distinctive the clusters are, the less they will tend to compete with one another. For instance, when a distinctive stimulus is presented to SUSTAIN, it will tend to strongly activate the appropriate cluster and will only weakly activate the competing clusters. Reduced cluster competition with distinctive stimuli favors both identification and category learning, but differentially benefits identification learning (or more broadly, learning at lower levels of abstraction) because there are generally more clusters present (i.e., potential competitors) in identification learning. Simulations support this analysis. When SUSTAIN is modified so that clusters do not compete, SUSTAIN reaches criterion more often and overall accuracy is much higher in the category learning condition.

## Experiment

SUSTAIN’s ability to fit Medin et al.’s studies on item and category learning is notable because other models cannot predict the advantage for identification learning or the interaction between learning task and stimulus distinctiveness. More importantly, SUSTAIN offers a framework for understanding the results. At the same time, it seems impor-

<sup>1</sup>The data actually fit was from Nosofsky et al.’s (1994) replication of Shepard et al. (1961).

tant to place SUSTAIN's account of these findings on firmer ground. To begin with, one should be cautious about accepting SUSTAIN's characterization of Medin et al.'s (1983) results. SUSTAIN's successful fit of Medin et al.'s (1983) studies depended on the choice of input representation. The idiosyncratic information in each photograph was represented by adding a number of input dimensions. Each item had a unique value on each added dimension. This manipulation had the effect of making all the items less similar to each other and making between and within category similarity virtually the same in the category learning condition. This input representation led SUSTAIN to predict that identification learning should precede category learning with distinctive stimuli.

The general intuition that guided my choice of input representation seems justified. Unlike artificial stimuli, the photographs do vary along a number of dimensions. Still, replicating the results from Medin et al. (1983) under more controlled circumstances with artificial stimuli would bolster my claims. Also, it is possible that there may be something "special" about faces (c.f., Farah, 1992).

The stimuli used in the Experiment were schematic cars that varied on a few dimensions. Like the Medin et al.'s (1983) study, subjects were assigned to either an identification or a category learning task. To manipulate the distinctiveness of the stimuli, some subjects viewed stimuli that were uniquely colored, while other subjects viewed stimuli that shared a common color. In essence, this experiment augments Medin et al.'s (1983) design with two non-distinctive stimuli conditions. The key prediction SUSTAIN makes is that category level and distinctiveness should interact such that identification learning performance should improve more than category learning performance as the stimuli become more distinctive. The choice of stimuli in this experiment directly tests SUSTAIN's characterization of the Medin et al. (1983) results.

Unfortunately, whether or not the interaction crosses over (i.e., whether or not identification learning with distinctive stimuli turns out to be faster than category learning with distinctive stimuli) cannot be predicted by SUSTAIN because the size of the effect depends on the saliency of the color dimension (the distinctive dimension). A crossover interaction can be accommodated by SUSTAIN, but is problematic for many other models.

The Experiment's design also allows for a secondary prediction to be tested related to cluster encoding and attention. When clusters only respond strongly to one item (i.e., "exception" clusters), does the cluster focus on the distinctive item information? Conversely, when a cluster encodes a number of items (i.e., an "abstraction" or "rule" cluster), does the cluster focus on what is general to the items and suppress distinctive item information? If the answer to both of these questions is "yes", the results would strongly suggest that attention is not dimension-wide (e.g., Nosofsky, 1986; Kruschke, 1992), but is cluster specific (c.f., Aha & Goldstone, 1992). In other words, different clusters can attend to different stimulus di-

Figure 1: The stimuli varied in size (small or large), the number of wheels (two or three) and the shape of the cockpit (rounded or boxy shaped). Only one car size is shown in the figure. In the Experiment, eight different items were used.

mensions.

## Methods

**Subjects** Two hundred eighty-eight Northwestern University undergraduate students participated in the experiment for course credit or pay.

**Stimuli** Example stimuli are shown in Figure 1. In two of the four experimental conditions, each car was a different color. The eight colors were yellow, light blue, black, red, navy blue, pink, green, and grey. In the two other conditions, subjects viewed cars that were all the same color (either yellow, light blue, black, red, navy blue, pink, green, or grey).

**Design and Overview** The two variables (category level and distinctiveness) were crossed for a 2 X 2 between subjects factorial design. Subjects were randomly assigned to one of these four conditions.

The category level variable had two levels: identification learning and category learning. Subjects performing the identification learning task partitioned the eight items into eight categories (i.e., each stimulus formed its own category). Subjects performing the category learning task partitioned the eight items into two categories that had the same logical structure as Shepard et al.'s (1961) Type IV problem (see Table 2).

The distinctiveness variable had two levels: distinctive and non-distinctive. In the distinctive conditions, each item was a unique color. In the non-distinctive conditions, each item shared a common color. The learning phase ended when subjects completed consecutive error-free blocks of trials or after the completion of thirty-second block (each stimulus was presented in a random order once per block).

After completing the learning phase, sixty-six subjects completed two transfer blocks. Transfer trials were identical to learning trials with the exceptions that feedback was not provided and that each item was colored orange (a color not used during the learning phase).

## Procedure

Text was displayed in black on a white background. Trials began with a message displayed in the upper left corner of the screen alerting the subject to prepare for the next trial. After 1500 ms, this message was removed and the stimulus was displayed along with a message below it indicating that the subject should respond. Subjects were instructed to push the spacebar as soon as they decided on a response. After pressing the spacebar, subjects were prompted for their response. Subjects pressed either the “A” or “B” key in the category learning conditions. In the identification learning conditions, subjects used keys “A” through “H” to indicate their response. After responding, subjects received feedback. When subjects were correct, the message “Correct!” was displayed at the bottom of the screen. When subjects were incorrect, a message alerted the subject to the error and the correct response was displayed at the bottom of the screen. Following the subject’s response, the stimulus and all messages were displayed for 1500 ms. After another 1500 ms, the next trial began.

On transfer trials, text was displayed in black on a white background. Trials began with a message displayed in the upper left corner of the screen alerting the subject to prepare for the next trial. After 1500 ms, this message was removed and the stimulus was displayed along with a message below it indicating that the subject should respond. Subjects were instructed to push the spacebar as soon as they decided on a response. After pressing the spacebar, subjects were prompted for their response. Subjects pressed either the “A” or “B” key in the category learning conditions. In the identification learning conditions, subjects used keys “A” through “H” to indicate their response. Subjects did not receive feedback. Whether or not the subject responded correctly, the message “Thank You” was displayed. Following the subject’s response, the stimulus and all messages were displayed for 1500 ms. After 1500 ms, the next trial began. All possible factors were counterbalanced or randomly varied.

## Results

**Criterion** The mean of the number of blocks required by subjects in each condition is shown in Table 3. Table 3 also shows the mean of the reciprocal of the number of blocks required (this measure is less sensitive to outliers). A 2 X 2 (category level by distinctiveness) ANOVA was performed on both the untransformed scores and the transformed reciprocal scores. The transformed scores’ distributions were more similar to the normal distribution than were the distributions of the untransformed scores. Means are given only for the untransformed scores. Subjects required more blocks (14.5 vs. 12.9 blocks) in the category learning conditions than in the identification learning conditions (untransformed:  $F(1,218)=3.65$ ,  $MSe=140.5$ ,  $p=.06$ ; transformed:  $F(1,218)=4.40$ ,  $MSe=.00608$ ,  $p<.05$ ). Subjects required more blocks (17.0 vs. 10.5 blocks) in the non-distinctive conditions than in the distinctive conditions (untransformed:  $F(1,218)=60.95$ ,  $MSe=2348$ ,  $p<.001$ ; trans-

Table 3: The mean number of blocks required for each condition. In parenthesis, the mean of the reciprocals of the number of blocks required is shown.

	Identification Learning	Category Learning
Non-Distinctive	17.1 (.0661)	16.8 (.0753)
Distinctive	8.7 (.130)	12.2 (.100)

Table 4: The proportion correct for learning trials. In parenthesis, the proportion of subjects reaching the learning criterion is shown.

	Identification Learning	Category Learning
Non-Distinctive	.76 (.98)	.85 (.88)
Distinctive	.90 (1.00)	.90 (.96)

formed:  $F(1,218)=78.4$ ,  $MSe=.108$ ,  $p<.001$ ). The key prediction SUSTAIN makes is that category level and distinctiveness should interact such that identification learning performance should improve more than category learning performance as the stimuli become more distinctive. As predicted, distinctiveness and category level interacted such that distinctiveness sped up learning more (8.4 vs. 4.6 blocks) in the identification learning conditions than in the category learning conditions (untransformed:  $F(1,218)=5.08$ ,  $MSe=195.8$ ,  $p<.05$ ; transformed:  $F(1,218)=15.59$ ,  $MSe=.00216$ ,  $p<.001$ ).

A series of t-tests were conducted to probe individual cell differences. All differences were statistically significant at the .01 level except for the comparison (17.1 vs. 16.8 blocks) between the identification learning/non-distinctive condition and the category learning/non-distinctive condition (untransformed:  $t<1$ ; transformed:  $t(109)=1.54$ ,  $p=.13$ ).

Table 4 shows the proportion subjects that reached the learning criterion (the completion of consecutive error-free blocks) for each condition. Subjects reached the learning criterion more often in the identification learning conditions than in the category learning conditions ( $p<.05$  by a binomial test). Subjects also reached the learning criterion more often in the distinctive conditions than in the non-distinctive conditions ( $p<.05$  by a binomial test). Individual cell differences were not probed because of ceiling effects. Cell differences and interactions are explored in other analyses.

**Learning Trial Accuracy** In addition to analyzing the number of required learning blocks, the accuracy data were analyzed. We assume that after reaching the learning criterion subjects would respond correctly on the remaining trials if they maintained their motivational level. We scored the remaining post criterion blocks accordingly. The proportion correct for each condition is shown in Table 4.

A 2 X 2 (category level by distinctiveness) ANOVA was performed with the subjects’ accuracy rates serving as the dependent variable. Subjects were more accurate (.88 vs. .83) in the category learning conditions than in the identification learning conditions ( $F(1,218)=16.45$ ,  $MSe=.132$ ,  $p<.001$ ). Subjects were more accurate (.90 vs. .81) in the

Table 5: The proportion correct for transfer trials.

	Identification Learning	Category Learning
Non-Distinctive	.97	.93
Distinctive	.47	.81

distinctive conditions than in the non-distinctive conditions ( $F(1,218)=60.65$ ,  $MSe=.485$ ,  $p < .001$ ). The key prediction SUSTAIN makes is that category level and distinctiveness should interact such that identification learning performance should improve more than category learning performance as the stimuli become more distinctive. As predicted, distinctiveness and category level interacted such that distinctiveness led to a larger improvement in accuracy (.14 vs. .05) in the identification learning conditions than in the category learning conditions ( $F(1,218)=12.75$ ,  $MSe=.102$ ,  $p < .001$ ).

A series of t-tests were conducted to probe individual cell differences. All differences were statistically significant at the .01 level except for the comparison between the identification learning/distinctive condition and the category learning/distinctive condition ( $t < 1$ ).

**Transfer Trial Accuracy** Sixty-six subjects engaged in transfer trials after finishing the learning phase. The proportion correct for transfer trials for each condition is shown in Table 5. A 2 X 2 (category level by distinctiveness) ANOVA was performed with the subjects' accuracy rates serving as the dependent variable. Subjects were more accurate (.87 vs. .72) in the category learning conditions than in the identification conditions ( $F(1,62)=15.62$ ,  $MSe=.2838$ ,  $p < .001$ ). Subjects were more accurate (.95 vs. .64) in the distinctive conditions than in the non-distinctive conditions ( $F(1,62)=82.92$ ,  $MSe=1.506$ ,  $p < .001$ ). Distinctiveness and category level interacted such that identification learning led to a larger decrement in accuracy (.342 vs. -.0478) in the distinctive conditions than in the non-distinctive conditions ( $F(1,62)=34.34$ ,  $MSe=.6238$ ,  $p < .001$ ).

**Analyses of the Attentional Clustering Hypothesis** The tests presented here explore the possible existence of imperfect rule or abstraction clusters (focused on the non-distinctive dimensions) and exception clusters (focused on the distinctive dimension). Only the category learning data are relevant to the analyses presented here.

The Type IV problem used in the category learning conditions has essentially two types of items in each category: the prototypes (111 and 222) and all the other items. Within a category, each "other" item matches the prototype on two out of the three stimulus dimensions and mismatches on the third. Drawing this distinction between prototypes and other items proves useful in evaluating the attentional clustering hypothesis.

Although it is very difficult to analyze a subject's data and identify which items were exceptions and which items clustered with other items, SUSTAIN offers some direction. According to SUSTAIN, it is much more likely for an "other" item to be an exception than it is for a prototype item to be

Table 6: The proportion correct for Learning trials (to the left of the slash) and for transfer trials (to the right of the slash) by item type.

	Others	Prototypes
Non-Distinctive	.83 / .92	.92 / .96
Distinctive	.89 / .77	.94 / .93

an exception (prototypes are much more likely to cluster with other items). Drawing on this knowledge, 2 X 2 (item type by distinctiveness) ANOVAs can be performed to evaluate the hypothesis. If the hypothesis is correct, the advantage of the distinctive category learning condition over the non-distinctive category learning condition should largely be attributable to the greater ease in memorizing exceptions (i.e., non-prototype items) made possible by focusing on distinctive information. Thus, in the learning data, we should observe an interaction in which item type and distinctiveness interact such that non-prototype items benefit more from distinctiveness than prototype items. This prediction was confirmed (analysis below).

Conversely, for the transfer trials (where the distinctive information is obscured), the advantage of the non-distinctive condition should largely be attributable to better performance on the non-prototype items. In other words, the two factors should interact such that the distinctiveness hurts performance more for the non-prototype items than for the prototype items. This prediction was confirmed (analysis below). **Accuracy Data** A 2 X 2 (item type by distinctiveness) ANOVA was performed on the learning data from the category learning conditions with subjects' accuracy rates serving as the dependent variable (see Table 6). Subjects more accurately (.93 vs. .86) classified the prototypes than the other items ( $F(1,110)=139.18$ ,  $MSe=.264$ ,  $p < .001$ ). Subjects were more accurate (.92 vs. .87) in the distinctive conditions than in the non-distinctive conditions ( $F(1,110)=7.39$ ,  $MSe=.104$ ,  $p < .01$ ). One prediction of my proposed account of clustering and attentional focus is that item type and distinctiveness should interact such that learners in the distinctive conditions should see greater facilitation with non-prototype items than with prototype items in comparison to the non-distinctive conditions. As predicted, distinctiveness and item type interacted such that distinctiveness led to a larger improvement (.06 vs. .02) in the classification of non-prototype items in the distinctive conditions in comparison to the non-distinctive conditions ( $F(1,110)=7.33$ ,  $MSe=.0139$ ,  $p < .01$ ).

**Transfer Data** A 2 X 2 (item type by distinctiveness) ANOVA was performed on the transfer data from the category learning conditions with subjects' accuracy rates serving as the dependent variable (see Table 6). Subjects more accurately (.94 vs. .85) classified the prototypes than the other items ( $F(1,32)=15.78$ ,  $MSe=.155$ ,  $p < .001$ ). Subjects were more accurate (.94 vs. .85) in the non-distinctive con-

ditions than in the distinctive conditions and this result was marginally significant ( $F(1,32)=2.91$ ,  $MSE=.125$ ,  $p < .10$ ). One prediction of my proposed account of clustering and attentional focus is that item type and distinctiveness should interact such that transfer performance in the distinctive conditions should decline more for non-prototype items than for prototypes in comparison to item performance in the non-distinctive conditions. As predicted, distinctiveness and item type interacted such that distinctiveness led to a larger decline in performance (.15 vs. .03) in the classification of non-prototype items in the distinctive conditions in comparison to performance in the non-distinctive conditions ( $F(1,32)=5.49$ ,  $MSE=.054$ ,  $p < .05$ ).

## Discussion

SUSTAIN predicts that category level and distinctiveness should interact such that identification learning performance should improve more than category learning performance as the stimuli become more distinctive. SUSTAIN also predicts that identification learning can become easier than category learning as the stimuli become more distinctive. These predictions were borne out in an analysis of the number of learning blocks required by subjects and in another analysis of accuracy. This robust effects occurred by simply manipulating the color of the stimuli.

The experiment makes a bridge to the Medin et al.'s (1983) study in which subjects performed identification and category learning tasks with rich stimuli (photographs of human faces). SUSTAIN suggests that the identification advantage in the Medin et al. studies arises from the distinctiveness of the stimuli. The experiment tested this prediction directly and completed Medin et al.'s (1983) design with two non-distinctive conditions to complement the two distinctive conditions, allowing for natural comparisons to be made between the various conditions.

Another interesting aspect of the data was that subjects apparently emphasized (or attended) to different stimulus dimensions depending on which stimulus was being classified. In particular, when a stimulus was encoded by its own cluster, the distinctive aspects of the stimuli were emphasized. In contrast, when items shared a cluster, the cluster emphasized the non-distinctive aspects of the cluster members.<sup>2</sup> These results suggest that attention is not dimension-wide and is instead cluster specific. While SUSTAIN (in its current form) exhibits dimension-wide attention, it can be modified so that attention is cluster specific. The interpretability of SUSTAIN, which arises from its internal cluster representation of categories, suggested the analyses related to item type and attentional focus. Although the results of these analyses actually run counter to the specifics of the model, they speak favorably of SUSTAIN's general framework and its utility for directing empirical investigations.

<sup>2</sup>The idea that divergent examples are encoded in terms of how they differ from a default type is in the spirit of Kruschke's (1996) ADIT model of inverse base rate phenomena.

Overall, the results of the Experiment are troublesome for current models of category learning. Existing models have difficulty accounting for the interaction between category level and stimulus distinctiveness, the advantage of identification learning with distinctive stimuli, and attention not being dimension-wide. The first two findings are predicted by SUSTAIN and the third can be accommodated. SUSTAIN's ability to cluster together similar items from the same category (an ability that exemplar models lack) allows it to account for the results from the Experiment.

## Acknowledgments

I would like to thank Doug Medin for collaborating with me on this project. I would also like to thank Greg Ashby, John Kruschke, and James Tanaka for helpful comments on a related paper.

## Abstract

McKoon and Ratcliff (1992) presented a theory of mediated priming where the priming effect is due to a direct but weak relatedness between prime and target. They also introduced a quantitative measure of word relatedness based on pointwise mutual information (Church and Hanks, 1990), and showed that stimuli chosen with the measure produced graded priming effects as predicted by their theory. Using stimuli from Balota and Lorch (1986), Livesay and Burgess (1998a,b) replicated the mediated priming effect in humans, but found that in HAL, a corpus-derived semantic space (Lund et al., 1995), mediated primes were in fact further from their targets than unrelated words. They concluded from this that mediated priming is not due to direct but weak relatedness. In this paper we present an alternative semantic space model based on earlier work (McDonald and Lowe, 1998). We show how this space allows a) a detailed replication of Ratcliff and McKoon's experimental results using their stimuli and b) a replication of Livesay and Burgess's human experimental results showing mediated priming. We discuss the implications for theories of mediated priming.

## Mediated Priming

Mediated priming is an important test for theories of semantic memory (Neely, 1991). According to spreading activation theory (e.g. Anderson, 1983), when a word is presented it activates its representation in a network structure in which semantically related words are directly connected; more generally, the semantic similarity of two words depends on the number of links that must be traversed to reach one to the other. The level of activation controls the amount of facilitation received by the corresponding word. Although ultimately every word can be reached from any location in the network, activation decays during memory access so only a few of the most related words are facilitated. Spreading activation theories predict that a prime word should facilitate pronunciation or lexical decision on a target word directly, for example when "tiger" facilitates "stripes". Spreading activation theory also predicts that "lion" will facilitate "stripes" when activation spreads from the representation of "lion" to that of "stripes", via the related concept of tiger (de Groot, 1983; Neely, 1991).

Small but reliable mediated priming effects have been demonstrated for pronunciation tasks though they are less reliable for lexical decision (Balota and Lorch, 1986). Spreading activation theory explains the size of the priming effect by arguing that "lion" and "stripes" are only indirectly related in semantic memory so that activation has decayed significantly by the time activation from "lion" reaches "stripes".

Theories that do not assume the existence of activation or a network structure in semantic memory, e.g. compound cue theory (Ratcliff and McKoon, 1988; McKoon and Ratcliff, 1998), cannot take advantage of either of the priming explanations above. In compound cue theory, direct priming is explained roughly as follows: the prime and target are joined in a compound cue that is compared to representations in long-term memory. The comparison process generates a 'familiarity' value which controls the size of the priming effect. The essential feature of this explanation is that, unlike spreading activation theory, there is no mention of the intermediate representation "tiger" when explaining how "lion" facilitates "stripes". But is less clear how compound cue theory should explain mediated priming.

In response to this difficulty, McKoon and Ratcliff (1992) have argued that the mediated priming effects are not due to activation spreading through an intervening representation, but are the result of direct but weak relatedness between the prime and target words. To address the issue of priming effect magnitude they provided a quantitative method for generating prime target pairs with various degrees of relatedness. The method is based on pointwise mutual information (Church and Hanks, 1990) computed over a corpus. McKoon and Ratcliff's (1992) Experiment 3 showed that their method produced stimuli that reliably generated a range of priming effect sizes, and that the effect sizes could be controlled. They then argued that mediated priming is simply a special case of graded priming.

Livesay and Burgess (1998a,b) replicated the mediated priming effect in human subjects using a pronunciation task, but had less success with lexical decision (the same situation that was reported in Balota and Lorch's original paper). In an attempt to understand the nature of the priming mechanism they found that mediated primes from the Balota and Lorch stimuli could be divided heuristically into contextually appropriate and contextually inappropriate word pairs. Subsequent analysis revealed that only contextually appropriate pairs were responsible for generated a priming effect.

They then compared distances between each type of prime (direct or mediated) and their targets in HAL, a semantic space model (Lund et al., 1995). Burgess and colleagues have argued that distances in HAL reflect semantic relatedness; shorter distances reflect greater semantic relatedness (Burgess et al., 1998). Directly related primes were on average closer to their targets than the corresponding unrelated primes, so HAL successfully replicated the direct priming effect. However, both contextually appropriate and contextually

ally inappropriate mediated primes were *further* from their targets than unrelated controls. Thus distances in HAL predict that the mediated primes should slow responses to their targets, relative to an unrelated word baseline. Subsequent analysis showed that even for contextually consistent primes, greater distance correlated 0.6 with larger priming effects.

Livesay and Burgess concluded that mediated priming could not be due to direct but weak relatedness between mediated primes and their targets on the grounds that HAL predicted the wrong effect. They then explored the possibility, suggested in McKoon and Ratcliff’s paper, that mediated priming is determined by raw co-occurrence frequencies between prime words and their targets, but found no significant correlations.

Below we present replications of two priming experiments using a semantic space model. In Experiment 1 we replicate human performance on the stimuli generated by McKoon and Ratcliff using pointwise mutual information. We will refer to these stimuli as the mutual information stimuli. These results demonstrate that McKoon and Ratcliff’s direct theory of mediated priming is consistent with explanations of priming based on semantic space. In Experiment 2 we tackle mediated priming directly by replicating the results of Livesay and Burgess’s mediated priming experiment. From these two experiments we argue that our semantic space constitutes a model of mediated priming that is ‘direct’ in the way that McKoon and Ratcliff suggested.

## Experiment 1

### Materials

In this experiment we use materials from McKoon and Ratcliff’s Experiment 3. Each target (e.g “grass”) has a prime taken from association norms (“green”), a high-t prime (“acres”) and a low-t prime (“plane”). High and low-t primes were chosen by first calculating a measure of lexical association based on the T-statistic between each target word and a large number of candidate primes (Church and Hanks, 1990, see Appendix A for details). McKoon and Ratcliff divided the candidate primes for each target into those with high values of the T-statistic (high-t primes) and low values (low-t primes). Unrelated primes were related primes from another target.

### Methods

We constructed a semantic space from 100 million words of the British National Corpus, a balanced corpus of British English (Burnage and Dunlop, 1992). Word vectors were generated by passing a moving window through the corpus and collecting co-occurrence frequencies for 536 of the most reliable context words within a 10 word window either side of each stimulus item. Appendix B describes the method of choosing reliable context words. We used positive log odds-ratios to measure the amount of lexical association between each context word and each of the experimental stimuli.

A brief justification of the positive log odds-ratio as a measure of lexical association is appropriate at this point: Table 1 describes the true co-occurrence probabilities for a stimulus word  $t$  and context word  $c$ .  $p(c, \neg t)$  is the probability of seeing  $c$  with a word other than  $t$ . The odds of seeing  $t$  rather than some other word when  $c$  is present are  $p(c, t)/p(c, \neg t)$  and the odds of seeing  $t$  in the absence of  $c$  are  $p(\neg c, t)/p(\neg c, \neg t)$ , so if the presence of  $c$  increases the probability of seeing  $t$  then

Table 1: The true probabilities of seeing combinations of words  $t$  and  $c$  in text.  $p(c, t)$  is the probability of seeing words  $c$  and  $t$  together in a window.  $p(c, \neg t)$  is the probability of seeing  $c$  together with a word that it *not*  $t$ .

	Target	Non-target
Context	$p(c, t)$	$p(c, \neg t)$
Non-context	$p(\neg c, t)$	$p(\neg c, \neg t)$

the odds ratio

$$\theta(c, t) = \frac{p(c, t)/p(c, \neg t)}{p(\neg c, t)/p(\neg c, \neg t)} = \frac{p(c, t) p(\neg c, \neg t)}{p(c, \neg t) p(\neg c, t)}$$

is greater than 1. When  $\theta > 1$   $c$  and  $t$  are said to be positively associated. In contrast, if the presence of  $c$  makes it *less* likely that  $t$  will occur then  $\theta < 1$  and  $c$  and  $t$  are negatively associated. Finally, when the presence of  $c$  makes no difference to the probability of seeing  $t$  then  $\theta = 1$  and we can conclude that  $c$  and  $t$  are distributionally independent.

An important advantage of the odds ratio for measuring lexical association is that takes into account differing marginal word frequencies. For example, consider two target words  $t_1$  and  $t_2$  that have baseline occurrence probabilities  $p(t_1)$  and  $p(t_2)$ . For simplicity we assume that co-occurrences are counted in a window extending exactly one word to one side of stimulus. When neither word is related to a context word  $c$  then all three words will distributionally independent. Under distributional independence the expected values of co-occurrence counts  $f(c, t_1)$  and  $f(c, t_2)$  depend only on their occurrence probabilities:

$$\begin{aligned} E[f(c, t_1)] &= p(c) p(t_1) N \\ E[f(c, t_2)] &= p(c) p(t_2) N \end{aligned}$$

where  $N$  is the number of words in the corpus<sup>1</sup>. If  $p(t_1)$  is much larger than  $p(t_2)$  then the expected co-occurrence counts may differ substantially, despite the fact that  $c$  has no relation to  $t_1$  or  $t_2$ . In other words if raw co-occurrence counts are used to measure lexical association then a more frequent target word will be judged more strongly associated with  $c$  than a less frequent target word, whether or not they are actually related. Also, the fact that vector elements for two target words with different frequencies will be tend to have different magnitudes will bias the Euclidean distance measure to treat target words from different frequency bands as further away from each other than those in the same band. This occurs because the measure depends on squared differences between vector elements.

The odds ratio is well-known to be a measure of association that takes chance co-occurrence into account (Agresti, 1990). When  $t_1$  and  $c$  are distributionally independent then  $p(t_1, c) =$

<sup>1</sup>Strictly speaking  $N$  is the number of bigrams in the corpus, which is one less than the number of words.

$p(t_1)p(c)$ . The odds ratio is

$$\theta(c, t_1) = \frac{p(c)p(t_1)p(-c)p(-t_1)}{p(c)p(-t_1)p(-c)p(t_1)} = 1,$$

and it is clear that the value of  $\theta(c, t_1)$  does not depend on target and context word frequencies.

$\theta(c, t_1)$  is estimated from a corpus by setting the elements of Table 1 to their Maximum Likelihood values. The odds ratio estimate can then be computed using only occurrence and co-occurrence frequencies (see e.g. Agresti, 1990)

$$\hat{\theta}(c, t) = \frac{f(c, t) f(-c, -t)}{f(c, -t) f(-c, t)}.$$

We log the odds ratio to make the measure symmetric around 0 (denoting distributionally independent words) and set all negative odds-ratios to zero. This reflects our belief that information about the whether a word occurs with another *more* often than chance is psychologically salient, whereas the knowledge that a word tends *not* to occur with some other word (one of, say, 60,000 others in the lexicon) is not psychologically salient and need not be represented in the model. Empirical studies show that neither logging nor truncation of the basic odds-ratio measure make much difference to the results presented below. The most important step seems to be taking into account chance when using co-occurrence to quantify lexical association. The g-score (Dunning, 1993) is another useful measure for this purpose (McDonald and Lowe, 1998).

We created vectors for each of the experimental stimuli by calculating lexical association values between it and each context word. Unrelated primes were primes from the previous target word<sup>2</sup>. We use the cosine of the angle between word vectors as a similarity measure corresponding to semantic relatedness (McDonald and Lowe, 1998).

When modeling priming experiments, the cosine between a prime and its target should be inversely proportional to the corresponding reaction time. The size of a priming effect is calculated by subtracting the cosine between the unrelated prime and target from the cosine between the related prime and target. Cosines are entered directly into analyses of variance.

## Results

McKoon and Ratcliff’s subjects responded fastest to target words preceded by an associated prime, next fastest to a high-t prime, slower to a low-t prime and slowest of all to an unrelated prime (see Table 2, line 1.) Priming effects were reliable in all except the low-t condition.

The cosine similarity measure shows similar results (see Table 2, line 2). The following analyses are for items only since there are no subjects. The prime conditions were significantly different,  $F(3,156)=33.32$ ,  $p<.001$  so we performed pairwise analyses of variance to examine the differences more closely, correcting for multiple comparisons according to the Bonferroni method. There was a reliable associative priming effect: associated pairs were significantly more related

<sup>2</sup>Since the stimuli have no inherent ordering, this will not produce any spurious effects. Other methods of choosing primes have been tested and give equivalent results.

than non-associated pairs (0.412 vs. 0.078),  $F(1,78)=80.645$   $p<.001$  and high-t pairs were significantly more related than unrelated pairs (0.216 vs. 0.078),  $F(1,78)=19.727$   $p<.001$ . The mean value for low-t pairs was higher than the unrelated baseline (0.139 vs. 0.078), but this was not significant  $F(1,78)=5.268$   $p=.024$ .

Table 2: Mean reaction times in msec. (line 1) and cosines on (line 2) for the mutual information stimuli (from McKoon and Ratcliff, 1992)

	Related	High-t	Low-t	Unrelated
M&R	500	528	532	549
Space	0.412	0.216	0.139	0.078

## Discussion

Experiment 1 shows a close fit to human reaction time data. The experiment also demonstrates that semantic space models are capable of representing the kind of weak but direct relatedness that McKoon and Ratcliff argue underlies mediated priming. If we can also account for mediated priming data, we will not only have uncovered additional evidence that direct but weak relatedness is sufficient to explain mediated priming, but also have found a ‘direct’ alternative explanation for the apparent mediation process. We address mediated priming in Experiment 2.

## Experiment 2

### Materials

Materials for Experiment 2 are taken from Balota and Lorch’s (1986) paper. Each target (e.g. “stripes”) has a directly related prime (“tiger”) and a mediated prime (“lion”). One target had to be discarded because it had a prime with very low frequency in the corpus. A randomly chosen prime target combination was discarded from each of the other two prime conditions to maintain balance.

### Method

The semantic space was the same as in Experiment 1.

### Results

In the pronunciation task both Balota and Lorch and Livesay and Burgess’s subjects showed direct and mediated priming (see Table 3, lines 1 and 2). The semantic space measure for related, mediated and unrelated pairs is shown in Table 3, line 3. The prime conditions were significantly different  $F(2,132)=12.065$   $p<.001$  and we performed pairwise analyses of variance to examine the differences in more detail. There was a reliable direct priming effect (0.212 vs. 0.085),  $F(1,88)=24.105$   $p<.001$  and also a reliable mediated priming effect of smaller magnitude (cosines 0.164 vs. 0.084),  $F(1,88)=13.107$   $p<.001$ .

## Discussion

The results of Experiment 2 show that it is possible to model mediated priming using a semantic space. The experiment also demonstrates the plausibility of McKoon and Ratcliff’s theory that direct but weak relatedness underlies mediated priming phenomena. There is no mediation mechanism in

Table 3: Mean reaction times in for the pronunciation experiments of Balota and Lorch (B&L, line 1) and Livesay and Burgess (L&B, line 2) in msec. Similarity measures for the same materials are on line 3.

	Related	Mediated	Unrelated
B&L Pron.	549	558	575
L&B Pron.	576	588	604
Space	0.212	0.164	0.084

the space, so the most parsimonious explanation of mediated priming is that it is due to direct relatedness.

On the other hand, Livesay and Burgess's distinction between contextually consistent and contextually inconsistent prime target pairs suggests an alternative view. Perhaps only some of the mediated priming stimuli are causing priming, and the rest are unnecessary.

Unfortunately the distinction between contextually consistent and inconsistent pairs appears to resist characterization in quantitative terms, e.g. in terms of distance in HAL. To investigate the possibility that a subset of primes were carrying the mediated priming effect we examined the distribution of differences between a) cosines between unrelated primes and their targets and b) mediated primes and their targets. The larger these differences are, the larger the mediated priming effect. If only a subset of materials carry the priming effect then we might expect that some targets have larger differences than the rest. However, we found that differences clustered symmetrically around the mean effect size. Ideally we would correlate priming effect size in milliseconds to the cosine measure to identify a subset of relevant primes; this is further work.

In an attempt to understand why HAL does not produce mediated priming, we attempted to replicate its behaviour on the mediated priming stimuli by changing the parameters of our semantic space. First, we used co-occurrence counts for the 536 reliable context words to create vectors for the Balota and Lorch materials and computed Euclidean distances between each prime and target combination. There were no significant differences between conditions,  $F(2,132)=0.043$   $p=.958$ . We then performed the same analysis with vectors normalized to length 1 to offset the effects of large co-occurrence counts. The conditions were still not reliably different  $F(2,132)=1.257$ ,  $p=.288$ . However, in this case the model hinted at a direct priming effect and a smaller mediated effect. Finally we constructed vectors from 500 higher frequency context words<sup>3</sup>, in case our choice of context words had adversely affected the measure. We used normalized vectors because they had previously given a slightly better match to the priming magnitudes. Again there was no significant difference between the conditions  $F(2,132)=0.493$   $p=0.612$ , but the model suggested a larger direct than mediated priming effect.

In conclusion, we were not able to replicate HAL's behaviour by changing the parameters of our model, so it is

<sup>3</sup>The context words had rank frequencies from 200 to 700. Occurrence frequencies ranged between 61926 to 220 occurrences per million.

not easy to explain why the cosines in the space replicate human mediated priming effects while distances in HAL do not. It is possible that relevant differences between the space and HAL depend on HAL's method of choosing context words, or its window weighting function for collecting co-occurrence counts. Comparisons between the space and HAL are the subject of ongoing work.

## Conclusion

In Experiments 1 and 2 we have presented detailed replications of human performance on graded and mediated priming stimuli using a semantic space. Since there is no mediation mechanism in the space we have argued that direct but weak relatedness, as reflected by the cosine measure in our space, is sufficient to yield a mediated semantic priming effect. This result supports McKoon and Ratcliff's contention that weak relatedness, rather than spreading activation, underlies mediated priming effects.

The results presented here stand in marked contrast to HAL's failure to generate mediated priming effects. However, we were not able to replicate HAL's behaviour in our model, so it is presently unclear why the HAL model does not work for this data.

We conclude by noting that graded and mediated priming can now be added to the list of psycholinguistic phenomena which may be accounted for by semantic space models.

## Appendix A

The pointwise mutual information or *association ratio* between a target word and candidate prime is

$$AR = \log_2 \frac{p(\text{prime and target})}{p(\text{prime})p(\text{target})}.$$

The numerator is estimated by normalizing the number of co-occurrences between prime and target words over the corpus. The denominator is estimated from the occurrence frequencies of the prime and target words separately. When prime and target words are distributionally independent *AR* should, like the log odds-ratio, take the value zero. When the prime word is occurs with the target more than would be expected by chance *AR* is positive with greater magnitude for greater levels of association. The T-statistic may be used to determine whether the ratio is significantly different than 0, although Church and Hanks (1990) use the value of the statistic itself as a lexical association measure. The *AR* measure is called pointwise mutual information in analogy to mutual information, an information theoretic measure which is the expectation of *AR* with respect to the distribution  $p(\text{prime and target})$ . Manning and Schütze 1999 discuss uses and shortcomings of pointwise mutual information as an association measure.

## Appendix B

We assume that the ease that two words can be substituted for one another in text reflects their semantic similarity. Substitutability in context, defined over word pairs or *targets*, is the underlying continuous quantity that a semantic space model needs to capture (Finch, 1993). Measuring substitutability in context entails holding linguistic context constant and swapping in targets. This is equivalent to holding targets constant and examining possible surrounding linguistic contexts because targets that are easily substitutable are those that occur in similar contexts.

Any large balanced corpus, such as the BNC, realizes a subset of the possible linguistic contexts that can surround a target. Given sufficient target instances the subset will be representative because the number of times a context surrounds a target is proportional to how meaningful the resulting sentence is. We represent contexts using finite set of *context words*. The linguistic contexts that surround a target are represented by the number of times each context word occurs within a 10 word window surrounding the target. These co-occurrence counts and the marginal frequencies of each context word and the target are used to create vectors of positive log odds ratios. To represent linguistic context adequately context words should be *reliable*.

To quantify reliability we treat context words like human raters and use standard ANOVA methods to assess their reliability: First, we choose several thousand candidate context words from the high frequency portion of the BNC (excluding stop words). Second, we pick randomly another set of words called meta-context words, and compute log odds ratios as described above for each context and meta-context word combination over  $k$  disjoint sections of the corpus. The resulting  $k$  matrices can be seen either as sets of column vectors describing the positions of the meta-context words in a space defined by the candidate context words, or as a set of row vectors describing the positions of the candidate context words in a space given by the meta-context words. The meta-context words are so-called because they are context words for the candidate context words. Each candidate context word is then associated with  $k$  vectors. We consider the vectors to be the results of  $k$  rating tasks and use a within subjects ANOVA to

test whether each context word generates significant variation in vector elements between the  $k$  tests. Context words that are reliable have  $k$  vectors with similar values so their rating do not vary significantly across corpus sections. Context words for which we cannot reject the null hypothesis of no variation between corpus sections are retained.

In these experiments we chose  $k=4$  sections from the BNC, each containing 10M words, and used the rather conservative critical significance level 0.1. The procedure generated 536 context words.

# Zen in the Art of Language Acquisition: Statistical Learning and the Less is More Hypothesis

## Abstract

It seems an obvious truth that children are better language learners than adults. Children seem able to master a second language with ease, while adults are rarely successful at second language acquisition. Newport's (1990) Less is More hypothesis represented an attempt to explain these observations by invoking general cognitive mechanisms. This hypothesis takes as its starting point the observation that children exhibit reduced working memory capacity relative to adults and suggests that this reduction serves as a filter to aid children in deducing the structure of the language they are learning. We present two experiments testing a specific prediction that follows from the Less is More hypothesis, namely that adults will perform better on language learning tasks if their available working memory capacity is reduced. The experiments examined the learning of word boundaries and syntactic agreement, each with and without a concurrent cognitive load. The results of these experiments were contrary to the Less is More prediction, suggesting that other explanations must be found for the observed superior language learning performance of children over adults.

## Introduction

In *Zen in the Art of Archery* (Herrigel, 1953), the German philosopher Eugen Herrigel recounts his endeavor to learn Japanese archery from a great Zen master. During his many years of training, Herrigel struggles with his need to control the bow, to think about the target. The more he tries to control the bow, the Master tells him, the less control he will have over it; the more he thinks about the target, the less accurate his shots will be. Rather, the Master tells Herrigel to strive for less control, less conscious thought of the act of releasing the arrow from the bow, for only then will he gain mastery over the bow. The idea that Less is More is a dominant theme of Zen Buddhism. However, this notion is not limited to the realm of Oriental philosophy; it is one that pops up again in Western developmental psychology, in particular, in the area of language acquisition.

It is generally acknowledged that children's cognitive abilities, working memory in particular, are considerably constrained relative to those of adults (Gathercole, Willis,

Baddeley & Emslie, 1994). At the same time, it has also been widely observed that children are much more successful at learning language than adults. After all, virtually all children learn a first language, while few adults ever master a second. Furthermore, children seem to learn language with such effortlessness, as opposed to the great expense of effort necessary for an adult to acquire even marginal proficiency in a second language. To Newport (1990), this seemed a perfect example of a Less is More situation: children have less cognitive ability yet learn language more easily, while adults have more cognitive ability yet learn language less easily. This observation led to the formulation of the Less is More hypothesis (Newport, 1990), which not only maintained that the restricted working memory of children was an advantage to language acquisition, but also attempted to explain the causal nature of that relationship.

The idea for the Less is More hypothesis came out of studies on critical periods in first and second language acquisition performed by Newport and her colleagues. For example, Johnson & Newport (1989) conducted a study of 46 native Chinese and Korean speakers living in the United States who had learned English as a second language. The participants were divided into two groups, those who had arrived in the US before age 15 (dubbed Early Arrivals), and those who had arrived in the US after age 17 (dubbed Late Arrivals). All participants had spent at least the last three years prior to the experiment in the US. Johnson & Newport (1989) found an inverse linear relationship between age of arrival in the US and ultimate performance in English. In that study, only those participants who had arrived in the US by the age of seven achieved native speaker proficiency as measured on a grammaticality judgment task. Beyond age seven, performance on this task decreased as age or arrival increased. Johnson & Newport (1989) also examined attitudinal variables, but found statistical significance for the age of arrival variable over and above and other variables they looked at.

In a subsequent study, Newport (1990) examined critical periods in first language acquisition, in particular in American Sign Language (ASL). She studied three groups of congenitally or pre-lingually deaf adults who used ASL as their predominant language and had limited skills in English. The first group, dubbed Native Learners, had been exposed to

ASL since birth or shortly thereafter. The second group, dubbed Early Learners, had been first exposed to ASL between the ages of 4 and 6. The last group, dubbed Late Learners, had been exposed to ASL only after age 12. All participants were tested on their knowledge of ASL sentence structure and morphology. While all three groups performed at ceiling on the sentence structure test, there was a significant decline in performance in morphology across the three groups from Native to Early to Late Learners.

Newport (1990) took these findings as clear evidence for a critical period in language acquisition, and in an attempt to explain the mechanism responsible for this critical period she posited the Less is More hypothesis. The hypothesis takes as its starting point the notion that the working memory capacity of children is limited compared to that of adults. The hypothesis then proposes that this limitation is actually advantageous. According to Newport (1990), language acquisition requires a componential analysis. Adults take in too much of the language input at one time because of their expanded working memory capacity relative to children. This wider perceptual window in adults leads to a combinatorial explosion of possible analyses for the language input, hence the likelihood of hitting upon the right analysis is small. Children, with their limited working memories, are constrained by the size of the input they do take in to a more limited number of possible analyses. Hence, the likelihood of hitting upon the right analysis is greatly increased. According to Newport (1990), it is the limitations of the child's ability to process information that provides the basis for successful language acquisition.

Elman (1993) tested the Less is More hypothesis with a connectionist model of syntactic agreement acquisition. He trained a simple recurrent network (Elman 1990) on a corpus of sentences based on a simplified English grammar. In this grammar, subjects and verbs agreed in number, verbs differed in argument expectations, and sentences could contain multiple embeddings. The corpus contained sentences such as *cats chase dogs* and *dogs see boys who cats who mary feeds chase*. The context units of this simple recurrent network represented the working memory of the network, and the capacity of this working memory was a parameter that could be varied. When the network was trained on the entire corpus with working memory at full capacity, the network failed to learn.

Elman (1993) then tried incrementing the capacity of the working memory of the network. Working memory capacity was manipulated by an automatic flushing of the context units after every three or four words. As training progressed, the interval between flushings was gradually increased. The result was that the network was then able to learn how to process the input. Elman (1993) interpreted this finding as consistent with the Less is More hypothesis.

Relevant empirical data came from a study by Santelmann & Jusczyk (1998), who used a headturning paradigm with 15- and 18-month-old infants to test their sensitivity to morphosyntactic dependencies in English. The experimental condition consisted of well-formed English sentences with the structure *...is...<verb>ing*, while the control condition consisted of ill-formed sentences with the structure *...can...<verb>ing*, such as *Everybody is baking* vs. *\*everybody can baking*. Santelmann & Jusczyk (1998) also varied the distance in syllables between auxiliary verb (*is* or *can*) and main verb by the insertion of adverbs, as in *Everybody is often baking*. They found that at distances of 1-3 syllables, 18-month-old infants preferred well-formed over ill-formed sentences. However, at distances over 3 syllables, the 18-month-olds showed no preference for either form, nor did the 15-month-olds at any distance. Santelmann & Jusczyk (1998) concluded that their findings were "consistent with the hypothesis that 18-month-olds are working with a limited processing window, and that they are only picking up relevant dependencies that fall within this window." Although the authors found no evidence to determine whether these limitations in processing space facilitated or hampered language acquisition, the Santelmann & Jusczyk (1998) study nevertheless does lend support to a basic premise of the Less is More hypothesis, namely that infants are processing the language input in shorter chunks than adults are, justifying the approach Elman (1993) took in modeling the syntax-acquisition process.

Work on statistical learning by Saffran and her colleagues has also been relevant to the Less is More hypothesis. Saffran, Newport & Aslin (1996a) asked adult participants to listen to a nonsense language that contained words but no meanings or grammar. The task was to try to figure out where the word boundaries were. At the end of 21 minutes of exposure, the participants were asked to choose which of two items sounded more like a word from that language. The participants performed significantly above chance, with a mean score of 76% (chance was 50%). This type of exposure condition was referred to as the explicit learning condition in this and later Saffran studies.

Saffran et al. (1997) tested the learning of word boundaries in an incidental learning condition. In this condition, participants were asked to draw a picture while the stimulus played in the background. Subjects were told nothing about the stimulus. After 21 minutes of exposure, the participants were administered the same test as in the explicit condition. Saffran et al. (1997) tested two groups, adults (college students) and children (6-7 years old). Mean percent correct identification scores for each group were significantly above chance (50%) at around 59%, with no significant difference between children and adults. Because of the low scores after one exposure period, the experiment was redone with two exposure periods on consecutive days. In this second experiment, adults averaged 73% and children 68%, with the difference between adults and children being nonsignificant. Saffran et al. (1997) concluded that passive exposure was

sufficient at least for some aspects of the language acquisition process.

In her dissertation, Saffran (1997) extended her research in statistical learning to the acquisition of syntax, in particular, hierarchical phrase structure. The stimulus set in each experiment consisted of a sample of sentences from an artificial language, with the only cues to syntactic structure being statistical. In an explicit learning condition, the participants were exposed to the stimulus for 30 minutes a day for two days, and tested on their knowledge of the phrase structure at the end of each listening period. Mean adult performance in this explicit learning task was 68%<sup>1</sup>. (No children were run in this condition.) In an incidental learning condition in which participants listened to the stimulus while drawing a picture, both adults and children (aged 6-9) showed performance significantly above chance after the first exposure period, with no significant improvement after the second session.<sup>2</sup> Children's scores (57%) were significantly worse than those of the adults (67%). There was no significant difference between adults in the explicit and incidental conditions.

The results of these various experiments by Saffran and her colleagues seem inconsistent with the Less is More hypothesis. Specifically, the Less is More hypothesis predicts that children will perform better than adults in language learning tasks, and furthermore that adults will perform better in an incidental learning task than an explicit one. But these predictions are belied by the data. Not only was there no significant difference in performance between children and adults in the incidental word boundary learning task (Saffran et al. 1997), children in fact fared worse than adults in the implicit syntax learning task (Saffran, 1997). Furthermore, there was no significant difference between explicit and incidental conditions in adult performance on the syntax learning task (Saffran 1997).

The various results described above paint an inconsistent picture of the impact of working memory resources in language learning. The studies by Elman (1993) and Santelmann & Jusczyk (1998) appear to support the Less is More hypothesis, while the results of the studies by Saffran et al. (1996) and Saffran et al. (1997) are inconsistent with that hypothesis.

The experiments described below were aimed at examining the following question: Is adult performance on a language learning task superior when working memory resources are reduced, as the Less is More hypothesis would predict? Although the results of Saffran

et al. (1997) are inconsistent in this regard, they are difficult to interpret because they were obtained under different experimental conditions. The present experiments attempt to address this question systematically. Experiment I addresses this question in the domain of word boundary learning while experiment II addresses this question in the domain of syntax learning.

## Experiment I: Word Boundaries

Because the exposure periods in Saffran et al.'s explicit (1996a) and incidental (1997) word boundary learning tasks were not equivalent, a direct comparison cannot be made. Experiment I represents an attempt to replicate these two experiments under identical exposure conditions. To insure this, the difference between these two tasks was reduced to the presence or absence of a concurrent cognitive load (drawing a picture) during the exposure to the stimulus. For this reason, in this and the following experiment, Saffran et al.'s (1996a) explicit condition is referred to by the more theory-neutral term No Load, while Saffran et al.'s (1997) incidental condition is referred to as the Load condition. If the Less is More hypothesis is true, then we would expect superior performance in the Load vs. the No Load condition.

## Method

Thirty-two participants were recruited for the experiment from the University of Iowa Psychology Department subject pool. The participants received partial credit toward fulfilling requirements for an introductory psychology course. These participants were randomly assigned to two groups of 16 each, constituting the No Load and Load groups for this experiment. The exposure and test materials were reconstructed per the specifications given in Saffran et al. (1997).

In the No Load condition, participants were informed that they would be listening to an artificial language that consisted of a small number of words but no meanings or grammar. They were not told the exact number of words or anything about the structure of those words. The participants were asked to listen to the language and try to figure out where the word boundaries were. They were also told that they would be tested on their knowledge of the word boundaries later in the experiment. These instructions were made as similar as possible to those given in Saffran et al. (1996).

In the Load condition, participants were asked to draw a picture using a computer drawing program. They were informed that an auditory stimulus would play while they drew, and that the experimenter was looking at a certain effect that would be explained to them later in the experiment. The participants were told nothing at the outset of the experiment about the content of the stimulus, nor were they informed that they would be given a test based on the auditory stimulus later on. These instructions were made as similar as possible to those given in Saffran et al. (1997).

The exposure procedure was identical for both the No Load and the Load groups, and consisted of three seven-minute listening periods with five-minute breaks between. This exposure procedure is the same as that used in Saffran et al.

---

<sup>1</sup> This and the following three composite scores were calculated from the data in Saffran (1997).

<sup>2</sup> Saffran (1997) acknowledges that this incidental task was not as incidental as it was in the word boundary experiments. In the incidental learning condition of the phrase structure experiment, participants were told about the nature of the background stimulus and the test they would be given at the end of the drawing period.

(1996). After the three listening sessions were finished, the experiment proceeded to the test phase, in which the participants were asked to listen to each pair of sound items and to decide which of the two sounded more like it came from the stimulus.

Figure 1: Results of Experiment I, Statistical Learning of Word Boundaries (Mean percent correct on vertical axis).

## Results and Discussion

The results of both groups are in line with the results of the word boundary learning experiments of Saffran et al. (1996) and Saffran et al. (1997), and are shown in Figure 1. The mean score for the No Load group was 74%. A single-sample  $t$  test (two-tailed) showed that performance was significantly above chance,  $t(15) = 9.94, p < .01$ . The mean score for the Load group was 65%, which was significantly above chance as well,  $t(15) = 5.20, p < .01$ . A two-sample  $t$  test of the No Load vs. Load means was significant ( $p < .03$ ), indicating superior performance on the part of the No Load group over the Load group.

In the present experiment, both groups exhibited learning. However, the Load group did not outperform the No Load group, contrary to the prediction of the Less is More hypothesis. Rather, this finding is consistent with a More is More hypothesis, that is, with the idea that enhancing cognitive resources enhances cognitive performance.

## Experiment II: Syntactic Agreement

While the results of Experiment I were inconsistent with the Less is More hypothesis, it could be argued that segmenting words from a stream does not involve the sort of componential analysis that Newport (1990) considered necessary for successful language acquisition. Experiment II consists of a task that would require such a

componential analysis: the learning of the pattern of syntactic agreement in an artificial language. The Less is More hypothesis predicts that participants with a reduced working memory capacity (experimentally induced by the imposition of a cognitive load) will perform better than participants with no reduction of working memory.

## Method

Thirty-two adult college students were recruited from the subject pool of the University of Iowa Psychology Department and randomly assigned to two groups (No Load or Load) as in Experiment I.

An artificial language with a small vocabulary and a simple grammar was created for this experiment. The vocabulary of this language consisted of twenty one-syllable noun roots and twenty one-syllable verb roots. The grammar consisted of two rules. First, all sentences were two words in length, each composed of a noun followed by a verb. Second, the noun and verb of each sentence agreed in number, with singular nouns marked with the suffix *-bo*, plural nouns with *-za*, singular verbs with *-ki*, and plural verbs with *-nu*. Thus, the noun *da* and the verb *me* could form both the sentence *da-bo me-ki* (singular) and the sentence *da-za me-nu* (plural). The exposure and test corpuses were set up such that all the words in the test phase had been heard in the exposure phase, but that all of the test sentences were new.

For the sake of comparison across Experiments, the instructions and procedures in Experiment II were made as parallel as possible to those used in Experiment I.

Subjects in the No Load condition were told that they would hear an artificial language consisting of a series of two-word sentences. They were told nothing about the number of different words or the length of the words. The participants were told that this language was spoken by a computer speech-synthesis program that did not put pauses between words or sentences. Their task, then, was to listen to the language and see if they could figure out where the sentence breaks were supposed to be. They were also told that they would be tested on their ability to find the sentence breaks at the end of the experiment. The rationale for giving the participants this task during exposure was twofold: One was to keep the participants focused on the stimulus, and the other was to keep the procedures in Experiment II as parallel as possible to those in Experiment I. During the test phase, the participants were told to listen to each pair of sound items and decide which of the two sounded more like the training stimulus.

Subjects in the Load condition were given a drawing task and cover story as in Experiment I. During the test phase, they were asked to decide which of the two items in each trial sounded more like the stimulus that played while they were drawing. However, at no time were they told about the content of the stimulus.

## Results and Discussion

The results of Experiment II are shown in Figure 2. Mean performance of the No Load group was 56%. A single-sample

*t* test showed that performance was significantly above chance,  $t(15) = 4.57, p < .01$ . Mean performance of the Load group was 52%. This performance was not significantly above chance,  $t(15) = 1.23, n.s.$  A two-sample *t* test comparing No Load vs. Load means, however, was significant,  $p < .05$ .

Figure 2: Results of Experiment II, Statistical Learning of Syntactic Agreement (Mean percent correct on vertical axis).

Contrary to the predictions of the Less is More hypothesis, the No Load group did not outperform the Load group; on the contrary, the Load group significantly outperformed the No Load group. However, the null result in the Load condition makes the findings of this experiment hard to interpret. It is not clear whether the Load group failed to learn due to the inherent difficulty of the task, or if they would have exhibited learning had they been given a longer exposure period. When Saffran et al. (1997) increased exposure in their incidental word boundary learning task to two 21-minute sessions on consecutive days, the participants' performance improved significantly. However, the participants in Saffran's (1997) phrase-structure learning experiments showed no significant improvement from Day 1 to Day 2 in either the explicit (No Load) (Saffran, 1997) or incidental (Load) (Saffran, 1997) conditions. At the very least, the results of the present experiment suggest that increased working memory capacity leads to better performance. There could also be a role for attention in the acquisition of syntax, as the null result in the Load condition suggests that syntax may not be learnable at all without attention.

Results across Experiments I and II were analyzed in a two-way ANOVA of task (Word Boundaries vs. Syntactic Agreement) by condition (No Load vs. Load). The results, as shown in Figure 3, indicate main effects for both task and load, but no interaction. In other words, performance

in the Word Boundary task was significantly better than in the Syntactic Agreement task, regardless of condition. Likewise, performance in the Load condition was significantly worse than performance in the No Load condition, regardless of task. The results of this ANOVA suggest, first of all, that the syntactic agreement task was inherently more difficult than the word boundary task was. In addition, they suggest that the imposition of a cognitive load leads to reduced performance in either of these tasks, a finding that runs counter to the predictions of the Less is More hypothesis.

### General Discussion

Experiment I clearly indicates that, at least with regard to the segmentation of words in a speech stream based on statistical regularities, the Less is More hypothesis does not hold. Under that hypothesis, we would expect to see better performance on the part of the Load participants. What we see instead is significantly better performance on the part of the No Load participants, exactly the opposite of what we would expect if the Less is More hypothesis were true. The same pattern of results obtained in Experiment II, suggesting that the Less is More hypothesis does not hold in the domain of syntax acquisition, either.

A key issue in the Less is More hypothesis is the issue of the role of working memory in language acquisition. The Less is More hypothesis posits that the restricted working memory in children aids them in language learning, and furthermore maintains that the larger working memory capacity of adults hinders their language learning ability. An alternative to the Less is More hypothesis would be a More-is-More hypothesis predicting that the greater the cognitive resources available, the better the language learning (or any other) performance will be. The data presented in this paper are consistent with that view.

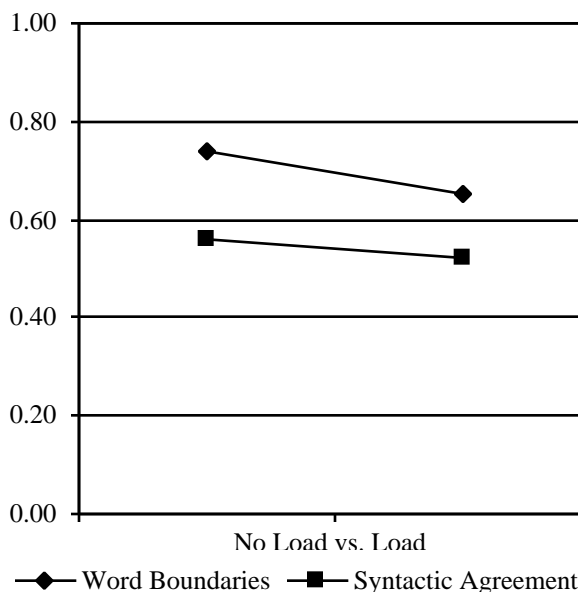

Figure 3: Result of ANOVA across Experiments I and II.

Even if it were the case that the lower performance in the No Load condition were in part because participants were not attending to the stimulus (and not merely because of working memory limitations imposed), this would still in some sense represent a reduction of available cognitive resources and thus, according to the Less is More hypothesis, should still result in better performance. We recognize that there is a potential confound in the two experiments presented here between the effect of the manipulation on working memory and on attention. Research currently underway in our lab is testing the separate effects of working memory and attention on the acquisition of syntax.

We would also like to address three concerns with the present research that have been brought to our attention. The first concern is that Experiment I may not be relevant to the Less is More hypothesis. However, a similar result in both experiments suggests similar mechanisms at work in both the word boundary learning and syntactic agreement learning tasks, making Experiment I relevant to our argument. The second concern is that the dependencies were too close, creating a situation in which the Less is More hypothesis would predict no advantage for a limited working memory capacity. But if this were the case, then we would expect no difference in performance between the Load and No Load groups. Rather, we see that even when dependencies are only a syllable apart, the Load group performs significantly worse than the No Load group. The third concern is that the low performance in Experiment II may be due to having too many words to learn; in other words, syntax acquisition was hindered by the demands of vocabulary acquisition. However, it is not at all clear that it is necessary to learn the words in order to learn the syntax. For example, it is doubtful that the infants in Santelman & Jusczyk (1998) knew all the words in the sentences they heard; nevertheless, they were sensitive to the long-distance dependency being tested for.

To the extent that the Less is More hypothesis is challenged, the question is raised of how to account for the observed critical period effect (Lenneberg 1967) in language acquisition. The Less is More hypothesis makes the implicit assumption that the only relevant difference between children and adults approaching the language learning task is working memory capacity. However, it is very likely that there are other differences, motivational in particular, between the conditions under which children and adults enter a language learning situation besides just working memory capacity (Schuman, 1975, as cited in Johnson & Newport, 1989). In fact, empirical evidence suggests that when motivational factors are held constant in a laboratory situation, children fare worse than adults, as they did, for example, in the experiments reported by Saffran (1997).

## Conclusion

After seven years in Japan, Herrigel (1953) finally masters the bow, learning to send the arrow to its target with apparent effortless. Yet behind that appearance of ease lies seven years of struggle. Seeming effortless is the goal in mastering the bow, not the means to mastering it. Likewise in mastering a language. Facility in a language is achieved only by an arduous, extended process. The language learning process demands a great expense of cognitive effort, and it only stands to reason that the more cognitive resources one has available, the more likely one is to succeed at the task. This premise is borne out by the evidence presented here: adults performed better at language learning tasks when there were no other cognitive demands placed on them. At least for the aspects of language acquisition examined here, it is clear that less is less, not more.

# Two Views are Better than One: Epistemic Actions May Prime

Paul P. Maglio

## Abstract

*Epistemic actions* are physical actions people take more to simplify their internal problem-solving processes than to bring themselves closer to an external goal state. In the video game Tetris, for instance, players routinely over-rotate falling shapes, presumably to make recognition or placement decisions faster or less error-prone. Along these lines, an experimental study was performed to test the hypothesis that it is easier to recognize a two-dimensional shape if it is presented in two different orientations than if it is presented in only one. In particular, we tested whether performance on a shape-based video game task was facilitated by multiple views of a shape, and whether game performance (an indirect test of memory) differed from a direct test of memory for previously presented shapes. Results show that indeed task performance is both faster and more accurate when participants see two views of a shape than when they see one, but that more than two views do not improve performance further. In addition, multiple views lead to faster performance on the video game than on the memory test, but only in the earliest stages of training. We conclude that Tetris players may rotate falling shapes manually to see the shapes in more than one orientation, which leads to faster and more accurate placement decisions.

## Introduction

Studies of people playing the video game Tetris have shown players often take actions in the external environment that are not strictly necessary but that serve to simplify or speed up internal cognitive or perceptual operations (Kirsh & Maglio, 1994; Maglio, 1995; Maglio & Kirsh, 1996). Playing Tetris involves maneuvering falling two-dimensional shapes into specific arrangements on the computer screen (see Figure 1). It was found that even as players become faster with practice, they also tend to over-rotate falling shapes, leading to backtracking in the task environment as these over-rotations are corrected. To make sense of this backtracking, Kirsh and Maglio (1994) argued that sometimes physical rotation can serve the same purpose as mental rotation, effectively offloading mental computation onto the physical world (for other examples, see Clark, 1997; Kirsh, 1995; Maglio, Matlock, Raphaely, Chernicky & Kirsh, 1999). Such physical actions—taken to simplify internal cognitive computation rather than to move closer to the external goal state—are called *epistemic actions*.

Recent work suggests that mental rotation and physical rotation share at least some internal processes (e.g.,

Wexler, Kosslyn & Berthoz, 1998; Wexler & McIntyre, 1997; Wohlschlager & Wohlschlager, 1998). Specifically, physically rotating objects can be shown to facilitate or to inhibit mental rotation under certain conditions. The epistemic function of physical rotation in Tetris, therefore, might be far more complex than is suggested by the simple idea that physical rotation can substitute for mental rotation. In fact, Kirsh and Maglio (1994) speculated that physical rotation might serve the epistemic function of cueing retrieval. Because physically rotating a game piece (which we call a *zoid*) in Tetris provides the player two views of it (i.e., in each of two orthogonal orientations), it is possible that seeing two views makes retrieval of relevant information easier than does seeing just one. This idea makes computational sense; for example, if one conceives of memory in terms of an attractor space, such as a Boltzman machine, the first presentation of the shape is like placing the system near the top of the energy sink that represents the target shape in memory, and the second pushes the system closer to this attractor.

Of course, if shape recognition is orientation-dependent (Tarr & Pinker, 1989; Tarr, 1995; Ullman, 1989), we would not expect multiple views of a single shape to speed up recognition. However, it has been shown that shape identification can be facilitated when primed with orientations different from the target orientation (Cooper, Schacter, Ballesteros & Moore, 1992; Srinivas, 1995). Moreover, numerosity judgments can be facilitated even when test stimuli are not presented at the same orientation as the originally learned patterns (Lassaline & Logan, 1993), suggesting memory for the pattern may not require that the retrieval cue be specifically oriented.

That an epistemic action might cue retrieval raises the possibility that such cueing might be limited to specific types of retrieval demands. In particular, the effects of cueing might depend on whether the task requires *direct* or *indirect* access to memory information. Demands for retrieval while playing Tetris can be thought of as *indirect* tests of memory in that they allow for effects of prior experience to be expressed without requiring explicit memory for the original experience (e.g., Richardson-Klavehn & Bjork, 1988). Tasks requiring explicit memory for the original event—such as old/new recognition or recall—are referred to as *direct* tests of memory. Previous work has shown that direct and indi-

Figure 1: In Tetris, two-dimensional shapes fall one at a time from the top of the screen, eventually landing on the bottom or on top of shapes that have already landed. There are seven shapes, which we call *zoids*—, , , , , , . As a zoid falls, it can be rotated, and moved to the right or left. The object of the game is to fill rows of squares all the way across the screen. When a row is completely filled, it dissolves and all partially filled rows above it move down. The game ends when unfilled rows pile up to the top, blocking new zoids from falling.

rect tests of memory are differentially sensitive to characteristics such as orientation, object symmetry, and other physical aspects of visual objects (Srinivas, 1995, 1996; Srinivas & Schwoebel, 1998). Thus, in the experiment presented here, we used both direct and indirect assessments of memory to determine how effective previews are under different retrieval demands. In addition, because the effectiveness of memory cues generally depends on the time that elapses between presentation of cue and presentation of the item to be retrieved, we investigated the effect of various delays between onset of the first preview and onset of the test zoid by embedding the previews in a sequence of zoids presented prior to test.

In this paper, we empirically test the hypothesis that two different views of a falling zoid are better than one. In addition, we examine whether such a potential benefit might depend on the orientation of the preview relative to the zoid that must be placed, and whether these previews facilitate zoid recognition and Tetris performance.

## Method

To test whether two views of a falling zoid leads to faster or more accurate performance in Tetris than does one, we

created a controlled experimental situation that shared many attributes with the game of Tetris but that allowed fine-grained control over the parameters of interest. In our experimental set up, a Tetris configuration (i.e., a Tetris board and zoid floating above it) is preceded either by none, one, or two previews of the zoid in either the same or different orientations (see Figure 2). The participant's job is to quickly and accurately determine whether the zoid fits snugly on the board. Thus, the task creates situations similar to those faced by Tetris players during an actual game, and also requires responses similar to those required of players during an actual game.

Participants spent three days (one hour each day) playing this experimental version of Tetris. Separate groups of participants were required either (a) to make judgments about whether a target zoid fit in an accompanying board (the indirect test), or (b) to make this judgment *and* indicate whether they remembered seeing the test zoid in the set of zoids that were presented prior to the target (the direct test). Between 0 and 2 previews of the target zoid were presented in a sequence of zoids prior to the target, and the orientation of these previews (when present) varied relative to the target. As noted, by placing the previews in a sequence of events prior to the test, we were able to manipulate the interval over which the preview would have to be retained in memory.

## Participants

A total of 30 participants were recruited from psychology courses and participated voluntarily in exchange for course credit. All participants reported normal or corrected-to-normal vision and unencumbered use of both hands.

## Design

The experiment was conducted as a 3 (number of previews: 0, 1, 2)  $\times$  3 (orientation of the first preview relative to the target zoid: same, clockwise rotation of 90°, counter-clockwise rotation of 90°)  $\times$  3 (retention interval between first preview and target zoid, in frames: 0, 1, 2)  $\times$  3 (zoid type: , , )  $\times$  2 (status of target zoid relative to the board: fit, not fit)  $\times$  3 (day of testing: 1, 2, 3)  $\times$  2 (type of memory judgment at test: direct, indirect) mixed factorial design. All factors except type of zoid and type of memory judgment were manipulated within participants.

## Materials

All zoids and boards were constructed from 20  $\times$  20 pixel squares. Squares were outlined by light gray lines, 1 pixel in width, and were filled in solid black. The background for all displays was solid black as well. All zoid types were composed of four blocks. All receptor boards were six blocks in height and width. Four receptor types were defined for each zoid type, corresponding to four ways in which the zoid could be snugly placed. Each receptor type was used with equal frequency. Materials were displayed on a 33 cm VGA monitor controlled by a PC-compatible microcomputer. Onset and offset of each display was synchronized to the vertical scan of the

Figure 2: A schematic representation of some of the events in four frames prior to a test display in a single trial. The Xs indicate non-target zoids. (1) The events in a 0-preview trial. (2) The events in a 1-preview trial, with no retention interval (0 frames) between the preview and the test display. (3) The events in a 1-preview trial with a 1-frame retention interval between the preview and the test display. Here the preview is rotated 90° counter-clockwise relative to the test display. (4) The events in a 2-preview trial with a 2-frame retention interval between the *first* preview and the test display. Here the first preview has the same orientation as the test display, while the second preview is rotated 90° counter-clockwise relative to the test display.

monitor. The standard PC keyboard was used to collect and time (to  $\pm 1ms$ ) participant responses.

## Procedure

Participants were tested on three consecutive days, at approximately the same time each day, with each session lasting approximately 1 hour. All sessions were conducted in a darkened room, with participants seated at an unconstrained distance from the monitor, and began with a five min period for dark adaptation. Participants were told that, on each trial, they would see a sequence of zoids, presented very rapidly. At some random point in this sequence, they would see a combination of a zoid and a receptor board, and would need to make one of two types of responses, depending on whether they were in the indirect or direct memory test condition.

In the indirect condition, participants simply had to decide whether the presented piece would fit snugly into the board. Participants responded in the affirmative using the index finger of their dominant hand, and in the negative using the index finger of their non-dominant hand, pressing either the “z” or “/” keys on the lower row of the PC keyboard. In the direct condition, participants had to indicate with a single key-press both their judgment about whether the presented piece fit snugly in the board and their memory for any occurrence of the

test piece (in any orientation) in the sequence of pieces that preceded the target piece. Participants responded with the index finger of their dominant hand if the target piece fit and they remembered seeing this piece in the preceding sequence, with the middle finger of their dominant hand if the target piece fit and they did not remember seeing this piece in the preceding sequence, and with the index finger of their non-dominant hand if the piece did not fit.<sup>1</sup> Speed and accuracy were equally emphasized.

Each trial began with the presentation of between one and eight zoids (“non-target zoids”) designed to be distinct from the target zoid assigned to the participant. The actual number of these non-target zoids shown was randomly determined for each trial. Each non-target zoid was presented for 250 ms and then replaced by the next non-target zoid; the non-target zoids in this sequence did not repeat (i.e., all were unique). Following this, four zoids (between 0 and 2 target zoids, and between 2 and 4 non-target zoids) were presented for 250 ms each. After the last of these were presented, a target zoid and a receptor board were presented for 250 ms. Following the participant’s response, a tone was briefly sounded (100 ms) indicating a correct (880 Hz) or incorrect (440 Hz) response.

A total of 480 trials were presented in each session. Participants were allowed short breaks after every 80 trials. Feedback on overall accuracy and mean response time was provided at the end of each session.

## Results

First, we asked whether having one preview improved performance over having no previews, and found a pronounced effect in both accuracy and response time (RT). When participants were presented with a single preview, the resulting level of accuracy was significantly higher (0.86) than when they were not presented with a preview (0.53),  $t_{(1,59)} = 33.85, p < 0.001$ . Similarly, when participants were presented with a single preview, the resulting RTs were significantly shorter (869 ms) than when they did not see a preview (1791 ms),  $t_{(1,59)} = 2.01, p < 0.05$ .

Given that providing a preview had an effect on performance, we moved on to determining whether having *more than one* preview had an additional effect, and whether the provision of previews interacted with our other experimental factors. Our analysis of the accuracy data indicated that zoid, number of previews (1 vs. 2), and retention interval all failed to have an effect on accuracy (all  $F_s < 1.00$ ). However, test type did have a significant impact on performance, with participants in the direct test condition performing at a higher level of accuracy (0.95) than participants in the indirect condition (0.88),  $F_{(1,25)} = 4.59, MSE = 0.05$ . Orientation of the prime exerted a statistically significant effect on accuracy,  $F_{(1,25)} = 4.01, MSE = 0.01$ , but the magnitude of the difference between the previews presented in the

<sup>1</sup>We did not ask for a memory judgment on trials in which the piece was judged not to fit, as our primary concern was with the effects of previews on accurate placement of pieces in the board.

**Figure 3:** Effects of orientation of preview and block on accuracy. Practice affects the probability of making a correct response. However, whether the zoid was previewed in the same orientation or in a different orientation (as the test zoid) does not affect the probability of making a correct response.

same orientation (0.92) and those presented in a different orientation (0.91) suggests that the difference may not be meaningful. Exploration of these data across blocks of experience (see Figure 3) suggests that the difference between the two forms of preview was induced by the fact that performance with previews in a different orientation did not improve quite as quickly from the first to the second training block as did performance with previews in the same orientation, though this interaction was *not* significant. Finally, as expected, performance improved consistently across blocks,  $F_{(2,50)} = 6.67$ ,  $MSE = 0.03$ , as can be seen in Figure 3.

Analysis of the RT data indicated that test type, zoid, number of previews, orientation of the preview, and retention interval all failed to affect the speed of responding (all  $F_s < 1.00$ ). Although RTs consistently improved across the experiment,  $F_{(2,50)} = 57.56$ ,  $MSE = 44847.84$ , the form of improvement was dependent on test type (direct vs. indirect),  $F_{(2,50)} = 7.03$ ,  $MSE = 44847.84$ . As shown in Figure 4, the direct test condition (which required *two* response judgments) was slower than the indirect test condition (which required one response judgment), but only in the first block of trials.

## Discussion

Our results show that if participants are presented with two views (i.e., one preview) of the falling zoid (a two-dimensional shape), response times are faster than if only a single view (i.e., no previews) is presented. This sup-

**Figure 4:** Effects of test type and block on mean RT. Participants in the indirect test condition (i.e., deciding whether the zoid fits snugly) respond faster than participants in the direct condition (i.e., deciding whether the zoid fits *and* whether the zoid had been previewed) only on the first day of practice.

ports our hypothesis that *two views are better than one*. Nevertheless, it was a bit surprising to find that three views provide no advantage over two views. In terms of the simple Boltzman machine model mentioned previously, this would mean that the second view of the zoid pushes the system so close to the attractor that it is trapped, and so the third view is rendered irrelevant. Alternatively, the effect of the first preview might be to accelerate the system toward the attractor state to such an extent that a second preview provides no appreciable additional acceleration.

Note that response time was speeded up by a preview in any of the three orientations relative to the test zoid. The benefit was not restricted to previews that shared orientation with the test display. This finding is consistent with priming studies in which it was found that a prime need not be presented in the same orientation as the target to facilitate recognition or identification (e.g., Cooper, Schacter, Ballesteros & Moore, 1992; Srinivas, 1995). It is surprising, however, to find that different orientations prime just as strongly as the test orientation does. One possible explanation is that participants have stored multiple views of the zoids and so seeing one view is just as good as seeing another (Tarr & Pinker, 1989).

The only difference between the direct and indirect tests of memory was observed on the first day of training, and restricted to the latency data. On the first day, participants in the direct test condition required more time

to respond than did the participants in the indirect test condition. This difference may be easily accounted for by the fact that participants in the direct test condition had to make two response decisions and choose among three response alternatives. The *lack* of a difference in either accuracy or latency as a function of memory test suggests that the benefits obtained by having a preview do not depend on the manner in which memory for that preview is assessed.

Returning to the idea of epistemic action in Tetris, these data suggest that by rotating the falling zoids, players may be able to effectively cue themselves, enabling quicker responses in a Tetris situation. Previous research has established various ways in which Tetris players take actions for their epistemic effects (Kirsh & Maglio, 1994; Maglio, 1995; Maglio & Kirsh, 1996). The data reported here show that a preview of the falling zoid at least speeds up performance on a Tetris-like task, but the hypothesis that Tetris players over-rotate zoids in order to speed up performance is not directly tested. It remains to be seen whether actually taking the action of orienting the preview (i.e., physically rotating the falling shape) is a critical component of performance, independent of the presentation of the preview itself.

In the end, we can conclude that two sequentially presented views of the falling zoid lead to faster and more accurate performance than a single view of the falling zoid. In addition, it appears that having this single preview is sufficient to boost performance to something of a limit, as more than one preview adds little if any additional help. It also appears that the benefit of the preview is robust across the retention intervals considered here. Thus, if players are able to use rotations to self-cue, they may be able to get all they need from a single rotation, even one that is somewhat separated in time from the eventual judgment. The payoff associated with a small number of additional steps more than compensates for the temporal and physical costs of executing additional steps. The epistemic functions of physical rotations in Tetris, then, might not be merely to substitute for mental rotation or to provide a visual means for matching the contour of the board with contour of the falling shape, but also to cue or prime retrieval from memory of information associated with the falling shape, enabling faster recognition and faster placement decisions.

### Acknowledgments

# Preschool Children's Use of Category Information to Interpret Negations

Bradley J. Morris (bmorris@andrew.cmu.edu)

Dept. of Psychology, Carnegie Mellon University  
5000 Forbes Ave., Pittsburgh, PA 15213

## ABSTRACT

Two experiments examined 4 and 5 year old children's use of semantic category to interpret negations. In an 'I Spy' game, children were given a hint in the form of a negation then instructed to select a referent in a forced-choice procedure. Children used category information to infer that the referent was semantically related (near-neighbor) rather than semantically unrelated (far-neighbor) to the negated item, though both were logically correct choices. The results suggest that one type of 'pragmatic interpretation' children use for understanding negations is semantic relatedness that reduces the scope and indeterminacy of negations.

An important question in the development of reasoning and communication is how children develop an understanding of logical connectives such as AND, OR, and NOT. Logical connectives are unique problems in language acquisition since they do not directly refer to an object or action but are relational in nature. Negations are particularly vexing since a negation "has no referent...and is inherently indeterminate," (Pea, 1980, p. 156) referring to the absence of an object or set of objects. Negations pose a unique problem in reasoning since they do not specify a clear referent. For example, the statement 'Flipper is not a fish' does not indicate what 'Flipper' is; only what it is not.

A negation is a simple syntactic marker for changing the truth-value of an affirmed statement (Johnson-Laird, 1983). Previous research on understanding negations indicates that processing a negation involves two cognitive operations: creating a representation of an item, then inhibiting this representation (Johnson-Laird, 1983; MacDonald & Just, 1989).

The 'classical' interpretation of a negation is that it refers to anything outside of a designated set equally (Horn, 1989). In a classical interpretation of the previous example, 'Flipper' might refer to a whale, a human, or a car. A classical interpretation of negations presents two main difficulties in communication and reasoning: a) scope, or the limit to the objects or set of objects to which the negation refers and b) indeterminacy of reference, or determining to what a negation refers.

Negations are interpreted classically in formal reasoning- i.e.; a negation includes all objects except those that have been negated (Horn, 1989). However, cognition is bounded; that is, people consider only a small number of possibilities at any time. Thus, since cognition is bounded, people do not consider all possibilities for a negation since this would create a problem set far too

large to be cognitively tractable. Thus, to make operations tractable, children (and adults) must reduce the number of possible solution states, though they are capable of considering more than one possibility (Horobin & Acredolo, 1989). Therefore, either the number of states is reduced randomly or there is a process of determining which states are to be maintained. Such a heuristic must operate within young children's knowledge of negations.

In problem solving, an understanding of logical connectives is necessary to establish the mapping between evidence and form in order to draw a correct conclusion. An understanding of logical connectives is crucial to performance on logic problems. However no current theory gives a principled explanation of how syntactic and semantic information influences their interpretation (Johnson-Laird, 1983).

## Young children's knowledge of negation

By the end of preschool, children have some understanding of negations. Children are capable of assigning truth-values for negations (Kim, 1985). For example, when shown a banana and told that the object is not an apple, children are capable of judging the statement as true. Children are also sensitive to syntactic markers and how these markers limit the scope of negations (De Boysson-Bardies, 1977; Romaine, 1988). For example, children understand that negations refer to particular parts of speech (e.g., noun phrases) due to the position in a sentence. Finally, children have several functional uses for negations such as denying a request ("do you want some juice?" "No") or expressing disappearance ("No juice" when glass is empty) (Bloom, 1970; Pea, 1980).

One question that remains is how children infer a referent for a negation. That is, given a negated noun phrase, syntax alone is insufficient for determining a referent because all 'nouns' could be equally plausible. Another strategy seems necessary inferring a referent. Previous research suggests that children may use linguistic and non-linguistic cues to help them resolve problems of indeterminate reference (Oaksford & Stenning, 1992).

One such cue may be provided by semantic categories. A well-documented finding in developmental research is that young children have the capacity for category-based reasoning because "members of object categories...share deep, underlying commonalties" (Waxman et al., 1997, p. 1074). This category-based information can be used for induction in which the

properties of one entity are extended to another on the basis of similarity.

### **Semantic Category and Memory**

Previous research has also indicated that there is a reciprocal relationship between semantic categories and the structure of memory (Brainerd, Reyna, & Kneer, 1995; Ackerman, 1997). Encoding and recall of items in memory are related to semantic category because accessing an item tends to activate items within the same category more strongly than functionally related items (Brainerd, Reyna, & Kneer, 1995). Category-based information may also function as context, making similar items more salient, aiding retrieval because the process of categorization itself may form associations between concepts (Ackerman, 1997).

Category information may also interfere with retrieval. In the False Recognition Paradigm when similar items are activated increases in errors are directly related to the level of similarity between the distracter and the negated item (Brainerd, Reyna, & Kneer, 1995). Further, negating an item does not seem to reduce the salience of related items. Activation levels of similar items were increased when a target item was negated; even when the items themselves were contextually suppressed (MacDonald & Just, 1989).

To summarize, understanding negations involves a combination of syntactic and semantic/pragmatic processes. Syntax determines the part of speech that a negation modifies (e.g., noun phrase) providing a limit on the scope of a negation. Semantic understanding of negations is a two-step cognitive operation in which an item is represented, then inhibited. When the represented items are accessed in working memory, they activate similar items (i.e., other category members). Because activated items are inhibited in negations, then it is possible that category information guides induction of possible referents by providing a contextual 'frame' in which pragmatic inferences can be drawn. Thus, negating an item may provide a cue to the range of items to which a negation refers by providing context.

There is indirect evidence that category information may provide context for interpreting a negation. First, in a study examining conditional reasoning, phonological cues focused reasoners on intended contrasts (Oaksford & Stenning, 1992). For example, in the sentence *Tim did not travel from Chicago to Pittsburgh by car*, if one stresses the word *car* participants tended to infer probabilities of the mode of transportation *Tim* used mediated by the knowledge of the trip (i.e., plane, train).

A second example is taken from an early study of young children's understanding of negation. In a series of class-inclusion experiments, children were given a collection of objects that could be classified on various

dimensions such as shape or color and given instructions (phrased as negations) to sort these objects on one dimension (e.g., things that are NOT green) (Inhelder & Piaget, 1964). The results indicated that 5-9 year old children did not sort objects using class-inclusion rules (e.g., failing to understand the hierarchical inclusion of 'blue triangles' within the class of 'triangles'). A closer examination of the data indicates that a prominent error pattern was to sort objects on one dimension (e.g., shape). For example, when told to select objects that were 'NOT red circles,' children would often select only red triangles, ignoring other possible responses (such as other circles or non-red triangles). Perhaps 'circle' guided participants to infer that they should focus on a shape-based set of objects. A final example is drawn from a semi-structured interview in which a child implicitly states how such category-based inferences are useful for interpreting negations (from Inhelder & Piaget, 1964, p. 141):

Piaget: "And is it more correct to say that a cow isn't a bird, or that a house isn't. Or are both equally correct?"

Ros: "It's a little ridiculous to say that a house isn't a bird."

Piaget: "And a cow?"

Ros: "Well, it is an animal!"

There seem to be three possibilities for how young children might use category information to interpret negations. The first is that they simply do not use this information. However, if children do use this information, then there are (at least) two possibilities that reflect contrary pragmatic interpretations. One interpretation infers that the referent is something like the negated item. This would result in a 'near-neighbor' inference in which children would look for something within the same category as the negated item. A second interpretation infers that the referent is something unlike the negated item. This would result in a 'far-neighbor' inference in which children would infer that the referent is something outside the category of the referent. Using category information may help reduce the number of possibilities corresponding to a negation by providing a framework for evaluating which items may be relevant - either items that are closely related to the negated item (near-neighbor) or items that are unrelated to the negated item (far-neighbor). Using the category information to infer either type of relationship between the negated item and the referent demonstrates a structured understanding of pragmatics and an attempt to infer the meaning of the speaker.

The present study examines two questions. First, do young children use category information to infer a probable referent for a negation? If children do not use category information then the number of far-neighbor and near-neighbor choices should not differ from chance.

Second, if children use category information, do they infer that the referent is something like the negated item (near-neighbor) or something unlike the negated item (far-neighbor)? If the number of choices differs from chance, then this tendency reflects one of two possibilities. Above chance selection of near-neighbor items suggests that the child inferred that referent is something like the negated item. An above chance selection of far-neighbor items suggests that the child inferred that the referent is unlike the negated item.

Two experiments were conducted to examine young children's use of category-based inferences to induce the referent of a negation. A forced-choice paradigm was used for all experiments in which participants were presented with three objects: a negated item and two choices. Children were instructed that they were playing an "I Spy" game. Children were given a hint as to what the experimenter was "spying" phrased as a negation. They were then asked to infer the referent of the negated item by making a choice between the objects and placing it into a basket. The objects represented *logically correct* choices but differed only in the *degree of relatedness* to the negated object.

Three semantic categories were used for both experiments: animals, vehicles, and foods. Three objects were chosen from each category. Three factors were examined in the series of experiments: the impact of the familiarity of the objects, the number of near-neighbor choices, and the reference set.

In Experiment 1, the experimenter provided three familiar objects from each category and presented a 'hint' in the form of a negation. Children were then asked to choose between two objects: one from within the same category of the negated item and one from a different category. Experiment 2 used the same design as Experiment 1 but used objects that were unfamiliar yet fell into the categories.

## Experiment 1

### Methods

#### Participants

The participants were twenty-one 4-year-olds and 20 5-year-old children from two preschool classrooms. Children ranged in age from 4.1 to 5.5 years (25 girls, 16 boys). Most children were from middle class, white families. Children were selected on the basis of receipt of parental permission.

#### Materials

A total of nine objects were used. The objects were chosen to represent three semantic categories: foods-apple, banana, orange; animals- dog, cat, bunny; vehicles-car, plane, boat. The objects were chosen as familiar

based on rankings taken from the MacArthur Communicative Development Inventory (CDI) that established each object as being in receptive vocabulary before year 2 (Fenson et al., 1994). Each object was similar in size. All children named each object spontaneously.

#### Procedure

The procedure was a forced-choice selection task framed as an "I spy" game in which children were presented three objects: two within the same semantic category and one outside the semantic category. Children were told to guess to which object the experimenter was referring and to place that object in a basket. The child was told "What I spy is *NOT* (emphasized) the (negated object)" and asked to place one object in the basket. Each child was tested individually in a quiet room and took approximately 10 minutes. There were two phases: a warm-up and an experimental phase. The warm-up phase consisted of three questions intended to familiarize each participant with the game and to check understanding of basic negations.

#### Warm-up

The warm-up phase began by asking participant to name all objects and to correct any mistakes. Most participants named each object correctly and all correctly named the object set before warm-up tasks began. The same objects were used in the warm-up and experimental phases. Participants were then presented with three warm-up questions to learn the rules of the 'I spy' game. All children demonstrated an understanding of negations by not choosing target object on three of three trials and continued into the experimental phase.

#### Experimental Phase

Once the child was familiarized with the procedure, each array was presented and the child was told "What I spy is NOT the x" and instructed to place one object in the basket. Once the question was asked, eye contact with the participant and materials was avoided until after the selected object was placed in the basket in order to minimize nonverbal cues. The negated object (A1) always was one of two within the same category. The two possible choices included one from within the semantic category of the negated object (A2) and one from outside the semantic category of the negated object (B1). A total of nine trials were performed in which each object was negated only once and appeared in two other arrays, once as a near-neighbor choice and once as a far-neighbor choice. The placement of the negated object and possible referents was systematically varied. Order of

presentation was counterbalanced. All participants completed all nine trials.

### **Coding**

Responses were coded in one of two categories: within the same category as the negated item (near neighbor) or outside the category of the negated item (far-neighbor). Children could pick one or two objects per trial. If one object was chosen, then it was coded as either within the same category or outside the category of the negated object

## **Results**

Children's choices were examined two ways: across-individuals and within-individuals. Across-individual analyses examined overall response trends while within-individual analyses examined patterns of responses for consistency across the experiment. Responses were coded in one of two categories: near-neighbor or far-neighbor. Preliminary analyses indicated no gender or age differences thus were combined for further analysis.

### **Across-Individual Results**

Seventy-one percent of choices were within the category of the negated object leaving twenty-nine percent outside the category. A confidence interval test was conducted to compare whether children's item selection was at a level different than would be expected if they were choosing items randomly. Seventy-one percent of item choices were within the category of the negated item leaving twenty-nine percent of choices outside the category of the negated item. The selection pattern was significantly different than would be expected by chance ( $p < .01$ , confidence interval 66-75%). This indicates that children selected items from within the same category as the negated item at an above chance level.

### **Within-Individual Responses**

In order to evaluate the consistency of individual participants, a within-individual analysis was performed. A participant was coded as adhering to a pattern if they used the same selection pattern on seven of nine trials. Seven of nine trials represent an above chance pattern of responses whose conditional probability was less than .10. Twenty-eight children were coded as using a consistent response pattern and of these participants, 23 used a near-neighbor selection pattern while 5 used a far-neighbor pattern.

## **Discussion**

The results indicated that young children demonstrated a preference for choosing an object from within the same category as the referent for a negation (though both choices were logically equal). For example, given an apple and a boat and asked "What I spy is NOT a banana", children overwhelmingly selected the apple. Individual analysis revealed a large number of children responded consistently across tasks, primarily using a near-neighbor strategy, in which a near-neighbor object was chosen 7 of 9 times. No age-related differences were found between the 4 and 5 year olds.

These findings suggest that children are sensitive to the semantic information provided in a negation as providing a context for pragmatic interpretation. This information was used most frequently to infer a near-neighbor relationship between the item negated and the referent. Thus, inferring that 'not a cat' is a dog was more frequent than inferring that 'not a cat' referred to a car. It is also plausible that this same marker may indicate that the object is outside of the category of the referent, as demonstrated by the five children who made such an interpretation. However both are clearly category based inference patterns.

Although the results of the study are clear their interpretation could be limited by the familiarity of the materials. Perhaps with familiar objects there are thematic relationships (e.g., dogs and cats are often in the same house) along with the taxonomic relationships, and these additional links increased near-neighbor choices. Thus, a second study was designed to examine the influence of less familiar materials to eliminate the possibility that labels and thematic relations may have influenced the results.

## **Experiment 2**

In order to address the familiarity bias that may have influenced the results of Experiment 1, Experiment 2 extended the same procedure and categories of Experiment 1 using unfamiliar stimuli. A similar procedure was utilized using novel materials (yet within the same semantic categories as Experiment 1) to reduce the possibility that the familiarity of materials might be influencing the results. A second procedural change was introduced to reduce the focus on familiar labels: only naming the target object only during the experimental phase.

## **Methods**

### **Participants**

The participants were 21 4 and 21 5-year-old children from two preschool classrooms in a different preschool than in Experiment 1. Children ranged in age from 4.4 to 5.3 years (22 girls, 20 boys). Most children

were from middle class, white families. Children were selected on the basis of receipt of parental permission.

### **Materials**

Nine objects were chosen as unfamiliar, within the same three semantic categories as Experiment 1: food-eggplant, zucchini, cabbage; animals- lynx, tapir, gazelle; vehicles- diving bell, seacopter, hovercraft. Each object was similar in size.

### **Procedure**

The basic procedure was similar to Experiment 1. The procedure was slightly different in that only the target objects were named. This procedure was used to reduce the emphasis on labels. Responses were coded as in Experiment 1.

## **Results**

### **Across-Individual Results**

Preliminary analyses indicated no significant differences between four and five-year-olds and the two ages were combined for further analysis. A confidence interval test was conducted to compare whether children's item selection was at a level different than would be expected if they were choosing items randomly. Seventy percent of choices were within the category of the negated item and thirty percent of choices outside the category of the negated item. The number of within-category selections was above chance ( $p < .01$ , confidence interval 64-76%).

### **Within-Individual Responses**

As in Experiment 1, a participant was coded as adhering to a pattern if the same selection pattern was used on seven of nine trials. Twenty-two of 42 participants used a near-neighbor selection pattern on at least 7 of 9 trials.

## **Discussion**

Experiment 2 was conducted to replicate the findings of Experiment 1 and examined the possibility that the results of Experiment 1 may have been influenced by the familiarity of the materials. As in Experiment 1 almost all children chose only one object per trial and this object was most often (66%) within the same taxonomic category as the target. Once again there was considerable individual consistency, with 22 children choosing the near-neighbor objects at least 7 of 9 trials. One interesting difference from the previous experiment was that no child consistently chose the far-neighbor object.

These data suggest that when given a choice among unfamiliar objects as the referent of a negation, there is a tendency to choose an object from the same taxonomic category. Thus, the semantic information in a negation provides one clue as to how the negation might be interpreted.

## **General Discussion**

The findings indicated that most children used category information to interpret negations and they used this information to infer that a referent was related to the item negated rather than unrelated. The findings suggest that children tend to make these inferences regardless of whether objects are familiar or unfamiliar.

The first research question investigated the possibility that children used category information to infer the intended referent of a negation. Children selected items at levels above chance; that is, they demonstrated a preference for one type of item, presumably due to category information.

The second research question examined the type of selection preference. There were two possibilities for a selection preference: selecting items within the category of the negated item (near-neighbor) or selecting items outside the category of the negated item (far-neighbor). The two patterns involve different assumptions about the pragmatics of negation. A near-neighbor pattern uses category information to find an item similar to the negated item. For example, NOT CAT would mean DOG (rather than CAR) since both are animals. A far-neighbor pattern uses category information to find an item unrelated to the negated item. Using the previous example, NOT CAT would mean CAR (rather than DOG). The results clearly demonstrated that children selected an object from within the same category as the negated item. Individual analyses indicated that children's near-neighbor selection patterns were quite consistent across the problem set with roughly half of the children selecting near-neighbor items on at least 7 of 9 trials.

The findings suggest that semantic information may help reduce the scope and indeterminacy of negations by providing a contextual 'frame' for pragmatic inference. That is, choosing to negate an item may provide a cue to its interpretation: by choosing to negate item  $x$ , some property of item  $x$  may be relevant to understanding the referent. For example, the sentence 'Whiskers is not a cat' provides a clue that there is something about this object (cat) that is relevant to figure out what 'Whiskers' is- otherwise another object might have been negated. For example, we would probably be more surprised if 'Whiskers' was a book than if 'Whiskers' was a hamster since a near-neighbor interpretation favors the latter. Thus, the pragmatics of a near-neighbor interpretation may reduce the search for

possible referents to items within the category of the negated item (e.g., other pets). This strategy can be formalized using a simple inference rule: given NOT X, then search for items within the category of X as possible referents. Thus, this inference rule combined with semantic category information may provide a powerful tool for inferring the referent for a negation.

The findings suggest a principled explanation of interpreting negations. Since the structure of categories and memory are well established by previous research (Brainerd, Reyna, & Kneer, 1995; Ackerman, 1997), all that is required is a simple pragmatic rule easily derived from experience in which a negation indicates a near-neighbor relationship between the negated item and referent. These findings suggest that the semantic information from negations may provide one source of information with which one reduces the scope and indeterminacy of negations, thus reducing the number of possibilities while maintaining information. A near-neighbor relationship may be common in young children's language environments in word acquisition. For example, when children overextend labels onto unfamiliar objects (e.g., labeling a CAT a DOG) adults often implicitly utilize a near-neighbor negation in correcting the error ("No, that is not a dog, it is a cat).

Finally, these findings may provide one explanation for the interaction between pragmatics and deviations from normative reasoning lacking in current theories of logical development. Understanding children's interpretations of negations is important since children and adults do not appear to use classical logical reasoning (Johnson-Laird, 1983; Sharpe et al., 1996). That is, children and adults rarely solve logical problems as a trained logician would solve them. As noted earlier, current theories of logical development rely on pragmatics to explain performance, yet do not provide explanations of how pragmatics is achieved. Therefore, understanding how pragmatics influences reasoning solutions and strategies is useful for understanding performance and how to improve performance through instruction. This study provides evidence for one type of pragmatic interpretation- a near-neighbor interpretation of negations in which the category of the negated item provides context that guide item selection to an item within the same category.

# An Inquiry Into the Function of Implicit Knowledge and its Role in Problem Solving

Timothy J. Nokes (tnokes@uic.edu)  
Stellan Ohlsson (stellan@uic.edu)

Department of Psychology

Chicago, IL 60607, U.S.A.

## Abstract

Research on implicit learning has shown that the knowledge generated from memorizing patterned symbol sequences can be used to make familiarity judgements of novel sequences with similar structure. However, the degree to which these knowledge representations can be used for subsequent cognitive processing is not known. In this study, participants memorized either patterned number strings (patterned training) or random number strings (random training) and then solved either a number or letter sequence extrapolation problem. Patterned training participants performed significantly better on number problems than on letter problems, thus implying that patterned training influences performance, but only on near transfer problems.

## Function of Implicit Knowledge

To support successful performance on complex, unfamiliar tasks, knowledge must be both abstract and generative. The origin of such knowledge is a central question for cognitive psychologists, developmental psychologists, educators, machine learning researchers and philosophers of science.

Many theoretical proposals conceptualize the acquisition of deep knowledge as a deliberate, effortful and constructive process. For example, one frequently stated hypothesis with roots in both philosophy (Popper, 1972/1959) and psychology (Thorndike, 1898) claims that learners replace or revise their knowledge when the latter is *falsified* by contradictory information; on this view, deep learning is driven by the evaluation of evidence (Gopnick & Meltzoff, 1997; Posner, Strike, Hewson & Gertzog, 1982). The hypothesis of *analogical learning* (e.g., Holyoak & Thagard, 1995) claims that the learner retrieves a possible analog to his or her current problem from memory and discovers their shared structure by constructing a mapping between them. According to the idea of *representational redescription* (Karmiloff-Smith, 1992), the learner reflects on his or her knowledge and, as a consequence, generates a higher-order representation of it. Many other proposed learning mechanisms share this active character (Ram & Leake, 1995).

In contrast, research on implicit learning of artificial grammars (Reber, 1989, 1993) suggests that learning is a

passive, inductive process which is independent of any intention to learn and which creates knowledge that cannot be deliberately recalled. In the *training phase* of the standard artificial grammar learning paradigm, the participants memorize letter strings, one by one. The strings have been generated with an artificial grammar and hence embody some very abstract properties, but the participants are not informed of this fact. In the *test phase*, the participants encounter new letter strings which are derivable from the relevant grammar, mixed with distractors which are not. The task is to decide whether the test strings are of the same type as the strings seen during the training phase. A large body of evidence (Stadler & Frensch, 1998) shows that people perform better than chance in the test phase, indicating that they have acquired knowledge of the underlying grammar.

Servan-Schreiber and Anderson (1990) and Perruchet and Gallego (1997) have attempted to explain artificial grammar learning in terms of the learning of substrings. However, Manza and Reber (1997) report a series of six experiments in which the strings encountered in the test phase were expressed in different letters than the strings encountered in the training phase. People perform better than chance in this condition as well, indicating that what is learned is abstract enough to transfer and hence does not consist of knowledge about the relative frequencies of individual substrings. In short, the data imply that what is learned in the artificial grammar learning paradigm is an abstract representation of the relevant grammar.

This finding is counterintuitive, because string memorization is passive, incidental and purely inductive and so stands in contrast to the constructive learning mechanisms hypothesized in other areas of cognitive research. This leads us to inquire into the nature of the knowledge generated by the string memorization procedure. How does that knowledge function in subsequent processing? Can it support problem solving, text comprehension and other higher-order cognitive processes?

To investigate this question, we revised the standard artificial grammar learning paradigm by replacing the string classification task typically used in the test phase with a letter sequence extrapolation problem. Sequence extrapolation problems were first introduced into psychology by Louis L.

Thurstone and they have been studied from a cognitive perspective by Simon (1972), Greeno and Simon (1974), and Kotovsky and Simon (1973). In this type of problem, the problem solver is given a sequence of letters generated in accordance with some pattern and asked to extrapolate it. To solve the problem, he or she must thus first uncover the pattern in the given segment of the letter sequence and then use that pattern to generate the next N letters in the sequence.

The goal of the present study was to determine whether implicit learning of the pattern embedded in a sequence improves the ability to extrapolate that sequence. In the training phase, our participants memorized strings of double-digit numbers generated in accordance with a pattern. In the test phase, they tried to extrapolate a letter or number sequence that followed that same pattern. If string memorization produces an abstract and generative representation of the pattern underlying the strings and if people can access that representation during problem solving, string memorization should improve performance on sequence extrapolation.

To investigate the levels of abstraction we instantiated the extrapolation tasks in both numbers (near transfer) and letters (far transfer). If the knowledge generated from string memorization is encoded in terms of the surface features of the training strings, then that knowledge should not be available for problem solving. In contrast, if the knowledge gained during training is of limited abstraction, then it should be available to solve number problems (near transfer) but not letter problems (far transfer). Finally, if the knowledge gained is completely abstract it should be available to solve both number and letter problems.

## Method

**Participants** Ninety-eight undergraduate students from the University of Illinois at Chicago participated in return for course credit.

**Materials** The target tasks were two sequence extrapolation problems with a periodicity of six items. The target tasks were instantiated in both numbers (near transfer) and letters (far transfer); see Table 1. To enable the participants to induce the pattern, the given segments were 12 items long. That is, they covered two complete iterations of the underlying pattern. Problems were created specifically for this study with patterns similar to those used by Simon (1972) and Kotovsky and Simon (1973).

For example, pattern 1 in Table 1 can be described as follows: The pattern consists of two groups of two letters, separated by X and ending with Z. Within the first group of two, the second letter is two steps forward in the alphabet from the first. In the second group of two, the first letter is one step forwards from the last letter in the first group, and the second letter is one step backwards from that same letter. The second period has the same internal structure but begins with the letter that is one step forward from the second letter in the first group of two in the previous period.

Table 1. Two sequence extrapolation problems expressed in both letters and numbers.

Symbol Type	Given letter or number sequence & the correct 8-step extrapolation
<i>Problem 1</i>	
Letter	B D X E C Z E G X H F Z H J X K I Z K M
Number	25 27 47 28 26 49 28 30 47 31 29 49 31 33 47 34 32 49 34 36
<i>Problem 2</i>	
Letter	C D B E A M D E C F B N E F D G C O F G
Number	63 64 62 65 61 73 64 65 63 66 62 74 65 66 64 67 63 75 66 67

There were 24 training strings consisting of 12 double-digit numbers, twelve for each problem. The twelve strings associated with a problem followed the same pattern as the given letter or number sequence; see Table 2 for examples. In addition, there were 24 strings of random double-digit numbers used in the control condition. Participants in both number and letter problem solving conditions received the same training.

Table 2. Two training strings for Problem 1.

Example	String
1	13 15 35 16 14 37 16 18 35 19 17 37
2	59 61 81 62 60 83 62 64 81 65 63 83

Each participant received a booklet with two parts. Within each part, there were twelve sheets presenting the strings to be memorized, twelve blank recall sheets, one sheet for assessing the result of the training, one sheet presenting the sequence extrapolation problem, and one blank sheet to assess the participants knowledge of the pattern. Problems were counterbalanced across all conditions.

**Design and procedure** The participants were randomly assigned to one of four groups created by pairing training (patterned vs. random) with problem-type (letter vs. number): patterned near ( $n = 26$ ), patterned far ( $n = 27$ ), random near ( $n = 21$ ), and random far ( $n = 24$ ). In the patterned training groups, the participants memorized the strings that conformed to the same patterns as those in the extrapolation problems; see Table 2 for examples. In the

random groups, the participants memorized random number sequences. In the near transfer groups, the target problems were number extrapolation problems; see Table 1. In the far transfer groups, the target problems were letter extrapolation problems; see Table 1.

The participants were tested in groups of 25. The procedure consisted of two *cycles*. Each cycle was composed of training followed by problem solving. The participants memorized and recalled twelve strings, one by one. They were given 60 seconds to memorize each string. They were then told to turn the page and write down the string. This procedure was repeated through the twelve training strings. Next, the participants were told to turn the page and solve the sequence extrapolation problem. They were given 5 minutes to solve the problem. They were then asked to turn the page and describe the pattern in the extrapolation sequence as best they could. The second cycle proceeded in the same way. The procedure took approximately 70 minutes.

## Results

**Training** The first question is whether the participants in the patterned training group extracted the pattern embedded in the patterned training strings. If they did, they should perform better on the memorization task than the participants in the random training group. Knowledge of the pattern can be used to reconstruct the number sequence so it should improve recall performance.

The *memory score* for each participant was the number of double-digit numbers correctly recalled in the memorization task. Because there were 12 numbers to memorize, the memory score varied between 0 and 12. Mean memory scores for both patterned and random groups for each pattern are presented in Figure 1.

A 2 (training, patterned vs. random) by 2 (pattern-type, 1vs. 2) mixed analysis of variance revealed that there were main effects for both training and pattern-type. The patterned training group performed significantly better than the random training group,  $F(1, 96) = 88.28$ ,  $MSE = 8.68$ ,  $p < .05$ , indicating that the former benefited from the patterns embedded in the training sequences. As Figure 1 shows, this effect is present for each training pattern. There was also a main effect of pattern-type,  $F(1, 96) = 4.25$ ,  $MSE = 1.48$ ,  $p < .05$ , indicating that pattern 2 was easier to detect than pattern 1. Finally, type of training interacted significantly with pattern-type,  $F(1, 96) = 5.38$ ,  $MSE = 1.48$ ,  $p < .05$ , indicating that the advantage of the patterned training group was larger for pattern 2 than for pattern 1.

In summary, the data show that the patterned training group performed better on the string memorization task than the random training group. We infer that the participants in the patterned group learned the pattern embedded in the relevant training strings. It is noteworthy that the memorization strings did not share any substrings. Hence, this result contradicts that predicted by the substring hypothesis (e.g., Perruchet & Gallego, 1997).

Figure 1. Mean memory scores for both training groups on pattern 1 and 2.

**Problem-solving** The second question is whether the relevant training group performed better on the problem solving tasks. The *problem solving score* was the number of letters or numbers correctly extrapolated in each problem solving task. Because the participants were asked to continue the sequence to eight places their problem solving scores varied between 0 and 8. Figure 2 shows the mean problem solving scores for both patterned and random groups on each problem.

Figure 2. Mean problem solving scores for patterned and random groups on problems 1 and 2.

Although the patterned training group performed better than the random group on each problem, a 2 (treatment, patterned vs. random) by 2 (problem-type, 1 vs. 2) by 2 (transfer, near vs. far) mixed analysis of variance revealed no main effect for treatment condition,  $F(1, 94) = 1.03$ ,  $MSE = 15.33$ , *ns*. However, there was a main effect of transfer,  $F(1, 94) = 10.42$ ,  $MSE = 15.33$ ,  $p < .05$ , indicating that participants in the near transfer groups performed significantly better than participants in the far transfer groups. There was also a main effect of problem-type,  $F(1, 94) = 16.99$ ,  $MSE = 6.34$ ,  $p < .05$ , indicating that problem 2 was easier than problem 1. This is consistent with the higher memory performance on pattern 2; see Figure 1.

In addition, the interaction of treatment by transfer was marginally significant,  $F(1, 94) = 3.94$ ,  $MSE = 15.33$ ,  $p = .05$ , indicating that the advantage for participants in the patterned group was larger on near transfer problems than on far transfer problems. Figure 3 shows the mean problem solving scores for both patterned and random groups as a function of transfer. Main comparisons show that the patterned group performed significantly better than the random group on near transfer problems but not on far transfer problems,  $F(1, 94) = 6.41$ ,  $p < .05$ , and  $F(1, 94) = .87$ , *ns* respectively. These results show that participants in the patterned group only benefited from training when solving near transfer problems.

Figure 3. Mean problem-solving score for patterned and random groups on near and far transfer problems.

**Individual differences** To further investigate the relationship between string memorization and problem solving, we compared mean memory performance for each position in the sequence to the number of participants who correctly solved that position in problem solving. Participants were classified as either high or low memory

based on a median split of the memory scores for both patterned and random training. Median splits were calculated at each position of the pattern and the number of participants to correctly extrapolate each position was recorded. Table 3 shows the average number of participants to solve any given position correctly for both patterned and random groups as a function of memory.

Table 3. Percentage of subjects to solve any given problem position correctly

Memory Performance	Training Condition	
	Patterned	Random
Low	39%	56%
High	79%*	48%

In addition, chi square tests were calculated at each position of the problem to compare the number of high memory participants to correctly solve a particular position to the number of low memory participants to correctly solve that position. Chi square tests revealed that for patterned training, significantly more high memory participants solved corresponding extrapolations than low memory participants,  $\chi^2(1, N = 53) = 10.43$ ,  $p < .05$ . Chi square tests also showed that high-low memory groups with random training did not significantly differ in problem solving performance,  $\chi^2(1, N = 45) = .20$ , *ns*.

Similar position by position analyses were conducted comparing participants who solved near transfer problems to those who solved far transfer problems for both training groups. Table 4 shows the average number of participants to solve any given position correctly for both patterned and random groups as a function of transfer.

Table 4. Percentage of subjects to solve any given problem position correctly

Problem	Training Condition	
	Patterned	Random
Near transfer	76%*	55%
Far transfer	41%	48%

Chi square tests revealed that for patterned training, significantly more participants solved near transfer (number) problems than far transfer (letter) problems,  $\chi^2(1, N = 53) = 5.84$ ,  $p < .05$ . Chi square tests also revealed that participants in the random group did not significantly differ when solving near and far transfer problems,  $\chi^2(1, N = 45) = .64$ , *ns*.

## Discussion

As expected, the patterned training group performed significantly better than the random training group on the memorization task. The number strings were equivalent in the two conditions except for the fact that the strings memorized by the patterned group contained a pattern, while

the strings memorized by the control group were random. The higher performance of the patterned group is strong evidence that they acquired a schema for the underlying pattern during memorization. This replicates the common result found in implicit learning experiments (Berry, 1997; Reber, 1993; Stadler & Frensch, 1998).

The question asked here is whether the participants could apply this implicitly learned schema in deliberate problem solving. The patterned group was slightly better than the random group on the problem solving tasks, but the difference was small in magnitude (see Figure 2). However, significant differences appear when we take the type of problem and individual differences into account. There was a significant interaction between type of training and type of problem solved. The patterned group performed significantly better than the random group on near transfer problems but not on far transfer problems, indicating that the knowledge generated from the memorizing the pattern facilitated problem solving, but only when solving problems instantiated in surface features similar to those used in the training sequences.

This conclusion is also supported by the position-by-position analyses. Participants in the patterned training condition who performed above the median on the memorization tasks were consistently more likely to solve any one position during sequence extrapolation than those who performed below the median. This result was true for both problems 1 and 2 (see Table 3). In addition, the number of subjects who correctly solved any one position during extrapolation was consistently larger for participants in the patterned training condition who solved near transfer problems than for those who solved far transfer problems. Again, this result was true for both problems (see Table 4). No effect was observed in the random training conditions.

A plausible explanation for why the participants could not apply what they learned during training to the letter strings is that the relations in the patterns are less obvious on the alphabet than on numbers. For example, to solve pattern 1, the subject needs to realize that the letters E and C are the predecessor and successor, respectively, to D, a fact which is less obvious than the fact that the numbers 26 and 28 have those positions with respect to 27. This explanation implies that memorization of letter strings might produce different results. We are currently conducting studies to explore this implication.

In summary, our results are consistent with the hypothesis that what is acquired by memorizing patterned symbol sequences is a knowledge representation that is potentially generative but of limited abstraction. Such a representation might not be available for recall, conscious inspection or verbalization, but is nevertheless available to other high-level cognitive processes such as problem solving.

Although people do not go through life memorizing symbol strings, they do experience sequences, repetitions, and recurring events. Everyday tasks like starting a car has an intrinsic sequential structure: A person has to insert the

key before he or she can turn it; he or she must be inside the car in order to insert the key; he or she must open the door in order to get inside the car; and so on. In symbolic domains, sequential patterns of various kinds are perhaps even more prevalent. An example is the set of computer commands for accomplishing an elementary task such as a writing and sending an email message. Sequential patterns are consequences of the fundamental fact that actions have preconditions.

Given the importance and prevalence of sequential patterns, it is plausible that human beings have evolved cognitive mechanisms for identifying and encoding them. The output of this mechanism are what cognitive scientists often call schemas (Marshall, 1995). The data presented in this paper are consistent with the hypotheses that this mechanism operates even when the learner is not deliberately trying to extract a schema. We find this conclusion compatible with everyday experience: We doubt that human beings walk around and deliberately attempt to find patterns in experience; they find those patterns anyway.

If this conclusion is supported in future studies, the problem for cognitive theory is to elucidate the mechanism by which a schema that is not available for deliberate recall nevertheless influences problem solving, decision making, conceptual change and other cognitive processes. Hybrid models that combine symbolic representations with subsymbolic operations on activation levels (e.g., Anderson & Lebiere, 1998) seem the right kind of model, but the precise specification of such a model has to await replication and elaboration of the empirical observations reported in this paper.

## Abstract

Cognitive scientists have become increasingly interested in doing research on the nature of interdisciplinary collaboration. This new direction raises questions about the role that discipline specific practices may have when scientists from different disciplines collaborate. In this paper we explore one such discipline-specific belief: the importance of hypothesis testing in psychology research.

## Introduction

We interviewed scientists about their collaborative processes (Okada, Schunn, Crowley, Oshima, Miwa, Aoki, & Ishida 1995), and a computer scientist who had collaborated with a cognitive psychologist mentioned the following:

“The most important benefit of participating in this interdisciplinary collaboration is that there are scientists who have a different sense of value on science. For example, when working with researchers in the same discipline, we share a common ground and a common language. We can make progress in our project very quickly without wondering about what the co-researcher meant. Now, I think that my co-researcher in this interdisciplinary project and I didn’t share that common ground when we started our project. Therefore, we could not make any progress for about one year. We could not understand what confused us... The difference of disciplines related to the differences in the sense of value on science, methodology that we use, and more concretely speaking, evaluation criteria. Those differences made me feel this interdisciplinary collaboration was very interesting!” [Translated from Japanese]

We have also had similar experiences when working with computer scientists. It seemed that the computer scientists were more concerned with creating phenomena on a computer system, while we, as psychologists, were concerned with understanding phenomena in the real world, through experimental design, hypotheses, and manipulating variables.

These episodes suggest that scientists have beliefs about how science should proceed and be evaluated, and that

these beliefs are discipline-specific. These beliefs influence scientists’ research activities, such as conducting research projects, writing research articles, and advising students’ research projects. In this paper, we will focus on a discipline-specific belief about science that is widely shared in the psychology community. Recently, research interests in interdisciplinary collaboration have been growing in the cognitive science community (Derry & Gernsbacher, in press). An interdisciplinary collaboration, by nature, is an enterprise by collaborators with different beliefs from different backgrounds. Thus, it would be extremely important for us to know what kind of beliefs each discipline brings into the collaboration.

## Hypothesis-Testing as a Prescriptive Method

Scientific psychology has emphasized the importance of justification as a measure for being scientific. The hypothesis-testing style (i.e., entertaining clear hypotheses and testing them based on data) has been adopted as a prescriptive means for justification. When conducting scientific research, many psychologists believe that they must first develop clear hypotheses before testing them against the available data.

This hypothesis-testing style seems to be an offshoot of several dominant movements that emerged in Western psychology in the 1930s: logical positivism and operationism, hypothetico-deductive method, and inferential statistics.

Logical positivism aims to clarify the language of science and investigate the conditions under which empirical propositions are meaningful, then verify the propositions by means of a concrete procedure. This movement in the philosophy of science was introduced to the psychology community in the 1930s by Stevens (1939). Operationism (Bridgeman, 1928), which claims that a scientific concept should be defined by concrete operations to achieve the concept, was integrated into the logical positivism movement. These movements served as a strong theoretical background for the formation of scientific psychology.

The hypothetico-deductive method (H-D method) is a scientific method in which investigators are required to adopt a postulate tentatively and deduce its logical implications, and then check the validity of them by observation. Hull, a founder of neo-behaviorism, adopted it

as a core research method for his studies (Hull, 1943). As neo-behaviorism became dominant in psychology for the next several decades, Hull's emphasis of the H-D method had a strong influence in the psychology community.

With the development and introduction of inferential statistics to psychological research, investigators then had tools to implement logical positivism and the H-D method in their research (Fisher, 1935).

These movements had strong influences on the psychology community, the effects of which are still being felt today. In the rest of this paper, we will address the following questions related to the hypothesis-testing style of research in the community of psychology: How and when was such a belief formed in the psychological community in Japan? What kind of role does this belief about science play in shaping research activities?

The primary data are from the Japanese psychology community. However, we feel that this data reflects the situation of psychology in the Western community as well, since the Japanese psychology community has been strongly influenced by Western psychology, particularly by the USA. Moreover, Kerr (1998) found a similar pattern of researchers' beliefs on the hypothesis-testing style in the psychology community in the USA using a similar questionnaire survey with somewhat a different focus.

### Three Aspects of Research Activities

We will focus on three important aspects of scientific research: 1) Writing journal articles; 2) educating psychology students, and, most importantly; 3) conducting research projects.

#### On Writing Journal Articles

When submitting articles to psychology journals, authors sometimes receive comments that may have been motivated by the belief that research papers without hypotheses are unscientific. Following are examples of comments that our colleagues received from journal reviewers:

"The authors do not make any predictions or provide the foundation for predictions." (Cognitive Science)

"The most serious problem of this paper is that there is no clear hypothesis mentioned. ...You should predict what kind of result you would acquire and describe what the paper would contribute if the result is obtained." (Japanese Journal of Psychology) [Translated from Japanese]

In order to verify whether or not these examples reflect the current situation of the psychology community in Japan, we conducted a questionnaire survey of psychology researchers in 1998. Participants were first and second authors of articles published in the Japanese Journal of Psychology and the Japanese Journal of Educational Psychology over the previous year. Those two journals are bulletins of the two major scientific psychology societies in Japan. A questionnaire was mailed to 137 authors. We received replies from 111 authors—a response rate of

81.2%! The questionnaire included questions about the timeline of developing the hypotheses mentioned in each article and authors' past experiences of hypothesis formation in research activities. Each question will be described in detail in later sections of this paper.

Participants were asked if they had ever received reviewer comments that recommended revising the article to clarify the hypothesis: 25.7% of respondents answered yes. Considering the fact that this question only applies to authors who have previously submitted at least one paper to a journal without including any hypotheses, this rate should be regarded as higher than it appears. This suggests that the Japanese psychology community encourages researchers to write articles with clearly stated hypotheses. On the same issue, Kerr (1998) conducted a similar study, giving a questionnaire to 156 behavioral scientists in the USA. It asked them to estimate what percentage of publishable research articles should state an explicit hypothesis, according to journal editors and reviewers. Respondents thought journal editors and reviewers would say that research articles should state an explicit hypothesis about 80% of the time. Though this research did not focus on respondents' actual experience with reviewers, it does suggest that beliefs about the hypothesis-testing style in journal review processes are widely shared among psychologists, not only in Japan, but also in the USA.

In order to see how such journal review processes affect the style of journal publications, we coded the empirical articles (i.e., articles with data) in the 1997 volume in the Japanese Journal of Psychology (Okada & Shimokido, in press). If any hypotheses, predictions, or expectations were stated in an article, it was coded as an "article with hypothesis." Sometimes, hypotheses were clearly stated in the articles: "The hypothesis of this research is..." or "We have three hypotheses. The first one is..." Sometimes, the expression in an article was more subtle such as, "...was expected" or, "If it is true, this result would happen." We included all of them as "article with hypothesis" because, with this analysis, we wanted to capture how authors were influenced by the hypothesis-testing style of writing. Using this criterion for hypotheses, we divided the empirical articles into four categories. The first category is articles with no hypotheses mentioned. The second category is articles with hypotheses mentioned after the first experiment. The third category is articles with one or more hypotheses mentioned in the introductory section. The fourth category is the articles with two or more hypotheses mentioned in order to distinguish a correct one from wrong ones (i.e., a diagnosis test). The third and fourth categories were regarded as "articles with hypotheses."

The results showed that, in 1997, 58.8% of the empirical research articles in the Japanese Journal of Psychology had some kind of hypotheses written in the introductory section. Note that the other empirical articles, that didn't have any hypotheses, focused mainly on clinical case studies, testing the validity of a questionnaire, or psychophysics, which traditionally are types of articles written without hypotheses. Taking this into account, we can say that the hypothesis-testing style of writing articles

Figure 1: Hypotheses in the Japanese Journal of Psychology

is currently dominant in the Japanese community of psychology.

Do research articles in other disciplines follow the same hypothesis-testing style? We checked the 1996 volumes of Japanese science journals—these were the most recent volumes available in our university library at the time. We looked at the publication lists of the faculty members of each discipline in our university, then chose journals in which they were frequently published. We used the same coding scheme as the one previously mentioned, for the 1997 volume of the Japanese Journal of Psychology.

Table 1. Articles with hypotheses in various disciplines.

journal	Articles with hypotheses
Solid-state physics	0% had hypotheses
Earth Science	0% had hypotheses
Analytical chemistry	0% had hypotheses
Environmental medicine	0% had hypotheses
Neuroscience	0% had hypotheses
Ocean & Sky (Meteorology)	0% had hypotheses
Analytical Chemistry	2.8% had hypotheses
Polymer chemistry	24% had hypotheses

The main result of this analysis is shown in Table 1. As we can see, many research articles in other scientific disciplines do not follow the hypothesis-testing style of writing. Despite the belief about a scientific writing style that our psychology community shares, it seems that many scientists in natural science disciplines do not adhere to the hypothesis-testing style of writing. Are we willing to say that these articles without hypotheses are unscientific?

The next question that occurred to us was whether or not psychology articles have always used the hypothesis-testing style. If movements such as logical positivism, H-

D method, and inferential statistics had influenced research activities in psychology, the hypothesis-testing style of writing should have emerged at some point thereafter and spread throughout the psychology community. In order to answer this question, we conducted a historical analysis of the Japanese Journal of Psychology. It has been published since 1925, is the official journal for the Japanese Psychological Association, and is the oldest and most prestigious psychology journal in Japan. We coded the journal articles using the same coding scheme as previously described.

Figure 1 shows the results of the historical analysis of empirical articles in this journal. We examined every tenth volume of the journal from 1935 to 1998. (The most recent volume was Volume 69 at the time of this analysis.) As shown: 1) There were almost no articles with hypotheses in the introduction published prior to WWII; 2) the number of articles with hypotheses gradually increased after WWII; and, 3) the majority of the articles in the current volumes have hypotheses.

These results suggest that after WWII Japanese psychology researchers formed the standard that scientific articles should have hypotheses clearly stated in the introduction. This standard is quite different from that of the journals in other scientific disciplines. (Currently, we are conducting the similar analysis with American scientific journals so we can verify whether or not this trend is unique to the Japanese psychology community.)

The results of the historical analysis of the Japanese Journal of Psychology agree with the historical evidence regarding the import of the aforementioned movements—logical positivism, hypothetico-deductive method, and inferential statistics—from Western psychology to Japan. Although those movements emerged in Western psychology in 1930s and 1940s, World War II prevented Japanese psychologists from being exposed to

them. When World War II ended, these movements were introduced and gradually adopted into the Japanese psychology community. Theoretical articles on logical positivism and operationism appeared in the 1948 volume (the first volume after WWII) of the Japanese Journal of Psychology. Before WWII, there was very little research in behaviorism in Japan. After WWII, neo-behaviorism was introduced. For example, symposia on behaviorism were held at the 13th annual conference of the Japanese Psychological Association in 1949. Inferential statistics were introduced to Japan right after WWII. In the Japanese Journal of Psychology, the first theoretical article on inferential statistics appeared in the 1948 volume of the Japanese Journal of Psychology and the percentage of articles with inferential statistics increased dramatically during the 1950s (Omi, 1997).

From this evidence, we believe that it would be a fairly valid inference that a new belief about the hypothesis-testing style of writing articles among Japanese psychology researchers was influenced by logical positivism, hypothetico-deductive method, and/or inferential statistics.

### On Teaching How to do Research

During four years of teaching in a psychology department in Japan, the first author found that many psychology majors were taught that they must form clear hypotheses before collecting data. An undergraduate student in a research methods course complained to him, "Although I want to study this topic, I cannot come up with a clear hypothesis. So, I cannot study this topic." A graduate student writing a master thesis came to his office one day and confessed, "Though I conducted three experiments for my master thesis, I could only come up with a clear hypothesis in the last experiment. So, I may not have the ability to conduct scientific research."

In the process of learning about psychology, many students seem to acquire the idea that they have to form a clear hypothesis in order to conduct a psychological research study. In the questionnaire survey mentioned in the last section, we asked the following questions:

1. When you were a student, had you ever received advice from someone telling you that you should start a research project by developing clear hypotheses? *77.4% of respondents answered yes.*
2. When writing papers, had you ever received advice telling you that you should write clear hypotheses in the paper? *65.1% of respondents answered yes.*
3. Have you ever read a textbook on research methodology of psychology suggesting that you should start with clear hypotheses when conducting research? *70.8% of respondents answered yes.*
4. Have you ever given advice to someone telling him or her that when conducting research they should develop clear hypotheses before collecting data? *69.8% of respondents answered yes.*

Overall, the percentage of the respondents who answered yes to at least one of the above questions was

90.1%. Thus, the hypothesis-testing style seems to be the dominant practice in Japanese psychology.

The results of this survey are not surprising because many research methodology textbooks in psychology also mention that psychological research should proceed by finding questions and entertaining clear hypotheses first, then by collecting data. This is an excerpt from popular Japanese textbooks about research method in psychology.

*How to conduct research and write a paper*, Sirasa (1987): "The research process is the process of testing hypotheses... Thus, entertaining hypotheses is a very important first step to start research. If you think that you can discover something when conducting a survey or experiment with vague ideas, you will never succeed in your research."

The same trend was found in textbooks in the USA (Kerr, 1998). It seems that both in Japan and in the USA, psychology undergraduate and graduate students have been taught to use the hypothesis-testing style of research and to write articles following that style.

### On Conducting Research Projects

Our questionnaire survey was individualized for each respondent. We identified hypotheses in an article they had published and asked the authors specific questions about the hypotheses. If no hypothesis had been stated in their article, the same question was asked without identifying any specific hypothesis. The question was regarding whether they had developed the hypothesis written in their paper before they had collected the data. Respondents had to choose one of the following answers: a) The same hypothesis was entertained throughout; b) a different hypothesis was entertained; c) a vague hypothesis was entertained; d) no hypothesis was entertained; or (e) others.

In the case of articles with hypotheses, 70.6 % of the respondents said that the same hypotheses had been entertained throughout the study. However, 23.5% of the respondents admitted that they had different hypotheses, vague hypotheses, or no hypotheses at all before collecting data. Thus, we found that even if there are hypotheses clearly written in journal articles, it does not necessarily mean that the authors used the hypothesis-testing style when conducting their research. That is, in some cases hypotheses may have been developed between data collection and the writing of the paper. When interpreting the data, we have to consider that this survey was addressed to authors who have successfully published articles in mainstream psychology journals in Japan. It is highly possible to imagine that many psychologists who conducted research without hypotheses either could not publish their work in those mainstream journals or did not have the courage to submit them.

These results tell us somewhat contradictory stories about psychologists' research activities. While researchers in psychology conduct research in diverse ways (i.e., sometimes starting with a hypothesis and sometimes without), when they write journal articles they often imply that they had conducted the hypothesis-testing style of

research. When researchers teach others how to conduct research, they strongly emphasize employing the hypothesis-testing style. Does this mean that those psychologists who could not come up with any hypothesis before collecting data are not practicing the “correct” method of scientific research? Is the hypothesis-testing style really the best and the most scientific method of conducting research?

### **Potential Problems with the Hypothesis-Testing Style of Research**

Many philosophers of science have pointed out that scientists are not necessarily using the hypothesis-testing style of research when conducting scientific research (e.g., Hanson, 1958). Scientific discovery processes have two main phases: discovery of an explanation and justification for it. The hypothesis-testing style of research is strongly related to the justification side of scientific discovery processes, but not as much to the discovery side. Therefore, it does not completely reflect the actual process of scientific discovery. For example, Hanson (1958) stated in his famous book, *Patterns of discovery*:

“Physicists do not start from hypotheses: They start from data. ...H-D accounts begin with the hypothesis as given. ...The H-D account describes what happens after the physicist has caught his hypothesis; but it might be argued that the ingenuity, tenacity, imagination and conceptual boldness which has marked physics since Galileo shows itself more clearly in hypothesis-catching than in the deductive elaboration of caught hypotheses.”

Like Hanson, it seems that the majority of philosophers of science abandoned the concept that the hypothesis-testing style of research was the ideal scientific method a long time ago. However, as we have described, many psychology researchers still believe that this method is the best (and sometimes the only) scientific method that psychology should follow.

### **Various Styles of Research in Science**

Some scientists have pointed out that they are actually conducting research and producing prominent findings using other research styles. For example, Herbert A. Simon (1991), one of the founders of the fields of cognitive science, artificial intelligence, and cognitive psychology, has written about his research style as follows:

“When I examine my other experimental research, I find to my embarrassment that this fundamental condition for sound experimentation is seldom met. What have I been up to? What can I possibly have learned from ill-designed experiments? The answer (it surprised me) is that you can test theoretical models without contrasting an experimental with a control condition. And apart from testing models, you can often make surprising observations that give you ideas for new or improved models...”

“Perhaps it is not our methodology that needs revising so much as the standard textbooks on methodology, which perversely warn us against running an experiment until precise hypotheses have been formulated and experimental and control conditions defined. Perhaps we need to add to the textbooks a chapter, or several chapters, describing how basic scientific discoveries can be made by observing the world intently, in the laboratory or outside it, with controls or without them, heavy with hypotheses or innocent of them.” (pp. 383-385.)

Simon (in press) describes a case study of Faraday and further argues that curiosity and careful observation, which often lead to surprising results, are centrally important values to the scientific enterprise.

It seems that, at least in some scientific disciplines, scientists conduct research without using the hypothesis-testing style. They form hypotheses after observing phenomena.

### **The Cognitive Psychology of Scientific Thinking**

This point is supported by further evidence from studies in cognitive psychology. In the field of cognitive psychology, there have been substantial numbers of studies focused on scientific discovery processes (e.g., Klahr & Dunbar, 1988; Okada & Simon, 1997; Schunn, 1995). These studies suggest that: 1) Subjects frequently design experiments without hypotheses; 2) the frequency with which subjects design experiments without hypotheses is higher at the beginning of research; 3) there are individual differences in whether people tend to design experiments without hypotheses (experimenters who start experiments without hypotheses versus theorists who start experiments with hypotheses). These results fit with our findings from the questionnaire survey. Together, they converge to tell us that there are various research methods and styles in science.

### **Advantages and Disadvantages of Scientific Styles**

Hypothesis-testing styles of research, which are based on the H-D method and strong inference (Platt, 1964: i.e., develop alternative hypotheses and devise a crucial experiment that excludes one or more of the hypotheses, then carry out the experiment so as to get a clean result), are probably useful when the research field has been well-developed or the research project has progressed up to the level that the researchers do not need to create any new paradigm or theory. Although the percentage of articles which used strong inference in psychology journals is not high (see Figure 1), Platt (1964) claimed that this scientific method is the most productive way to conduct scientific research.

However, we feel that his claim is probably too strong to generalize. In certain situations, the H-D method (especially strong inference) might not work well. For example, when the research field is not well formed yet, or the research project is at the starting stage, the hypothesis-testing style of research might force researchers to form a hypothesis prematurely. Toyoda (1998) pointed out that

even a study with a precise statistical analysis to distinguish rival hypotheses might only be able to distinguish the rival hypotheses that are located very close to each other in a highly complicated hypothesis space. Therefore, when there is no valid reason to form hypotheses with the currently available data and theory, there is a possibility that the researchers will focus on hypotheses that are far apart from the correct hypothesis. In such a case, they might be stuck with irrelevant questions or irrelevant hypotheses that might not lead to any major discovery.

### Conclusion

In the historical and social context of Japanese psychology, many psychology researchers in Japan acquired the belief that the hypothesis-testing style was the best, and sometimes the only, scientific way. Such a belief creates a cognitive constraint (Miyake & Hatano, 1991; Siegler & Crowley, 1994) on the way that psychology researchers participate in research activities such as conducting research, writing research articles, and teaching research methods. Such a belief, on one hand, has a positive effect in enhancing effective research activities—many research articles have been published using this hypothesis-testing style. However, on the other hand, there could be situations in which such a belief has negative effects on research activities. As we have shown above, it was suggested that some articles without hypotheses have been rejected by journal reviewers as non-scientific even though such articles might have made a great contribution to the community of psychology, had they been published. It was also suggested that such a belief shaped types of research procedures that might have distorted researchers' views on scientific discovery. As for the educational aspect, it was suggested that some of the psychology students felt discouraged to explore new research directions because they received advice emphasizing the hypothesis-testing style of research.

We believe that the information from these analyses about researchers' beliefs in psychology would be useful when we try to understand cognitive processes among psychologists and other scientists in an interdisciplinary collaboration.

## Abstract

An exemplar-based algorithm, PROBEX, (Juslin & Persson, 1999) is shown to make robust decisions in multiple-cue inference tasks when very few exemplars are known. We demonstrate the crucial role of knowledge of cue directions for performance and confront PROBEX with an artificial environment specifically construed to favor a non-compensatory algorithm like Take The Best (Gigerenzer & Goldstein, 1996). PROBEX is demonstrated to perform well even in these unfavorable conditions. The explanation for the robust performance is that PROBEX approximates Dawes Rule by using information of the cue directions for all cues, while yet making few a priori assumptions about the structure of the environment.

## Introduction

In this paper we will discuss the importance of knowledge of cue directions for probabilistic inference. The cue direction refers to the valence of the relationship between two variables, for example, as represented by the sign of a correlation, or a coefficient in a linear equation (e.g., a beta weight in linear regression). We will concentrate on a simple binary choice task format of the following sort, “Which German city has the higher population: a) Bonn, b) Hamburg?”. In this case, knowledge of a cue direction corresponds to knowing if a binary probability cue, say, that Hamburg, but not Bonn, has a soccer team in the Bundesliga, increases or decreases the probability that alternative (a) (Bonn) is the correct answer to the question.

The constraints on a plausible cognitive mechanism for learning cue-directions are complex and multifaceted. In some tasks, learning cue-directions is not important because they are known a priori. In those cases, it is the relative weight of the cues that is important. On the other hand, it is sometimes proposed that knowledge of cue directions is *the* crucial aspect of learning to make probabilistic inferences (Dawes & Corrigan, 1974). Moreover, inferences have to be made for new and unexpected tasks for which little previous experience is available. This means that the system cannot rely extensively on pre-computed knowledge—which cues are predictive, and the direction of predictive validity, has to be detected on the spot. Finally, a flexible algorithm should map both linear and nonlinear aspects of an environment.

These constraints boil down to whether we can find an algorithm integrating the ability to represent non-linearity with

on-the-spot detection of cue directionality. Is this possible without violating psychological plausibility? In this paper, we show that PROBEX (PROBABILITIES from EXemplars: Juslin & Persson, 1999) is such an algorithm. It relies on similarity-guided retrieval of exemplars to capture nonlinear relationships and to estimate cue directions. An added bonus is that because PROBEX belongs to the class of *lazy algorithms* (Aha, 1997), which do not require pre-computed knowledge, this is achieved in a fast and frugal fashion.

An important development in the judgment literature is the concern with evaluating cognitive algorithms within real environments (Gigerenzer & Goldstein, 1996; Gigerenzer, Todd, & the ABC-group, 1999). Gigerenzer and Goldstein (1996) demonstrate that, when applied to the structure of a real environment, simple heuristics that only rely on a single cue perform on par with complex algorithms that integrate multiple cues. Take-The-Best (TTB) relying on the single most valid cue that is applicable, performed as well as linear multiple regression that integrates 9 cues. It was concluded that although TTB falls short of classical norms of rationality, it provides the same accuracy at a minimum of computation: It is “fast and frugal”. One shortcoming of the simulations in Gigerenzer and Goldstein was that all algorithms were provided with a priori knowledge of cue directions.

Connectionist, exemplar-based and decision-tree architectures have been shown to compete evenly with TTB in regard to accuracy (Chater et al, 1999). Specifically, in Juslin and Persson (1999) it was shown that PROBEX outperformed TTB and linear multiple regression in regard to accuracy while relying on no pre-computed knowledge. PROBEX further provided a good quantitative fit to the quantitative point-estimates, binary decisions, and probability judgments made by human participants (see Dougherty, Gettys, & Ogden, 1999, for a similar approach).

In this paper, we complement Juslin and Persson (1999) in three respects: First, we illustrate the crucial role of estimating cue directions for the performance of any algorithm. Second, we explore boundary conditions for the robust performance of PROBEX by exposing it to an environment deliberately construed to favor a non-compensatory algorithm like TTB and a linear, additive algorithm like linear multiple regression. Finally we present a simple demonstration to elucidate why evolution should favor decisions algorithms that are robust in states of limited knowledge.

## PROBEX—The Algorithm

Many theories in cognitive science stress the storage of exemplars (traces, instances) (e.g.; Kruschke, 1992; Logan, 1988; Medin & Schaffer, 1978; Nosofsky, 1984, Nosofsky & Palmeri, 1997). One property of exemplar-based models is that they describe algorithms that respond to both frequency and similarity. In this respect, they map onto well-known properties of human probability judgment (Juslin & Persson, 1999). PROBEX was developed from one of the well-known and successful exemplar-based model, the *context model* (Medin & Schaffer, 1978; Nosofsky, 1984). PROBEX amends the context model in the following respects (see Juslin & Persson, 1999): (a) With a sequential sampling mechanism that allows prediction of response times (as such PROBEX provides a humble cousin of the EBRW model presented by Nosofsky & Palmeri, 1997); (b) A dampening in order to predict pre-asymptotic performance (see also Nosofsky et al., 1992); and (c) response rules that allows prediction of point-estimates and subjective probability judgments. The simple stopping rule and the mechanisms for point-estimation and probability judgment are the main differences from previous exemplar-based models.

Knowledge of the environment is modeled by an  $R \times C$  matrix, with  $R$  exemplars,  $C$  cue dimensions and one vector with  $R$  target values. The exemplars in the knowledge matrix represent distinct psychological entities, either traces of dated events from episodic memory or semantic knowledge. Exemplars are described in terms of binary feature values, except for the continuous target dimension  $t$ . Each exemplar is represented by  $D$  binary features  $x_i = [x_{i1}, x_{i2}, \dots, x_{iD}]$ , where  $1$  denotes presence of the feature and  $0$  its absence. The participant is presented with a new exemplar  $\bar{t}$  and is required to make a judgment or a decision. The similarity between  $\bar{t}$  and stored exemplar  $y$  is computed by the multiplicative similarity rule of the context model,

$$S(\bar{t}, y) = \prod_{j=1}^D d_j, \quad d_j = \begin{cases} 1 & \text{if } t_j = y_j \\ s & \text{if } t_j \neq y_j \end{cases}, \quad (1)$$

where  $d_j$  is 1 if the values on a feature match and  $s$  if they mismatch. Similarity  $s$  is a parameter in the interval  $[0, 1]$  for the impact of mismatching features. For low values of  $s$ , the similarity is close to one only for an exemplar that is almost identical to the new exemplar, but for high values of  $s$  all of the stored exemplars are deemed very similar.

We examine PROBEX with  $s=0.5$  for all cue dimensions which is a compromise between these extremes. The idea is that this compromise, referred to as *similarity-graded probability*, is a particularly robust and efficient way to exploit states of limited knowledge (Juslin & Persson, 1999).

The stored exemplars race to determine the response (Logan, 1988; Nosofsky & Palmeri, 1997). The stored exemplars are retrieved one-by-one from an initial set  $K$  to yield a sequence  $x_1, x_2, \dots, x_N$ . The probability that exemplar  $y$  is the sampled exemplar  $x_n$  at iteration  $n$  is:

$$\forall y (y \in K_n), \quad P_n(x_n = y) = \frac{S(\bar{t}, y)}{\sum_{z \in K_n} S(\bar{t}, z)} \quad (2)$$

The summation in the denominator is performed across exemplars not yet sampled. A response is generated at iteration  $N$ , where the decision rule specified below terminates the sampling process.  $N$  is a random variable, the distribution of which can be used to predict response times.

To estimate the target value  $v'(\bar{t})$  of the new exemplar  $\bar{t}$ , the target values  $v(x_i)$  of the retrieved exemplars  $x_i$  are considered. The estimate of the target value at iteration  $n$  is,

$$v'(\bar{t}, n) = \frac{\sum_{i=1}^n S(\bar{t}, x_i) v(x_i)}{\sum_{i=1}^n S(\bar{t}, x_i)}, \quad (3)$$

a weighted average of the retrieved target values, where the similarities are weights. The final estimate is  $v'(\bar{t}) = v'(\bar{t}, N)$  where  $N$  is the first iteration where the conditions for the stopping rule are satisfied. Eq. 3 can also be produce probability assessments (Juslin & Persson, 1999).

The sampling of exemplars is terminated at the first iteration  $N$  where the following condition has been satisfied. The stopping rule is:

$$|v'(\bar{t}, n) - v'(\bar{t}, n-1)| < k \cdot |v'(\bar{t}, n)|. \quad (4)$$

The free parameter  $k$  decides the sensitivity of the stopping rule. One can interpret this rule as a way of judging when the change in the point estimate from  $v'(\bar{t}, n-1)$  to  $v'(\bar{t}, n)$  is too small to merit further sampling.

## Is PROBEX Frugal?

Gigerenzer and Goldstein (1996) proposed the notion of 'fast and frugal' as a conceptual threshold that a model of human decision making must reach in order to be plausible. At first sight, the mathematics of PROBEX that model retrieval of exemplars seems too complex to be "fast and frugal". But there are two major issues that resolve this dilemma. First, the complex part of PROBEX models quick and effortless memory processes that operate in parallel. Secondly, it is not enough to prove that an algorithm is efficient at the moment the decision is made, without concern for the requirements on pre-computation. PROBEX belongs to the class of *lazy algorithms* (Aha, 1997) in artificial intelligence, that avoid the processing of data before the task is given. On the other hand, all algorithms discussed in this paper, except PROBEX, rely on pre-computed representations. TTB (Gigerenzer & Goldstein, 1996) for example need to compute a sorted list of cue validities for the specific task, which in it self is computationally demanding. Arguably, if PROBEX makes good decisions by retrieving few exemplars and without using pre-computed representation, it is fast and frugal in a more general and important sense.

## The Ecological Rationality of Five Algorithms

**The German City-population Task** The task in the initial study on ecological rationality was the German city-population task (Gigerenzer & Goldstein, 1996; see Gigerenzer, et al., 1999, for applications to other environments). The task is to answer questions such as "Which city has the larger population: Heidelberg or Erlangen?" The decision process is modeled by an algorithm that relies on some strategy to make intelligent guesses about the populations of German cities. The simulation also requires an environment-model containing facts about German cities which—once known to the algorithm—can be used to infer city-populations. The environment is represented by nine binary cues that characterize each city, for example, whether a city is a state capital or not, whether it has a university or not, where the nine cues vary in predictive validity.

**The Algorithms** PROBEX was compared to four algorithms for guessing which of two objects have the largest value on the target dimension: (1) A linear multiple regression model with cues as independent variables and population as dependent variable. In a pair-wise comparison task, the algorithm decides on the city with the higher estimate. The direction of the cues is the sign of the regression weights. Linear multiple regression is included because it is routinely claimed to provide robust and accurate predictions. However, it cannot handle situations with few observations unless one amends it with a method such as Ridge Regression to compensate for cue dimensions with no information<sup>1</sup>.

(2) Dawes' Rule (Gigerenzer, et al., 1999): A heuristic version of the linear model that counts how many of the cues support each of the two cities and decides on the city implied by more cues. Cue direction is represented as 1 or -1 if there is positive or negative correlation in the training data respectively and zero if it was not computable. As detailed below, two versions of Dawes' Rule were implemented in order to investigate the importance of a priori knowledge of the cue directions. (3) TTB (Gigerenzer & Goldstein, 1996): In pair-comparisons, TTB decides on the task implied by the first most valid cue that differentiates between the pair.

(4) QUICKEST (Gigerenzer, et al., 1999) is an algorithm appropriate for skewed distributions like the German city-populations, where most cities have small populations. For each cue, the mean population for cities with negative cue-values is computed (negative cue values are those that go with small populations, e.g., not being a state capital). Cues are rank-ordered from the cue with lowest mean given a negative cue value to the cue with the highest mean given a

negative cue value<sup>2</sup>. To estimate a population the algorithm starts by checking if a city has the cue value that is first in this rank-order, then the next, and so on until a match is encountered. Then the mean population for the cities which have this cue is the estimate. Given the skew of the city-population distribution with mostly small cities, this algorithm is frugal in the sense of minimizing the number of cues that have to be accessed (i.e., for most cities the algorithm will stop for the first negative cue values in the rank-order). In pair-comparisons, QUICKEST decides on the city with the larger estimate.

Gigerenzer and Goldstein (1996) tested the algorithms by feeding them with all the pair-wise comparisons between German cities with more than 100 000 inhabitants. One weakness of this procedure was that the knowledge of the algorithms was assumed to consist of all the cities. A better test (Gigerenzer, et al., 1999) is to split the set of German cities into a training set and a test set. The training set is used to train the algorithm and the test set is the pool from which the test questions are constructed. This cross-validation is a true test of the robustness and detects any over-fitting to the training set. Moreover, it highlights the issue of learning the cue directions.

**Learning Cue Directions** In the simulations, all algorithms except A Priori Dawes' Rule have no a priori knowledge of the cues, but have to learn them from the known exemplars. In some tasks it, may be possible to infer cue direction by reasoning, but this topic is not addressed in this paper.

To illustrate the importance of knowing the cue directions, two versions of Dawes' Rule were implemented. The first version is the A Priori Dawes' Rule and it assumes that cue directions are known a priori. Its purpose is to show the theoretical upper limit of Dawes' Rule with a priori knowledge of cue directions. The second version, Dawes' Rule, relies on observed training exemplars to estimate cue directions by calculating whether each cue is positively or negatively correlated with the target dimension among the training exemplars. The difference between the variants indicates the importance of a priori knowledge of cue directions.

It is important to make special solutions for several of the algorithms below. With Dawes' Rule, insufficient data can make the correlation between a cue and the target variable undefined and then this cue is never used in the test phase. TTB must also be treated with care, because it use a sorted list of cue validities. When there are few exemplars it is often the case that several cue validities get the same numerical value and then these have to be listed in random order within the list. If this is not done the computer implementation can lead to a biased cue order which may either increase or decrease the accuracy of the algorithm.

---

<sup>1</sup> Ridge regression has the drawback of biasing the predictions towards the mean, and thus lowers the predictive accuracy when the weights are calculated from many observations without problems with correlated variables. We hand-picked an intermediate ridge constant, 0.1, that increased accuracy with limited information (small training set) but did not lower performance with much information (large training set).

---

<sup>2</sup> We did not implement QUICKEST exactly as Gigerenzer et al. (1999) did as we did not use approximations to natural numbers which probably implies that our implementation gives slightly better predictions.

## Study 1: Pair-Comparisons in the German City-Population Task

From an evolutionary perspective, it is important that an algorithm is good also when information is limited, because a decision maker has to survive as a "beginner" (see Study 3 below). Performance with small training sets is therefore a most important aspect of the robustness of an algorithm. Also, each algorithm soon reaches an asymptote that depends on both the cue structure and the algorithm itself. In the first simulation we thus compared the algorithms in the standard binary choice task with a particular eye to their performance in states of severely limited knowledge.

Figure 1. Accuracy and robustness of the algorithms. For each training set size, 1000 sets were randomized.

**Method** The dependent variable was proportion of correct inferences among the pair-comparisons of the test set. For each training set-size (2-80), as many as 1000 participants were simulated in order to make the errors of the means negligible. For each simulated participant, the German cities were randomly partitioned into training and test sets. Each algorithm was given the training set and the remaining cities were combined into all possible unique pairs and used as the test set. The data for the 83 German cities were collected from Gigerenzer and Goldstein (1996).

**Results and Discussion** Aside from A Priori Dawes' Rule that gets a head-start by virtue of its initial knowledge, Probex seems to be the winner in Figure 1. At minimum knowledge, Probex, Ridge Regression, and Dawes' Rule utilize the information equally well. TTB seems to have problems sorting the cues in a good order with little information, but does very well with 6 or more training exemplars. Quickest trade off accuracy for speed which is seen clearly in the cross validation paradigm. Note that A Priori Dawes' Rule does not define the asymptote that the other algorithms converge on, because it does not depend on the training set and does not suffer from over-fitting. This effect of cross-validation explains why it is constant at the high proportion correct of .74. It is surprising that Dawes' Rule performs worse with more information, but this is because the correlation between two cues in the full training

set is negative. With less information there is a greater chance to get a training set with only positive correlations. If cue validities had been calculated instead of correlations, Dawes' Rule would have done better.

In sum: The algorithms that use all information, such as Probex, perform robustly in states of limited knowledge. Probex, however, also performs best when more information is available. The superior performance of A Priori Dawes' Rule shows that a crucial aspect to be acquired by any algorithm is knowledge of the cue directions.

## Probex and Dawes Rule

In order to understand why Probex performs better than TTB with few training exemplars, it is instructive to consider only two optimal training exemplars: Big-city with all cues set to 1 and Small-city with all cues set to 0. For simplicity, all cues are assumed to be positively correlated with population. For Probex the similarity of the probe to Big-city decreases monotonically as a function of the number of cues in the probe that are not 1. The opposite holds for the similarity to Small-city which increases for each cue not set to 1. Because it is the number of cues set to 1 that differentiate the probes, Probex has the same high accuracy as Dawes' Rule.

TTB computes the cue direction for all cues but cannot apply this information, because the order of the cues is selected at random when the cue validity is the same for all cues. The data point with two training exemplars in Figure 1 suffers from this problem because the search order will be picked at random from those cues that have a well defined direction. Probex, Ridge Regression and Dawes' rule, on the other hand, integrate cue direction information from all cues in every decision in a similar way, which explains why they have identical proportions correct for the case of two training exemplars in Figure 1.

## Study 2: A Non-Compensatory Data Set

When is Probex outperformed by other algorithms, like linear multiple regression and TTB? A good guess is in an environment with additive and non-compensatory cues. The cues are non-compensatory if the optimal regression weights are such that the largest weight is bigger than the sum of the smaller weights. The second largest cue should likewise be larger than the sum all the remaining cues, and so on (Gigerenzer et al., 1999). An environment with linear, additive relations favors the regression model and a non-compensatory cue-structure favors TTB. A simple environment for which this is true can be defined by ordinary binary numbers. Each binary number can be used as a cue. For example, 5 is written as 00101 in binary numbers, and gives the cues  $c_1=0$ ,  $c_2=0$ ,  $c_3=1$ ,  $c_4=0$  and  $c_5=1$ . The optimal weights here are  $\{16, 8, 4, 2, 1\}$ , respectively (i.e.,  $16 \cdot 0 + 8 \cdot 0 + 4 \cdot 1 + 2 \cdot 0 + 1 \cdot 1 = 5$ ).

How much better than PROBEX will linear multiple regression and TTB perform in this environment specifically construed to fit the latter two algorithms?

**Method** The same procedure was used as in Study 1, except that the data were binary numbers between 0 and 32. Analogously with the German city-population task, the task was to guess which of two binary vectors has the highest number.

Figure 2. PROBEX in an artificial environment composed of the binary numbers.

**Results and Discussion** Ridge regression is clearly superior in Figure 2, but suffers slightly from biased estimates with 8-15 exemplars in the training set. TTB does not reach the asymptote unless it is trained with almost every exemplar, and is easily beaten by PROBEX when there are few training exemplars. The two variants of Dawes Rule cannot use the non-compensatory nature of the cues and are stuck at about the same level of performance as in Study 1.

As expected, multiple regression is perfectly suited for this environment, but both TTB and PROBEX converge on the same asymptote. More surprisingly, PROBEX is better than TTB with few exemplars. TTB only evens the score when more training exemplars are available, despite the fact that this cue structure is optimal for TTB. Thus, linear multiple regression converges more rapidly on the asymptote, but TTB enjoys no clear advantage over PROBEX.

### Study 3: An Unforgiving Environment

Does it matter if a decision algorithm is a few percentages better for decisions made in states of limited knowledge? The answer to this question, of course, depends on the consequences of these decisions. In this final section, we provide a simple demonstration that in an environment where poor decisions are fatal, and experience is only gained conditional on the survival of previous decisions, a small difference in decision quality may add up quickly. Arguably, these are the living conditions of many animals, including those of humans for a large portion of the evolutionary history.

**Method** In order to cover a wider range of possibilities and simplify the demonstration, we modeled three ideal deci-

sions strategies, *Early Learner* (EL), *Late Slow Learner* (LSL) and *Late Fast Learner* (LSF), as linear functions roughly similar to the functions in Figure 1 and 2. EL is PROBEX-like in the sense that it has a slight advantage early in the learning process. LSL and LSF are more TTB-like in that they start at a lower level but increases in accuracy, where LSF increases at a higher speed.

$$p_{EL}(\text{correct}) = 0.55 + 0.010 \cdot i \quad (5)$$

$$p_{LSL}(\text{correct}) = 0.50 + 0.015 \cdot i \quad (6)$$

$$p_{LFL}(\text{correct}) = 0.50 + 0.020 \cdot i \quad (7)$$

Equation 5, 6 and 7 define the probability of a correct decision if the decision maker has  $i$  training exemplars as guidance. Two simulations were made where EL was pitted once against LSL and once against LFL. Ten generations were simulated, where the relative proportion of surviving decision makers decided the relative proportion in the next generation. Each generation made 11 decisions, where  $i$  was varied from 0 to 10. For example, a member of the EL-species had a 0.55 chance to survive the first decision and 0.65 chance to survive the last. LSL and LFL both had to start off at 0.5, but ended with 0.65 and 0.7, respectively.

LSL is an example of a decision strategy that starts off poorly and barely catches up with EL. LFL, on the other hand, is better than EL for the last 5 trials. Note that, if the decisions were not fatal, LFL and EL would both make the same overall amount of correct decisions.

Figure 3: Two simulations of decision making in a unforgiving environment. Open symbols present Early Learners vs. Late Slow Learners, filled symbols present Early Learners vs. Late Fast Learners.

**Results and Discussion** Figure 3 presents the relative population proportions in a competition between EL and LSL, on the one hand, and EL and LFL, on the other. LSL would vanish very quickly in such a harsh environment. LFL are better but the losses in the beginning of every generation cannot be repaired despite the superior performance at the end of each generation (experienced decision makers).

This example is artificial and simplified, but shows that it is important to be a few percent better with little information than a few percent better with a lot of information, if learning is potentially dangerous. Indeed, the differences need not be large if they sum up over thousands of generations.

### General Discussion

We propose that a plausible model of the cognitive processes that underlie memory-based judgment and decision making should have at least three properties: *First*, the model should be consistent with—and preferably extend on—previous models with independent support in the cognitive science literature. PROBEX is a moderately modified version of one of the most successful models from the categorization literature—the context model (Medin & Schaffer, 1978; Nosofsky, 1984). *Second*, algorithm-details that pertain to implementation in judgment and decision making needs to be tested. First steps along these lines have been taken by fitting the predictions by PROBEX to empirical judgment data (Juslin & Persson, 1999).

*Third*, as implied by the research on ecological rationality (Gigerenzer et al., 1999), a cognitive algorithm should make sense also from an evolutionary perspective. An algorithm favored by natural selection should produce accurate judgments when applied to the constraints of a real environment, require a minimum of mental effort, and be robust in states of limited knowledge. In this paper we have scrutinized the ability of PROBEX to infer and use cue directions, in comparison with a number of fast-and-frugal algorithms discussed by Gigerenzer et al. (1999).

PROBEX provides a flexible and efficient way to compute and use directions of many cues on the spot, that is, without requiring any pre-computed knowledge. Moreover, TTB enjoys no systematic advantage over PROBEX in an environment specifically designed to favor a non-compensatory strategy. Importantly, in contrast to the other algorithms, PROBEX brings no strong commitment in regard to the presumed structure of the environment (e.g., linear, compensatory), but applies equally well to nonlinear environments (such as the classic X-OR-problem). Arguably, this is the kind of flexibility favored by evolution in adaptation to a complex and uncertain environment.

# Effects of Presentation Format on Memory for Order

Margaret J. Peterson (mpeters2@gmu.edu)

Erik M. Altmann (altmann@gmu.edu)

Human Factors & Applied Cognition

Fairfax, VA 22030

## Abstract

Memory for order is important in everyday settings, for example in eyewitness testimony about who started a conflict. Although current theories claim that memory for order is different from memory for the to-be-remembered items themselves, many of the same manipulations that affect item memory also affect order memory. One manipulation that has shown effects in item memory, but that has not been tested in order memory, is presentation format. The hypothesis tested here is that order memory will be better for actions described as pictures than for actions described by text. The hypothesis is not supported by a main effect. However, presentation format does interact with serial position, suggesting that format effects are analogous to modality effects across auditory and visual presentation. Moreover, primacy is greater than recency, undermining Estes's (1997) perturbation model of memory for order.

## Introduction

Suppose that several witnesses to a knife fight agree that two knives were pulled, that a fight ensued, and that one person was killed. However, the witnesses' recollection of who drew a knife first is less exact. Although the to-be-remembered items are not in question, the recollection of order spells the difference between life in prison and acquittal on grounds of self-defense. If we can understand under what conditions people are most likely to be accurate about the order in which things happened, it could help us make better decisions about when to believe eyewitness and other accounts of history.

Understanding order memory also has important implications for our understanding of memory in general. Order memory is central to skill and language acquisition, both of which depend on sequence information. Also, order memory underlies the construct of episodic memory. For example, in some models of forgetting, people do not forget the word "bird", they only forget that "bird" was presented to them in a particular temporal window (Nairne, 1990b).

Memory for order is often claimed to be separate from memory for to-be-remembered items themselves (Bjork & Healy, 1974; Nairne, 1990a). Indeed, Whiteman, Nairne and Serra (1994) go so far as to say that order memory operates in a way that is fundamentally different from processes seen in both item recall and recognition. However, many manipulations that affect item memory have similar effects on order memory (Glenberg & Swanson, 1986; Nairne, 1990b; Naveh-Benjamin, 1990), even when the manipulation was designed to factor out the effects of item memory (Neath, 1997). For example, Glenberg and Swanson (1986) found that auditory presentation produces higher accuracy than vis-

ual presentation, especially for the last items in a list. This pronounced recency effect for auditory modality is similar to the effect seen in item memory. Similarly, Neath (1997) showed that set-size, presentation modality, and word concreteness all have similar effects on order memory as they do on item recognition and recall.

If order memory is similar to item memory, one might expect it to differ across other manipulations that produce differences in item memory. One such difference is between pictures and text. In recall and recognition tasks, pictorial presentation of items produces higher accuracy than verbal presentation (Baggett, 1979; Snodgrass, Wassner, Finkelshtein, & Goldberg, 1974). Dual-coding theory provides one possible explanation for these results. People usually encode pictures verbally as well as pictorially, but may or may not encode verbal material pictorially. This dual encoding of pictures creates a stronger memory trace, which leads to better item recall or recognition (Snodgrass et al., 1974).

Further evidence that memory for pictures is better than memory for text comes from Baggett (1979), who compared memory for a story across presentation formats. The story was presented either as a movie or as text, and was structurally equivalent in both formats. After subjects saw or read the story, they were asked to free-recall as much detail as they could about a specific episode, either immediately after study or after seven days. For those who saw the movie, still pictures were used to cue the beginning and end of the to-be-recalled episode. For those who read the story, textual cues were given. Although there was no effect of format in the immediate recall condition, participants in the seven-day condition recalled significantly more detail if they had seen the movie (Baggett, 1979).

This paper examines the effects of presentation format – pictures versus text – on accuracy of order memory. Our hypothesis is that memory for order should be better when items are presented as pictures. This hypothesis is primarily based on the findings cited above that suggest that item memory is better for pictures than for text. However, the hypothesis is also based on the intuition that order information is fundamental to how people function in the world. In particular, as we suggested in the knife-fight scenario above, order memory is a cornerstone of causal inference. Similarly, a picture is often worth a thousand words because it can make functional inferences easier to generate (Larkin & Simon, 1987). Thus, there is reason to ask whether order memory, given its basic nature, is facilitated by presentation formats more primitive than language.

## Experiment

The most common way to test order memory, while factoring out the effects of item memory, is to show participants a sequence of items at study time, and then show them the same items at test time in scrambled order. Their task is then to place the items back in their original order. Nairne (1992) claims that this type of task can be seen as a pure test of position memory without being confounded by item memory processes because all of the item information is made available at the time of recall.

The current study follows Nairne (1992) in testing incidental memory for order. In that study, subjects were asked to make pleasantness ratings on each word in five lists of five words each. The purpose of the rating task was to ensure that subjects would not be expecting any type of memory test and that the learning of order would be incidental. This type of deception is necessary because if participants are expecting any kind of memory test, even if they do not know that it will be a test of order, it is not truly incidental learning (Naveh-Benjamin, 1990). Tests of incidental memory for order have the highest ecological validity for assessing how order memory functions in everyday life.

Nairne's participants were brought back at time intervals ranging from 30 seconds to 24 hours and were then given a surprise test on the order of the items. The time delay variable is important to study not only to see the effects of decay over time, but also to be able to generalize any findings across short and long term memory. We adopted the three intervals (30 seconds, 4 hours and 24 hours) that Nairne cites as being the most representative of decay of order memory over time.

## Method

### Participants

The participants were 76 undergraduates at George Mason University who participated in the experiment for course credit in psychology classes. One subject's data were excluded due to failure to follow instructions. The experimental sessions were conducted in small groups ranging from four to fourteen participants each with four singletons.

### Materials and Design

The experiment consisted of 30 actions arranged into six thematic groups. The themes were primarily place-oriented; for example, things that might happen in an office setting, or buying items at a supermarket. Care was taken to ensure that actions had no logical or causal sequence of order (e.g. having to knead the dough before baking the bread). All actions in a group were presented either in picture format or in text format. Order of groups, and order of actions within groups, was determined randomly by sampling without replacement. The picture format consisted of a silent, color video segment that depicted an actor performing the target action. The actor's gender for each group was determined randomly before shooting and the same actor in the same clothing was used for each picture within a group. A text group consisted of a set of one-to-three-word phrases that described the actions in a corresponding picture group.

Black and white still shots representative of the video sequences and the corresponding text phrases are given in the Appendix.

Both text and picture actions were presented on videotape played on 27 to 35 inch standard televisions. Phrases were presented in large white block letters against a black background. Participants saw a video with three groups presented in picture format and three groups presented as text. Two different videos were used, each with a different mapping of groups to format. That is, if group was presented as text in one video, it was presented as pictures in the other, and vice versa. The purpose of this counterbalancing was to control for any interaction of format and the theme of the group.

Delay between presentation and test was manipulated between groups at levels of 30 seconds, 4 hours and 24 hours of delay. The within-subject manipulations of format and serial position combined with the between-subject manipulation of delay to produce a 2x5x3 mixed factorial design.

### Procedure

Participants were asked to watch the video and make pleasantness ratings about each picture or phrase they saw on a scale ranging from 1 (unpleasant) to 3 (pleasant). The rating task was used as a decoy to make intentional learning of the items or of the order unlikely. Each picture and phrase was visible for five seconds and was followed by 2.5 seconds of black screen. Between each group of five items, five seconds of blue screen was shown. Participants were not informed about the subsequent memory test, nor were they given any information as to why some of the items were presented as pictures and others as text. They were simply led to believe that they were participating in a rating task evaluating their affect toward everyday actions. Participants wrote their ratings on a response sheet containing six rows of five blanks; one row was designated for each group.

After completing the rating task, participants in the 4 and 24 hour delay groups were excused and instructed to return at the designated time for further rating exercises. Participants in the 30-second condition were asked to turn their rating sheets over and write down numbers counting backwards from 100 by threes. After thirty seconds, they were told to stop and their rating sheets were collected as test sheets were handed out. At the time of test, participants in all delay conditions were handed a response sheet that corresponded to the videotape that had been presented to them. Each test sheet consisted of six rows of five blanks labeled 1<sup>st</sup>, 2<sup>nd</sup>, 3<sup>rd</sup>, 4<sup>th</sup> and 5<sup>th</sup> in that order. Above each row of blanks were the items that had been presented, but in a new random order. For groups presented as text, phrases were typed with the letters A through E to the left of each phrase. For groups presented as pictures, black and white still pictures representative of the action were presented and were labeled A through E directly above each picture. Participants were told that each group on the text sheet contained all five actions that were in that group at study. They were then asked to put the letter corresponding to each action in the correct blank to reconstruct the original order of presentation. Because all of the to-be-remembered actions were presented at test time, this type of free reconstruction task can be seen as a pure test of position or order memory

## Results

The measure we focus on in this analysis is the proportion of items placed correctly in their original order. These data are shown in Figure 1 (by format, aggregated over delay) and Figure 2 (by format and delay). All analysis of variance (ANOVA) was repeated measures on the format variable.

There was a significant effect of delay ( $F(2,73) = 19.4$ ,  $p < .0001$ ). However, there was no main effect of format ( $F(1,73) < 1$ ), nor was there an interaction between presentation format and delay ( $F(3,72) = 1.9$ ,  $p > .05$ ).

Characteristic primacy and recency effects are reflected in a main effect of position ( $F(3,72) = 41.0$ ,  $p < .0001$ ) and a significant quadratic trend ( $F(1,73) = 115.0$ ,  $p < .0001$ ). However, the linear trend was also significant, ( $F(1,73) = 21.2$ ,  $p < .0001$ ), and a post-hoc comparison of accuracy on the first and last items shows that primacy is greater than recency ( $t(75) = 3.0$ ,  $p < .005$ ). The linear trend and post hoc comparison were significant for five out of six combinations of format and delay, the exception being 24 hour text. There was no significant interaction between position and delay time ( $F(2,73) = 2.7$ ,  $p > .05$ ), indicating that the curves were roughly the same shape at each level of delay.

Although format did not have a main effect, it did interact with position ( $F(3,72) = 3.2$ ,  $p < .05$ ). As Figure 1 shows, the difference between primacy and recency is more pronounced in the picture format (that is, the serial position curve for pictures is rotated slightly clockwise compared to the curve for text). This interaction remains significant across all of the three time delays, as shown in Figure 2.

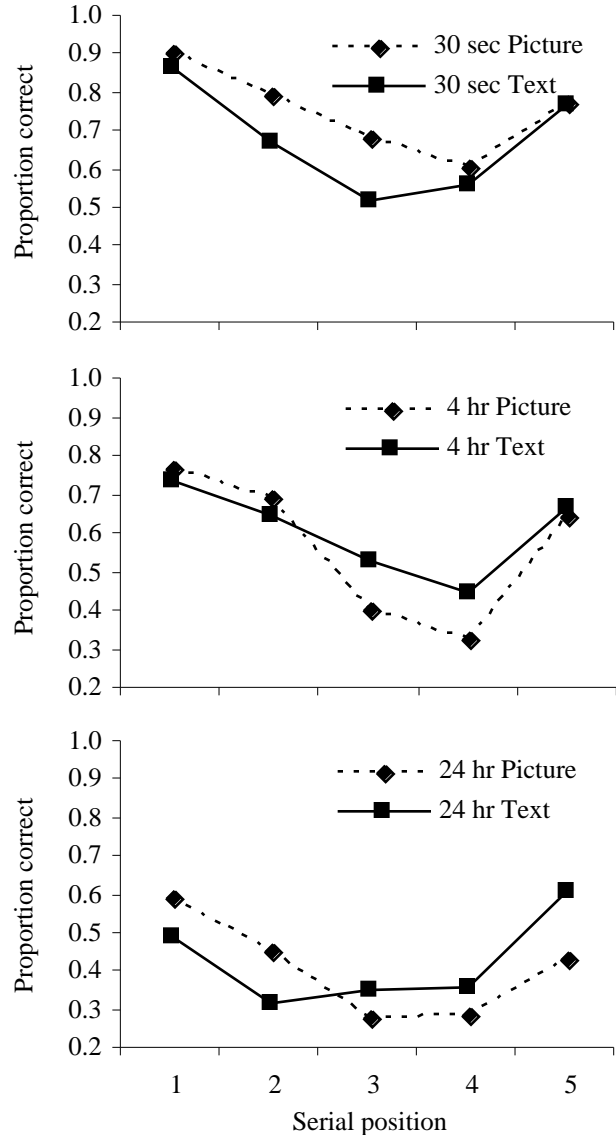

## Discussion

The hypothesis that pictures produce more accurate memory for order than text was not supported. This surprised us, given that pictures are consistently better than text in memory for items (e.g. Baggett, 1979; Snodgrass et al., 1974) and that many item-memory manipulations transfer to order memory (Naveh-Benjamin, 1990; Neath, 1997).

Our results point to a possible confound in how the effects of presentation format have been interpreted with respect to item memory. Another variable that may be correlated with format is whether sequential information is im-

**Figure 1:** Accuracy as a function of format and serial position.

**Figure 2:** Accuracy as a function of format and serial position, by delay (panels).

portant in understanding the stimulus. For example, Anderson (1976) found that order retention for linguistic materials (spoken words) was actually higher than for static pictures. Anderson's explanation for this superiority in his study depended on the sequential properties of the stimuli. In his view, language (in particular, the verbal stimuli in his study) is highly dependent on sequential information, and is therefore processed sequentially. In contrast, Anderson argued that the line drawings he used as pictures were not dependent on sequential processes for interpretation. He maintains that this sequential processing of linguistic material is robust enough to continue even when strings of non-related words are presented as stimuli. Thus, whether pictures are remembered better than words, or vice versa, may depend on the sequential structure (or other structure) of the stimuli across the two conditions.

The sequential structure of stimuli could easily be confounded with presentation format. For example, actions

presented as movies may be perceived to be more coherent than stills of the kind used by Anderson, because they fill in the details of natural action. If movies do communicate sequential structure more effectively, and if sequential structure facilitates memory, then our null effect is consistent with Anderson because the benefit of movies works against the benefit of text. However, the benefit of pictures in other studies (e.g., Baggett, 1979; Snodgrass et al., 1974) then becomes a puzzle. Our results suggest that these studies should be re-examined for other structural aspects of stimuli that may confound the effect of presentation format.

Another factor that may explain our null effect of format is that participants may use the same dual codes to represent both formats. An informal debriefing of participants after the experiment supports this view. Most of those questioned reported that they not only thought about the actions verbally while watching the video, they also visualized themselves doing the actions when they were presented textually. When asked why they had visualized the textual material, participants indicated it was because they needed to see it in their minds to be able to judge its pleasantness. Changing the distracter task used at study time (for example, asking for frequency counts rather than pleasantness ratings) may produce the asymmetrical recoding (pictorial to verbal) seen by Snodgrass et al. (1974). Thus the nature of the distracter task will have to be manipulated in future studies to isolate its effects on memory for order.

Despite the null effect of format, there was an interaction between format and serial position. A similar interaction has been observed between modality (visual and auditory) and position (Glenberg & Swanson, 1986; Neath, 1997), raising the possibility that these interactions are related. In the modality interaction, auditory presentation produces better order memory than visual presentation, but only for last one or two items (Neath, 1997). Early theories of this interaction implicated differences in sensory storage mechanisms across modalities. However, Gardiner and Gregg (1979) showed that the interaction was still pronounced when auditory distracter information was presented during the retention interval. These findings suggest that the modality interaction is caused by a variable that was confounded with echoic memory in earlier studies. The implication for our results is that the format interaction and the modality interaction may in fact stem from the same underlying process.

The interaction between format and serial position could also be due to a primacy benefit for pictures that is related to release from proactive interference. As we noted above, participants reported visualizing themselves performing the actions across all of the text groups. This may have made the text groups less distinct from one another than the picture groups, which each had a new actor and a new context. If a new picture group is more distinct by virtue of these visual cues, one would expect a stronger release from proactive inhibition and hence improved memory immediately afterwards. Thus the format interaction could stem from a recency benefit for text (similar to a modality effect), from a primacy benefit for pictures, or from some combination.

The difference between primacy and recency in our data helps to distinguish among formal models of order memory (see Brown, 1997, for a review of such models). The most

widely discussed is the perturbation model (e.g., Estes, 1997; Nairne, 1992). In this model, primacy and recency occur because there is only one direction in which the first and last items can “perturb”, namely toward the middle of the list. In contrast, middle items can drift in both directions, increasing the likelihood that they will be placed incorrectly at test. Importantly, the model predicts that primacy and recency should be symmetrical, because there is no difference between the two ends of the list. Although Estes (1972) presented this model as pertaining to short-term order memory, Nairne (1992) applied this model to the study of long-term, incidental learning for order memory, with fair results. What the model fails to predict, however, is the difference between primacy and recency effects, in which the first item in a group is placed more accurately than the last item. Nairne (1992) suggested that this difference may prove significant, and the support for this result found in our data raises a substantial problem for the perturbation model.

Two later models do make the prediction that primacy should be greater than recency in memory for order. The primacy model (Henson, Norris, Page, & Baddeley, 1996) is based on the ad hoc assumption that items earlier in a list have higher activation levels. These items are then suppressed by another ad hoc mechanism as they are output at test time. Recency arises from this model because there are fewer remaining choices nearer the end of the list, and therefore fewer chances to make an error based on noise in the activation levels. In addition to being largely ad hoc, this model makes the problematic assumption that participants place items in forward order at test time. However, informal debriefing of several participants in our study suggests that items are often placed in orders other than strictly forward. Indeed, others have observed a pattern in which participants initially place the first and last items, and only then place the middle items (Lee & Estes, 1977). Because sequential placement of order is a basic assumption of the primacy model, further study on the order in which participants actually place items is necessary.

The second model that predicts greater primacy than recency is the dual-code associative model (Altmann, in press). This model represents each item with two codes – one for the item itself and one for its location – and links them together in a chain at encoding time. Errors in linking codes produce order errors at test. Items at either end of a list have an advantage in that they can only be linked to an incorrect code in one direction. However, items at the start of the list have a greater advantage, because they suffer less interference at encoding time (Altmann, 2000). This model has the benefit of explaining how memory for order is encoded, an issue that the primacy model fails to address.

To advance our theoretical understanding of order memory, follow-up studies will have to differentiate among the primacy and dual-code associative models. In addition, existing models fail to account for modality, set-size, presentation format or any of the other effects that appear in studies of both item and order memory. Our goal should be to integrate these phenomena across item, order, short-term, long-term, semantic, episodic and all of the other pigeonholes in which we classify memory, into one unified theory.

## Conclusion

We expected that pictures would produce better memory for order than text, based on similar effects in memory for items and on considerations of the foundational nature of memory for order. This hypothesis was not supported, but we did find an interaction between format (picture vs. text) and serial position. Recency effects were greater for text across a range of retention intervals, an effect that may be related to the modality interaction observed by others. We also found that primacy was greater than recency in aggregate, and, in a finer-grain analysis, in almost all combinations of presentation format and time delay. This finding, foreshadowed by Nairne (1992), suggests that the perturbation model is incorrect and lends credence to models that capture directional processing of items at study.

## Abstract

Though very often quantitative problem solving is accentuated in physics instruction, psychological as well as educational research indicates that this emphasis is misleading. In an experimental study, we compared physics instruction with a focus on quantitative problem solving to physics instruction with a focus on qualitative problem solving. Initially, students were taught quantitative as well as qualitative concepts of classical mechanics by means of concept maps. Thereafter, the students attempted to solve four problems whose solutions demanded the coordinated application of knowledge about quantitative and qualitative concepts. During problem solving, the students received support from tutors. While one group of students was supported in qualitative problem solving, the other group was supported in quantitative problem solving. Before and after the problem solving, the students worked on tests. In accord with our expectations, students who were supported in qualitative problem solving improved significantly more from the pretest to the posttest than students who were supported in quantitative problem solving.

## Introduction

Very often, students are not able to successfully approach problems in classical mechanics by means of the knowledge they have acquired during physics instruction. Classical mechanics embodies concepts and relationships between concepts which allow for the description, explanation and prediction of motion. Many concepts and relationships between concepts involve qualitative as well as quantitative information.

Quantitative information is frequently expressed by means of laws which are formalized as algebraic or vector-algebraic equations. Students frequently approach problems which ask for a quantitative solution by only making use of their knowledge about quantitative information. Usually, they start from the variable whose value is in question. Afterwards, they attempt to apply dynamics and kinematics laws in order to determine the variable's value. Very often, however, the students get lost in a muddle of algebraic equations with no means at hand in order to guide their application effectively and efficiently (e.g., Chi, Feltovich & Glaser, 1981; Larkin, 1983).

In contrast to students, experts make use of both their knowledge about qualitative and their knowledge about quantitative information. Initially, they attempt to qualitatively identify the concepts relevant to the problem posed.

Subsequently, they take advantage of the qualitative information in order to select the appropriate dynamics and kinematics laws which quantitatively relate the identified concepts to each other (e.g., Chi, Feltovich & Glaser, 1981; Larkin, 1983). Finally, they apply the selected dynamics and kinematics laws in order to determine the value in question.

While experts seem to possess knowledge structures in which knowledge about qualitative and quantitative information is closely related, students' knowledge frequently is not only fragmentary and weakly related but also includes conceptualizations which are inconsistent with the concepts taught during physics instruction (cf. Pfundt & Duit, 1994). Due to these deficiencies, students seem not to be able to take advantage of their knowledge in the same way that experts do. As a consequence, students have to fall back on so-called weak problem solving methods such as operator subgoalings and means-ends analysis (cf. VanLehn, 1996). These methods, however, provide little guidance for solving problems in classical mechanics.

How can students be supported to acquire and to flexibly apply both knowledge about qualitative and quantitative information on classical mechanics? Though very often the emphasis in physics instruction is on quantitative problem solving, this emphasis seems to be misleading (e.g., Hestenes, 1987; Reif & Heller, 1982). Because very often successful quantitative problem solving presupposes qualitative understanding, physics instruction with an emphasis on qualitative problem solving might be more beneficial (e.g., Ploetzner, 1995; White, 1993).

In this paper we present an experimental study in which physics instruction with a focus on quantitative problem solving is compared to physics instruction with a focus on qualitative problem solving. Because psychological research (e.g., Chi, Feltovich & Glaser, 1981; Larkin, 1983), educational research (e.g., Hestenes, 1987; Reif & Heller, 1982) as well as research in artificial intelligence (e.g., de Kleer, 1977) indicate that successful quantitative problem solving presupposes qualitative understanding, we hypothesize that emphasizing qualitative problem solving is more effective than emphasizing quantitative problem solving.

## Knowledge about Qualitative and Quantitative Concepts in Classical Mechanics

The application domain is made up of textbook problems which refer to one-dimensional motion with constant accel-

eration. The knowledge investigated is on qualitative and quantitative information involved in concepts of dynamics (e.g., gravitational and normal force) and kinematics (e.g., displacement, velocity and acceleration).

With respect to qualitative information, the focus is on the conditions under which concepts are applicable, the attributes possessed by concepts and the values which concept attributes might have. For instance, knowledge about the kinetic friction force might comprise the qualitative information that a kinetic friction force acts on a body, whenever a normal force acts on the body and the body is moving on a surface which is not frictionless.

With respect to quantitative information, the emphasis is on dynamics and kinematics laws which are formalized as algebraic or vector-algebraic equations. For example, knowledge about the kinetic friction force might comprise the quantitative information that the magnitude  $F_f$  of the kinetic friction force on a body equals the magnitude  $F_N$  of the normal force on the same body times the coefficient of friction  $f$ :  $F_f = F_N \cdot f$ .

Qualitative and quantitative information can be conceptualized as complementary information (e.g., de Kleer, 1977). Qualitative information refers to essential features to be taken into account as well as to important distinctions to be drawn. While quantitative information frequently helps to resolve ambiguities inherently involved in qualitative information, the appropriate use of quantitative information very often seems to presuppose the utilization of qualitative information.

Ploetzner (1995) implemented formal representations of qualitative and quantitative information on classical mechanics in a simulation program. If the program is applied to the formal representation of a problem, it simulates how a qualitative problem representation can be taken advantage of to guide the construction of a quantitative problem representation. The program coordinates qualitative and quantitative problem representations in two different ways. Firstly, the information included in a qualitative problem representation is partially transformed into algebraic expressions in order to construct additionally required quantitative information. Secondly, the information contained in a qualitative problem representation is exploited to constrain the use of already available quantitative information.

## Method

### Design

The study comprised two groups of students and was made up of five sections.

In the first section, all students worked on an introduction to concept maps as well as on an introduction to a computerized concept mapping tool. In the second section, all students studied the same instructional unit which described qualitative and quantitative information on classical mechanics by means of concept maps. In the third section, all students worked on a multi-component test which assessed the knowledge about qualitative and quantitative information the students had acquired during the study of the instructional unit.

In the fourth section, the students attempted to solve four problems which demanded the coordinated use of knowledge about qualitative and quantitative information. During problem solving, the students took advantage of the computerized concept mapping tool. In addition, the students received support from tutors. While one group of students was supported in qualitative problem solving, the other group of students was supported in quantitative problem solving.

Finally, all students worked on a parallel multi-component test which assessed the knowledge about qualitative and quantitative information the students had acquired due to the support from tutors.

## Materials

**Introduction to Concept Maps** To be knowledgeable in a domain means to know the relevant concepts as well as the relationships between them. This structural aspect of knowledge can be represented by means of concept maps (e.g., Jonassen, Beissner & Yacci, 1993). Concept maps form an external representation in which information is structured by means of graphs. Individual nodes represent concepts; the directed and undirected links between the nodes represent relationships between the concepts. In an earlier study, Ploetzner, Fehse, Kneser and Spada (1999) demonstrated that concept maps can be equally well employed to teach qualitative as well as quantitative concepts in classical mechanics.

Because qualitative and quantitative information on classical mechanics were taught to the students by means of concept maps, in the first section of the study, the students worked on an introduction to concept maps in order to learn how concept maps are structured. The concepts addressed in the introduction referred not to classical mechanics but to well-known household furniture.

**Computerized Concept Mapping Tool** When concept maps are constructed by paper and pencil, they are frequently difficult to extend and to modify. Furthermore, the construction of concept maps can hardly be reconstructed by conventional observation methods. The use of a computerized concept mapping tool, however, allows one to overcome these drawbacks. Therefore, whenever the students had to construct concept maps, they took advantage of such a tool (cf. Ploetzner, Hoppe, Fehse, Nolte & Tewissen, 1996).

In a computerized concept mapping tool, the concepts and relationships relevant to the domain under scrutiny may be made available to the students in advance by means of menus, for example. If needed, the students may fill in additional concepts and relationships at run time. Complete concept maps as well as parts of concept maps may be selected by the mouse and subsequently be moved, copied or deleted. Concept maps are easily re-arranged as well as saved and re-loaded. In addition, every step taken to construct, extend or modify a concept map can be saved for later analysis.

In order to learn how to use the computerized concept mapping tool, in the first section of the study, the students worked on an introduction to the tool. As in the introduction to concept maps, the concepts addressed in the introduction to the concept mapping tool referred not to classical mechanics but to well-known household furniture.

**Instructional Unit** We designed an instructional unit to teach the students qualitative and quantitative information on classical mechanics by means of concept maps. It was made up of three parts. In the first part, coordinate systems and vectors as well as the addition and resolution of vectors were described. In the second part, qualitative and quantitative information on kinematic concepts such as displacement, velocity and acceleration was presented. In the third part, qualitative and quantitative information on dynamic concepts such as gravitational force, normal force, friction force and resultant force was delineated.

The qualitative and quantitative information on the different concepts was described by means of concept maps. One or more concept maps were followed by several examples and exercises. The solutions to the exercises were also presented. In 100 pages total, the unit comprised 30 concept maps, 18 examples and 20 exercises along with their solutions.

The students worked on the instructional unit in the second section of the study. In a first step, they attempted to elaborate the information included in a concept map. In a second step, the students had the opportunity to consider an example. It illustrated the consequences of applying the information included in a concept map to a certain arrangement. In a third step, the students themselves exercised the application of the information included in a concept map to other arrangements. While some of the exercises asked for the construction or completion of diagrams, other exercises asked for the construction of concept maps. The students always constructed diagrams by paper and pencil. Concept maps were always constructed by taking advantage of the computerized concept mapping tool. Finally, the students were allowed to compare their solution to an exercise with the solution presented in the instructional unit.

**Problems to be Solved with Support from Tutors** Four different problems for problem solving with support from tutors were set up. For example:

A sledge of mass  $m = 10$  kg moves on a horizontal surface with a velocity of  $v_0 = 4.8$  m/s. The coefficient of friction between the runners of the sledge and the surface equals  $f = 0.12$ . After which distance  $r$  has the sledge's velocity reduced to  $v = 0$  m/s?

By making use of a simulation program of qualitative and quantitative problem solving in classical mechanics (Ploetzner, 1995), the problems were designed in such a way that – relative to the information presented in the instructional unit – their solutions demanded the coordinated application of knowledge about both qualitative and quantitative information. In order to design the problems, the simulation program was equipped with formal representations of the qualitative and quantitative information which was presented in the instructional unit. Afterwards, the simulation program was applied to formal representations of the four problems. When the simulation program was furnished with either qualitative or quantitative information, its problem solving attempts failed. The problem solving attempts succeed only when the simulation program was furnished with both qualitative and quantitative information.

**Strategies Applied by the Tutors** In the fourth section of the study, the students attempted to solve the four problems with support from tutors. While one group of students was supported in qualitative problem solving, the other group of students was supported in quantitative problem solving. Two physics students from the School of Education at Freiburg served as tutors. Both were trained to support the students in either qualitative or quantitative problem solving by means of two different problem solving strategies. The strategies are described in Table 1. The strategy to support qualitative problem solving focused on the construction and interpretation of free-body diagrams. The strategy to support quantitative problem solving addressed the systematic use of algebraic equations.

**Table 1:** The strategies applied by the tutors

---

**Strategy to support qualitative problem solving**

1. Drawing a sketch:
  - Identify the body!
  - Is the body in contact with the surface?
  - Draw a sketch!
2. Determining the resultant force:
  - Determine the forces on the body!
  - Draw an arrow for each force!
  - Determine the resultant force on the body!
  - Describe the resultant force algebraically!
  - Is it possible to simplify the algebraic description?
  - Draw a coordinate system!
  - Describe the magnitude of the resultant force relative to the coordinate system!
3. Relating the resultant force to the acceleration:
  - How is the resultant force related to the body's acceleration?
  - Determine the direction of the body's acceleration!
  - Determine the direction of the body's velocity!
  - How does the acceleration affect the velocity?

**Strategy to support quantitative problem solving**

1. Identifying the given and sought variables:
    - Identify the variables whose values are given!
    - Identify the variables whose values are sought!
  2. Selecting an algebraic equation:
    - Select an equation which includes a variable whose value is sought!
    - Attempt to apply Newton's second law  $\Sigma F = m \cdot a$ !
  3. Applying an algebraic equation:
    - Identify the variables whose values are known!
    - Identify the variables whose values are unknown!
    - If the values of all variables in an equation are known except the value which is sought, then substitute the variables for their values and compute the value which is sought!
    - Otherwise, select equations which include variables whose values are unknown and determine the unknown values!
    - After applying an equation, verify the units!
- 

Initially, the tutors explained and demonstrated the problem solving strategy they supported. Thereafter, the students attempted to solve the four problems. They worked on each problem in two phases. In the first phase, the students approached a problem on their own. To describe a problem's solution, the students constructed diagrams by paper and pencil as well as concept maps by taking advantage of the computerized concept mapping tool.

In the second problem solving phase, the students received

support from the tutors. The tutors assisted the students after they completed the first problem solving phase or when they did not show any further progress in their problem solving attempts. If the students raised questions which concerned problem solving steps addressed by the tutors' problem solving strategy, the tutors delineated the problem solving steps and encouraged the students to carry them out. If the students were not able to accomplish this, the tutors explained and demonstrated the problem solving steps. Afterwards, the students had to reproduce the tutors' explanation using their own words.

The tutors also encouraged the students to explain their partial or complete solution to a problem. Whenever a problem solving step addressed by the tutors' problem solving strategy was correct, the tutors provided affirmative feedback to the students. Whenever a problem solving step addressed by the tutors' problem solving strategy was incorrect or missing, the tutors indicated the error or omission to the students. Thereafter, the tutors encouraged the students to correct or add the problem solving step. Again, if the students were not able to accomplish this, the tutors explained and demonstrated the step. Afterwards, the students had to reproduce the tutors' explanation using their own words.

**Multi-Component Tests** In the third as well as in the fifth section of the study, the students worked on a multi-component test which assessed their knowledge about qualitative and quantitative information on classical mechanics. Each test was made up of three different components and comprised 16 problems in total. In order to design the problems, we again took advantage of the simulation program of qualitative and quantitative problem solving in classical mechanics (cf. Ploetzner, 1995).

The first component comprised four problems which assessed knowledge about qualitative information on classical mechanics. These problems were designed in such a way that – relative to the information presented in the instructional unit – their solutions only demanded the application of knowledge about qualitative information on classical mechanics. Correspondingly, the second component comprised four problems which only required the application of knowledge about quantitative information. The third component was made up of eight problems whose solutions demanded the coordinated application of knowledge about both qualitative and quantitative information.

Both tests comprised parallel problems. Each pair of parallel problems were designed in such a way that the same knowledge was applied by the simulation program of qualitative and quantitative problem solving to solve them. However, non-structural features such as the involved entities and numerical values varied across parallel problems. Within each test, the problems were arranged in random order.

The design of the tests allows one to hypothesize which problem solving performance should be observable in the three test components of the pre- and posttest.

With respect to the first test component on qualitative information, we predict that many problems can already be solved in the pretest after studying the instructional unit. While the qualitatively supported students should further improve from the pre- to the posttest, the quantitatively sup-

ported students should not do so.

With respect to the second test component on quantitative information, we also hypothesize that many problems can already be solved in the pretest. While the quantitatively supported students should further improve from the pre- to the posttest, the qualitatively supported students should not do so.

In contrast, with respect to the third test component on the coordination of qualitative and quantitative information, we predict that only few problems can already be solved in the pretest. Both qualitatively and quantitatively supported students should improve from the pre- to the posttest. We especially hypothesize, however, that qualitatively supported students improve considerably more than quantitatively supported students.

## Subjects

Twenty-four tenth graders, 11 girls and 13 boys, from three different high schools volunteered for the study. While the group of students which was supported in qualitative problem solving comprised 6 girls and 6 boys, the group of students which was supported in quantitative problem solving comprised 5 girls and 7 boys.

Before the study was conducted, the students' general ability was assessed by means of the Advanced Progressive Matrices Test (Raven, 1976). Subsequently, two students who had received the same or almost the same test scores were assigned to different groups. While the average test score of the students who received support in qualitative problem solving was 24.33 (SD = 3.60), the average test score of the students who received support in quantitative problem solving was 23.92 (SD = 3.85). Students from different schools also were equally distributed among the two groups. Furthermore, in each group of students, one half of the students received support from one tutor and the other half received support from the other tutor. The students were paid for their participation.

Because in German high schools Newtonian mechanics is commonly taught to eleventh graders, none of the students had attended classes on Newtonian mechanics as it was addressed in this study.

## Procedure

The students were investigated individually for four days running. On the first day, they worked on the introduction to concept maps, on the introduction to the computerized concept mapping tool, and on the first part of the instructional unit. On the second day, the students worked on the remaining parts of the instructional unit and on the pretest. On the third day, the students attempted to solve the first two problems with support from tutors. Finally, on the fourth day, the students attempted to solve the remaining two problems with support from tutors and worked on the posttest.

## Results

### Times Spent

On average, both groups spent virtually the same amount of

time on the different sections of the study ( $M = 73$  vs.  $M = 75$  minutes on the introduction,  $M = 221$  vs.  $M = 219$  minutes on the instructional unit,  $M = 78$  vs.  $M = 85$  minutes on the pretest,  $M = 154$  vs.  $M = 159$  minutes on problem solving and  $M = 88$  vs.  $M = 86$  minutes on the posttest).

### Problem Solving Performance

The average relative solution frequencies in the first test component, which assessed knowledge about qualitative information on classical mechanics, are displayed in Figure 1. In accordance with our expectations, the students had acquired considerable knowledge about qualitative information by studying the instructional unit. With respect to the first test component, although statistically not significant, only the qualitatively supported group improved a little from the pretest to the posttest.

**Figure 1:** Problem solving performance in the test component on qualitative information.

The average relative solution frequencies in the second test component, which assessed knowledge about quantitative information on classical mechanics, are shown in Figure 2. Again, as expected, the students had acquired substantial knowledge about quantitative information by studying the instructional unit. Furthermore, on average, the qualitatively as well as the quantitatively supported group improved significantly from the pretest to the posttest ( $F(1, 22) = 27.72$ ,  $p < .001$ ).

Figure 3 displays the average relative solution frequencies in the third test component which assessed the coordinated use of knowledge about qualitative and quantitative information on classical mechanics. In accord with our expectations,

**Figure 2:** Problem solving performance in the test component on quantitative information.

with respect to this test component, the students exhibited rather poor performance after studying the instructional unit. On average, both groups improved significantly from the pretest to the posttest ( $F(1, 22) = 46.48$ ,  $p < .01$ ). Furthermore, the interaction *Test* x *Group* indicates that the qualitatively supported group improved significantly more from the pretest to the posttest than the quantitatively supported group ( $F(1, 22) = 4.47$ ,  $p < .05$ ).

**Figure 3:** Problem solving performance in the test component on qualitative and quantitative information.

### Problem Solving Approach

With respect to the third test component, which assessed the coordinated use of knowledge about qualitative and quantitative information on classical mechanics, it was also analyzed how frequently the students approached these problems qualitatively and quantitatively.

**Figure 4:** Qualitative problem solving approaches.

The average relative frequencies of qualitative and quantitative problem solving approaches are shown in Figure 4 and 5. The average relative frequency of qualitative problem solving approaches increased significantly from the pretest to the posttest ( $F(1, 22) = 54.68$ ,  $p < .01$ ). Due to the support from tutors, the students who were supported in qualitative problem solving drew more frequently a free-body diagram than the students who were supported in quantitative problem solving ( $F(1, 22) = 28.73$ ,  $p < .01$ ). The interaction *Test* x *Group* further demonstrates the consequences of the support from tutors. While the qualitatively supported group largely increased the number of qualitative problem solving attempts from the pretest to the posttest, the quantitatively supported group even decreased the number of qualitative

problem solving attempts ( $F(1, 22) = 103.38, p < .01$ ).

The average relative frequency of quantitative problem solving approaches also increased significantly from the pretest to the posttest ( $F(1, 22) = 17.75, p < .01$ ). As expected, however, with respect to the use of algebraic equations the qualitatively supported group did not differ significantly from the quantitatively supported group. There is also no statistically significant interaction *Test x Group*.

**Figure 5:** Quantitative problem solving approaches.

## Discussion

We presented an experimental study which started from the hypothesis that physics instruction with an emphasis on qualitative problem solving is more effective than physics instruction with an emphasis on quantitative problem solving. The focus of our analysis was on the solution of problems which demand the coordinated application of knowledge about qualitative and quantitative information on classical mechanics.

In such a context, the support of qualitative reasoning as well as the support of quantitative reasoning should enhance the students' problem solving performance. However, while quantitative information frequently helps to guide the use of qualitative information, the appropriate use of quantitative information very often seems to presuppose qualitative understanding (e.g., Chi, Feltovich & Glaser, 1981; de Kleer, 1977; Ploetzner, 1995). Without qualitative understanding, the duality of the physical situation under scrutiny and the quantitative structure set up gets easily lost. Therefore, we expected that the support of qualitative reasoning improves the students' problem solving performance more than the support of quantitative reasoning.

The results are in accord with our expectations. Both the support of qualitative reasoning and the support of quantitative reasoning significantly improved the students' problem solving performance. Especially, students who were supported in qualitative problem solving improved significantly more than students who were supported in quantitative problem solving.

Our results also underline an observation repeatedly made in psychological and educational research on problem solving in formal sciences such as physics. When problems have to be solved which ask for a precise quantitative solution, students strongly tend to focus on the use of quantitative-numerical information and to neglect the use of qualitative-conceptual information. While in the presence of quantita-

tive problems the necessity to make use of quantitative-numerical information seems to be obvious to the students, the necessity of applying qualitative-conceptual information needs again and again to be pointed out to the students as well as its use needs to be encouraged and supported.

## Abstract

In this paper we argue for a new role for experiment in science teaching and learning. Our proposition is based on the conception of experiment as an active ingredient of theory construction and not as a mere tool for theory testing. This latter view is based on the classical conception of the mind-world interaction, according to which human action purports to test the validity of a tentative solution to a problem and follows after mental processing. We present the new framework that views the interactions with the environment as active ingredients of the mind's problem solving activity. We also adduce evidence for this new role of experiment from the history of science. Finally, we discuss the repercussions of this view of cognition, as the activity of a mind-environment inseparable whole for the role of experiment in knowledge construction.

## Introduction

Experimentation was traditionally deemed to be the main prerequisite for the successful teaching of physical sciences in school, mainly because the experiment was construed as a means of confirmation of theories. As such, it could persuade the student about the adequacy of the theory presented in class and lead her to embrace it. This construal of experiment was based on the thesis that experiment follows theory with a view to testing it empirically (which was the prevalent view in philosophy of science until the 1960's).

This conception about the role of experiment in science, first, and education, later, was subsequently criticized on philosophical, psychological, and educational grounds. The main argument against the standard conception of the experiment was that:

(a) the student has formed a well established body of beliefs, intuitive theories, or phenomenological primitives (diSessa, 1993) about the world before she attends school, which constitutes an alternative, well entrenched, theory to

those taught in class (psychological critique);

(b) the knowledge that the student brings to a given learning situation influences the meaning that she constructs in that situation;

(c) experiments are not sufficient to establish the adequacy of theoretical ideas, since by themselves they do not constitute the basic criterion of choice among alternative theories (philosophical critique).

Therefore, experiments should abdicate their decisive role in science education, since even if the student actively participated in their making, they do not suffice to allow her to build the required concepts and to persuade her to abandon her intuitive theories. To demonstrate this point further, one could cite extensive research showing the failure of instruction with regard to classical physics.

In this paper we will briefly present the theoretical framework that led to the dispute about the role of experiment in education. We will argue that this framework is based on an erroneous conception of the role of experiment in problem solving, and *a fortiori* in science. We will claim that this error is based on the classical conception of the mind-world interaction in cognitive science and we will present the new framework emerging in cognitive science that views the interactions with the environment and experimentation not as a follow up of the mind's output purporting to test the validity of a tentative solution to a problem, but as an active ingredient of the mind's problem solving activity, that extend mind beyond its biological boundaries to the world (Clark, 1997). We will also adduce evidence for this new role of experiment from the history of science. Finally, we will discuss the repercussions of this view of cognition as the activity of a mind-environment inseparable whole for the role of experiment in knowledge construction and we will argue for the importance of experiment not as a test of theory only but as an integral part of theory construction.

## 1. Undermining the Role of the Experiment:

### An Overview

Logical positivism, the main philosophical paradigm during the first half of the 20th century conceived of experiment as a scientific activity that follows the theoretical, or mental, processing of raw data aiming to provide empirical testing of scientific theories. Hanson (1958), Kuhn (1962), Gregory (1973), Lakatos (1978) and others criticized this classical conception of science. They outlined the non linear and non cumulative character of the scientific enterprise, a conception that undermined the role of experience and of the experiment in the rationalistic choice among competing theories. In this context, the realization that experience is always interpreted through the lenses of a theoretical framework, led, on one hand, to diminishing the importance of the experiment as a means of theory testing, and on the other hand, to the marking out of the role of theory as the framework within which empirical data are interpreted.

This crisis regarding the role of experiment could not bypass the experiment as an instructional medium. The tendency towards criticizing experiment was strengthened in the early 1970's by the findings of psychologists (Carey, 1985, 1992; Chi, 1992; Karmiloff-Smith, 1992; Medin, 1983; Nersessian and Resnick, 1989; Rosch, 1978; Spelke, 1990) that a child's mind is no *tabula rasa* upon which the educator is called to imprint the acceptable scientific theories included in the curriculum by proving them experimentally. On the contrary, children have innately acquired, or constructed very early on the basis of some innate constraints, a set of persistent beliefs about the world (intuitive or naive theories).

Seen in this context, the experiment loses its function as the means par excellence of testing and proving theories, since the child has already an intuitive conceptual background from which she can formulate various interpretations of the experimental results that are not compatible with those interpretations that the instructor seemingly wishes the student to acquire. Thus, the mere presentation of, or participation in conducting, experiments does not suffice to prompt the student to accept the intended interpretations.

Leaving aside the issue of whether this set of beliefs constitute a theory, or merely a body of incompatible principles, one notes that even though they contain principles that allow children to make personal sense of their world-experience, they generally deviate from established scientific theories (Carey, 1985; Clement, 1982, 1983; Halloun and Hestenes, 1985; McCloskey, 1983; Nersessian and Resnick 1989; Viennot, 1979). These persistent ideas are epistemological obstacles that instruction must guide students to overcome, if it is to be effective. These obstacles are not merely erroneous pieces of knowledge about the world that the child could easily be persuaded to reject. Since they constitute the schemata on the basis of which she has come to interpret the world, they function as organizing principles. All experiences are made meaningful on the basis of these principles, and as a result, they are the least likely items to be put under experimental inquiry (Quine, 1961).

The criticism of experiment and of its role in science education was reinforced by the well established failure of traditional instruction of, say, Newtonian physics.

This intense criticism of experiment was accompanied by the realization of the need to complement instruction by exposing students in a systematic way to their own intuitive theories and guiding them to compare them explicitly and in detail with current scientific theories. The aim was to make students conscious of the implicit principles that they use to organize and understand the world, to render clear the points at which their intuitive theories are in conflict with the acceptable scientific theories, to make them realize that the latter are more adequate in explaining the world, and finally to lead them to construct the salient concepts of established scientific theories.

Theory becomes, thus, predominant in science education, while experiment loses some of its shine. This criticism of experiment does not imply of course the abandonment of experiments as educational means. It simply points out that experiments by themselves, without the presentation and discussion of the appropriate theoretical background, are no panacea for proper instruction in the natural sciences.

The educational paradigm that emerged in this new framework continued to conceive of the experiment as a follow-up to theory, a discrete step in the scientific enterprise of theory construction, whose role is the empirical testing of theory. Once this empirical testing is put in doubt, experiment automatically loses its appeal. In that regard, this new paradigm does not differ from the one it superseded.

This classical conception of the experiment is based on the belief that all cognizers (and *a fortiori* scientists) when engaged in a problem solving activity function according to the scheme: reception of external input (the data of the problem), mental processing of the internal representations of these data to figure out a solution (problem processing that consists in a search of the problem space) and, finally, output of a tentative solution to the problem that is tested for empirical adequacy and for compatibility with a body of accepted knowledge. This is the well known <input → mental processing → output> scheme of classical cognitivism, which in the case of scientific problem solving becomes the well known positivist scheme <experience → mental formal processing → experiment>.

## 2. A new Role for Experiment: Its Cognitive Background

The classical view of the interaction between cognizers and their environment, and therefore the classical view of experiment in everyday problem-solving and the scientific enterprise is severely questioned by some new tendencies in cognitive science and by the research findings in the history of science. Some cognitive scientists (Bickhard, 1993, 1998; Clark, 1993, 1997; Clark and Thornton, 1997; Elman, 1991; Hutchins, 1995; Rutkowska, 1993, Varela, et. al., 1993) on the one hand hold a different view for the cognizer-environment, and thus the theory-experiment,

interaction, which radically revises the relation between the mind and the world. Research in the history of science (Franklin, 1986; Gooding et. al. 1989; Gooding, 1990; Hacking, 1983; Nersessian, 1984), on the other hand, reveals that the experiment plays a much richer role than merely being a test of empirical adequacy of scientific theories.

According to the new conception of cognition, the mind does not function autonomously from the environment, in the sense that its relation with it does not consist simply in passively receiving input from it, and eventually processing it in its effort to find a solution to a certain problem. Instead, the strategies of mind include actions upon the world as an integral part of its problem-solving activity (Clark 1997), and, one might add, as a part of theory construction. This active intervention of the mind may transform the problem space, affecting the problem-solving process itself.

This can be done in various ways. First, the intervention upon the world may bring into light new data that could transform the problem-space, rendering its search more effective or even possible. Our action, for instance, might reveal some regularities that shed new light upon the existing data allowing perhaps their re-categorization, opening thereby new research avenues. Or, this same action may reveal some structural similarities, that were not lying in the surface structure of the problem-space, which allow the conceptual redeployment from another different field on to the given problem.

Second, the active intervention upon the environment may scaffold it so that the problem-space is structured in such a way that its effective search could be conducted, even allowing for the limited cognitive, perceptual and motor resources of the cognizer (Clark, 1997; Elman, 1991; Raftopoulos, 1997).

All these are ways of reducing, what Clark and Thornton (1997) have called, type-2 difficult problems, (i.e., problems whose statistical regularities do not lie on their surface structures but in their deep structure), to type-1 problems that wear their statistical regularities on their sleeves, and thus can be effectively solved by means of inductive heuristics.

The intervention on the environment, viewed as a part of theory construction, allows one to make sense of what it means to say that the learning process itself induces changes in the structures involved in learning. One way to understand this claim is to say that the neural substrate undergoes changes while it learns, as a result of this learning (Quartz and Sejnowski, 1997). Another way, is to interpret this statement to mean that the learning process changes the representational basis in which the search of the problem space takes place and this change influences this learning.

The active role of the mind and its action upon the environment results in the construction of new representations (either external or internal). This offers an alternative to the classical picture of learning as a search within a defined representational problem space (the problem of selective induction.) The cognizer builds representations as she learns, and thus shapes the

hypothesis-space. Since learning depends crucially on the statistical regularities of the problem input and the structural characteristics of the learner, the structure of the training data (and thereby the structure of the problem domain from which these data are drawn) and the processing characteristics of the learner shape the hypothesis space to their constraints and requirements.

Learning, thus, need not be an inductive search through a hypothesis space delineated by fixed representations that restricts search to solutions that can be expressed only by means of the pre-existing representations, in so far as new representations can be built during learning. The result is that processing strategies and representations co-evolve (Clark, 1993; Horgan and Tienson, 1996).

In this sense the result of our action upon the environment does not consist simply in testing a tentative solution to a given problem, and herein lies the fallacy of cognitivism's view of the mind, but in an active intervention upon the environment with a view to discovering new data and building new representations that might help the mind in solving the problem. This action becomes an active ingredient of the problem-solving process, and in the case of the scientific activity, an active ingredient of theory construction.

Schunn and Klahr (1995) offer a computational account of problem solving seen as a search in four problem spaces. These are the *data representation space* (from which representations of the salient data are chosen), the *hypothesis space* (in which hypotheses about causal relations amongst the data are drawn), the *experimental paradigm space* (the classes of experiments relevant to the problem at hand are chosen), and the *experiment space* (in which the values of the parameters within the selected paradigm are chosen). Though we do not have the space here to discuss this model in detail here, one can safely say that the upshot of the model is that the solution of a problem involves a constant flow of information among the four spaces. As a result, the processing within each space depends crucially upon the state of the research in the other spaces. This model shows clearly what it means to say that the learning process itself induces changes in the structures involved in learning, that new kinds of representations are developed which affect the search of the hypothesis space and so forth.

Our world is not merely a place in which we can store information and the testing ground of our theories and tentative solutions, although it certainly functions this way as well. It is also, and perhaps predominantly, the space upon which we act by transforming it and by building external representations so that it becomes an aid to the mind. Understanding the mind presupposes the rejection of the conception of the mind as isolated from the world building internal representations and models and processing them to discover solutions to problems (Rutowska, 1993). This view must be replaced by a mind situated in the world that uses it to facilitate its work and which shows that "the real power of human cognition lies in our ability to construct functional systems that accomplish our goals." (Hutchins 1995, 316).

This movement in cognitive space helps explain, and thus is being strengthened by, findings in the history of science that show that the experiment plays a much richer role in the scientific enterprise than being a mere test of empirical adequacy. The study of the actual processes of theory construction, based either on the notebooks and letters of scientists (Newton or Faraday, for instance) or on the in-situ observation of the workings of a research team renders clear that the experiments transcend the theory in the context of which they are first conceived. They acquire their own autonomy, they become themselves objects of inquiry independently of the theory and they are used not just to test the theory but also to discover new evidence that would facilitate the theoretical enterprise. They accomplish this either by revealing structural similarities with other domains, allowing thus conceptual redeployment, or by bringing forth certain basic regularities that reorganize the existing data, transform the problem space and, thereby, allow the discovery of the hidden structure. They also actively participate in the construction of the (partial) meaning of the theoretical terms of the theory.

### **Discussion: A New Educational Role for the Experiment**

We have seen that, according to cognitivism, the cognizer receives environmental input, builds internal representations and models of the world-situation pertaining to the problem, processes these representations and produces, as output, a tentative solution to the problem. The view of cognition that emerges from our discussion is entirely different. The cognizer is not a passive processor of information from the environment. She acts upon the environment, discovers new data that transforms the problem-space and diminishes the cognitive load of the problem. Hence, the problem space and the opportunities it offers for exploitation become an inseparable part of the problem-solving activity. Thus, the mind transcends its biological boundaries and extends itself to the world. This means, in return, that the well arranged triplet <input-processing-output> cedes its place to an action loop, that is, an interaction in which thought leads to actions which in turn change or simplify the problems confronting thought (Clark 1997). The continuous interaction between mind and environment becomes so intricate and complex that it is difficult to talk of two distinct factors that interact and is better to conceive them as forming an inseparable whole, which gives rise to cognition.

Learning in the physical sciences constitutes the development of a coherent conceptual framework that consists of a network of conceptual models within which mental models are constantly re-negotiated in dynamic interaction with the framework. Conceptual models are robust mental constructs that can be developed through appropriate instructional intervention. In effective learning environments, both mental and conceptual models are processed and manipulated consciously and explicitly by the learner.

In the context of our discussion, learning in science emerges as a process of elaboration of mental models through dynamic interaction between mind and environment. In this interaction, experiment as well as logical argumentation and syllogism both contribute in a dynamic and integral manner to the constructive process.

This view of the experiment has important implications for current classroom interpretations of the constructivist paradigm. Constructivism has attracted a lot of attention in science over recent years partly as the overarching framework underpinning active and collaborative learning. Constructivist classroom strategies invariably seek to facilitate learning outcomes by taking the students through a cycle of stages including formulation of ideas, cognitive conflict, knowledge re-organisation and extension. However, the assumptions that underlie the development and implementation of such constructivist strategies are at odds with the framework that we have presented here.

Before we go on to discuss this, we need to elaborate on two issues. Firstly, the conceptual models whose construction is the objective of effective science learning environments are not necessarily identical with established scientific theory. Learning is the outcome of individual construction of meaning even when that happens in a collaborative environment. Research in science education has repeatedly demonstrated that instructional approaches that rely on a knowledge transmissive model of teaching lead to rote memorization rather than real learning. Examples include rote applications of Ohm's law without fundamental understanding of the current model for electric circuits (McDermott and Shaffer, 1992), calculation of image magnification without basic understanding of geometrical optics (Wosilait et al., 1998) and rote application of the work-energy theorem without the basic realization that work is done by one body on another (O'Brien et al., 1998). It would appear that any effort to transmit knowledge to a group of learners does not usually result in effective construction of meaning.

Second, conceptual models are not in one to one correspondence with the phenomena they seek to model. The learning outcome in science is a series of mental constructs that seek to code and process specific aspects of the behavior of physical phenomena. For the individual learner, both the science discipline and the conceptual models should be aligned with the physical world in the way that this is observed and coded by the learner's mental processes. In other words, both the outcome of research (a socio-cultural construct by a community of researchers) and the outcome of learning (a cognitive construct of the learner) cannot be conceived as a mental reflection of physical reality but only as mental constructs that aid us in systematically pursuing this interaction between mind and matter. For instance, the theory of the Big Bang does not describe the birth of the Universe as we currently know it; rather it seeks to describe the birth of the Universe had an observer been there to observe what happened, for Physics and other sciences are constrained to formulate questions, hypotheses and theories that are epistemologically compatible with the mind-environment

interaction that is inherent in their development.

In view of these, the experiment in natural sciences plays a more fundamental and complex role than was traditionally thought. It is not just a means for testing and confirming a theory (as was conceived and implemented by traditional instruction with the laboratory as a supplement to the theoretical lecture-based transmission of the knowledge to be learned), or a means of choosing among conflicting predictions and alternative theories (as is conceived by the modern proponents of the constructivist model in education). In view of the fact that learning is a process of mental construction, and as such the product of the interaction of the mind with the physical world, the experiment provides the means of this interaction and implements it by enabling the construction of meaning.

Inquiry-based approaches to teaching science are closer to this reconceived formulation of the role of experiment in the construction of meaning. In particular, the implementation of inquiry developed by the Physics Education Group at the University of Washington (McDermott, 1996) seeks to familiarize students with the process of using experimental evidence as a medium for recognizing the need of new concepts, constructing operational definitions of useful quantities and using those and the experimental evidence to synthesize models that are, in their turn, continuously open to validation and constant reformulation in the light of new evidence.

To demonstrate the way experimenting can influence the mental representation, it would be useful to present an example from electric circuits. In *Physics by Inquiry*, students initially explore how they might be able to light a bulb with a single wire and a battery. At this stage, post-test data indicate that students have one of several models concerning the underlying cause. Although most often they give the name current flow to their models, they tend to describe flow models that begin at one point and end at another, or alternatively are unidirectional, always running from the battery to the light bulb, or even more commonly involving current consumption along the way. In subsequent experiments they short-circuit a battery with a bare wire and make the observation that both the battery and the wire get warm, and that all points of the wire at some distance from the battery get equally warm simultaneously. All three of these observations contradict different aspects of their initial models. When the issue is raised of what flow model might account for these observations, students have to tackle specific aspects of their initial model one by one until they arrive at a more valid representation of current flow. In the process they have to go back and forth between their observations and their model every time improving on both. The emerging representation is aligned with continuous flow that upon closure of the switch starts instantaneously at all points of the circuit and uniformly cover all parts of the circuit. Once students have developed a model for electric current, they can then use it to make predictions of the relative brightness of light bulbs in fairly complex circuits.

In the context of the interaction between mind and environment, the experiment accomplishes various

essential functions. Firstly, the experiment determines which aspects of a hypothesis or working theory are valid or in need of reformulation. The experiment also enables us to identify interacting variables and, via the confirmation of hypotheses, plays a substantial role in the construction of theory. Second, the degree to which the learning outcome is correct is not determined by the extent to which the outcome and hence the student ideas overlap with current scientific thinking. Rather this is determined by the experiments that are accessible to the learner up to the time that instruction takes place. The degree of correctness and of the validity of the learning outcome is determined by the epistemological basis of the experimental process that led to the construction of meaning. Real learning is a result of logical argumentation that feeds on experimental data.

This last point is in stark contrast to current innovative approaches that seek to implement the constructivist paradigm by shifting the student conceptions from the naïve to the established through cognitive conflict and knowledge reconstruction events. The experiment cannot be conceived as an instructional means of shifting student conceptions or as a means of embedding theoretical knowledge. The experiment is a viable tool in the science classroom, a tool that is continuously used in the construction of a coherent conceptual framework and guides subsequent theory development and evaluation by mediating the interaction between mind and matter that extends the boundaries of our cognition beyond the biological confines of the brain.

# Evidence for the processing of re-representations during the mapping of externally represented analogies

Michael Ramscar

michael@cogsci.ed.ac.uk

## Abstract

High level descriptions of the analogical reasoning process in cognitive science have now converged to present a relatively unified account (Hummel and Holyoak, 1997). However, the broad, consensual account of analogy is still far from complete: whilst it is possible to give a good explanation of the mapping of larger, structured representations in analogy, accounts of the mappings of individual sub-elements in these representations are still under-specified. Here, we review some possible approaches to this problem, describe an experiment that provides some empirical support for the 're-representation' approach to sub-mapping, and then identify some shortcomings in the 're-representation' approach as it is currently conceived.

## Introduction

Cognitive science has made great strides towards answering the important question of 'How do humans reason by analogy?' If we take a familiar example, the analogy between the solar system and Rutherford's model of the atom, then it is possible to explain – in broad terms – exactly how it is that two seemingly disparate objects can both remind us of one another in the first place, and then how it is that we can make meaningful correspondences between them.

Studies have shown that reminding (or retrieval) is driven by a computationally inexpensive process that initially matches surface (or semantic) elements in representations (witness the frequency – and mundanity – of most similarity based reminders, such as a lamp-shade reminding a party joker of a hat; see Gentner, Ratterman and Forbus, 1993).

Analogical mappings, on the other hand, are determined by a relatively more computationally expensive process. Global, systematic structural similarities between items to be matched need to be detected in order to make the kind of 'deeper', inference supporting correspondences that characterise analogy (Gentner, 1983; Goswami, 1992; Holyoak and Thagard, 1995; Hummel and Holyak, 1997).

Whilst theories and models of analogy are very compelling at one level of abstraction, there are certain assumptions made by *all* analogical theories that beg interesting questions if one seeks a more detailed explanation. As one increases the resolution of the question 'How do humans reason by analogy?' it appears that there are important gaps in current theories and

process models. Here, we wish to consider just one aspect of one of these gaps: the problem we focus on is that of matching the 'semantics' of elements during the analogical mapping process. This problem can be summarised as follows: suppose that in your representation of the atom, you describe the motion of an electron in relation to the nucleus in terms of it "revolving around" the nucleus (perhaps this is how you ordinarily think about this motion). On the other hand, suppose that in your representation of the solar system you conceive the motion of the planets in terms of their "orbiting" the sun.

At one level of abstraction, it may be sufficient to say that similarities in the meanings – or usage – of these words determine these mappings. However, in a more detailed account – and model – of analogy we might wish to do more than appeal to humanistic intuitions about similarities of meaning. We might wish to account for the way in which these sub-elements of our representations of the atom and the solar-system are mapped onto one another with the same level of detail with which we account for the mappings between the representations themselves.

If we are to fully explain high-level mapping in analogy, we must also account for the way lexically distinct but 'semantically' similar items in representations are reconciled with each other in a way that allows high-level mappings to be made. Here, we review some possible approaches to this problem, and present some evidence that offers some support to a popular proposal in the literature: the *re-representation* hypothesis.

## Semantic reconciliation and the re-representation hypothesis

Perhaps the most straightforward way to explain the mapping between "revolving around" and "orbiting"<sup>1</sup> would be in conceptual terms. If "revolving around" and "orbiting" could be shown to decompose into some canonical conceptual representation (say "circumnavigating"), then the link between them could be explained by reference to that concept, and the process by which it is made. This proposal is put forward by Gentner, Ratterman and Forbus (1993):

"[the...] constraint of matching identical predicates assumes canonical *conceptual* representations, not lexical strings. Two concepts that are similar but not identical (such as "bestow" and "bequeath") are assumed to be decomposed into a canonical

<sup>1</sup> We shall refer to this as the problem of semantic reconciliation in analogy.

representation language so that their similarity is expressed as a partial identity (... “give”)” Gentner, Ratterman and Forbus (1993, p 553)

The main drawback to this proposal is the lack of any specification of what a canonical conceptual representation (or a canonical representation language) is. Research into the mental representation of concepts suggests that human conceptual representations are anything but canonical; the proposals for generalised theories of representation that exist in the concepts literature fall well short of providing the kind of ‘neat’ account of concepts that canonical conceptual representation assumes (see Komatsu, 1992; Ramscar and Hahn, 1998 for reviews).

This problem has not gone unrecognised. In conjunction with other factors, such as evidence of the important role that structural commonalities (the ‘what’ of analogy) play in ‘ordinary’ conceptual tasks (e.g. Ahn, 1998), and the sheer difficulty of distinguishing analogy from ‘ordinary’ conceptual tasks (Ramscar and Pain, 1996), a widespread view has emerged that suggests that analogy *itself* may play an important role in semantic reconciliation (Forbus, Gentner, Markman and Ferguson, 1997, Hummel and Holyoak, 1997).

The basic idea behind this is outlined by Forbus, Gentner, Markman and Ferguson (1997) who propose that semantic terms might be decomposed into sub-predicate re-representations, with mapping between these being determined using the same process as similarity based transfer:

“re-representation allows relational identity to arise out of... analogical alignment, rather than as a strict constraint on the input descriptions” Forbus, Gentner, Markman and Ferguson (1997, p 246).

A similar re-representation proposal is advanced by Hummel and Holyoak (1997):

“With the notion of chunked predicates and objects, LISA hints at a kind of recursive representation for meaning that may ultimately ground itself in basic perceptual primitives. In its current implementation, LISA can represent and map hierarchical propositions of arbitrary. Analogously, it is possible to imagine structures for roles and objects that are, themselves, deeply embedded recursive structures. The depth to which a role or object would need to be decomposed for the purposes of mapping would depend on the task at hand. For example, mapping ‘John lifted the hammer’ onto ‘Bill raised the book’ may require little or no decomposition of the predicates ‘lift’ and ‘raise’, which will have substantial overlap in their *semantic features*.<sup>2</sup> On the other hand, mapping ‘John lifted the hammer’ onto ‘Bill pushed the cart’ where the predicates have less feature overlap, may be more likely to depend on decomposition of ‘lift’ into ‘caused to rise’ and ‘push’ into ‘cause to move laterally’, thereby making explicit the parallelism of their internal structures. Recursively ‘rise’ and ‘move laterally’ might be decomposed into structures relating simpler predicates with basic perceptual primitives representing motion and locations in space residing at the very bottom.” Hummel and Holyoak (1997, p.457).

Whilst re-representation is a popular idea in the analogy literature, its current status is largely hypothetical: re-representation proposals are usually couched in terms that relate to computational models, and as yet no evidence has been offered to support the psychological validity of the proposal.

The following experiment was designed to formulate a concrete re-representation proposal, and explore it empirically. The problem of semantic reconciliation

revolves around supplying an account of what happens when two ‘semantically similar’ terms – “revolving around” and “orbiting” – are encountered during the mapping process. In ordinary usage, the representations of human category information involved in these processes are implicit; people know what – “revolving around” and “orbiting” mean, and they reconcile (or map between) the two terms accordingly. But the exact nature of *what* they know, and *how* such knowledge is represented appears to be inaccessible at the level of detail required to specify and model the underlying cognitive processes involved in the semantic reconciliation of the two terms.

Participants were asked to make inferences with the aid of two candidate bases (see figure 1). In both the target and each of the two candidate bases, the term that was crucial to determining the representation of higher order structure in the scenarios was a novel, artificial term. By supplying ‘definitions’ for that term, we hoped to be able to control the representations participants used for semantically reconciling particular terms during their analogising. By doing this, we hoped to test the prediction that participants would use the same *process* to match semantic items in their representations as they would in ultimately determining their analogies - i.e. that in these externally represented analogies, at least, participants would use and process re-representations to facilitate semantic reconciliation.

---

## SCENARIOS

### TARGET - The Guralaga

*can be found in Australia  
lives in Rainforests  
only eats gau-gau berries  
has a cronomus lucundus  
the cronomus lucundus enables the Guralaga to eat gau gau berries.*

### BASE 1 - The Mongret

*can be found in Australia  
lives in Rainforests  
only eats gau-gau berries  
has a probus razoris  
the probus razoris enables the Mongret to eat the gau gau berries.  
Thanks to the way they eat, Mongrets live to a ripe old age and rarely suffer from cancer*

### BASE 2 - The Crany Dog

*can be found in Papua new Guinea  
lives in the grassy backlands  
eats vegetation  
has a remulum grandoso  
because of the remulum grandoso the Crany Dog can eat vegetation.  
Crany Dogs are particularly prone to cancer, which originates in their digestive system.*

---

**Figure 1:** A base and two targets. The surface similarities between the target and base 1 are highlighted. The target and base 2 share few surface similarities

<sup>2</sup> The emphasis is ours

	Surface Match Base (SMB)	Structurally Similar Base (SSB)
Analogy Level	Shares <b>surface</b> features with target  <i>Structural</i> overlap with target determined by dictionary mapping	Doesn't share surface features with target  <i>Structural</i> overlap with target determined by dictionary mapping

Inference	In <b>type A</b> sets, the <b>B</b> inference is only supported by <b>surface</b> matches between target and SMB the dictionary entries  In <b>type B</b> sets, the <b>A</b> inference is only supported by <b>surface</b> matches between target and SMB the dictionary entries	In <b>type A</b> sets, the <b>A</b> inference is only supported by <b>structural</b> matches between target and SSB the dictionary entries  In <b>type B</b> sets, the <b>B</b> inference is only supported by <b>structural</b> matches between target and SSB the dictionary entries

Figure 2: The relationships between the base, targets, dictionary entries and inferences in the main stimulus groups.

## Experiment

### Participants

The participants were 170 volunteers, a mixture of postgraduate and undergraduate students from the Department of Artificial Intelligence, Centre for Cognitive Science, Department of Psychology and the Faculty of Music at the University of Edinburgh.

### Materials, Design and Hypotheses

The materials comprised 5 groups of specially constructed scenarios (figure 1) with corresponding sets of novel dictionary entries (figure 3) and candidate inferences for each group (figure 4).

To control for biases towards particular inferences, each scenario group was further sub-divided into two versions of the scenario sets, and two versions of the dictionary entry sets, so that each scenario / dictionary sub-set supported one of the two different candidate inferences.

To classify the different structural / featural relation amongst the scenarios, we used Gentner, Ratterman and Forbus's (1993) taxonomy of similarity relationships:

- *Literal similarity* matches include both common relational structure and common object descriptions;
- *Surface matches*: based upon common object descriptions, plus some first order relations;
- *Structural similarity*, matches based upon common system of relations.

The relations between the various scenarios in a given scenario group can be summarised as follows (see also figure 2): In a group in which re-representation supported inference A, the target and one candidate base scenario (the SSB, or structurally supported base) shared only structural matches; mappings between the SSB's dictionary entry and the base dictionary entry also shared only structural matches.

There was a structural correspondence between the target structure supported by the target dictionary entry and the SSB's dictionary entry which in turn structurally supported the transfer of candidate inference A in the base.

Mappings between the target and the other candidate base scenario (the SMB, or surface match supported base) were supported by shared surface features, and mappings between the SMB's dictionary entry and the target dictionary entry also shared common object descriptions. However, there was a structural correspondence between the base structure supported by the base dictionary entry and the SMB's dictionary entry which supported candidate inference B. This allowed participants to use shared surface features to determine semantic reconciliation, but still use structural correspondences (c.f. Gentner, 1983) to determine their inferences (in this case, making a 'literally similar' match at the analogy level; see figure 2).

In a group where re-representation supported inference B, this pattern of correspondences was reversed.

### "DICTIONARY ENTRIES"

#### BASE DICTIONARY ENTRY

##### Cronomus lucundus

*are unique to certain types of bird*  
*are important to berry eaters*  
*is a long spleen-like organ*  
*keeping berries in the cronomus lucundus allows the berries to slowly ferment, allowing the goodness inside the bitter skins to be released*

#### SMB DICTIONARY ENTRY

##### Probus razoris

*are unique to certain types of bird*  
*are important to berry eaters*  
*is a long plier-like bill*  
*crushing berries in the probus razoris allows the goodness inside their bitter skins to be released without the skins having to be swallowed*

#### SSB DICTIONARY ENTRY

##### Remulum grandoso

*is unique to certain types of dog*  
*are important to dogs which eat a wide range of vegetation*  
*is a short intestine-like organ*  
*keeping vegetation in the remulum grandoso allows it to slowly ferment, allowing the goodness inside the outer skins to be released*

Figure 3: Dictionary entries for the Target and two Bases in figure 1. Surface similarities between the Target and SMB are in bold italic print; the structural match between the Target and the SSB is in normal italic

---

## INFERENCES

A. *Guralaga live to a ripe old age and rarely suffer from cancer.*

B. *Guralaga are particularly prone to cancer.*

---

**Figure 4:** The target inferences for the stimulus group shown of the following pages. In a type A set, structural commonalities would support the A inference; surface similarities would support the B inference. In a type B set, structural commonalities would support the A inference; surface similarities would support the B inference.

To try and simplify the above: in each group of stimuli, the target and candidate base scenario, and their corresponding dictionary entries, shared surface features, and a higher order structural correspondence that corresponded with one candidate inference, whilst the target and the other candidate base scenario, and their corresponding dictionary entries, shared structural correspondences, and a higher order structural correspondence that corresponded with the alternative candidate inference. Each stimulus set was divided into two subsets: in one, structural features in the bases and their novel term dictionary entries supported one set of inferences (Type A), whilst in the second sub-set, the same kind of matches supported the contrasting inference (Type B), so that biases towards a given inference could be eliminated (see figure 2).

### Experimental Hypothesis

In keeping with the analysis presented above, we expected that participants would use analogy to reconcile semantic terms in order to perform analogical mappings between the scenarios and generate support for one candidate inference. We predicted that in order to be able to carry out the top level analogy, participants would carry out another analogy in parallel - mapping structures only in the dictionary entries - reconciling semantic terms in a way that supported the top-level 'analogical' structure mapping over the top-level surface mapping, and favour the inference that corresponded to the structurally similar scenario over the scenario that shared only surface features.

### Additional Controls and Control Hypotheses

In addition to the basic stimuli, 3 sets of control stimuli were also created:

1 In the main control, the dictionary entries were eliminated, and participants were given only the target and the two candidate bases. In this control, in the absence of any structural support from the dictionary entries for the SSB inference, we expected participants to use the surface commonalities between the target and the SMB to determine their inference choice (i.e the prediction was that when subjects were asked to make an inference in a situation where neither of the base inferences benefitted from any structural bias, participants would prefer the inference which was additionally supported at the object level over the inference that received no such support; consistent with the findings of previous studies, such as Gentner, Ratterman and Forbus, 1993, we expected weak similarity to provide more support than no similarity).

2 In the second control, participants were given materials in which the novel terms were removed, and the structural information in the dictionary entries was added to the bases and target - in effect creating 'normal' analogy materials (see figure 5). In this control, where no re-representation was required, we expected the structural commonalities between the target and the SSB to determine the choice of inference, overriding the surface commonalities between the target and the SMB (this would be consistent with previous findings such as Gentner, 1983).

---

#### Chateau Bogusse:

**is a vineyard.**

**is in the southern French district of Pretence.**

**has sandy soils, with a lot of surface pebbles**

**has a warm microclimate which enables grapes to be produced.**

**the particular microclimate results in ripe grapes.**

*the ripeness causes the sugar level in the grapes to rise.*

*this makes the walls of the grapes weaken and collapse.*

#### Domaine Fraudulent:

grows plums.

has clay soils in which wildflowers grow

is in the western Departement of Maidoop.

its warm microclimate causes melons to grow

the particular microclimate yields extremely ripe plums.

*the extreme ripeness causes the plums to become very sweet*

*this super-sweetness makes the plums soft and squashy*

Because of their squashiness Domaine Fraudulent's plums are held in low esteem, and sell poorly.

#### Mas de la Fiction:

grows grapes.

**is in the southern Departement of Whaupper.**

**has sandy soils, with a lot of surface pebbles**

**its fine microclimate causes grapes to grow.**

**the particular microclimate results in ripe grapes.**

the ripeness causes some of the moisture in the grapes to evaporate

this evaporation leads to extremely concentrated flavours

Because of their concentrated flavours Mas de la Fiction's grapes are prized and sell for high prices.

#### Inferences

A. Chateau Bogusse's grapes are highly prized and sell for high prices.

B. Chateau Bogusse's grapes are held in low esteem, and sell poorly.

---

**Figure 5:** A control set in which the structural information in the dictionary entries has been included in the bases and target to create an 'ordinary' analogical problem. Surface similarities are illustrated in bold; structural similarities are italicised.

3 In the final control set the dictionary entries were altered so that surface and structural commonalities all supported the same mapping (the LSB, or literally similar base). In this final control, both structural and surface commonalities between the target and the LSB, and their dictionary entries were aligned in support of one inference. Since structure was predicted to be the key factor in deciding inferences (in line with the findings of previous studies), we did not expect the results from this control to differ significantly from the main experimental task.

In all of the controls, the inference supported by the various similarities was again randomised to control for any inherent biases towards particular inferences.

## Procedure

Participants were presented with 2 x 6-page questionnaires, each of which contained one scenario set, with its dictionary and candidate inferences, a diversionary task and a scenario set and pair of candidate inferences without a dictionary (the main control). The order in which the sets were presented ('with-dictionary' versus 'without-dictionary' control), was randomised, as was the presentation order of the targets within the sets. A second, smaller group of participants were given the other two controls in similar fashion.

Participants were asked to infer one candidate inference, and give a confidence rating (1=not at all confident; 5=very confident). They were told that the dictionary entries might be useful to them, but told explicitly that the use of them was left to participants' discretion.

## Results

Consistent with the initial hypothesis, in the main control condition where no dictionary entries were provided, the inference that received common surface-feature support was favoured by 67% of participants, with only 33% preferring the inference that was not supported by any commonalities,  $\chi^2(1, N=140) = 17.1, p < .001$ .

However, in the main experimental condition, where definitions – which offered the possibility of structural mappings – were provided, participants reversed their preferred inference for a given target / candidate bases set. Again consistent with the initial hypothesis, in this condition, if participants had preferred the A inference in the first control, when provided with scenario sets where structural commonalities in the dictionary supported the B inference, then participants now chose the B inference. Overall the inferences which received structural support were favoured by 71.2% of participants, with only 28.8% preferring the inference that was supported by surface commonalities alone,  $\chi^2(1, N=125) = 20.748, p < .001$ .

Also consistent with the initial hypothesis, in the control condition with no novel terms, where structure in the dictionary entries was included in the base and targets, inferences which received common surface-feature support were favoured by only 27.0% of participants, with 73.0% preferring the inference that was supported by structural commonalities,  $\chi^2(1, N=26) = 3.869, p < .05$ .

There was no deviation from this pattern in the final control condition, where the dictionary entries were altered so that surface and structural commonalities all supported

the same base - target (the LSB) mapping, the inference supported by the LSB was favoured by 75.0% of participants,  $\chi^2(1, N=28) = 5.17, p < .05$

Analysis of participants' confidence scores in the main control show significantly greater confidence for inferences based on surface commonalities when no structure was present,  $t=8.72, p < 0.001$ . However, this trend was reversed in the other controls and the main experiment - given the choice, participants seem to prefer structurally supported inferences. In the second control condition (analogies) inferences based upon structural commonalities received a significantly higher confidence rating than those based on surface features,  $t=3.982, p < 0.001$ . Similarly, in the main experimental condition, when definitions were provided, inferences based upon structural support received a significantly higher confidence rating than those based only on surface commonalities,  $t=2.9, p < .005$ . This trend was repeated in the third control, though mean differences were not significant,  $t=1.02, p = 0.33$ .

## Discussion

This experiment seems to show, consistent with the re-representation hypothesis, that participants can use the same process that they used to make analogical inferences to reconcile the semantic discrepancies they encounter in the representations of base and target analogs.

Participants made inferences with the aid of two targets. By controlling the structure of the information representing the 'semantics' of the term that was in turn crucial to the determination of the representation of higher order structure in the base and each of the targets, we were able to control the representations participants used for semantically reconciling particular terms during their analogising. The re-representation processing prediction – that participants would use the same mapping process to match semantic items in their representations as they would in ultimately determining their analogies – appears to be supported by the results of this experiment.

## General Discussion

Two very reasonable objections might be made to the results of this experiment:

1. Firstly, the 'dictionary entries' in the main task were artificial: there is a wealth of evidence that definitions are an inadequate basis for conceptual semantics (see Komatsu, 1992). Since the 'dictionary entries' are no more than definitions, it seems reasonable to question whether the use of definitions in exploring conceptual reconciliation affects the validity of our results.

2. A second obvious objection to the findings of the experiment is that participants were presented with the tasks on paper, and had unlimited time in which to solve the inferencing problems, and reconcile and map any 'semantics' in the various base and target specifications. It might be said in objection that since structure mapping is a computationally expensive process – especially in comparison to mapping surface features – this experiment has little relevance to the on-line demand characteristics of analogical processing 'in the wild'. Since participants in this experiment had unlimited time, and external representations of the problems, their behaviour is no predictor of the kind of processes used in making

analogical mappings in memory, where working memory limits will impose restrictions on processing.

Though we acknowledge our sympathy for these objections, neither of them should militate against our interpretation of these results: that the processing of re-representations is possible with externally represented problems. Obviously the second objection – which relates to internal representations – cannot apply to this interpretation. In respect of the first, we note that even though participants used what amounted to definitions in reconciling semantics in the main inferencing task, it is the *processing* that they used to map re-representations in semantic reconciliation (and not the particulars of the representations themselves) that is of interest here. To the extent that participants' processing matched our predictions (and what empirical findings there are in respect of natural representations in similar tasks, e.g. Ahn, 1998), it seems reasonable to assume that this processing was ecologically valid, even if the representations it worked with were not.

These objections do, however, highlight aspects of the re-representation hypothesis that are still seriously under-specified. In particular, the re-representation hypothesis lacks detail concerning the representations it supposes, and the processing demands it appears to make.

In the experiment above, we concentrated on the semantic reconciliation of *one* set of similar-but-not-identical terms, and followed this reconciliation process down through *one* level of recursion, where we saw – consistent with the re-representation hypothesis – that the same process was used to resolve semantic ambiguities as was used to determine analogical mappings.

However, it is unlikely that realistic representations of real-world analogies will contain such a small number of similar yet non-identical predicate matches to reconcile. These representations will contain many more such predicates, and the re-representations of these predicates – whose predicates will need to be matched during semantic reconciliation of the original predicates – may contain many more non-identical but semantically similar predicates, potentially as a factorial of the original number of predicates re-represented in semantic reconciliation.

Logically, at least, this seems to point to both a combinatorial explosion – in terms of the number of predicates to be reconciled, and hence individual semantic reconciliation sub-processes to be run – and a potential infinite regress: if an *identical* mapping process is to be run recursively, and if re-representation doesn't ultimately uncover *identical* predicate-decomposition representations at some level, then mapping may not terminate.

One solution to this problem might be the basic perceptual primitives posited by Hummel and Holyoak (1997; see above). We see two problems with this account: firstly, quite what 'perceptual primitives' are is unclear: at present, they offer no more explanatory clarity than 'concepts' when it comes to explaining semantic reconciliation; and secondly, and more worryingly, this proposal – like all re-representation hypotheses – assumes an almost unlimited capacity for structural mapping in memory. However, recent research (Halford, Wilson and Phillips, 1998) indicates that in reality this is far from the case: human capacity for representing and processing

structured information appears to be seriously constrained.<sup>3</sup> In the light of these considerations, we are cautious in inferring too much from the findings reported here. We have shown that re-representation is possible in externally represented tasks. Whether these results *can* be replicated in ecological analogy tasks in memory – and the extent to which re-representation is a viable psychological account of semantic reconciliation – remain open questions in need of further empirical investigation.

## Acknowledgements

Thanks to Lera Boroditsky, Ken Forbus, Dedre Gentner, Usha Goswami, Mark Keane, John Lee and Helen Pain for insightful discussions about this work. I'm grateful to Andrew Wishart, Dan Yarlett and Alex Heneveld for comments on an earlier draft of this paper.

## Abstract

Searching for alternative solutions of an indeterminate reasoning task is an important and necessary step in order to draw certain inferences as in the case of deduction. To elucidate the underlying mental representations and processes of the search for alternatives in spatial reasoning, an experiment was conducted that used specific material stemming from AI research of Qualitative Spatial Reasoning. The results showed that searching for alternative solutions can be best explained as a revision process starting with an initial mental model of the premises. Proceeding from one solution to an alternative is apparently achieved by local transformation. Interestingly, local transformations have a "logic of their own": They can lead to systematic errors of omission and to errors of commission.

## Spatial Reasoning and Mental Models

Dealing with spatial problems is a frequent and important challenge in everyday as well as in professional life. It occurs across various fields like spatial navigation or spatial configuration and design. In this paper, we will concentrate on a special sort of spatial problem solving, namely reasoning based on spatial relational descriptions. This type of reasoning can be investigated with recourse to several background theories of thinking developed in cognitive psychology. According to previous research in spatial reasoning (Byrne & Johnson-Laird, 1989; Evans, Newstead, & Byrne, 1993) and according to our own previous findings (Knauff, Rauh, & Schlieder, 1995; Knauff, Rauh, Schlieder, & Strube, 1998; Rauh & Schlieder, 1997) the most promising and most successful framework is the theory of mental models.

## Mental Model Theory as Framework

The core assumption of the mental model theory (Johnson-Laird, 1983; Johnson-Laird & Byrne, 1991) states that when we reason we build an integrated representation of the situation that the premises describe. This integrated representation—the mental model—is in certain aspects analogous to the state of affairs and, as a consequence, lacks the information whether relationships are explicitly mentioned in the

premises and or are implicitly determined by the representational format.

A further consequence of the assumption of integrated representation becomes evident when certain kinds of inferences have to be drawn. Take deductive inference for example: To test whether a contingent relationship in the initial mental model is necessarily true, the reasoner has to test all the alternative models of the premises. If a contradictory example is found, the putative conclusion will be rejected; if not it will be accepted as a valid conclusion.

The search for alternative models takes place during what we call the phase of model variation. It seems to be a deliberate mental process so fragile that it causes many systematic reasoning errors. There are errors of omission, i.e. inferences that could have been validly drawn, and there are errors of commission, i.e. inferences that are not justified by the premises.

Therefore, model variation has attracted much attention, but little is empirically known about how the mental search for alternative models is accomplished by the human process of reasoning. For a precise investigation of the model variation phase, there is the need for relational material with a rich inherent structure and unambiguous semantics.

## Spatial Reasoning with Interval Relations

Traditional investigations of spatial reasoning used relations like *left-of*, *right-of*, *in front of*, and *behind*. As argued elsewhere (Knauff et al., 1998), these spatial relations have no clear semantics. Therefore, studies of reasoning using these spatial relations are problematic because it is unclear whether the results obtained can be attributed to the inference processes, or are due to the ambiguity of these relations. To remedy this situation, we use Allen's (1983) set of 13 qualitative interval relations that enables one-dimensional spatial reasoning. These relations have clear geometric semantics based on the bounding points of the intervals, i.e. their starting points and ending points. They also have the property of being jointly exhaustive and pairwise disjoint (JEPD)—a property that also reduces the risk of misinterpre-

tations. In Table 1, we shortly introduce these relations together with verbalizations that we use in our experiments.

Table 1: The 13 qualitative interval relations, associated natural language expressions, and a graphical example (adapted and augmented according to Allen, 1983).

Relation symbol	Natural language description	Graphical example
$X < Y$	X lies to the left of Y	
$X m Y$	X touches Y at the left	
$X o Y$	X overlaps Y from the left	
$X s Y$	X lies left-justified in Y	
$X d Y$	X is completely in Y	
$X f Y$	X lies right-justified in Y	
$X = Y$	X equals Y	
$X fi Y$	X contains Y right-justified	
$X di Y$	X surrounds Y	
$X si Y$	X contains Y left-justified	
$X oi Y$	X overlaps Y from the right	
$X mi Y$	X touches Y at the right	
$X > Y$	X lies to the right of Y	

With these relations, reasoning tasks known as three-term series problems can be constructed. One example is "X overlaps Y from the left. Y surrounds Z." The example also shows that there are many three-term series problems generated from these relations that have more than one solution. To be precise, there are 42 three-term series problems that have three solutions, 24 that have five solutions, 3 that have nine, and another 3 that have thirteen solutions. We utilize this property in order to construct indeterminate three-term series problems to investigate precisely the phase of model variation. In the next section, we will present a more formal analysis of these tasks. From this analysis and the revealed properties of the different tasks, hypotheses can be derived that we will test in a model variation experiment.

## A Formal Framework for Model Variation

In principle, there are two ways to construct alternative models of the premises. The first consists of repeating the complete construction of alternative models one after another (*model iteration*). We will examine the more plausible varia-

tion strategy that consists of generating alternative models by *locally* transforming the *initial model* (see also Schlieder, 1998), i.e. the first model constructed during model variation (*model revision*).

In this view, any sequence of models  $M_0, M_1, \dots, M_n$  corresponds to a *sequence of transformations*  $T_1, T_2, \dots, T_n$ , where the output model  $M_i$  of  $T_i$  is the input model of  $T_{i+1}$ . The set  $\{M_0, \dots, M_n\}$  is *ordered* by the sequence  $T_1, T_2, \dots, T_n$ .

Since models of a three-term-series problem are completely determined by only one relation, namely the one between X and Z, we can treat models and relations equivalently. Seen this way, a transformation is a transition from one relation  $r_1$  to another relation  $r_2$ , or, in short,  $r_1 \rightarrow r_2$ .

## Conceptual Neighborhoods

Freksa (1992) introduced the notion of conceptual neighborhood between interval relations. Formally, the three conceptual neighborhoods are defined by the graphs in Figure 1. Two relations are *neighbors* iff they are connected by an edge of the corresponding graph.

Figure 1: Freksa's (1992) conceptual neighborhoods.

The common generic principle underlying the three types of neighborhood reads as follows: Interval relations  $r_1$  and  $r_2$  are said to be *conceptual neighbors* if a model of intervals X and Y satisfying  $X r_1 Y$  can be continuously transformed into a model of intervals X' and Y' satisfying  $X' r_2 Y'$  such that during the transformation no model arises in which a relation different from  $r_1$  and  $r_2$  holds (see Schlieder & Hagen, in press). Their peculiarities arise from different transformation processes. The A-neighborhood is based on a transformation that can be described as the movement of one single bounding point of one interval whereas the B-neighborhood relies on the movement of a complete interval of fixed length. The transformation defining the C-neighborhood consists of keeping the center of the changing interval fixed and varying its length. The types of transformations defining the A(B,C)-neighborhoods will be called *A(B,C)-transformations*.

## Local Transformations: Steps between A-Neighbors

An examination of sequences of A-transformations revealed a need to formally refine the conceptual framework. In order to describe the model revision process adequately the definition has to include the movement of bounding points and its direction. An A-transformation between intervals X and Y does not specify the moving bounding point since it can always be accomplished in two ways by movements of a suitable bounding point: Either by moving one bounding point of interval X in one direction or one of Y in the opposite direction (see Table 2). An A-transformation with specified moving point  $p$  will be called a *step (of bounding point  $p$  in direction  $d$ )*.

Table 2: The relation of A-transformations and steps.

A-transformation	step right	step left
$< \rightarrow m$	$E_X$	$S_Y$
$m \rightarrow o$	$E_X$	$S_Y$
$o \rightarrow fi$	$E_X$	$E_Y$
$fi \rightarrow di$	$E_X$	$E_Y$
$di \rightarrow si$	$S_X$	$S_Y$
$si \rightarrow oi$	$S_X$	$S_Y$
$oi \rightarrow mi$	$S_X$	$E_Y$
$mi \rightarrow >$	$S_X$	$E_Y$
$o \rightarrow s$	$S_X$	$S_Y$
$s \rightarrow d$	$S_X$	$S_Y$
$d \rightarrow f$	$E_X$	$E_Y$
$f \rightarrow oi$	$E_X$	$E_Y$
$s \rightarrow =$	$E_X$	$E_Y$
$= \rightarrow f$	$S_X$	$S_Y$
$= \rightarrow si$	$E_X$	$E_Y$
$fi \rightarrow =$	$S_X$	$S_Y$

Note that tracking sequences of interval relations does not permit the direct observation of steps. *Step-sequences*, i.e. sequences of steps that refer to the same point  $p$  moving in constant direction  $d$ , can explain errors of omission or commission that cannot be explained on the level of A-transformations. In order to show this, we need one more definition. A step-sequence  $S_1, \dots, S_n$  is *extendible at the beginning (or the end)* iff there exists a step  $S_0$  (or  $S_{n+1}$ ) such that  $S_0, S_1, \dots, S_n$  (or  $S_1, \dots, S_n, S_{n+1}$ ) is a step-sequence. If it is extendible at the beginning or at the end it is (*totally*) *extendible*.

**Errors of Omission and Errors of Commission.** Our general assumption about the implications of this formalism for the traversal of solution sets is as follows: Moving along a step-sequence, i.e. keeping the moving point and its direction constant, is easier to process than changing them or even performing a non-A-transformation.

Therefore, errors of omission should be observed more frequently if the end of a step-sequence is reached but the solution set is not completely traversed. Errors of commission, in turn, should occur more frequently with non-solutions which are a continuation of a step-sequence.

## Hypotheses

In the following we present hypotheses specifying the implications of the above considerations in more detail. They can easily be verified consulting Table 2 and Figure 2, which displays solution sets of all three-term series problems with multiple models.

Figure 2: The solution sets of three-term-series problems with multiple models. The valid relations are represented as points at corresponding positions of Figure 1.

**3-Model-Tasks.** The relations determining the solution set of a 3-model-task can be ordered in two ways by sequences of A-transformations (e.g. for (3-1):  $< \rightarrow m \rightarrow o$  or  $o \rightarrow m \rightarrow <$ ). Each of these sequences can be accomplished in two ways as step-sequence (e.g.  $< \rightarrow m \rightarrow o$  by steps to the right of the ending point  $E_X$  of interval X or by steps to the left of the starting point  $S_Y$  of Y). One of these sequences is extendible except for the solution sets (3-7) and (3-8) where all sequences are non-extendible. There are two interesting hypotheses concerning 3-model tasks: (1) 3-model-tasks having extendible solution sequences are prone to errors of commission, and (2) 3-model-tasks with solution sets (3-7) and (3-8) have significantly less errors of commission than the other 3-model-tasks.

**5-Model-Tasks.** The solution set of a 5-model-task can be ordered in two ways by sequences of A-transformations. Each of these sequences can be accomplished in two ways, as step-sequence that is non-extendible, or as a sequence  $S_1, S_2, S_3, S_4$ , where  $S_1, S_2$  and  $S_3, S_4$  are non-extendible step-sequences, having the same direction but referring to different

bounding points of the same interval. Accordingly, we can formulate the hypothesis, that errors of omission will most frequently occur between step 2 and step 3.

**9-Model-Tasks and 13-Model-Tasks.** The solution set of a 9-model-task or of a 13-model-task can be ordered in multiple ways by sequences of A-transformations. Each of them fall into several step-sequences, including necessary changes of direction between them. So we expect a decreased number of correct and complete solution sequences for these tasks.

## Experiment on Model Variation

### Participants

24 students (12 female, 12 male) of the University of Freiburg were paid for participation.

### Materials

The material consisted of the 72 indeterminate three-term series problems that can be constructed by the 12 interval relations, if the trivial "=" relation is omitted. In each three-term series problem the spatial relationship between a red and a green interval is described in the first premise, and the relationship between the green interval and a blue one is given in the second premise.

### Procedure

The computer-assisted experiment was divided into three phases. During the *definition phase* participants were given the verbalizations of the interval relations together with an explanation of the semantics with respect to the ordering of starting points and ending points. Additionally, a pictorial example was displayed.

During the *learning phase*, participants read sentences describing the relation between a red and a blue interval. For each sentence they had to specify the relationship of the two intervals graphically by clicking the mouse in rectangular regions on the screen. After having confirmed the final choices, the participant got feedback about the accuracy of the configuration. If the configuration did not match the relation, additional information about the correct answer was given, i.e. a verbal description of the ordering of start points and end points. Learning trials were blocked with 13 sentences using the interval relations. If one relation was answered correctly in three consecutive blocks, the learning criterion for this relation was accomplished. As soon as the learning criterion was reached for all relations, the learning phase stopped.

During the *inference phase*, participants were given 3 practice trials, and then received the 72 indeterminate three-term series problems. After self-paced reading of the premises, the premises vanished, and the participants were asked to generate all possible relationships between the red and the blue interval. By clicking the mouse they specified

the spatial relationships analogous to the interval-specifying procedure in the learning phase. After finishing the configuration, participants could either continue specifying other solutions, or stop working on the present task and go to the next three-term series problem.

We recorded premise processing times, drawing times, and, of course, the sequence of solutions by pixel coordinates and by interval relations.

### Results

In the following, data analyses are applied to the constructed solution sequences. Since all participants passed the learning phase successfully, all data collected in the inference phase were included in the statistical analyses.

First, we tested the hypothesis that solution sequences followed the principles of conceptual neighborhood. All transitions in the solution sequences were analyzed for the existence of A-, B-, and C-transformations. We found that the significant majority of the transitions (3145 of 4462 [= 70.48%]) conformed to A-transformations. Transitions conformed to B- or C-transformations in 64.95% or 64.34% of all the cases, respectively. The three values are rather similar, since most transitions are consistent with all three types of conceptual neighborhood. Only transitions involving the "=" relation discriminate between different types of conceptual neighborhood (see Figure 1). Therefore, we performed an analysis for these transitions and found the frequencies listed in Table 3.

Table 3: Number of "="-transitions conforming to different types of conceptual neighborhood.

	Absolute	Percent
A-transformation	296	75.13%
B-transformation	49	12.44%
C-transformation	22	5.58%
Other	27	6.85%
Total	394	100%

We obtained the results in Table 4 by exclusively analyzing correct and complete solution sequences of 3-, 5-, 9-, and 13-model tasks.

The interesting fact is the nearly monotonic decrease of the number of correct and complete solution sequences in dependence of the number of models. Besides, it is noteworthy that correct and complete sequences of the 9- and 13-model problems (i) are rarely observed (as predicted by our hypothesis), and (ii) that none of these sequences conformed perfectly to any of the neighborhood transformations. We will return to the latter point below.

Table 4: Number of correct and complete solution sequences

	Percent	A-Transf.
3-model-tasks	52.88% (533 of 1008)	75.61% (403 of 533)
5-model-tasks	34.20% (197 of 576)	86.29% (170 of 197)
9-model-tasks	13.89% (10 of 72)	0% (0 of 10)
13-model-tasks	16.67% (12 of 72)	0% (0 of 12)
Total	43.52%	73.27%

**Errors of omission.** To test for the hypothesis of systematic errors of omission between step 2 and step 3, we looked at the solution generated last in the whole solution sequence for all 5-model-tasks. In Table 5 the results for the six 5-model-tasks with solution set (5-2) (see Figure 2) are listed. As stated above, we expected an increasing number of solution sequences terminating after the second step, i.e. for relation  $o$ .

Table 5: Frequencies of relations as last solution for 5-model tasks with solution set (5-2).

di	fi	o	m	<
10	7	22	8	87
7.46%	5.22%	16.42%	5.97%	64.93%

As Table 5 shows, there are indeed many solution sequences terminating with the relation  $o$  (22 of 134). This pattern of results was also obtained for the 5-model-tasks with the other three solution sets. The result confirms our predictions of systematic errors of omission between steps 2 and 3.

**Errors of commission.** According to our predictions of systematic errors of commission, the 3-model-tasks with solution sets (3-1) to (3-6) were analyzed for transitions from relation  $o$  ( $oi$ ) followed by an erroneous one. The number of such transitions was 57. It turned out that 26 of them were steps with the  $o$  ( $oi$ ) relation as precursor. Given that there are at least 8 other erroneous relations that are not A-transformations of  $o$  ( $oi$ ), this shows that the transition from a correct solution to an erroneous one is about three times more probable if the erroneous solution is the next step in the step-sequence. The result corroborates our hypothesis of systematic errors of commission. Additionally, the 3-model-tasks with solution sets (3-7) and (3-8) had 13.5 commission errors on the average, much less than the 72.0 commission errors that could be observed on the average for the 3-model tasks with solution sets (3-1) to (3-6).

**Strategies for 9- and 13-Model-Tasks.** As shown in Table 4 none of the correct and complete solution sequences of the 9-model-tasks and the 13-model-tasks conformed perfectly to any of the conceptual neighborhood transformations. In an exploratory data analysis, we identified two classes of strategies for navigating through the solution set that guided the successful search for alternatives in solving 9- and 13-model-tasks.

*Constant-Direction-Strategies.* The first class of strategies consists of three sequences of A-transformations following one after another. The two transformations joining them are not A-transformations, but *jumps* in the graph of the A-neighborhood. (see the diagram in Figure 3)

As the pseudo code description in Figure 3 shows this strategy can be accomplished in a simple way: All steps refer to points of the same interval and proceed with the same direction. For each step the other bounding point of the interval is tested if a step leads to a valid model, and the information determining this model is stored if necessary. The jumps occur only if proceeding within a step-sequence is not possible. Then the stored information is retrieved again to construct the corresponding model to begin the next step-sequence.

The success of this kind of strategy depends highly on the choice of the initial model since the moving direction is constant and an omitted model will never be reached.

Choose an initial model;  
 Choose an interval (with bounding points  $p$  and  $q$ ) that is part of the relation between the first and the third interval;  
 Choose  $p$  and direction  $d$  such that  $step(p, d)$  possible;

```

while step(p, d) or step(q, d) possible
begin
  if step(p, d) possible then
    begin
      if M empty and step(q, d) possible then
        Store info identifying the result of step(q, d) in M;
        step(p, d);
      end
    else
      begin
        if M not empty then
          Continue with the model
            identified by M;
        else if step(q, d) possible then
          step(q, d);
        end
      end
    end
end
  
```

Figure 3: Constant-Direction strategies as pseudo code and a diagram of a possible path in the Freksa-graph. Details of the algorithm are specified only as far as necessary;  $step(p, d)$  represents a step-transformation of  $p$  in direction  $d$ ,  $M$  information identifying a model.

*Symmetry-Strategies.* The second class of strategies is based on the use of symmetric transformations mapping relations to their inverses (*transposition-symmetry*). Their limitations and strengths concerning the traversal of the solution set arise from the fact that the solution sets of 9- and 13-model tasks fall into several disjointed subsets that are closed in relation to symmetry-transformations. An extended version involves additional *reorientation-symmetry*. This type of symmetry can be described as reflection of the graphical example in Table 1 at the vertical axis. All relations are symmetrical to themselves with respect to reorientation except the pairs  $f$ - $s$  and  $f$ - $si$ . In place of the closed subsets  $\{f, fi\}$  and  $\{s, si\}$  their union now forms a closed subset.

For the traversal of the solution set of a 13-model-task following the extended type of strategy this implies that at least 5 non-symmetric transformations (out of a total of 12 necessary transformations) are needed to traverse all relations. A 9-model-task needs at least 3 non-symmetric transformations (out of a total of 8). The type of strategy that relies only on transposition requires one more non-symmetric transformation. Especially for 13-model-tasks we cannot expect complete solutions without an additional guiding principle. Furthermore, errors in finding a closed subset will lead to omitting it completely. On the other hand due to the cyclic structure of a closed subset, its traversal is insensitive to the first relation established.

## General Discussion

In summary, the presented results corroborate the assumption that searching for alternatives is based on a model revision process proceeding from an initial model to alternatives by local transformations. We demonstrated and specified this for one-dimensional spatial reasoning, where local transformations appear as movements of a point along a step-sequence. Additionally, we were able to show that local transformations have a logic of their own: They can systematically suppress certain inferences on the one hand, but, on the other hand, lead to false ones. Again, we specified these conditions with the help of our relational material, and thus were able to predict errors of omission and errors of commission precisely. This point is also very important for augmenting our existing cognitive modeling of mental model construction with an empirically adequate revision process.

With respect to psychological theories of reasoning, our results are pretty much in accordance with the mental model theory. In particular, the decline of number of correct and complete solution sequences with the number of models corresponds well with mental model theory assumption that the difficulty of a reasoning task is dependent on the number of models. Likewise, the notion of local transformation only makes sense with recourse to analog representations, e.g. mental models. Therefore, our data also present a new challenge for other theories of reasoning.

## Acknowledgements

This research was supported by the German National Research Foundation (Deutsche Forschungsgemeinschaft; DFG project *MeMoSpace* under contract no. *Str 301/5-1* to Gerhard Strube, Christoph Schlieder, and Reinhold Rauh). We would like to thank Goran Sunjka for his extensive help in implementing the computer-aided experiment, Katrin Balke for running the experiment, and Rebecca Ellis and Patrick Mueller for proof reading an earlier draft.

# Memory for Continually Changing Information: A Task Analysis and Model of the Keeping Track Task

Wolfgang Schoppek (wschoppe@gmu.edu)  
Human Factors and Applied Cognition Program  
George-Mason University  
Fairfax, VA 22030-4444, USA

## Abstract

Keeping track of continually changing information has been investigated since Yntema & Mueser's (1960) seminal work. The fact that types of mappings between objects and values and of memory load affect performance are well established, but have never been integrated in a theory. As a step toward such a theory, this paper describes a mathematical model that combines a task analysis with a set of assumptions derived from the ACT-R theory about the dynamics of memory traces. The model's remarkable reproduction of data published by Venturino (1997) demonstrates that standard memory concepts are sufficient to explain the results related to this paradigm. The model yields a clear implication about what causes interference and helps specify open questions.

In many areas of supervisory control, operators have to keep track of the changing values of a number of variables. Knowing the current state of a dynamic system is an important component of situational awareness (Endsley, 1995). For example, a pilot flying a modern automated aircraft needs to know the current altitude, speed, and course of the aircraft, the current settings and modes of the flight management system, just to mention a few of the variables.

In the experimental paradigm for keeping track of continually changing information, introduced by Yntema and Mueser (1960), object-value pairs are presented successively, interrupted by queries about the value associated with a certain object. The most common variables manipulated are the number of objects and the number of attributes from which the values are selected.

In Yntema and Mueser's (1960) experiment, subjects either had to keep track of changing values of many attributes for one object or changing values of the same attribute for many objects. Memory performance was worse in the latter condition. This was attributed to a high degree of interference when only one attribute is used.

Venturino (1997) argued that Yntema and Mueser (1960) confounded attribute similarity and information organization. Figure 1 illustrates how the former factor is defined by the number of attributes, the latter defined by the number of objects. In order to investigate the relative influence of the two factors on memory performance,

Venturino (1997) completely crossed these two factors, such that all four possible combinations between high and low attribute similarity and high and low information organization were included. A third factor was memory load. Attribute similarity had a large effect on memory performance, which confirmed Yntema and Mueser's (1960) findings. Information organization also had a significant effect, but this effect was much weaker. As expected, performance declined with memory load.

Figure 1: Illustration of the relations between objects, attributes, and values in the paradigm of continually changing information

This same paradigm was used by Hess, Detweiler and Ellis (1999) to prove the superiority of spatially rich displays over displays that show values of different attributes in the same location. Although their research goal was different from Yntema and Mueser's, the basic findings of the paradigm were confirmed in these experiments.

To summarize, the effects of attribute similarity and of memory load are well established. Although the main effects can be explained through the interference that occurs between values of the same attribute, the interactions between attribute similarity and memory load are understood less well. There is no integrative theory that accounts for all the effects. Venturino (1997) interpreted his results as suggesting a distinction between memory capacity for static information and memory capacity for dynamic information, because memory performance in

the same-attribute condition was worse than what would be expected in a comparable static memory task.

The goal of this work is to explore if the results about keeping track of dynamically changing information can be explained more parsimoniously with standard assumptions about memory. As a means for this exploration, I developed a mathematical model of the experiment by Venturino (1997). The model combines a task analysis with a set of assumptions about the dynamics of memory traces that are derived from the ACT-R theory (Anderson & Lebiere, 1998). The model may also contribute to an integrated understanding of all the effects related to the paradigm.

In the following sections, I first describe Venturino's experiment in more detail before I present and discuss the model.

### Venturino's Experiment

The material used in the experiment consisted of the names of six different fire engines and six different attributes with six values each. Continually changing attribute values were assigned to the fire engines. The task was to memorize these values. After a series of five to seven updates, the subject was asked for the current attribute value of a certain fire engine. For example, in keeping track of the current values of two fire engines, a subject might have to keep track of the number of firefighters for a pumper engine and the location of a tanker engine.

This continual updating is shown with a detailed example in Table 1. Time is represented in discrete steps, where 1 denotes the time of the most recent update, 2 the time step before, and so on. I will refer to these steps as lag, indexed by the variable *i*.

Table 1: Illustration of the continual updating of values (asterisks indicate an updating event)

lag time	stimuli		current value of		
	fire engine	n fire-fighters	tanker	ladder	pumper
...	...	...	...	...	...
4	tanker	4	*4	...	...
3	ladder	7	4	*7	...
2	tanker	5	*5	7	...
▼1	pumper	4	5	7	*4
now					

The example shows tanker being updated with the value four at lag 4, ladder being assigned the value seven at lag 3, tanker updated with the value five at lag 2, and pumper being assigned the value four at lag 1. Every fire engine keeps its value until it is updated. These update events are indicated by asterisks in Table 1. The three current values "now" are five firefighters for tanker, seven firefighters for ladder, and four firefighters for pumper. Note that the values differ in "age".

Three independent variables were manipulated in the experiment: number of objects (one vs. many fire en-

gines), attribute similarity (same vs. different attribute), and memory load (two, four or six values to keep track of). The first two factors were varied between subjects; the last factor was varied within subjects. In the many-object/different-attributes condition, unique mappings between objects and attributes were used, such that each of the two, four, or six engines had a value of a different attribute. In the many-objects/same-attribute condition, two, four, or six fire engines had multiple values of the same attribute. In the one-object/different-attributes condition, one engine had values of two, four, or six attributes. In the one-object/same-attribute condition, one fire engine had a value of one attribute. In order to manipulate memory load in this condition, subjects had to memorize the history of the last two, four, or six values. Despite the different mappings, the same number of values had to be remembered in each memory load condition.

Each block began with an initialization of values, followed by 75 to 105 updates, presented at a rate of one update each seven seconds. The updates were randomly interrupted by 15 queries. There were 100 subjects total, randomly assigned to one of the four conditions. In a first session, subjects studied the experimental material and, after a few practice trials, worked on the block with memory load 2. Two days later, the blocks with memory load 4 and 6 were administered.

Performance was measured as the proportion of correct answers. The outlined markers of Figure 3 illustrate the main results. All three independent variables had significant main effects on performance, but they were differently strong. Attribute similarity accounted for 15% of the variance, information organization (number of objects) for only 1%. The main effects were qualified by a significant three-way interaction of all factors. Separate analyses revealed significant interactions between attribute similarity and memory load in both object conditions: Memory load affects performance much more when the same attribute is used than when different attributes are used.

In the same-attribute condition, there was a significant interaction between memory load and number of objects: In the many-object condition performance decreased more sharply as memory load increased than in the one-object condition. In the different-attribute condition, the number of objects had no significant effect on performance.

An error analysis revealed that 44% of the errors were previous state errors, i.e. a subject responded with the previous value of an attribute rather than its current value. Interestingly, subjects responded significantly faster ( $M = 4.58$  s) when making a previous state error than when making any other type of error ( $M = 5.30$  s).

### Model

In this section, a model will be described that is able to reproduce the results of Venturino's experiment. The predictions of the model are not derived from simulation, but from a mathematical combination of the probabilistic

Table 2: Task analysis of the keeping track task

lag $i$	fire-engine	value $v_i$	$v_i$ current now?	$p$ ( $v_4$ current after lag $i$ )	$p$ ( $v_3$ current after lag $i$ )	$p$ ( $v_i$ current now) = $q_i$
4	tanker	4	no	1	...	$0.75^3$
3	ladder	7	yes	0.75	1	$0.75^2$
2	tanker	5	yes	$0.75^2$	0.75	0.75
1	pumper	4	yes	$0.75^3$	$0.75^2$	1
<b>now</b>						

structure of the material and basic assumptions about the dynamics of memory elements. The psychological assumptions originate from the ACT-R theory (Anderson & Lebiere, 1998).

Suppose that each update event is stored as a unique memory trace. The probability that this trace contributes to a correct answer equals the probability that the trace represents a current value times the probability that it is retrieved from memory. The first factor is given by the task analysis described below, the second factor is derived from a cognitive model. Summing up the probabilities of contributing to a correct answer for all memory traces gives an estimate of the number of correct answers for all possible probes.

### Task Analysis

The first component of the model is an analysis of the probabilistic structure of the material used in the experiment. This task analysis allows us to determine the probability that a value is current as a function of the update time and the memory load condition.

Table 2 is built on the example given in Table 1 and contains information that is relevant to understanding the task analysis. Time is again indicated by lag. The values that were presented at each time step are referred to as  $v_i$ . Column 4 contains the "currency" of the respective values  $v_i$  at present time (now), i.e. immediately after lag 1. The values  $v_1$ ,  $v_2$ , and  $v_3$  are still current, but  $v_4$  is not, because it was overwritten with  $v_2$ . Column 5 shows the probability of  $v_4$  being current at the end of each time step. At the end of lag 4,  $v_4$  is current (probability equals 1.0), because it has just been updated. At lag 3, one of the four vehicles is randomly chosen for an update. Thus, the probability of  $v_4$  being updated at lag 3 is 0.25. Put another way, the probability of  $v_4$  being current at the end of lag 3 is  $1 - 0.25 = 0.75$ . The same considerations hold for the following steps.

Because the updates are independent events, the probabilities for each time step must be multiplied to obtain the overall probability that a value is still current. Thus, the probability of  $v_4$  being current after lag 1 ("now") is  $0.75^3$ . Column 6 exemplifies that for the update of "ladder" at lag 3. The last column of Table 2 contains the resulting probabilities of being still current for  $v_1$  through  $v_4$ . Equation 1 is the generalized form of the probability  $q_i$  of value  $i$  still being current.

$$q_i = p_s^{i-1} \quad (1)$$

In Equation 1,  $p_s$  is the probability of not being updated in the following step. This variable depends on the memory load  $n_c$  (i.e. number of current values given by the number of vehicles and/or attributes), according to Equation 2.

$$p_s = 1 - 1/n_c \quad (2)$$

Applying Equations 1 and 2 to Venturino's experimental materials results in the probabilities depicted in Figure 2. Each memory load condition results in one curve. Memory load condition 6 involves six current values, distinguished by the type of vehicle, the attribute, or a unique mapping between vehicle and attribute. Similarly, memory load conditions 4 and 2 involve four and two values, respectively. It is obvious that the probabilities of being current diminish much faster the fewer current values there are, because the probability for each value being updated is higher when there are fewer dimensions (attributes and/or objects).

The task analysis also reveals that the probabilistic structure of the one-object/same-attribute condition deviates considerably from this scheme. Because in this condition, the last two, four, or six values of the same attribute have to be remembered for only one object, the probabilities of these values being current are one, the probabilities of all other values are zero. This different structure was entered at the appropriate places in order to calculate the model's prediction.

Figure 2: Probabilities  $q_i$  that a value that was updated in a certain time step is still current.

## Cognitive Model

The second component of the model is a set of assumptions about the dynamics of the memory representations that are formed from the update events. The first assumption is that for each update event a new memory element is created which represents the information given in the update. The second assumption is that each element is rehearsed a number of times, thus being strengthened. The remaining assumptions are part of the ACT-R theory.

According to the rational analysis basis of ACT-R, the activation of a declarative memory element reflects the probability that the element is needed in the current context and determines its retrieval. The two additive components of activation are baselevel activation and net activation. The former reflects the baserate probability, the latter the conditional probability given the current context. In this application, current context means the cues that are active and enhance retrieval of the correct memory element. Since this model makes no specific assumptions about cues, we can focus on baselevel activation.

The baselevel activation of an element is defined as the log odds that the element is needed. The odds are calculated with Equation 3, where  $n$  is the number of times the element has been needed, and  $L$  is the lifetime of the element<sup>1</sup>. Lifetime is the time that has passed since the creation of the element. The more frequently a memory element has been needed in its lifetime, the higher is its baselevel activation. If an element is not needed for some time, its baselevel activation decays. These changes of baselevels depending on use and time are referred to as *baselevel learning*.

$$odds = \frac{2n}{\sqrt{L}} \quad (3)$$

As mentioned earlier, I assume that a new memory element is created for each updating event and that this element is rehearsed a number of times after its creation. Each single rehearsal involves a retrieval of the element, which increases the respective  $n$ . The number of rehearsals is a free parameter of the model. The lifetime  $L$  is determined by the lag at which the element was created and the duration of each step (which was seven seconds in Venturino's experiment).

Odds can be transformed into probabilities using the definition  $odds = p/(1-p)$ . This gives us Equation 3a.

$$p = odds/(odds+1) \quad (3a)$$

<sup>1</sup> Equation 3 is an approximation of the original ACT-R equation. The approximation includes the default value 0.5 of the "baselevel-learning" parameter. The similarity between the time functions of Equations 1 and 3 illustrates the ACT-R notion that memory processes reflect the probabilistic structure of the environment.

With this equation, the probability of retrieval  $p$  can be predicted for each memory element that was created to represent an update event.

This probability is assumed to be degraded in the same-attribute conditions where interference is expected, depending on the number of competing memory elements. Assuming that only the elements that represent current values of the same attribute are competing, the respective numbers  $n_c$  are two, four, and six. Note that in the different-attribute conditions there is only one current value of each attribute, so no interference is expected there.

I assume further that the interference effect is "buffered" by a constant  $c$ , which is the second free parameter of the model. Equation 4 shows the degrading function. To ensure that the degraded probability value ranges between 0 and 1,  $c$  may vary between 0 and 0.5.

$$p' = \left\{ \begin{array}{l} p \mid \text{condition} = \text{different - attributes} \\ p \cdot (c + 1/n_c) \mid \text{condition} = \text{same - attribute} \end{array} \right\} \quad (4)$$

It is important to realize that the cognitive component of the model makes no assumptions about the influence of the information organization factor. This can be justified by the result that this factor accounted for only 1% of the variance in the experiment. Nevertheless, the predictions for the one-object conditions are slightly different from those for the many-object conditions, because of the different probability structure of the one-object/same-attribute condition.

Equation 5 describes how the prediction of the model is obtained by summing up for each time step the probability that its value will lead to a correct answer and dividing the sum by the number of current values (i.e. memory load).  $q_i$  is the probability that the value of step  $i$  is still current,  $p_i'$  is the probability that the memory element representing that value is retrieved, and  $n_c$  is the number of current values.

$$P = \frac{\sum_{i=1}^s q_i \cdot p_i'}{n_c} \quad (5)$$

Summing up the probabilities of all memory traces gives a generalized estimate of their potential to answer all possible probes. The prediction of the model should be the expected proportion of correct answers. Therefore, the sum must be divided by the number of current values, because, depending on memory load, all traces contain two, four, or six traces that represent current values.

The two free parameters of the model, number of rehearsals  $n$  (Equation 3) and  $c$  (Equation 4), were estimated to optimize the fit to the data. The resulting values were  $n = 12$  rehearsals and  $c = 0.5$ . With these values, the prediction of the model matched the data with an  $R^2$  of 0.89 and a root-mean-square deviation (RMS) of 0.07.

Although an  $R^2$  of 0.89 might not seem very high, one has to take into account that twelve degrees of freedom were predicted by adjusting only two parameters. For the many-objects conditions alone, the  $R^2$  is 0.97 and the RMS is 0.04.

Note that the task analysis contributes to the prediction only in combination with the memory assumptions. Since  $\sum q_i$  equals  $n_c$  (cf. Equations 1 and 2), a constant probability of retrieval  $p'$  would simplify the numerator of Equation 5 to  $n_c \cdot p'$ , and Equation 5 would yield the constant  $p'$ . The variation of probabilities of being current,  $q_i$ , would be completely neutralized by a constant probability of retrieval,  $p'$ , and no differences would be predicted.

If only the assumption about baselevel learning would be omitted, Equation 4, which models the interference effect, would still create variations in  $p'$ . I tried to fit the data without the calculation of retrieval probabilities as a function of time (i.e. without baselevel learning), using a single value for the probability of retrieval  $p$ . This value was estimated as  $p = 0.85$ . The resulting values of  $R^2 = 0.77$  and RMS = 0.08 show that the interference assumption alone accounts for a fair amount of variability, but the prediction is clearly improved by the assumption about baselevel learning.

Figure 3: Mean proportions of correct answers from Venturino (1997) and the model (DA: different attributes, SA: same attribute)

## Discussion

It is remarkable that a model that combines a task analysis with a small set of basic assumptions about the dynamics of memory elements can reproduce the data so well. This demonstrates that there is no reason to distinguish between memory capacity for static information and memory capacity for dynamic information, as it was suggested by Venturino (1997). The model implies a simple rehearsal strategy in which only the most recent value is rehearsed about twelve times. This number is slightly higher than the number of rehearsals that were needed to encode the instruction in a model of serial attention by Altmann (2000). Because the present model does not include activation spread by cues, which would also in-

also increase the probabilities of retrieval, this number of rehearsals is probably overestimated.

The simplicity of the rehearsal strategy was not assumed for sake of parsimony, but is actually functional. If more than the most recent value would be rehearsed, this would strengthen older memory traces to a degree that new traces could hardly compete with the older ones, thus preventing the system from retrieving newer traces which are more likely to represent current values. This prediction of the model should be tested in future research.

Although the model is successful with standard assumptions about memory, there is one feature that points in a similar direction as Venturino's (1997) speculation about different types of memory capacity. The parameter  $c$  in Equation 4 and its estimated value of 0.5 establish a threshold of two memory elements up to which no interference occurs. This raises the question if there might be a preferential type of representation for a very small number of elements. Such an assumption, implemented in a simulation model, would remedy the model's underestimation of performance in the lowest memory load conditions. ACT-R provides opportunities to model such a preferential representation, for example if one assumes that one or two of the most recent values are always elements of the focus of attention.

Another interesting question that can be stated more precisely thanks to the model is what interferes with the correct answer. The present model assumes that only the *current* values that share the same attribute interfere with each other, resulting in no interference in the conditions with different attributes. The small memory load effect in these conditions is due to the increasing mean "age" of the memory representations with higher memory load. Also in the same-attribute conditions, the interference factor (Equation 4) depends on the number of *current* values.

This assumption, although critical for the predictions and supported by the data, can be questioned. It might be more plausible to assume that not only the current values of an attribute compete, but all of them. Interestingly, this assumption predicts more interference for lower memory loads in the different-attribute conditions. Suppose there are twelve memory elements representing the twelve most recent values, some of them current, some not. Under memory load 2, there are two different attributes, thus on average six of the elements share the same attribute. Under memory load 4, three elements, and under memory load 6, two elements share the same attribute. Thus, the lower the memory load, the more elements of the same attribute compete with each other, producing higher interference - a pattern that is contradicted by the data.

All these observations converge at the question of what happens with the memory elements that represent outdated values. The decay of baselevel activation certainly contributes to the diminishing interference potential of outdated memory elements, but the decay guarantees this effect only if no noise is assumed. If one assumes some noise, which seems to be realistic, much more interfer-

ence would be expected than predicted by the present model and found in the data. I have started to investigate this problem using a rather process oriented, symbolic type of modeling. It will be interesting to see if additional processes such as active inhibition have to be assumed to explain the rather low interference effects.

Another advantage of symbolic modeling is that it demands more details about cues. In the present model, it was implicitly assumed that only one strong cue is in effect. It is the attribute in the different attribute condition. In this condition, only one value of each attribute is a current value. This value is always the most recent - and thus the most active value of that attribute. Therefore, using the attribute as a constraint and retrieving the most active memory element delivers the correct answer.

The reason why the attribute is assumed to be the only strong cue is that the relation between an attribute and its values is the only one that stays constant throughout the experiment. In their Experiment 4, Hess et al. (1999) established a constant relation between a spatial cue and attribute values in a many-objects/same-attribute condition. This cue was strong enough to abolish the interference effect that is usually observed in that condition.

The objects on the other hand are much less potent cues, because the relation between objects and attribute values varies. This is probably the reason why the information organization factor (which is operationalized through the number of objects) exerts so little influence. The model even justifies to doubt if there is a real effect at all, because the difference between the one-object and many object conditions is partially explained by the different probability structure of the material in the one-object/same-attribute condition. One data point that contributes much to the difference is the performance in memory load 4 of that same condition where the model's predictions deviate most highly from the data. A replication would be necessary to find out if this deviation is rather due to noise in the data or to inappropriate assumptions of the model. In such a study, the probability distribution of the one-object/same-attribute condition should be approximated to the distributions of the other conditions in order to draw clearer conclusions about information organization.

## Conclusions

The model has demonstrated clearly that a task analysis combined with a small set of assumptions about the dynamics of memory traces is sufficient to reproduce the basic results related to the keeping track paradigm. No distinction between memory capacities for static and for dynamic information is needed. The model implies that interference occurs between representations of current values. Hence, an issue of future research should be to investigate what happens with the representations of outdated values. As to the factor information organization, it has been shown that the effect of this factor is partially due to the deviating probability structure of one of the conditions. To clarify the influence of information organization, the probability structures should be assim-

lated in future studies by means of the presented task analysis.

## Acknowledgments

I wish to thank Mike Venturino for providing me with detailed information about his experiment. I am grateful to my colleagues at the Human Factors and Applied Cognition Program, especially to Deborah Boehm-Davis and Erik Altmann for their comments on this paper. Thanks also to Wayne Gray who encouraged me to model this paradigm. This research has been supported by grants NAG 2-1289 from the NASA and 99-G-010 from the FAA.

# Motivating Base-Rate Sensitivity (Sometimes): Testing Predictions of the RCCL Framework

Christian Schunn (schunn@gmu.edu) & Thuy L. Ngo

Department of Psychology; George Mason University  
Fairfax, VA 22030 USA

## Abstract

In choice situations, people are usually (but not always) sensitive to the base-rates of success of the options, and this base-rate sensitivity usually (but not always) goes up when motivation levels are increased. The RCCL framework, which emphasizes what information is represented by the individual and what strategies are used, provides an explanatory framework for these types of effects. In particular, RCCL predicts that manipulations of motivation levels should produce changes in the strategies being used, which will not produce a change in base-rate sensitivity for dimensions not represented in the strategies. This paper reports an empirical test of these predictions; changes in strategy use and a lack of change in base-rate sensitivity are found, as predicted by RCCL.

## Introduction

In making optimal choices in an uncertain world, a problem-solver must pay attention to the base-rates of success of each of the possible choices: the past success rates are usually good indicators of future success rates. For example, travel routes that were generally congested in the past are likely to be congested in the future. While one often finds base-rate insensitivity when base-rates are presented verbally in textual problems (e.g., Ginossar & Trope, 1987; Tversky & Kahneman, 1982), one usually finds extremely good base-rate sensitivity in experiential paradigms (e.g., Estes, Campbell, Hatsopoulos, & Hurwitz, 1989; Maddox, 1995). That is, when problem-solvers experience many decisions during problem solving, they are typically very sensitive to the base-rates of success that they have experienced. However, there are a few well-documented exceptions to this general trend of good base-rate sensitivity (Goodie & Fantino, 1995; Goodie & Fantino, 1996; Medin & Edelson, 1988).

A challenge for cognitive science is to come up with models that explain why and to what degree one observes base-rate sensitivity (or base-rate neglect). Recently Lovett and Schunn (1999) proposed RCCL (pronounced "ReCY-CLe") as a framework for providing such an explanation.

RCCL specifies how task representations can influence choice in experiential base-rate situations. The four main stages of processing in RCCL are: (i) Represent the task, (ii) Construct a set of action strategies consistent with that task representation, (iii) Choose among those strategies according to their success rates, and (iv) Learn new success rates for the strategies based on experience. The primary theme underlying RCCL is that a task representation constrains the set of strategies an individual will use for taking

actions in the task environment. Making choices according to the learned success rates of a certain set of strategies enables RCCL to produce base-rate sensitivity or base-rate neglect in direct-experience situations; sensitivity arises only when the constructed strategies include stimulus features that are important to success in the task. The RCCL framework also includes re-cycling through the above processes when the current representation and strategies lead to low success rates. This implies that an individual's task representation and strategy set need not be static but rather can develop with experience.

At this level of description, the components of RCCL may seem intuitive to the point of being obvious: how else could it be done? However, the central contribution of RCCL may be to forefront processes that are highly likely to be going on yet have been ignored in previous accounts of human choice processes. Moreover, there are accounts of choice processes that do not invoke (and perhaps even deny) the role of mental representations (e.g., Goodie & Fantino, 1995; Goodie & Fantino, in press).

Lovett and Schunn (Lovett & Schunn, 1999) described two experiments that provided empirical support for the RCCL framework. In one experiment they showed that people prefer representations and strategies that make use of information predictive of successful problem solutions. In the second experiment, they demonstrated that one could change the superficial characteristics of the task environment such that participants would prefer one representation or another, and that this manipulation determined what base-rates participants would learn.

The current paper seeks to further test RCCL specifically, and strategy-based accounts of choice processes more generally (e.g., ACT-R). The insight is to examine the effects of performance motivation on base-rate sensitivity in a problem-solving context.

To tease apart strategy and non-strategy-based accounts of choice processes, one needs to distinguish between simple and complex choice situations. In a simple choice situation there is a direct, one-to-one mapping between the person's strategies and external alternatives. That is, one can adequately describe the person's strategies in terms of simple external choices. For example, when presented with a left and right button to press, the person represents the choice strategies as Select-Right and Select-Left. By contrast, in a complex choice situation, there is not a simple mapping between strategies and external alternatives. That is, a given strategy might map onto different external alternatives on different trials; two different strategies may map onto the same external alternative on the given trial.

In very simple choice situations, strategy-based and non-strategy-based accounts make very similar predictions about the effects of motivation on base-rate sensitivity. The greater the value of a success, the more participants (human or otherwise) will prefer the more successful choice (see Anderson, Lebiere, & Lovett, 1998). In other words, greater motivation levels should produce higher base-rate sensitivity.

In complex problem-solving situations, however, RCCL makes two novel predictions regarding the effects of motivation. First, RCCL predicts shifts in strategy choice as a function of motivation changes when the strategies vary in terms of effort and success. That is, it is the selection among strategies (rather than externally defined alternatives) that is directly influenced by motivation. This prediction is easily formalized using various forms of expected utility theory (e.g., see Anderson et al., 1998). However, intuitively this prediction can be understood as people becoming more willing to put out the extra effort associated with a more effortful but more successful strategy when they are more motivated to succeed.

RCCL's second prediction is that this change in strategies may produce increases or decreases in base-rate sensitivity depending on whether the new or old strategies represent the external alternative feature whose base-rate is being manipulated. As an abstract example (the next section presents a concrete example), suppose there is a strategy S1 that does represent an external feature F1 (i.e., S1 makes direct use of feature F1 to make a choice) and a strategy S2 that does not represent external feature F1 (i.e., S2 makes choices without making use of feature F1). Then, when people use strategy S1, they will be sensitive to the base-rates with which F1 predicts success, whereas when they use strategy S2, they will not be sensitive to the base-rates with which F1 predicts success. Thus, if increasing motivation leads people to move from S1 to S2, then base-rate sensitivity to F1 will go down. By contrast, if increasing motivation leads people to move from S2 to S1, then base-rate sensitivity to F1 will go up. In general, for situations in which increases in motivation level cause a person to shift to a strategy that does not represent the relevant base-rate, then RCCL predicts decreases in base-rate sensitivity with increases in motivation level.

By contrast, non-strategy-based accounts would always predict an increase in base-rate sensitivity with increasing performance motivation. As the value of currently picking the best option increases, one should find better base-rate sensitivity (or even over-matching). Intuitively, the more incentive one has to do well, the more one pays attention to cues (e.g., base-rates) that will predict accurate choices.

The role of performance motivation in base-rate sensitivity and strategy adaptivity is also an important question for other reasons. Recent research (Schunn & Reder, 1998) has shown that there are individual differences in the degree to which people adapt their strategies to shifting base-rates of success, and that these base-rate sensitivity individual differences are correlated with individual differences in inductive reasoning skill. A remaining question, however, is whether these individual differences in base-rate sensitivity can also be partially explained by motivational differences (i.e., are the more base-rate sensitive participants simply the

more motivated ones). The current research will show the degree to which base-rate sensitivity is influenced by motivation levels and thus whether there is a potential confound in the individual differences research in this area.

## Methods

### Participants

Ninety-two George Mason University undergraduates participated for course credit and were randomly assigned to one of two conditions. Nine participants encountered technical difficulties with the computer setup, and their data is not included in the analyses.

### Building Sticks Task

In the building sticks task, participants are presented with 3 different-sized building sticks which they must choose among to create a given goal stick. To achieve the goal stick, participants add or subtract any combination of the buildings sticks provided.

For a given BST problem, using one of two approaches will result in the goal stick (Note, here I use the term "approach" to refer to an externally-defined alternative in contrast to a true strategy). Using the undershoot approach, participants start with a stick shorter than the goal stick and add to it to achieve the desired stick length. In the overshoot approach, participants pick a stick longer than the goal stick and subtract from it until the goal stick is created. Each problem is designed to be solved using one of the approaches, but not both.

For example, if the goal stick provided is 8 units in length and the 3 sticks A, B, and C, are 15, 6, 7, respectively, using the overshoot approach will solve this problem. To achieve the goal stick, participants start with stick A and subtract stick C ( $15 - 7 = 8$ ) to reach the solution. Using the undershoot approach in this case would never result in the desired stick length because picking stick B and adding to it will not equal 8 ( $B + C = 6 + 7 = 13$ ). Note that participants in the task are not given numerical lengths of the sticks. Instead, participants must estimate stick lengths and determine which sticks would lead to the goal stick before taking the appropriate steps. As a result, participants were forced to implicitly apply an approach (overshoot/undershoot) to solve each problem without knowing in advance whether it would work.

Participants were given 80 BST problems to solve. Participants worked through each problem until the goal stick was achieved. If a solution was not reached within 5 moves or less, participants were asked to reset the problem and start over again until the goal stick was reached. Each problem was designed to be solved by only one of the two approaches.

For the first 40 problems, the overshoot approach was biased to be more successful in solving the problems than the undershoot approach, with 70% and 30% success rates for each approach, respectively. For the second 40 problems, the success rates were reversed, with the undershoot approach biased to be more successful 70% of the time. This sequence was held constant across conditions. The degree to which participants adapted their approach choices to this

base-rate manipulation is one of two primary dependent measures.

Figure 1. Examples of Undershoot looking (top) and Overshoot looking (bottom) BST problems.

In addition, each problem was designed with a feature pattern, called a relative length cue, which was predictive of the correct approach to use for a given goal stick. One of the 3 building sticks was designed to appear closer in length to the goal stick, suggesting a bias towards use of one approach over another. As shown in the top of Figure 1, stick C looks closest in length to the goal stick. Therefore, participants are more likely to start with stick C (initiating the undershoot approach) and adding segments until the desired stick length is reached. In contrast, stick B in the bottom of Figure 1 looks closer in length to the goal stick than sticks A and C. Thus, participants will pick stick B and subtract segments until the goal stick is achieved.

Of the 80 BST problems, 40 problems appeared biased towards overshoot and 40 problems were biased towards undershoot. This cue was manipulated to be successful 70% of the time—the predictiveness of the relative length cue remained constant across both conditions. Table 1 summarizes how problem types were manipulated over time for all participants (in both conditions)—overshoot success rate being changed over time, while the predictiveness of the length cue was held constant over time.

Table 1. Overshoot success rate and predictiveness of the length cue over blocks of trials (in both conditions).

Predictive cue	Trials 1-40	Trials 41-80
Overshoot success rate	70%	30%
Predictiveness of length cue	70%	70%

Consistent with the RCCL account, participants in the BST tend to report a variety of strategies (Lovett & Schunn, 1999). The two most salient strategies are the hill-climbing and exclusive strategies. In the hill-climbing strategy, participants compare the goal stick to the building sticks and select the stick that most closely matches the length of the goal stick. In the exclusive strategy, participants simply select one approach, overshoot or undershoot, without regard to which appears to be closest to the goal. As long as hill-climbing distance is predictive of solution success (as it

was in the current experiment), the hill-climbing strategy is more likely to be successful than the exclusive strategy. However, the hill-climbing strategy also involves more effort because of the visual comparison component. Which strategy participants adopt across conditions will be the second primary dependent measure.

This task is a complex problem solving situation (according to the definition given in the introduction) because there is not a simple mapping between strategies and external alternatives. Table 2 presents the choices that participants would tend to make in each of the blocks under the hill-climbing and exclusive strategies. The exclusive strategy should tend to select the most successful approach regardless of what the problem looked like. By contrast, the hill-climbing strategy should tend to select approaches according to problem appearance, independent of the base-rate of success of each approach.

Table 2. Expected modal approach (O=overshoot, U=undershoot) under each strategy in each block for undershoot and overshoot biased problems.

Strategy	Trials 1-40		Trials 41-80	
	O-biased	U-biased	O-biased	U-biased
Hill-climbing	O	U	O	U
Exclusive	O	O	U	U

## Procedure

Participants were randomly assigned to one of two conditions. In the Unpaid condition (the control group), participants received course credit only. However, in the Paid condition (the motivated group), participants received compensation in addition to course credit. Payment was based on a \$10 scale and calculated according to the percentage of problems solved correctly within 5 steps or less. That is, participants who solved 80% of the problems in so few steps received \$8.00 while participants who solved 60% of the problems in this way received \$6.00.

At the beginning of the experiment, a computer tutorial provided participants with step-by-step instructions to the task, along with an animated demonstration of the undershoot and overshoot approaches. For participants in the Paid condition, the last page of the instructions informed the participants that they were being compensated for their participation based on their performance on the task. The instructor reiterated this to ensure participant motivation.

## Predictions

The hill-climbing strategy is a more successful but more effortful strategy than the exclusive strategy. Therefore, RCCL predicts that the motivation manipulation should increase the participants' use of the hill-climbing strategy. Let us define base rate sensitivity as the difference in frequency of overshoot approach use from the first to second halves of the experiment. Then, because the exclusive strategy is more sensitive to the base-rates of overshoot and undershoot, RCCL predicts no effect of the motivation manipulation (or perhaps a decrease) on base-rate sensitivity, at least as defined in terms of external choices. By contrast, non-representational accounts (and perhaps even common

sense) would suggest that the participants given the performance incentive should show greater base-rate sensitivity.

### Strategy Coding

At the end of the Building Sticks Task, participants were asked about what strategies they used. Responses were classified into one of 5 categories: using whatever the problem looked like (hill-climbing), always using one stick size first (exclusive), using what worked previously (memory), randomly selecting sticks (trial and error), and other strategies (miscellaneous). Based on a recoding of 20% of the data by a second coder, the reliability for this coding scheme was 93%.

## Results & Discussion

### Verifying Differences in Strategy Features

The predictions of strategy shifts rest on assumptions about the differential effort and success rates associated with the various strategies. The assumptions were tested by examining the relationship between 1<sup>st</sup> mentioned strategy and participant mean success rates (across all blocks) and mean time to make the first move on each trial (across all blocks). Note that time to execute the strategy is used as an approximation of the effort required by a strategy. We expect that the participants using the hill-climbing strategy should be more successful and require less time to make choices. However, given that participants in this task have been found to typically each use several strategies during the course of the session (Lovett & Schunn, 1999), one would expect analyses averaging performance data across the whole session to show diluted trends.

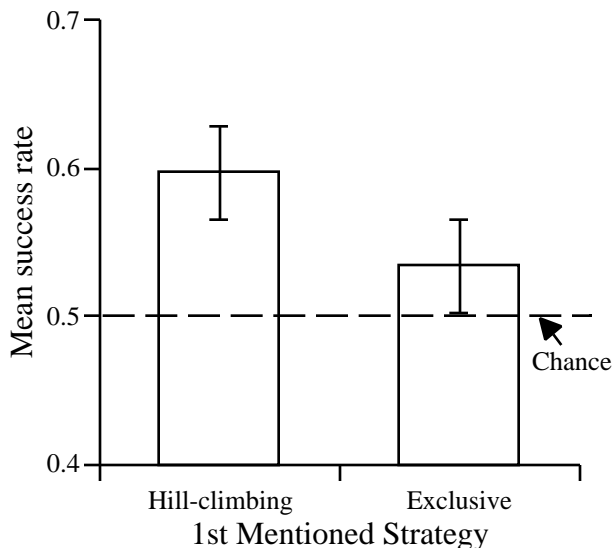

Figure 2. Mean success rate (and SE bars) for the hill-climbing and exclusive strategies.

Overall, there was a significant effect of 1<sup>st</sup> strategy mentioned on the mean success rates,  $F(2,54)=8.8$ ,  $MSE=0.004$ ,  $p<.005$  (see Figure 2). Specifically, exclusive strategies ( $n=10$ ) showed lower success rates than hill-

climbing strategies ( $n=46$ ). This trend was consistent within both conditions.

Overall, the timing data was more variable, with a non-significant overall effect of 1<sup>st</sup> strategy mentioned on the mean times to make the first move  $F(2,54)=2.1$ ,  $MSE=1.31$ ,  $p>.15$  (see Figure 3). However, exclusive strategies did show the expected lower mean times than did hill-climbing strategies. This trend was consistent within both conditions.

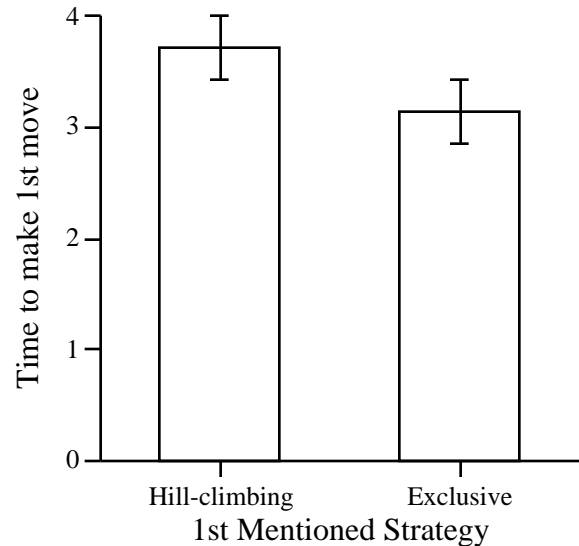

Figure 3. Mean time to make 1<sup>st</sup> move on each problem (and SE bars) as a function of the 1<sup>st</sup> mentioned strategy.

In sum, the assumptions about the differential effort and success rates between the hill-climbing and exclusive strategies were at least qualitatively supported.

### Strategy Changes

Table 3 presents the frequency of mention of each strategy type based on the first strategy mention. We see the predicted increase in the use of hill-climbing strategy and the predicted decrease in the use of the exclusive strategy.

Note also that the Memory strategy, a relatively effort intensive strategy, showed an increase in the Paid condition, and that the Trial & Error strategy, a relatively effort free strategy showed a decrease in the Paid condition. The predicted increase in reliance on effortful strategies was statistically significant,  $t(81)=1.6$ ,  $p<.05$  (one-tailed).

While these effects were not large, it is important to note that these analyses are likely to be an underestimate of the effects—participants did not indicate how often they used the mentioned strategies, and they do try multiple strategies.

Table 3. Proportion of participants mentioning each strategy within each condition.

Strategy	Unpaid (N=42)	Paid (N=41)
Hill climbing	0.50	0.61
Exclusive	0.17	0.07
Memory	0.10	0.15
Trial & Error	0.17	0.15
Misc.	0.07	0.02

Another important issue raised by RCCL is whether motivation has an impact on the degree of search for an optimal strategy. Towards this end, we examined the effect of condition on number of different strategies mentioned. There was no significant effect of condition on the number of strategies mentioned,  $F(1,81) < 1$ . Both the Paid and Unpaid participants mentioned a mean of 1.4 strategies per participant.

### Overall Base-Rate Changes Over Time

Both groups showed a rise in the amount of Overshoot use in the first half followed by a drop in the second half  $F(3,243)=16.6$ ,  $MSE=0.015$ ,  $p < .0001$  (see Figure 4). There was no main effect of condition,  $F(1,81) < 1$ , nor was there a significant interaction,  $F(3,243)=1.0$ ,  $MSE=0.015$ ,  $p > .3$ . To directly quantify the influence of condition on base-rate adaptivity, one can define base-rate adaptivity as the amount of drop in Overshoot use from the first half to the second half (difference of half means). On that measure, both Paid and Unpaid participants shifted exactly 7% in their use of Overshoot over time. As Figure 4 reveals, if anything, Paid participants were less sensitive to the base-rates. Thus, as predicted by RCCL, motivation manipulations produced changes in strategy use, not changes in base-rate sensitivity.

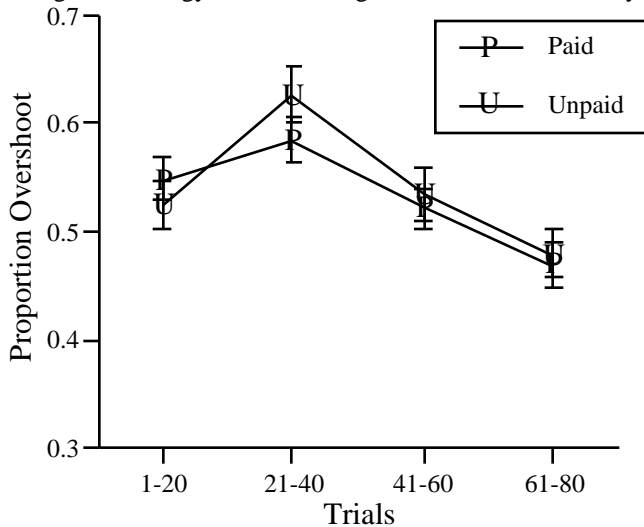

Figure 4. Proportion of overshoot choices within each set of twenty trials within each condition.

### Hill-climbing sensitivity

One can also analyze the effects of problem appearance (whether the problem appearance was biased towards overshoot or biased towards undershoot) on solution method and its interaction with condition and blocks. As one always finds in this task, there are large effect of problem appearance on the proportion of overshoot selections,  $F(1,81)=657.0$ ,  $MSE=0.038$ ,  $p < .0001$ . More interestingly, there was also a significant interaction of appearance with condition,  $F(1,81)=6.5$ ,  $MSE=0.038$ ,  $p < .02$ . In particular, Unpaid participants showed a significantly lower sensitivity to problem appearance than did the Paid participants (49% versus 60% differences between overshoot-biased and undershoot-biased problem types).

Figure 5. Proportion of overshoot choices as a function of problem appearance (Overshoot biased /Undershoot biased) and condition (Paid/Unpaid), for the first (1) and second (2) halves of the experiment.

This effect establishes that the payment manipulation did have some influence on participants, and thus clarifies the interpretation of the null effects on base-rate sensitivity. This effect is also consistent with increases in hill-climbing strategy use as a result of the manipulation.

### General Discussion

This experiment found that increasing motivation levels can produce strategy changes (as measured by self-report and patterns in choice) without producing changes in base-rate sensitivity. The changes in strategy choice were consistent with a shift in motivation levels—a shift from lower-success/lower-effort strategies to higher-success/higher-effort strategies. Thus, the key predictions of the RCCL framework with respect to the effects of motivation levels on choice patterns were met. These findings are not consistent, by contrast, with non-strategy-based theories of choice that focus entirely on external alternatives rather than internal representations and strategies.

It should be noted that RCCL is a general framework, not a detailed model. With respect to the predictions regarding the effects of motivation, there are several particular utility-based strategy models of choice processes that could be used to account for the obtained results, including ACT-R (Anderson & Lebiere, 1998), SAC (Schunn, Reder, Nhoyvanisvong, Richards, & Stroffolino, 1997), and ASCM (Siegler & Shipley, 1995).

Some of the results of the current experiment are potentially difficult to interpret because they involve null effects of a manipulation. However, the manipulation did produce some effects demonstrating that it was strong enough to influence behavior. Moreover, it is somewhat rare to find a case in which performance in a problem-solving task does not improve when undergraduates normally taking part only for course credit are suddenly paid for higher performance levels.

Our experiment is also not the first to find no effect of motivation manipulations on base-rate sensitivity. For example, Goodie and Fantino (1995) found no effect of a motivation manipulation on base-rate sensitivity. They also used conditions of course credit and pay versus course credit alone, although they paid their participants as much as \$40. While Goodie and Fantino did not explain their null result (it was also not the focus of their experiment), RCCL provides a potential explanation. The key is to examine whether the motivation manipulation produced changes in strategy use rather than changes in choices at the level of simple external alternatives. While the task used by Goodie and Fantino was not a complex problem-solving task, Lovett and Schunn (1999) established that participants do use a wide variety of strategies during that choice task as well.

Another consequence of the current experimental findings is that they resolve a question about individual differences. In particular, previous research on individual differences in sensitivity to base rates (Schunn & Reder, 1998; Stanovich & West, 1998) left open the possibility that the differences were due to motivational differences. The current research suggests that the observed individual differences in base-rate sensitivity are not so easily attributed to motivational differences.

The current experimental findings also permit some refining of the RCCL framework. RCCL posits that people will search for new representations and strategies when the success rates of the current alternatives are too low. An open question was whether motivational levels entered into determining when a search for new representations and strategies was begun. The current findings suggest that motivational levels do not have a large role of in the amount of search for alternative representations and strategies. Or, at least, all of the participants were sufficiently motivated to conduct such searches.

As a final note, the current experiment only manipulated one kind of motivation: extrinsic motivation. There are other types of motivation. For example, research (e.g., Button, Mathieu, & Zajac, 1996) has shown that people also differ in terms of their performance motivation (the degree to which they need to succeed) and learning motivation (the degree to which people prefer to learn new things). It is an open question whether those dimensions of motivation will have similar influences on choices processes generally, and base-rate sensitivity in particular.

### Acknowledgments

Work on this project was supported by funds to the first author from the Department of Psychology and the College of Arts and Sciences at George Mason University. We would like to thank Erik Altmann, Melanie Diez, Wai-Tat Fu, Eliza Littleton, Lelyn Saner, and Susan Trickett for comments made on an earlier draft.

# Now They See the Point: Improving Science Reasoning Through Making Predictions

Christian D. Schunn (schunn@gmu.edu) Christine J. O'Malley (comalley@gmu.edu)

Department of Psychology; George Mason University  
Fairfax, VA 22030 USA

## Abstract

Previous research on scientific reasoning has found that many students find it difficult to think about the theoretical level when asked to design experiments. Two studies are reported that explore whether forcing students to make predictions before running their experiments improves their scientific reasoning performance. Both studies find that, if they do make predictions, students become more focused on the theories they are being asked to test. The students become more likely to make conclusions about the theories under test and they design experiments more relevant to the theories under test.

## Introduction

Science education is a core component of education throughout the industrialized world, and the ability to reason scientifically is a generally valued skill. Nevertheless, relatively little is known about the details of how students become good scientific reasoners. There is one clear fact, however, about the developmental process that has been frequently documented: students do not come naturally to many aspects of scientific reasoning, and it is not easy to teach those skills (e.g., Kuhn, 1989; Lehrer, Schauble, & Petrosino, in press; Schauble, 1990). Even towards the end of a students' college education, many basic scientific reasoning skills are weak or missing (Schunn & Anderson, 1999, In press).

Developing an understanding of what can improve scientific reasoning skills is an important problem for cognitive science. It tends to involve many disciplines of cognitive science because it is a difficult problem that requires resolving: 1) what it means to reason scientifically (philosophy, history), 2) what cognitive processes are involved (psychology), 3) what kinds of interventions are successful (education), and 4) constructing complex computer environments that model and support it (computer science). What makes it an inherently cognitive science-like problem is that these four components are intimately interconnected.

This paper explores one simple method for improving scientific reasoning: forcing students to make predictions before running an experiment. It presents two empirical studies conducted in the psychology laboratory (as opposed to a classroom situation). The studies compare the scientific reasoning performance of students forced to make predictions before each experiment with students not asked to make predictions before each experiment. Before turning to the empirical studies, we will provide additional background on this particular issue.

To make a prediction, one needs a hypothesis or theory. Science textbooks generally recommend that one should

always have a hypothesis before running an experiment. However, philosophical, historical, and, more recently, psychological accounts of science agree that one need not always have a hypothesis before running an experiment (see Okada and Shimokido, in press, for a review).

We acknowledge that there are plenty of situations in which people do not have a theory before conducting the experiment (Klahr & Dunbar, 1988). A central aspect of doing science, however, is the development and testing of formal theories—unifying or explanatory accounts that sit at a level above simple beliefs about the effects of particular variables.<sup>1</sup> Thus, having a theory to test is a common and important situation.

A separate question (and the one we examine) is whether one should always make concrete predictions before running the experiment *when one does have a theory to test*. There are plenty of situations in which one does have a theory to test. What role do explicitly made predictions serve in those situations?

Several recently developed science education computerized training environments have components that prod students into making predictions before running the experiments (e.g., Loh et al., in press; White, 1993, 1995). While these systems as a whole have been demonstrated to be effective, the value-added of the prediction-making component of these complex systems has not been tested in isolation. Thus, little is known from that research about whether forcing predictions actually improves reasoning.

There are several reasons to think that making predictions will help scientific reasoning. First, making predictions may remind students to focus on the theories that they are supposed to be testing. Schunn and Anderson (1999, In press) found that even undergraduates pay little attention to the theories they are supposed to be testing and instead simply explore the effects of different variables.

Second, making predictions may lead participants to consider alternative theories, and thus design experiments that more uniquely target the theory under test. On a related point, Koehler (1994) found that generating one's own hypothesis rather than being given the hypothesis leads to more accurate evaluations of the likelihood that the hypothesis is correct (however, see Schunn and Klahr (1993) for the exact opposite finding).

---

<sup>1</sup> We will use the term *theory* to refer to these general accounts and the term *hypothesis* to refer to beliefs about particular concrete variables. For example, ACT-R (Anderson & Lebiere, 1998) or SDDS (Klahr & Dunbar, 1988) are theories; "making predictions should improve reasoning" is a hypothesis.

There are also several reasons to think that making precise predictions will hurt scientific reasoning. First, it could be that making predictions would direct students away from the theoretical level that they are supposed to be testing and instead focus on simple empirical effects of particular concrete variables.

Second, getting students to make precise predictions could push students into an engineering rather than scientific mode (Schauble, Klopfer, & Raghavan, 1991; Tschirgi, 1980). In other words, it could lead students to focus on how to produce a particular outcome rather than on finding out why certain outcomes occur. As a variant of this theme, focusing on concrete predictions might lead students adopt a goal of trying to maximize their prediction accuracy (i.e., see how well they can predict outcomes). This new goal could be seen as a kind of engineering goal that is potentially at odds with the scientific goal of testing the theory.

In sum, there is a general belief that making predictions is important to scientific reasoning, possible reasons for it to help or hurt scientific reasoning, and little evidence one way or the other. We examine the role of making predictions on scientific reasoning in two different situations: when students are designing an experiment to choose between two alternative theories (Study 1); and when students are designing an experiment to test only one given theory (Study 2).

### **The Simulated Psychology Lab**

To examine the influence of making predictions on scientific reasoning skills we selected a real scientific question from cognitive psychology: what is the cause of the spacing effect in memory? The spacing effect itself is intuitively understood by undergraduates—that spaced practice produces better memory performance than massed practice (i.e., cramming is bad). The advantage of using this particular question is that it is relatively easy to explain to undergraduates without the use of complex domain-specific jargon and yet it is an authentic scientific problem rather than a toy problem. Recent work in the psychology and education of science suggests that it is important to use realistically complex problems (Chinn & Malholtra, in press).

As we noted earlier, not all situations require a theory to be tested in the experiment. However, since we wanted to examine the role of predictions, it was important to place students in a theory-testing situation. The spacing-effect problem may be too complex for students to quickly develop their own theories to test from the start. For this reason, we gave students theories to test. In particular, the students were presented with two theories that had been proposed to account for the spacing effect and their goal was to develop experiments to tease the theories apart (i.e., determine if either, both, or neither of these theories adequately explained the spacing-effect phenomenon).

Briefly, the first theory was the shifting context theory, which stated that memories were associated with the context under study and that context gradually shifted with time. Thus, the spacing effect occurs because spaced practice produces associations to more divergent contexts, which in turn are more likely to overlap with the test context. The second theory was the frequency regularity theory, which stated that

the mind tries to estimate how long memories will be needed based on regularities in the environment and, in particular, adjusts forgetting rates according to the spacing between items. The students were given longer descriptions of the theories (and the spacing effect itself) with concrete examples, could look at the descriptions of the theories throughout the task, and had several opportunities to ask the experimenter questions about the theories. (In Study 2, participants were only given the shifting context theory to test).

With the spacing-effect phenomenon and two theories in hand, we could have then given the students paper and pencil and asked them to describe an appropriate experiment. However, science is more than just experimental design. It also involves data analysis (among many other things). Moreover, few scientific questions are answered in the first experiment. Instead, scientists iterate and refine their methodology in response to experimental results. In order to place students in such a more realistic iterative situation that also included a data analysis process, we asked the students to design and interpret experiments using an environment called the Simulated Psychology Lab (Schunn & Anderson, 1999).

The Simulated Psychology Lab is a computer environment that allows students to design a wide variety of experiments and examine the results of those experiments. Students create experiments by selecting values for six factors, of which up to four could be simultaneously manipulated for any single experiment. They are told that the computer had been given the results of many actual experiments, and that it will display the results of any type of experiment they chose to generate.<sup>2</sup>

There were two groups of factors, source task factors and test factors, that the participants could manipulate. The source task factors included 1) repetitions—the number of times that the list of words was studied; 2) spacing—the amount of time spent between repetitions; and 3) source context—whether the participants were in the same context for each repetition or whether they changed contexts on each repetition. The test factors included 1) the test task—free recall, recognition, or stem completion; 2) delay—the amount of time from the last study repetition until the test was given; and 3) test context—whether the participants were in the same context or a different context at test relative to study. Only three of the factors are highly relevant to testing the two theories: spacing, source context, and test context. (In Study 2, since participants were asked to investigate only the shifting context theory, then only two factors are relevant: source context and test context).

For each of these factors, the participants could either vary it or hold it constant. Values had to be chosen for all of the factors before participants were allowed to continue. There were no confines on the order of value selection, and

---

<sup>2</sup> In fact, in order to produce numbers for the large number of possible combinations that the students could generate, the computer uses a mathematical model based on ACT-R (Anderson & Lebiere, 1998) that is very consistent with previous memory and spacing effect results, and includes a small level of random noise for added realism. See Schunn and Anderson (1999) for details.

the participants could change any of their selections at any time up until they chose to run the experiment.

The results were displayed using a table format and the participants could decide how to organize their tables. If participants were in an experimental condition that asked them to make predictions, then they made numerical predictions in a table. For each cell in the designed experiments, the participant must predict the percent correct of the hypothetical subjects. For example, Figure 1 presents an example table in which source context, spacing, and delay are manipulated and predictions have been already made for the first 8 cells (the bold 5 is currently being entered). Note that the table also contains information about the settings of the factors not being manipulated.

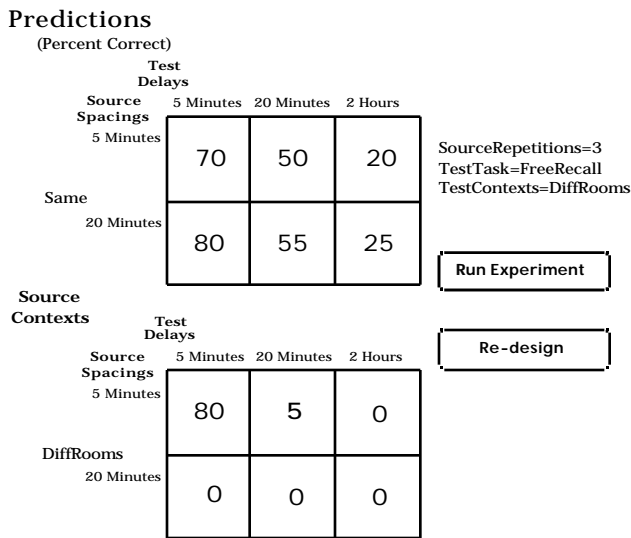

Figure 1. The interface used for making predictions.

A few words should be said about the form of the prediction task. In psychology, scientists are rarely asked to make precise numerical predictions. However, there are sciences in which one does make precise numerical predictions (indeed, in some sciences, predictions can only be made in quantitative terms because of the complexity of the theories). Moreover, it is not clear whether there is a simple method in a computer interface for asking students to make qualitative predictions for each of the factors (especially factors with 3 levels) and their interactions.

After making predictions, participants clicked on the 'Run' button and were shown the results of their experiments. Participants in an experimental condition that did not ask them to make predictions simply jumped straight to the experimental results. The results were shown in a table of the same format as was used to make predictions. If participants made predictions, the results table also showed their predictions (in smaller, italic text). Figure 2 presents an example results table (along with sample predictions). The correlation coefficient in the upper right is the Spearman correlation between the predictions and the actual outcomes, and was given to participants to provide a rough estimate of the accuracy of their predictions.

**Actual Outcome**

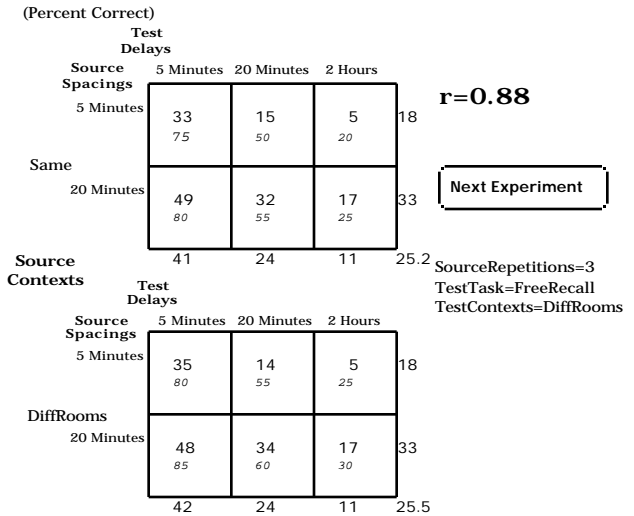

Figure 2. The interface used for displaying results (predictions, in italics, occurred only in the Prediction conditions).

For the purposes of this paper, there is one crucial performance dimension in this task: do participants focus on the theories under test? Previous research has shown that the majority of students in this task completely ignore the theories under test and simply focus on testing the effects of the 6 factors (Schunn & Anderson, 1998, 1999, In press). This focus on theories versus factors can be examined in two different ways. First, one can examine what types of conclusions the students make at the end of their experimentation: do the students make conclusions about the theories or the factors? Second, one can examine what types of experiments they design: do they focus on the factors that are actually relevant to the theories under test?

**Study 1**

**Methods**

**Participants** 56 George Mason undergraduates participated for course credit, of which 6 were removed due to computer problems. None of the participants had completed a research methods course, although a few (<10%) were currently enrolled in a research methods course.

**Procedure** Participants were randomly assigned to one of two conditions. Participants in the Prediction condition had to make numerical predictions for each cell in their experiments before viewing the outcomes of the experiment. By contrast, participants in the No Prediction condition skipped the numerical prediction phase entirely, both in the instructions and in the experiment itself.

Participants in both conditions were given a 15-minute tutorial on the computer that covered the spacing effect, the two theories, and how to use the Simulated Psychology Lab. The experimenter then reiterated the goals of the experiment (which had been presented on multiple computer screens including the very last one): to test the two theories of the spacing effect to determine whether one, both, or neither could account for the spacing effect. Participants worked on the task until they felt they understood the cause

of the spacing effect or until time had expired (40 minutes). Once finished, participants were asked what they found and their responses were recorded. They then answered a series of questions about the theories and any conclusions they came to about the effects of the six factors.

## Results & Discussion

**Overview** The results are broken into 3 sections. First, we verify that there were no background differences between the groups. Second, we examine the effects of the manipulation on what kinds of experiments the students generated. Third, we examine the effects of the manipulation on what kinds of conclusions the students made at the end of the task.

**Background Differences** To verify that the groups were roughly equivalent, we compared their reported SAT and status. There were no differences by group in either measure. For status, 18% and 21% of the undergraduates were upperclassmen in the Prediction and No Prediction groups respectively,  $\chi^2(1) < 1$ . For SAT, the combined Verbal + Quantitative scores were 1048 and 1052 for the Prediction and No Prediction groups respectively,  $F(1,53) < 1$ .

**Types of Experiments Conducted** The participants in the Prediction group ran marginally fewer experiments than did the participants in the No Prediction group, with means of 5.8 and 8.4 experiments respectively,  $F(1,55) = 3.4$ ,  $MSE = 29.4$ ,  $p < .1$ . This result is not surprising because the No Prediction subjects had more time to run experiments since they did not have to make predictions for each one.

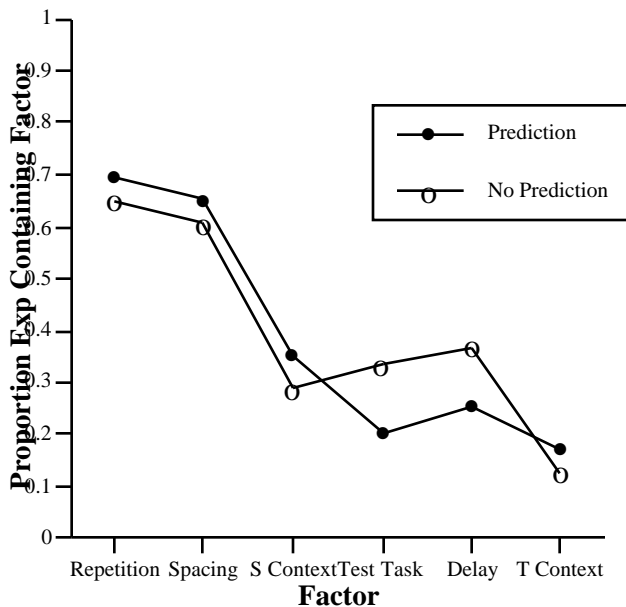

Figure 3. Mean proportion of experiments containing each of the factors within each group of Study 1.

More important than the number of experiments conducted are the types of experiments conducted. Figure 3 presents the proportion of experiments involving each factor. As one can see, the students in the Prediction group were generally more likely to focus on the factors relevant to

the theories under test (with the exception of the repetitions factor, which is the first option in the interface). Let Appropriateness be defined as the mean proportion of experiments involving Spacing, Source Context, and Test Context minus the mean proportion of experiments involving Repetitions, Test Task, and Delay. Then students in the Prediction group had a significantly higher Appropriateness score than the No Prediction students, with means of 0.01 and -0.11 respectively,  $F(1,53) = 4.1$ ,  $MSE = .05$ ,  $p < .05$ .

**Types of Conclusions Made** When the time was up or the students announced they were done, the experimenter asked the students what they had found. We coded whether the students responded to that question with a discussion of the factors that could be manipulated or a discussion of the theories under test. In the Prediction group, 31% of students mentioned the theories first, whereas in the No Prediction group, only 8% of students mentioned theories first,  $\chi^2(1) = 4.5$ ,  $p < .05$ . Thus, the manipulation did have a significant impact on whether the students focused on the theory testing nature of the task.

If they did not volunteer information about the factors at the end of the task, then the students were explicitly asked about each factor. There was no effect of the manipulation on the number of factors for which the students had correct statements about their effects, with means of 3.0 and 3.1 in the Prediction and No Prediction conditions, respectively,  $F(1,53) < 1$ . Thus, the difference in propensity to make conclusions about the theories at the end of the task was not a function of having learned less about the factors.

**Summary** Study 1 found that forcing students to making predictions did improve scientific reasoning in that problem. In particular, it led students to actually focus on the theories under test and manipulate factors relevant to those theories.

Study 2 examines whether these results generalize to a situation in which students have been given only one theory to test. Making predictions may only be helpful when it leads students to realize the key differences between theories and thus generate experiments that would tease the theories apart. Additionally, the frequency regularity theory is somewhat subtle and it may be that many of the students either did not understand it or did not know how to test it. Thus, in Study 2, students were only asked to test the shifting context theory.

## Study 2

### Methods

**Participants** 69 undergraduates participated for course credit, of which 2 were removed due to computer problems. None of the participants had completed a research methods course, although a few (<10%) were currently enrolled in a research methods course.

**Procedure** The procedure for Study 2 was identical to Study 1 with two exceptions. First, participants were never told about the frequency regularity theory and were given only the shifting context theory to test. Second, we did not

collect background information about the students (SAT, major, year, etc) since it did not prove predictive of performance in Study 1.

## Results & Discussion

**Types of Experiments Conducted** In study 2 the participants in the Prediction group ran approximately half as many experiments than did the participants in the No Prediction group, with means of 6.4 and 11.7 experiments respectively,  $F(1,65)=8.8$ ,  $MSE=52.6$ ,  $p<.01$ . Once again, this result is not surprising, since the No Prediction subjects had more time to run experiments because they did not have to make predictions for each one.

The size of the difference in number of experiments is larger than what was found in Study 1 and causes some problems for subsequent analyses. Specifically, it raises the question: are the differences in groups due to the number of experiments conducted or the cognitive consequences of the manipulation? Moreover, it appeared that in this Study, there were a significant number of participants running a very large number of experiments without much understanding (as many as 36 experiments in 40 minutes!)—they were simply clicking buttons. Therefore, we decided to remove from the remaining analyses all participants who ran more than 10 experiments (3 participants in the Prediction group and 6 in the No Prediction group). One consequence of this unequal reduction in condition Ns is that the subsequent condition comparisons should be more conservative tests of the manipulation: the ones removed from the analyses are more likely to not have understood the task and we have removed more of them from the No Prediction condition.<sup>3</sup>

Figure 4. Mean proportion of experiments containing each of the factors within each group of Study 2.

<sup>3</sup> Moreover, the same patterns of results were found if all subjects were included in the subsequent analyses

The more central analysis was of the types of experiments conducted. Figure 4 presents the proportion of experiments involving each factor. As in Study 1, the students in the Prediction group were generally more likely to select the factors relevant to the theories under test. Since there was only the Shifting Context theory to test in Study 2, the Appropriateness measure must be redefined as the mean proportion of experiments involving Source Context and Test Context minus the mean proportion of experiments involving Repetitions, Spacing, Test Task, and Delay. Under this measure, students in the Prediction group had a significantly higher Appropriateness scores than the No Prediction students, with means of -0.12 and -0.35 respectively,  $F(1,47)=3.9$ ,  $MSE=.17$ ,  $p<.05$ .

**Types of Conclusions Made** As in Study 1, we coded whether the students responded to the final “what did you find?” question with a discussion of the factors that could be manipulated or a discussion of the theory under test. Students in the Prediction group mention the theory 11% of the time, whereas students in the No Prediction group never mentioned the theory on their own ( $\chi^2(1)=2.9$ ,  $p<.1$ ). Thus, the manipulation did have the same trend of an effect as in Study 1. This time, however, all students were quite unlikely to mention the theory on their own. It is possible that the students did not feel that the theory should be part of their final report since there was only one theory to test and they could not come up with an alternative theory.

As in Study 1, if the students did not volunteer information about the factors at the end of the task, then the students were explicitly asked about each factor. This time, however, there was a significant effect of condition on the number of factors for which the students had correct statements about their effects, with means of 3.2 and 3.8 in the Prediction and No Prediction conditions, respectively,  $F(1,46)=4.77$ ,  $MSE=0.98$ ,  $p<.05$ . That the No Prediction students had more correct responses establishes that the difference in propensity to make conclusions about the theory was not due to differences in what was learned about the factors.

Why did students in the No Prediction group produce a larger number of correct responses? It is likely that this effect occurred because the participants in the No Prediction task designed more experiments and explored more of the factors (especially the irrelevant factors). There were no differences between groups on the two most important factors. For source context, the Prediction group had a non-significantly higher proportion of correct responses (.31 versus .18,  $F(1,46)<1$ ). For the test context, the less relevant factor of the two, the Prediction group had a non-significantly lower proportion of correct responses (.54 versus .68,  $F(1,46)=1.0$ ,  $p>.3$ ).

## General Discussion

The two studies found generally quite consistent results: forcing students to making numerical predictions improves their scientific reasoning performance because it leads them to focus on the theories being tested and design more appropriate experiments.

The effects found in these studies were not large. However, the task given to the students is a very realistic scientific discovery task and was quite difficult for the students—in other words, there may have been relatively small improvements because the task was so difficult and there were possible floor effects in performance. Moreover, designing experiments which actually address the theories under test is such a central and important aspect of science. Any improvement from such a simple manipulation is important. Finally, previous research (Schunn & Anderson, In press) with this exact task has shown that even an entire course in research methods has relatively little impact on these same measures. Thus, that we found any improvement with such a simple manipulation is impressive.

While students were found to have a difficult time overall focusing on theories, we do not want to claim that most students could not focus on theories if the situation were made simple enough. However, that caveat is of little use to the educational setting in which students must learn to deal with experiments in real content domains. This consideration is what led us to use an authentic problem.

Our manipulations involve forcing students to make quantitative predictions for each cell in the design. What about other methods of generating predictions (e.g., generating more qualitative predictions)? Lehrer et al. (in press) argue that focusing on quantitative aspects of science is fundamentally important to scientific reasoning generally. However, one might imagine other methods for generating quantitative predictions. For example, what if one used graphical tools for generating predictions, or only forced predictions for each factor being manipulated and simple interactions among factors (rather than each individual cell)?

Our manipulation also focused on college students working on a problem in psychology. What about students working on problems in the physical sciences? One might imagine students in physics also losing track of the larger theories under test and focusing on the roles of particular concrete factors instead. Along those lines, Chabay and Sherwood (1999) have argued that giving physics students simulators that allow them to see the precise predictions of different theoretical assumptions improves students' understanding of the theories.

What about students in high school or elementary school? If university students lose track of the theories that are supposed to be tested, one can only imagine that this problem would be compounded in younger children. Indeed Deanna Kuhn's (1991) work suggests that children generally have a lack of differentiation between theory and evidence in scientific reasoning situations. However, whether making predictions actually improves performance for younger students (who may have other reasoning difficulties as well), is an open question.

### Acknowledgments

Thanks to Elizabeth Mazzanti for her help in running and analyzing Study 1. Work on this paper was supported by funds to the first author from the Department of Psychology and the College of Arts and Sciences at George Mason.

# Dueling Theories: Thought Experiments in Cognitive Science

Sam Scott (sscott@ccs.carleton.ca)

## Abstract

Brook (1999) identified thought experiments as one of the key elements of philosophy's contribution to the cognitive sciences. In this paper, I tackle the question of how and why thought experiments work, and what exactly it is they do for us when they do work. I propose that thought experiments almost always involve two different theories of the world being compared to show that they do, or more often do not, fit together. Sometimes both theories are clearly articulated in the narrative of the thought experiment, but more often one of the two goes unarticulated - the thought experimenter instead relies on our shared folk theories of the world. The strength of some of the more famous and persuasive thought experiments lies in their ability to show that a given theory runs afoul of these deeply held folk intuitions. I will compare the "Dueling Theories" account of thought experiments to both Brook's "empirical" account and Brown's (1991) platonic account.

## Introduction

In Hilary Putnam's famous thought experiment, we are asked to imagine a possible world called "Twin Earth" identical in all respects to our own, but for the chemical composition of what is called "water" on both worlds. On our world, water is H<sub>2</sub>O, while on twin earth it is something else, say XYZ. Now we are asked to consider what happens when Adam on our world and his counterpart, "Twadam" on Twin Earth use the word "water". Do they mean the same thing? Apparently not. Even though their mental states are the same, the external referent is different. Hence, according to Putnam, "meanings just ain't in the head". (Putnam, 1975)

In Jackson's (1991) story of Mary the Colorblind Scientist, we are asked to imagine that Mary knows everything there is to know about color. That is to say, she knows everything that can be measured, described, and communicated about what color is and the process by which we perceive it. But she has never actually seen color before. Then one day she sees a color, say red, for the first time and learns something about color that she did not know before, namely what red looks like. The moral we are asked to draw is usually something about the uniqueness and indescribability of phenomenal experience.

In introducing these two famous thought experiments, what I am first interested in is how well they "work". Reactions tend to vary, but if you're like me, you will be immediately convinced by the story of Mary, but quite skeptical (at least at first) about the Twin Earth story. Perhaps your reactions differ, but the interesting question is

why we have the reactions we do. What makes a thought experiment "work" or "not work"? The thesis that I want to defend is that thought experimentation is a meta-activity - a duel between conflicting theories in which one appears to be a clear winner, thus challenging anyone who holds both theories. Thought experiments can never tell us something new about the world, because the world doesn't participate in the experiments. The objects of evaluation are theories of the world. On the other hand, thought experiments are a perfect device not only for revealing problems with various theories of the world, but in some cases, for making clear to us what our theories of the world actually are.

It may not be obvious that the two thought experiments described above fit this "Dueling Theories" story, but if we take the word "theory" to encompass both scientific and folk theory, then the story not only works but can be quite revealing. Consider Mary first. In one corner, we have some theory in which everything that is part of the physical world can be fully described in scientific terms. In the other corner, we have a folk intuition, based on our own experience of perception, that the phenomenal experience of color is indescribable and would therefore be unknowable to someone not directly acquainted with it. What makes this thought experiment so stunning to so many people is that they may not have realized that they held the folk theory, or that the folk theory was so difficult to give up, until it was put into direct conflict with the other theory. In the Twin Earth experiment, any theory that imparts semantic properties solely to brain states is supposed to lose to a reference theory of semantics. What makes someone embrace or reject Putnam's conclusion will be their pre-existing acceptance or skepticism about whether such reference theories of semantics can be made to work.

In what follows, I shall attempt to develop this Dueling Theories view in the context of two alternative views. The first, from Brown's *The Laboratory of the Mind* (Brown 1991), states that thought experiments can reveal a priori truths about the world through their investigation of Platonic universals. I hope to show that this idea should be rejected, mostly because it actually has very little to offer in aid of our understanding of the nature of thought experiments. The second view, from Andrew Brook's "Does philosophy offer cognitive science distinctive methods?" published last year in this forum (Brook, 1999), states that thought experiments get part of their value from their empirical content. This empirical content may make thought experiments capable of testing hypotheses against the real world. I believe that with

careful exegesis, Brook's view is actually quite close to my own. The main difference is that my conception allows in principle that there may or may not be empirical content to thought experiments, and in fact, a thought experiment need not actually have directly empirical content in order to make a useful contribution to science or philosophy.

### Platonic Thought Experiments

Brown's two paradigm cases of a priori reasoning about the world through thought experiments are Galileo's Coupled Falling Bodies and the photon-decay thought experiment by Einstein, Podolsky, and Rosen, which has become known as the "EPR Paradox". For the benefit of the uninitiated, both these experiments will be explained shortly.<sup>1</sup> But first, a short discussion of Brown's brand of Platonism is in order. According to Brown:

*A platonic thought experiment is a single thought experiment which destroys an old or existing theory and simultaneously generates a new one; it is a priori in that it is not based on new empirical evidence nor is it merely logically derived from old data; and it is an advance in that the resulting theory is better than the predecessor theory. (p.77, Brown's italics)*

Brown thinks that this kind of a priori thought experimentation is possible due to the existence of natural laws as abstract platonic universals, similar to the abstract objects that he supposes to exist in mathematics and logic.

Postulating abstract objects in a Platonic heaven is certainly a controversial move, and one that I am not sympathetic to. But rather than attempting to destroy the monolith of Platonism entirely, I will concentrate on trying to demonstrate that the Dueling Theories story does a better job of accounting for Brown's two favorite thought experiments than does his own Platonic account. But first I will digress briefly to point out two aspects of Brown's Platonism that are clearly problematic from a cognitive perspective.

### Cognitive Science and Abstract Objects

A central feature of Brown's defense of Platonism is its heavy reliance on the notion of "obviousness". According to Brown, without Platonism it is "an utter mystery why '3 > 2' seems intuitively obvious" (p. 56). Later, he continues, "if there were no abstract objects, then we wouldn't have intuitions concerning them; '2 + 2 = 4' would not seem intuitively obvious" (p. 64). Here we can take a lesson from research on mathematical cognition. What are we to make of the *non-obviousness* of mathematical facts like:

8329273847592 < 78374223847532, and  
89652 + 15265 = 104917 ?

---

<sup>1</sup> Unless otherwise referenced, more extensive descriptions of the thought experiments described here can be found in (Brown, 1991).

These mathematical facts are of the same order of complexity as '3 > 2' and '2 + 2 = 4'. That is, they use the same number of operators and the same number of arguments. Only the magnitudes differ. But the facts expressed are certainly not intuitively obvious to most people. The reason for the difference is easily accounted for in symbol-processing terms. We have memorized the order of the 10 digits, and this makes ordering judgements easy for single digit numbers, and more complicated for larger ones. Similarly, we have memorized all possible single-digit sums. Thus the obviousness of facts about small numbers and the *non-obviousness* of facts about large numbers can be accounted for in cognitive terms, whereas this difference is difficult to account for in Platonic terms. Perhaps some abstract objects are bigger than others? Or maybe some are further away than others? But what do "bigger" and "further away" mean in the abstract realm?

Brown also makes use of an analogy between sense perception of objects in the real world and our intuitions about objects in the abstract world. He defends this analogy by asserting "the perception of abstract laws of nature is certainly no more mysterious than [ordinary sense perception]." He justifies this by stating that,

at best we understand part [of visual perception] - the *physical* process starting with photons emitted by an object and ending with neural activity in the visual cortex. From there to *belief* about the object seen is still a complete mystery. (p. 87, Brown's italics)

Fair enough, but at least we do have: 1) an account of the links between an object and the visual cortex and 2) a research program capable of making progress in understanding how the visual system processes information from this link and communicates it to the rest of the brain. As far as I know, we have no account of the link between an abstract object and whatever organ of abstract sense perception we use to perceive it. Nor do we have an account of how these abstract perceptions would be processed in the brain.

The moral of this digression? Putting the logical neatness of Platonism aside and ignoring the natural fascination and attraction that many people feel towards abstract objects, there is much here to be suspicious of from a cognitive perspective.

### Coupled Falling Bodies and the EPR Paradox

Back to thought experiments. Galileo's Coupled Falling Bodies is one of Brown's favorite examples of a platonic thought experiment, and is at the very least an impressive piece of reasoning. Aristotle held the view that heavier bodies must fall faster than lighter bodies. This has now been refuted experimentally - we know that on earth, when air friction is removed, bodies of different masses fall at the same rate of acceleration. But before Aristotle's view was empirically refuted, Galileo supposedly refuted it with an act of pure thought. He did so by asking us to consider a

cannon ball and a musket ball attached by a string and asking what will happen when this entire assembly is dropped from the top of a tower.

According to Galileo, Aristotle would be forced into a contradiction. On the one hand, the combined system of musket ball, cannon ball, and string is heavier than the cannon ball alone. Therefore, the whole should fall faster than its parts. On the other hand, the lighter musket ball would try to fall more slowly than the heavier cannon ball, and would act as a drag on the entire system. Therefore the assembly should fall slower than its heaviest component, the cannon ball. So we have a contradiction. If  $C$  is the falling rate of the cannon ball, and  $S$  is the falling rate of the combined system, then both  $S > C$  and  $S < C$  are true. So Aristotle must be wrong. But the whole problem goes away if we propose that everything falls at the same rate ( $S=C$ ). Brilliant. But what is justifying this line of reasoning?

The theory that is clearly on trial here is Aristotle's. But another theory is being brought to bear here as well - our folk theory (or theories) of how objects behave in the real world. To see this, we have to poke around for the assumptions Galileo makes. The celebrated contradiction is derived from two inferences. First, Galileo assumes that if Aristotle is right, then the whole assembly should fall faster than the cannon ball alone. Why? Because if you put the whole assembly on a scale, it would weigh more than the cannon ball. So far so good. The second inference is that the musket ball must act as drag on the cannon ball. But what justifies this inference? Why does the small ball retain its autonomy as a lightweight when it becomes part of a heavier whole?

The answer to the above seems to be that we just *know* that it does! Imagine holding the two balls attached with string. If you put the musket ball in your left hand, and the cannon ball in your right, with the string stretched between the two, you just *know* that your right arm will tire more quickly. Our folk theory of the world, based on real experience, says that parts of wholes can in some cases be experienced as if they were autonomous. It is this folk theory that justifies the crucial second inference and allows Galileo to complete the contradiction. But what if our folk theory had been wrong? What if, despite our shared experience with lifting assemblies of objects, such assemblies in free fall actually do behave as integrated wholes? Well then, Galileo's conclusion would have been wrong, too. The moral of the story is that looking past the first theory on trial to the second (in this case unarticulated) theory that it is confronting leads us away from the idea that Galileo actually proved something through pure thought, and towards the more productive idea that he demonstrated that two theories were at odds and therefore one of them had to be discarded in favour of the other. The obvious choice for most people was to let go of Aristotle.

Figure 1: The apparatus for the EPR Paradox thought experiment. Picture from [www.reed.edu/~rsavage/epr.html](http://www.reed.edu/~rsavage/epr.html)

The EPR Paradox<sup>2</sup> is another of Brown's favorite platonic thought experiments, although this is a slightly less impressive story because in the end the conclusion of the thought experiment was tested and refuted in a real experiment. The target of the EPR Paradox was Heisenberg's uncertainty principle in particular, and the Copenhagen interpretation of quantum mechanics in general. Heisenberg's uncertainty principle states that we can never know the complete trajectory of a quantum particle. "Trajectory" here means position plus momentum, where momentum is a vector that encodes mass, as well as direction and velocity. The problem is that in order to observe a quantum particle, we have to bounce another quantum particle off it, and this interaction will necessarily change one of the two aspects of its trajectory. The Copenhagen interpretation of this result stated that the indeterminacy existed not in our knowledge of reality, but in reality itself. That is, the trajectory of a quantum particle is not actually fully determined until it is observed.

Einstein, Podolsky and Rosen did not accept the Copenhagen interpretation - they believed that the theory was incomplete, not that reality was indeterminate. To prove their point, they published a 1935 *Physical Review* article in which they proposed the following thought experiment. Imagine two quantum particles that interact and then fly apart. We could later measure one of the particles for either momentum or position and automatically, through conservation laws, deduce the corresponding property in the other particle, even though the particles were far apart and could no longer interact. (Einstein et al., 1935)

The crucial step in the EPR reasoning was to notice that we could make *either* measurement of the first particle, and deduce the corresponding measurement of the second

<sup>2</sup> The name of this thought experiment is rather misleading. "EPR" stands for Einstein, Podolsky and Rosen, but don't expect to find an actual paradox anywhere.

particle. Since the two particles are now far apart, and could not be influencing each other, the second particle must have predetermined real values for both position and momentum. It must not be indeterminate with respect to any property. Einstein et al. were aware that they were making a crucial assumption here, namely that distant particles cannot influence each other. They named this the *locality assumption* and even went as far as to suggest that quantum mechanics be modified to include this assumption, thus making it a complete theory again. That is to say, they put the Copenhagen interpretation into the ring with another theory (one that Brown calls *local realism*). Once again, as seems to happen so often in successful thought experiments, the second theory accords well with our folk intuitions about the world - so much so that the EPR Paradox became a powerful tool for the anti-Copenhagen crowd. Unfortunately for them, John Bell in 1964 managed to derive a mathematical result that could be used to pit local realism against the Copenhagen interpretation in a *real* experiment, and local realism made the wrong prediction. (See Brown, 1991 and Bell, 1987)

The main point in all of this is that we get further in understanding these thought experiments if we always assume that two theories must be doing battle. Brown's Platonic view of what Galileo and Einstein et al. were up to does not help us to decide whether their conclusions were right or wrong. That is to say, the assumption that they were exploring abstract universals does not help us decide whether the particular universals they discovered correspond to the universals that happen to operate as natural laws. Furthermore, the Platonic view does not give us any real insight into what the thought experimenters were actually up to in either case. Specifically, there is nothing in the Platonic story to explain what justified Galileo's reasoning or why the EPR Paradox failed in the end. Platonism just doesn't buy us anything here. On the other hand, viewing their work through the lens of Dueling Theories forces us to make clear which theories were being tested, leading in the case of Coupled Falling Bodies to the exposure of an unstated piece of folk theory, and in the case of the EPR Paradox, to a simple account of why the result, which seemed so persuasive, did not stand up in a real experiment.

### Other Types of Thought Experiments

Although Brown focuses most of his attention on Platonic thought experiments, his taxonomy actually includes a number of other categories as well. Brown's full set of thought experiment categories is reproduced in Figure 2 below. Thought experiments are broken down into two main groups, *destructive* and *constructive*. Roughly speaking, constructive thought experiments build new theories, while destructive thought experiments invalidate old ones. Constructive thought experiments are further subdivided into *direct* (those that begin with common, unproblematic phenomena and end with a well articulated theory), *mediated* (those that start with a well articulated theory and

help to reach a new conclusion), and *conjectural* (those that start with conjectured, rather than common and unproblematic phenomena and end with a well articulated theory.) Platonic thought experiments, such as Coupled Falling Bodies and the EPR Paradox, are those that are both destructive *and* directly constructive. That is, they start from common, unproblematic phenomena and end in both the destruction of an old theory and the construction of a new one in it's place.

Figure 2: Brown's taxonomy of thought experiments. Adapted from (Brown, 1991)

Most of the examples Brown uses in any category are well accounted for by the Dueling Theories idea, but in some of Brown's examples, one has to dig a little deeper to get at the "other" theory involved. Perhaps the best example of this is Schrödinger's Cat, a destructive thought experiment aimed at the Copenhagen Interpretation of quantum mechanics (Schrödinger, 1935). In this experiment, a quantum event is amplified to have an effect on the macroscopic world - a cat in a box either dies or does not. The idea is that if the Copenhagen interpretation is correct, and reality is indeterminate, then the cat in the box is both alive and dead at the same time. The second theory coming into play here is just our deeply entrenched theory of the determinacy of the world around us. Calling us on this theory is a brilliant move, in which Schrödinger bets that scientists can accept quantum uncertainty only as long as they can cut it off from their folk intuitions about how the macroscopic world works - a sort of philosophical "not in my back yard" mentality.

The only problematic area for the Dueling Theories story is in Brown's "mediative constructive" category. Mediative experiments seem to play an articulatory role only. In these cases, a theory is already well established, and the thought experiment behaves like a diagram illustrating some particular, perhaps counter-intuitive, aspect of it. Most of the examples here are difficult to analyze for competing theories, but I suspect that is because they are not the same sort of thing as the thought experiments in the other categories. Consider one of Brown's examples - Maxwell's demon. One of the consequences of the theories Maxwell was developing was that heat could (with infinitely small probability) flow from a cold body to a hot body, rather than the other way around. This is, of course, wildly counter-intuitive. So Maxwell told a cute little story about a chamber

of hot gas molecules and another of cold gas molecules connected by a gate. A little demon controls the gate and only lets fast (hot) molecules enter the hot chamber and slow (cold) molecules enter the cold chamber. All this story really does for us is provide a framework for understanding a counter-intuitive theory. Maxwell was not trying to prove anything new, and as a result neither Brown's conception of thought experiments nor my own has much to say about his thought experiment. I suspect we would do much better to reclassify mediative thought experiments as "thought experimental illustrations" and leave it at that.

### Thought Experiments in Cognitive Science

The most famous thought experiments in the cognitive sciences are destructive in nature. This is true of both Putnam's Twin Earth experiment, in which the target is all non-reference-based theories of semantic content, and of Jackson's Mary the Colorblind Scientist experiment, in which the target is the scientific descriptibility of phenomenal experience. It is also true of Searle's (1980) Chinese Room, arguably the most famous thought experiment in cognitive science (practically talked to death in the last 20 years.) For reasons of space, I will apply the Dueling Theories analysis in detail only to Searle's experiment - I will not develop the analysis of Putnam or Jackson any further. I want to show: a) that the Dueling Theories analysis can be applied, and b) that it would lead Searle's opponents directly to a particular line of attack.

The theory that Searle is attempting to demolish with the Chinese Room is the "Strong AI" theory that a computer programmed to behave indistinguishably from a human who understands Chinese would *really understand* Chinese. The thought experiment works by trading on our strong folk intuition (i.e. theory) that a non-Chinese-speaking human taught to behave like [a computer programmed to behave indistinguishably from a human who understands Chinese] would *not really understand* Chinese. Laying out the two theories explicitly makes it easy to see that in order for them to be in conflict, the computer and the human must be equivalent in their ability to execute computer programs. But that would clearly not be the case in the real world. Computers are much better and faster at executing programs than humans. Therefore, Searle must have a fictional super-human in mind, which leads us to ask why we feel entitled to any a priori judgements about what such humans would or would not "understand" about the task they were performing. The Dueling Theories analysis thus leads directly to a productive line of attack on Searle - one that has, in fact, been pursued in the literature (Hofstadter and Dennett, 1982).

### The Empirical Basis of Thought Experiments

Brook's (1999) paper emphasizes a slightly different way of looking at thought experiments - one which seems at least partially at odds with Brown's conception, and which differs in emphasis from mine. He asks:

...are thought experiments also empirical, at least in part? Yes; they are merely a particular way of manipulating material stored in memory, material originally gained from experience. (p. 104)

Since the materials and at least most of the relationships of the imagined situation are derived from experience, thought experiments are thus a *kind* of empirical investigation. (p. 106, Brook's italics)

Two related questions lurk in the above. First, what is what the nature of the "material stored in memory", and second, what is the sense of "empirical" that Brook is employing?

Concerning the first question, it seems clear that the material referred to must not simply be memories of events that the thought experimenter has witnessed. If that were the case, then most observers would have no opinion about what might happen even in the somewhat ordinary situation imagined in the Coupled Falling Bodies experiment, to say nothing of the strange situations of the EPR Paradox, Twin Earth, Schrödinger's Cat, the Chinese Room, and Mary the Colorblind Scientist. The material stored in memory must have some kind of predictive power in order for it to be applied to the novel situation of a thought experiment. Therefore, it must consist of generalizations over past experience - that is, theories, folk or scientific, about the world.

Concerning the second question, the word "empirical" is a loaded one, and calling an activity empirical can have a number of different meanings. In the strongest sense, an empirical activity might consist of observing events in the world and carefully recording them for future use. But that is clearly not the sense being used here. In a weaker sense, an empirical activity might be any activity that takes into account memories of actually experienced events. But for reasons stated above, this cannot be the correct sense either - we could not perform thought experiments based solely on remembered events. But there is another sense in which an activity is empirical if it involves generalizations (theories) that were derived, at least in part, from actual empirical experiences. This must be closest to the sense that Brook has in mind, and it also fits reasonably well with the Dueling Theories idea.

Brook goes on to situate thought experiments within an abductive, Popperian view of scientific progress, pointing out that thought experiments have historically played a role on both sides of the generate and test paradigm. It is easy to see how hypothesis generation can be aided by thought experiments. As Brook notes, "hypothesis generation is pretty much a pure act of the imagination." As such, it's not hard to see that thought experimentation can help here. Lots of counterfactual "what ifs" are bound to be involved, each of which is likely to be a thought experiment. On the Dueling Theories account, a thought experiment can also help to crystallize a folk theory that previously went unnoticed. This is not exactly the same thing as generating a hypothesis, but for the purposes of scientific investigation, it

is the same thing - in order to test a theory, it must first be articulated and acknowledged.

Where I take some issue with Brook is concerning the role of thought experiments on the testing side of the generate and test paradigm. On the one hand, Brook makes the uncontroversial claim that thought experiments *have* historically played a role in testing hypotheses - the paradigm case being Galileo's rejection of Aristotelian physics based on the Coupled Falling Bodies experiment. Where Brook and I may part company is on the question of whether thought experiments *ought to* play such a strong role in testing hypotheses. Recall that on the Dueling Theories account, Galileo's thought experiment made use of an unarticulated folk theory of ordinary objects to make it's point. Hence, his conclusion should not have been that Aristotle's theory was ruled out as a possibility but that the theory ran afoul of some very ordinary intuitions about the world. This is a very important result in and of itself. It's just that the appropriate reaction was not for Galileo to smile triumphantly from his armchair, but for him to get up and figure out how to test the two theories with a *real* experiment.

The goal of Brook's treatment (and my own) is to see how much thought experiments can do for us in the cognitive sciences. Brook's emphasis on the empirical nature of thought experiments leads to the idea that they can in some cases stand in for real hypothesis testing.<sup>3</sup> What I hope to have shown with the Dueling Theories account is that the usefulness of thought experiments actually lies in their meta-level ability to test theories of the world against each other, and not in their ability to test the world directly. There are two further reasons why I would avoid using the term "empirical" to describe thought experiments - one technical and one psychological. The technical reason is that folk theories and intuitions may not need to be based on anything empirical at all. In fact, there are some thought experiments, such as Putnam's Twin Earth, Searle's Chinese Room, and even the EPR Paradox for which it is difficult to nail down exactly what the relevant empirical evidence supporting our intuitions actually is. For that reason, it's safer to view thought experiments as a theory evaluation activity and leave the question of the empirical nature of the theories under test open to be evaluated on a case by case basis. The psychological reason is that we might mistakenly encourage the idea that thought experiments are empirical in a stronger sense than what we really mean. And if we do that, we've done ourselves a disservice.

## Conclusion

If I am right, then thought experiments are best viewed as a picturesque arena in which two competing theories of the world do battle. Sometimes the Dueling Theories are explicitly stated ahead of time, but often one of the two

---

<sup>3</sup> From personal communication. Brook also discusses the use of thought experiments for the elimination of possibilities. This idea also relies on the characterization of thought experimentation as an empirical activity.

lurks in the background assumptions. In fact, what gives thought experiments such as Coupled Falling Bodies and the EPR Paradox their rhetorical power is precisely their accord with some of our most deeply entrenched folk theories of the world of middle-sized dry goods. Thought experiments are more useful if they clearly contain some kind of empirical material. This empirical material is not direct observation, but instead takes the form of predictions encoded by theories formed on the bases of empirical data. But this is not the same as saying that thought experiments can be empirical in the way that real experiments are. Despite their potential for polemical power, thought experiments can never actually tell us anything about the world. No thought experiment can ever be as good as the corresponding real experiment.

## Abstract

An objective scoring system has been developed to quantify degrees of auditory evoked potential (AEP) abnormalities in patients suffering from mild traumatic brain injury (mTBI). In this study the AEP P300 responses for 20 patients with scores in the abnormal range were compared to the responses in 20 age and gender equivalent controls. The cortical imaging technique (CIT) was used to calculate the evolution of potential changes on the surface of the brain during a 50-millisecond epoch containing the AEP P300 response for both groups of subjects. AEP P300 condition recordings were obtained from 20 EEG and 2 EOG artifact channels. Previously published CIT results showed anterior and posterior peaks, implying multiple sources, for the P300 component. This study suggests that the anterior sources are significantly attenuated in the patient group and this anterior P300 attenuation appeared relatively more focal than that seen with scalp topographical maps alone and that the effects of the injury appear to be selective at the anterior sites.

## Introduction

This study compares the auditory P300 evoked responses of a group of subjects who have suffered mild traumatic brain injuries (mTBI), with those of a group of age and gender matched normal controls. Analyses were conducted using the cortical imaging technique (CIT), a mathematical procedure for constructing activity as it theoretically would appear on the cortical surface. The goal is to detect subtle differences in the evoked response that are not apparent from the scalp recordings, and may suggest the intracerebral site of injury.

A growing body of radiological, neuropsychological, electrophysiological, neuropathological and experimental evidence indicates that mild brain injury may occur in the absence of direct impact to the head, and in cases where there is no loss of consciousness [Binder, 1986; Evans, 1992a,b]. MRI, CT, routine EEG and conventional evoked potential (EP) recordings are often unremarkable in these cases, yet the patients may have sequelae that affect professional functioning and activities of daily living for months or years.

Sequelae of mild traumatic brain injury (TBI) have been

thoroughly reviewed [Evans, 1992c]. The most common of these are headaches, dizziness, blurred vision (or other visual disturbances), memory impairment, attention/concentration difficulties, increased reaction and information processing times, and personality changes including increased irritability, anxiety and depression.

Ford and Khalil [1996a,b] have developed an objective scoring system for AEP, VEP and EEG findings from patients with suspected mTBI. In these studies, significant group differences were found between patients and controls, a relatively objective scoring system was developed, and the patterns were used to identify about 60% of the patients, with no false positives. The following analysis is limited to the auditory P300 response.

The auditory P300 component is one of the most investigated of all the cognition-driven evoked responses. It is a prominent, posterior vertex positive component, peaking at approximately 300-350 ms post-stimulus in response to randomly presented "oddball" stimuli that are **counted** or otherwise **identified by the subject**.

The generator sources of the auditory P300 component have been suggested in the hippocampus [Halgren et al., 1980; Wood et al, 1984; Neshige & Luders, 1992] and, possibly, with neocortical localization with deep frontal and thalamic contributions [Yingling & Hosobuchi, 1984; Wood et al., 1984; Neshige & Luders, 1992]. Recent work [Pilgreen, 1995; Gevins & Cutillo, 1995] expand on these earlier studies.

In this study we compared the auditory P300 responses of two groups - a patient group identified by the scoring system referred to above with a normal group of age and gender matched controls. The comparison was performed as follows: the potential field for each subject was approximated at the cortical surface using the cortical imaging technique [Sidman, 1991] for a 50 msec epoch extending from 25 msec prior to the latency of the maximum voltage at Pz (the P300 latency) to 25 msec after the maximum. The average normal response and the average abnormal response on the cortical

surface were calculated and compared using t-scores. The average normal response during the N2a/P300/N3 endogenous complex of responses to the rare "oddball" auditory stimulus has been discussed and analyzed in [Ford, Sidman & Ramsey, 1993].

### **Mathematical Analysis-The Cortical Imaging Technique (CIT)**

The mathematical method that was used to perform the analyses reported here is the cortical imaging technique [Sidman, 1991]. Briefly, this method is a way of simulating the potential field on the cortical surface, presumably closer to the actual generators of the scalp-recorded field.

### **Subjects and Measuring Procedure**

Twenty normal subjects and twenty mTBI patients (as identified in [Ford and Khalil, 1996a]) were included in this study. Twenty channels of EEG and two channels of EOG activity were recorded with a NeuroScience Brain Imager, Series III (for amplification and on-line filtering) and a NeuroScan, Inc. software based system using two Dell 433/L PCs (for stimulus presentation, A-to-D conversion, data recording and off-line baseline correction, filtering, artifact minimization, averaging and group statistics).

Electrode sites were the twenty standard International 10-20 system placements (FP1/2, F3/4, F7/8, T3/4, C3/4, T5/6, P3/4, O1/2, Fz, Cz, Pz and Oz), with a linked ear reference. Vertical and horizontal eyeball and eyelid movements (VEOG and HEOG) were also recorded for possible artifact rejection. The recording protocol for all subjects included both resting and P300 auditory.

In the AEP P300 recording, 165 total responses were recorded to the frequent tone (1kHz, 95dB, 50ms duration, binaural) and to the "oddball" or rare tone (2kHz, 95dB, 50ms duration, binaural). There was a variable inter stimulus interval of 1.9-2.1 secs. The probability of an "oddball" or rare tone occurrence was 20%, and the same sequence of frequent and rare stimuli was presented to all subjects. The subjects were instructed to count the rare tone silently to themselves, and their answers were recorded at the end of the session.

The low pass filter was set at 100Hz, high pass filter set at 1.05Hz, with the 60Hz notch filter activated. Sweeps were automatically rejected for artifact if the voltage in either VEOG or HEOG channels exceeded  $\pm 100 \mu\text{v}$ . Analog to digital processing was performed at 320 Hz yielding 256 points and an EP epoch from -100ms to 700ms (3.125ms resolution) for all EP recordings.

### **Results**

All of the mTBI patients (20) and all but one of the normal controls (19) exhibited a well defined AEP P300 component,

as identified by a distinct voltage maximum primarily at Pz. The standard deviation of the latencies was 25 ms. In each case scalp (Figure 1) and cortical surface (Figure 2) potential maps were constructed for the epoch extending from 25 ms (one standard deviation) prior to the latency of the peak to 25 ms after the peak. The time point  $t_0$  is the latency of the AEP P300, different for each individual, and pairs of consecutive time points are 3.125 ms apart. The evoked responses were aligned at time point  $t_0$  for each group of subjects to obtain the average normal response and average patient response for 50 ms (see [Ford, Sidman & Ramsey, 1993]), on the scalp (Figure 1) and cortical surface (Figure 2). The SURFER® software was used throughout for making the graphical displays. The right-most column of pictures for each figure compares the two sequences of pictures by plotting the t-scores (degrees of freedom = 37) at each of the 20 scalp sites, for Figure 1, and for 160 cortical surface sites, for Figure 2.

Ford et al., 1993 [Ford, Sidman & Ramsey, 1993], contains a similar analysis for the entire ~250 ms epoch containing the N2a/P300/N3 complex of responses for normal subjects.

T-score differences between groups show significant attenuation in the patient group at time points leading into and including the P300 component peak, but not afterward. The differences were significant at the anterior source only.

### **Conclusions**

Scalp topography of the auditory P300 component typically shows the peak amplitude at posterior vertex area sites, with no strong indication of more than one generator site. In previous studies with CIT, using 28 channel data [Ford, Sidman & Ramsey, 1993], we have demonstrated that there are several apparent sources in normals, including an anterior one and symmetric, bilaterally homologous, centro-parietal sources. In another previous study, we found that individuals with histories and symptoms consistent with mild TBI showed attenuation of the scalp-recorded auditory (and visual) P300 component, with significant differences spread widely across all anterior sites. The primary purpose of the present study was to analyze the P300 recordings from the mild TBI cases using CIT to determine whether CIT was more sensitive in identifying group differences.

The results of the P300 scalp recordings from both groups showed the expected P300 peak in the area of Pz, with no anterior source indicated. Statistical differences between groups were negligible. CIT analyses of the recordings in both groups showed two clear sources - including one from Fz and the surrounding area. When compared statistically, the differences between groups were significant at the anterior - but not posterior - source. These results indicate that whatever injury is present in these cases differentially affects the anterior source contributing to the generation of the P300 component, while the posterior source remains unaffected.

Although it is not possible to determine the exact mechanism nor locus of injury, based upon the analysis of 20-channel scalp-recorded EP data, the results are not inconsistent with other reports of abnormal findings involving anterior or subcortical regions. (Parenthetically, the availability of 128- and 256-channel recordings may make the elucidation of the mechanism involved possible.) The purpose of the study was to determine whether CIT analyses provided additional information beyond that obtained from scalp recordings, and the results suggest a focal effect at the anterior midline area, thus suggesting subcortical involvement, since the differences from adjacent areas over frontal cortex were not significant.

In summary, the P300 has been shown to have significant amplitude attenuation and/or latency increases in association with a host of clinical disorders and conditions, including schizophrenia, dementia, alcoholism, brain injury, and some instances of learning disability, to name a few. The typical scalp recorded P300 waveform shows amplitude attenuation and/or latency increases across diagnostic groupings, and is thus concluded to be a nonspecific indicator of dysfunction. However, further analyses using analytical techniques such as CIT may ultimately show differential effects on the generator sources for the P300 component among groups, thereby yielding information that is valuable in understanding the underlying processes involved.

# What are fallacies good for? Representational speed-up in propositional reasoning

Vladimir M. Sloutsky (sloutsky.1@osu.edu)

School of Teaching & Learning & Center for Cognitive Science, The Ohio State University  
21 Page Hall, 1810 College Road, Columbus, OH 43210, USA

## Abstract

Two experiments examine speed-up in argument pairs of various propositional forms. In the first experiment, participants were presented with pairs of conditional arguments. Some of these pairs had a form of a valid Modus Ponens (MP) inference, whereas other pairs had a form of a fallacy of Affirming the Consequent (AC). In both argument pairs, presentation of the prime led to a significant speed-up in the probe argument. In the second experiment, in addition to AC-AC and MP-MP pairs, AC-MP and MP-AC pairs were also included. Results indicated that AC primes led to a speed-up of MP probes, and MP primes led to a speed-up in AC probes. The results are discussed in relation to theories of propositional reasoning.

## Introduction

The ability to reason deriving conclusions from available information is an integral aspect of human cognition. A large component of this ability is propositional reasoning, or reasoning with logical connectives AND, OR, IF...THEN, and NOT. There are two major theoretical approaches to propositional reasoning, the syntactic approach and the semantics approach. According to the former, reasoners extract the syntactic form of the argument and apply certain formal rules of inference, or inferential schemata, to the extracted form (Braine & O'Brien, 1991; Rips, 1994). For example, reasoners easily conclude that *B* is the case, using the modus ponens (MP) schema, when presented with the following premises:

$A \rightarrow B$  (If *A* then *B*)

*A*.

The syntactic approach thus hinges on assumptions that reasoners (a) veridically represent information in the premises and (b) automatically apply inferential schemata to these representations.

According to the semantic approach, the untrained mind is not equipped with formal rules of inference. Furthermore, reasoning, to a large extent, is a function of representations of information in the premises. In turn, these representations are not veridical but are often incomplete or defective (Johnson-Laird & Byrne, 1991; Evans & Over, 1996; Sloutsky & Goladvarg, 1999; Sloutsky, Rader, & Morris, 1998).

One of the semantic theories of propositional reasoning, the Mental Model Theory (Johnson-Laird & Byrne, 1991) suggests that inferences, such as considered above, occur in the following manner. First, the reasoner constructs the initial representation of the premises:

First premise	Second premise
$A \quad B$	$A$
...	

The first line in the leftmost column makes explicit the possibility in which both *A* and *B* co-occur, and the second model (ellipses) corresponds to those possibilities in which the antecedent of the conditional is false. The theory accordingly assumes that individuals do not normally make these possibilities explicit (Johnson-Laird & Byrne, 1991). The line in the rightmost column represents the second premise. Combining the two models together leads to the inference that *B*.

There is a plethora of empirical studies contrasting predictions stemming from the two approaches. One major result of these comparisons is that the Mental Model Theory is capable of accounting for a variety of systematic errors observed in reasoning (Johnson-Laird & Savary, 1999; Newsome & Johnson-Laird, 1996; Sloutsky & Johnson-Laird, 1999; Yang & Johnson-Laird, in press; see also Johnson-Laird, 1999; Johnson-Laird & Byrne, 1991, for reviews). One of these errors accounted for by the Mental Model Theory is the fallacy of Affirming the Consequent (AC). AC has the following form:

$A \rightarrow B$

*B*.

Therefore *A*.

The inference is a fallacy because there is nothing in the argument suggesting that *B* could not occur without *A*. The mental model explanation of this fallacy is that initial representations of MP arguments and AC arguments are identical. As a result, people tend to draw conclusions, both when presented with valid MP arguments and invalid AC arguments.

This paper offers a further examination this issue. If inferences in Modus Ponens arguments occur due to the MP schema, as specified by the syntactic approach, then the use of the schema should lead to a speed-up in subsequent applications of the schema (see Smith, Langston, & Nisbett, 1992). At the same time, inferring conclusions from AC arguments should not lead to a speed-up in MP arguments, because there is no schema for AC. However, if people reason from mental representations, as according to the semantic approach, then arguments that have identical mental representations should speed up each other. We therefore, predicted that (1) AC arguments should speed-up AC arguments and (2) MP arguments should speed-up MP

arguments. We further predicted that (3) AC arguments should speed-up MP arguments and (4) MP arguments should speed-up AC arguments. The first two hypotheses were tested in Experiment 1, whereas the last two were tested in Experiment 2.

There was also a critical point added to Experiment 1. According to the syntactic theory of mental logic (Braine & O'Brien, 1998), conjunctive arguments (CONJ) of the form *A* & *B* could be simplified using conjunction elimination schema of the form:

*A* & *B*

Therefore *A*.

On the other hand, the semantic theory of mental models

suggests that conjunctions have similar (although not identical) representations as conditionals. Therefore, an important question is whether or not conjunctive arguments can also be speeded up by subsequent use. There is evidence that during text comprehension, conjunctions do not result in automatic, on-line inferences, whereas conditionals do (Gernsbacher, 1997; Millis, Golding, & Barker, 1995). The importance of this question is that, if hypotheses are confirmed, the examination of conjunctive arguments will allow us to assess the generality of findings: whether all forms that have similar representations prime each other, or if priming is limited to If...Then forms only.

Table 1: Sample stimuli by argument type and prime type.

Prime Type	Argument Type		
	MP	CONJ	AC
Related Prime (select a conclusion)	If there is an Ace then there is a Jack. There is an Ace. <ul style="list-style-type: none"> <li>• No conclusion follows</li> <li>• There is a Jack</li> <li>• There is no Jack</li> <li>• There is a Two</li> </ul>	There is an Ace and there is a Jack. There is an Ace. <ul style="list-style-type: none"> <li>• No conclusion follows</li> <li>• There is a Jack</li> <li>• There is no Jack</li> <li>• There is a Two</li> </ul>	If there is an Ace then there is a Jack. There is a Jack. <ul style="list-style-type: none"> <li>• No conclusion follows</li> <li>• There is an Ace</li> <li>• There is no Ace</li> <li>• There is a Two</li> </ul>
Unrelated Prime (select a conclusion)	There is a Three or there is a Seven, but not both. There is a Three <ul style="list-style-type: none"> <li>• No conclusion follows</li> <li>• There is a Seven</li> <li>• There is no Seven</li> <li>• There is a Jack</li> </ul>	There is a Three or there is a Seven, but not both. There is a Three <ul style="list-style-type: none"> <li>• No conclusion follows</li> <li>• There is a Seven</li> <li>• There is no Seven</li> <li>• There is a Jack</li> </ul>	There is a Three or there is a Seven, but not both. There is a Three <ul style="list-style-type: none"> <li>• No conclusion follows</li> <li>• There is a Seven</li> <li>• There is no Seven</li> <li>• There is a Jack</li> </ul>
Probe (answer Yes or No)	If there is a Queen then there is a Six. There is a Queen. <ul style="list-style-type: none"> <li>• There is a Six</li> </ul>	If there is a Queen then there is a Six. There is a Six. <ul style="list-style-type: none"> <li>• There is a Queen</li> </ul>	There is a Queen and there is a Six. There is a Queen. <ul style="list-style-type: none"> <li>• There is a Six</li> </ul>

## Experiment 1

The first goal of this experiment was to test hypotheses 1 and 2, suggesting that there is AC-AC and MP-MP priming. The second goal was to examine whether or not there is priming of conjunctive arguments.

### Method

**Participants** A total of 86 participants from Ohio State University took part in the experiment for an introductory psychology course credit. These participants represented three groups, with each group receiving a particular argument type. There were 31 participants in the Modus Ponens (MP) group, 29 participants in the Conjunction group (CONJ) and 26 participants in the Affirmation of Consequent (AC) group. All participants were fluent English speakers.

**Materials** In each of the three groups, stimuli considered of 60 critical items and 120 filler items. Critical items consisted of 30 prime-probe pairs. Half of primes had the same argument form as probes, whereas another half of the primes had a different argument form. Examples of stimuli for each of

the group are presented in Table 1. Filler items consisted of primes and probes that were similar to those in the Table, except that they had a different logical form. Primes had a form of inclusive OR (e.g., There is a Joker or an Ace, or both), whereas probes had a form of exclusive or (There is a Joker or an Ace, but not both). Participants were randomly assigned to one of the three groups.

**Design and Procedure** The experiment had a 3 Argument Type (AC, MP, CONJ) by 2 Prime Type (Related, Unrelated) mixed design with Prime Type as a repeated measure. Stimuli were presented on a PC screen and controlled by Superlab Pro for Windows (Cedrus Corporation, 1997). Participants were tested individually. Participants were told that they would read arguments on the computer. They were further told that sometimes they would need to select a conclusion from a set of conclusions, and sometimes to determine whether or not a conclusion follows logically from the premises by answering either Yes (follows) or No (does not follow). Participants were asked to respond as quickly and accurately as possible. Then they were given examples of conclusions that do and do not follow logically from premises accompanied with explanations. Finally, they were

presented with four practice trials, two of which included selecting a conclusion from a list, and another two included a Yes/No response. These practice trials were accompanied by feedback, such that participants were told whether or not their inference was warranted and why. After finishing the practice trials, participants were presented with experimental trials. Each participant received 30 experimental items (60 arguments) and 60 filler items (120 arguments) with a total of 180 arguments. Participants read each argument in self-paced fashion. Once the argument that served as a prime was answered, a probe argument appeared on the screen. Argument pairs were separated by 300 ms interstimuli intervals. The experiment took approximately 40 minutes.

## Results and Discussion

In all reported analyses, degrees of freedom are based on subjects \* item variability. Accuracy by argument and prime type are presented in Table 2 and response times are presented in Figure 1. For AC arguments accuracy was below chance  $t(389) < -7, p < .0001$ , two-tailed. For MP and CONJ arguments, accuracy was above chance  $ts(389) > 7, p < .0001$ , two-tailed. Because comparisons of response times across between-subject conditions could be misleading, we perform only comparisons across within-subject conditions. For CONJ condition, there were no significant differences in responses to the probe questions between related and unrelated primes. In fact, unrelated primes resulted in slightly (but not significantly) faster responses than related primes. At the same time, in the AC condition,  $t(353) = 3.5, p < .0001$  and MP condition,  $t(425) = 3.8, p < .0001$ , related primes resulted in a significant speed-up of responses to the probe questions. These data indicate that while there was no speed-up in the CONJ condition, both AC and MP arguments were speeded-up by more 500 ms when preceded by a related prime. Having established that responses to both AC and MP arguments could be speeded up by a related prime, we deemed it necessary to answer another question: what constitutes a related prime? According to syntactic theories of reasoning, related prime would be the one that is based on the same inference rule. However, syntactic theories do not posit a rule for AC inferences. In accordance with the semantic approach, we hypothesized that the prime is related whenever it has a identical mental representation with the probe. For example, according to the Mental Model Theory, AC and MP have identical mental representations. In this case, both an AC prime should speed up both AC and MP probes, and MP prime should speed up AC and MP probes. This prediction was tested in Experiment 2. Note, that there was not priming in CONJ-CONJ pairs; this issue will be addressed in the General Discussion section.

Table 2: Percent of accurate responses by argument type and prime type.

Argument Type	Prime Type	
	Related	Unrelated
AC	32.80	31.28
MP	95.90	92.20
CONJ	68.50	68.00

Figure 1: Response times by argument type and prime type. Error bars represent standard errors of the mean

## Experiment 2

Experiment 2 differs from Experiment 1 in two respects. First, in Experiment 2, both types of argument and types of prime varied within subjects. Each participant received two types of arguments (AC and MP) and three types of prime (AC, MP, and XOR, which was considered unrelated). Types of argument were fully crossed with types of prime. Second, because there was no CONJ-CONJ speed-up, conjunctive arguments were eliminated.

## Method

**Participants** A total of 26 participants from Ohio State University took part in the experiment for an introductory psychology course credit. All participants were fluent English speakers.

**Materials & Procedure** The experiment had a 3 Argument Type (AC, MP) by 3 Prime Type (AC, MP, XOR) within-subject design. The experimental procedure was identical to that of the first experiment, except that the total number of items in the current experiment was 240. The experiment took approximately 55 minutes.

## Results and Discussion

As in the previous experiment, degrees of freedom are based on subjects \* item variability. Accuracy rates by argument and prime type are presented in Table 3. These rates were subjected to one-sample t-tests. The analyses indicate that for AC arguments accuracy was below chance,

$t < -7$ ,  $p < .0001$ , whereas for MP argument accuracy was above chance  $ts > 7$ ,  $ps < .0001$ . Figure 2 presents relative speed-up for prime-probe pairs; estimates for relative speed-up were derived as  $RT_{\text{unrelated prime}} - RT_{\text{related prime}}$ . Speed-up rates presented in Figure 2 were subjected to one-sample t-tests. Recall that it was predicted that for both types of arguments, MP and AC primes should lead to a speed-up above XOR primes that were considered unrelated. As depicted in Figure 2, all "related" primes resulted in a speed-up. Speed-up, however, did not reach significance above 0 for AC-MP pairs, while it was significantly above 0 for the other prime-probe pairs  $ts > 2$ ,  $ps < .05$ . Speed-up effects presented in Figure 2 were also subjected to a repeated measures ANOVA. The analysis reveal no overall differences between different prime-probe pairs,  $F(3, 320) = 2.13, p = .1$ .

These findings are consistent with predictions that speed-up occurs due to a common mental representation. Note that even though speed-up in the AC-MP pair did not reach significance, the difference between XOR-MP pairs and AC-MP pairs was in the predicted direction.

Table 3: Percent of accurate responses by argument type and prime type

Prime Type	Argument Type	
	AC	MP
AC	39.74	95.64
MP	39.75	98.21
XOR	39.49	97.69

Figure 2: Relative speed-up by prime-probe pairs. Error bars represent standard errors of the mean.

## General Discussion

The results of the two reported experiments indicate that both MP and AC arguments speed-up each other. These findings support predictions that priming could be due to a common mental representation rather than due to a common syntactic rule. Indeed, what do AC and MP arguments have

in common? First, they have the common linguistic form "If...then," and second, they have a similar mental representation. It seems more likely that the observed speed-up is due to the similarity of mental representation rather than due to the similarity of linguistic form. This suggestion is based on indirect evidence (e.g., Lea, 1995; Rader & Sloutsky, 2000) that when inference in the priming argument is blocked (e.g., *If there is an Ace then there is a King. I really need an Ace.*), priming does not occur.

It also seems important that there was no speed-up in CONJ-CONJ pairs, even though these arguments have identical linguistic form and identical representation. One important difference of conjunctive arguments is that, unlike conditionals, conjunctions do not lead to an automatic, on-line inference (Gernsbacher, 1997; Millis, Golding, & Barker, 1995). Taken together, these findings suggest that the identical mental representation is not sufficient for priming; only those forms exhibit speed-up that (a) have the identical mental representation and (b) lead to an automatic inference. Furthermore, priming effects occur in both valid (MP) and invalid (AC) conditional arguments.

One finding that deviates from predictions is that in the Experiment 2, where argument forms varied within subjects, AC-MP pairs resulted in a smaller speed-up than AC-AC, MP-AC, and MP-MP pairs. Recall that in the Experiment 1, where argument forms varied across subjects, both AC-AC and MP-MP pairs resulted in a comparable (approximately 500 ms) speed-up. Taken together, results of the two experiments suggest that the presence of MP arguments may lead participants to consider AC arguments as invalid arguments (after all the participants are college undergraduates who may be familiar with basic principles of logic). This consideration did not lead to an increase in accuracy, but could have slowed down their responses.

There are several issues that are to be tested in future research. In particular, it could be predicted that strengthening of the associative link between the antecedent and the consequent in the AC argument (*If it flies then it is a bird. It is a bird.*) should result in an increase in the speed-up in AC-AC pairs. This is because when the antecedent and the consequent are highly associated, people are less likely to notice that the inference is invalid (Markovits, 1993; Markovits, Fleury, Quinn, & Venet, 1998). Alternatively, weakening of the associative link between the antecedent and the consequent in the AC argument (*If you throw a watermelon to the window, the window breaks. The window is broken.*) should result in a decrease in the speed-up in AC-AC pairs.

While these possibilities will be tested in further experiments, results of the current experiments seem to indicate that independently of the validity, MP and AC conditional arguments tend to speed-up each other. This finding seems to support the idea that those arguments that share mental representation and lead to an automatic, on-line inference are likely to get primed by each other independently of their validity.

## Abstract

The paper compares predictions derived from the similarity-based and the theory-based accounts of young children's induction. The former predicts the primacy of induction from one single entity to another single entity (one-to-one induction), whereas the latter does not predict such primacy. Predictions were tested in three experiments where 4-5 year-olds and 11-12 year-olds were asked to perform inductive generalization of biological properties. Participants could generalize properties either from a single animal to another single animal (one-to-one induction) or from a group of animals to a single animal (many-to-one induction). Experiments 1 and 2 revealed that under various stimuli presentation conditions, young children exhibited a strong preference of one-to-one induction, performing generalizations in a similarity-based manner. At the same time, preadolescents exhibited a strong preference of many-to-one induction, performing generalizations in a theory-based manner. In Experiment 3, an alternative explanation that one-to-one induction stems from a tendency to match quantifiers or label endings was tested and eliminated. Results are discussed in relation to cognitive and developmental aspects of inductive inference.

## Introduction

Inductive generalization is prominently present both in low-level processes, such as sensation and perception, and in high-level processes, such as learning and transfer, categorization, analogy, rule discovery, and inductive inference (see Shepard, 1987, for a discussion). Inductive generalization involves at least two stimuli (or stimuli sets): the source and the target of generalization.

One issue that has been hotly debated is what aspects of the source and the target support inductive inference. One possibility that has been extensively discussed in the literature is that inductive generalizations are driven by similarity construed as featural overlap between the source and the target (see Estes, 1994; Medin, 1975; Nosofsky, 1986; Shepard, 1987; Tversky, 1977, for specific models of computing similarity). In this case, the more similar the source and the target, the more likely there will be generalization from the source to the target (see Medin & Smith, 1984; E. Smith, 1995; L. Smith, 1989 for discussions).

However, it has been counter argued that similarity construed this way does not sufficiently constrain

generalization processes (see Carey, 1985; Keil, 1989; 1994; Medin et al., 1993, for discussions). For example, there are many more overlapping features between a live monkey and a mechanical monkey than between the live monkey and a worm. However, people deem it more appropriate to generalize biological properties from a live monkey to a worm than to generalize biological properties from the live monkey to a mechanical monkey (Carey, 1985). Therefore, not all featural overlaps are equally important. Somehow people intuitively realize that it is appropriate to generalize certain biological properties from Elephant to Hippopotamus (as they both are mammals) and it is inappropriate to generalize these properties from Elephant to Paris (as they both are smaller than China). Hence, it has been argued that generalization must be constrained by some deep "theoretical" beliefs that could not be reduced to simple featural similarity. Proponents of this view have suggested that generalization processes are constrained by a set of core beliefs about the "essence" of a category. Those entities that have common "essential" properties (e.g., the same biological origins) should be also considered as members of a common group. Those biological properties that stem from the essence (and therefore from the common membership) could be legitimately generalized from one entity onto the whole group and subsequently to each member of this group (Murphy & Medin, 1985; Gelman & Coley, 1991; Gelman & Wellman, 1991; Keil, 1994).

In this paper we attempt to derive predictions from these positions and to empirically test these predictions. Inductive generalizations can be performed over individual entities (e.g., This dog has property X, therefore that dog has property X) or over classes (e.g., Dogs have property X, therefore cats have property X). Quantification of the source and the target define several types of induction. The current research focuses on two of these types of induction over individual entities, one-to-one induction and many-to-one induction. In the case of one-to-one induction, attributes or relations could be generalized from one single entity to another single entity (e.g., This sparrow has biological property X, therefore that sparrow has biological property X). In the case of many-to-one induction, attributes or relations could be generalized from a group of entities to a single entity (e.g., Sparrows have biological property X, therefore this sparrow has biological property X). Note that induction could be also performed strictly over classes (see

Osherson, Smith, Wilkie, Lopez, & Shafir, 1990, for a discussion of induction over classes).

The distinction between the two types of induction affords deriving specific and testable predictions from each of the above mentioned positions. If induction in young children is similarity-based, there should be primacy of one-to-one induction over many-to-one induction, whereas if induction is category-based, there should not be such primacy. As shown below, each prediction follows directly from the respective position.

Proponents of the similarity-based position have argued that induction in young children is not category-based, and that both induction and categorization are products of featural similarity between compared stimuli (Sloutsky & Lo, 1999). They have also suggested that (a) different attributes and attribute dimensions have different weights in the computation of similarity, (b) young children consider linguistic labels as attributes with greater weights than other attributes (Sloutsky & Lo, 1999). Finally, according to the similarity-based approach, when entities are novel, computation of similarity between two single novel entities should be simpler than computation of similarity between many novel entities and one novel entity. This is because it is possible to directly compute similarity between single entities, whereas computation of similarity between a group and a single entity is difficult. The latter requires one first to construe a composite representation of the group and then to compute similarity between the single entity and the group. Note that the argument may not apply to familiar entities, for which a composite representation had been established (see Estes, 1994, for a discussion). Therefore, if induction is a function of overall similarity, one-to-one induction should be easier for young children than many-to-one induction.

Recall that according to the theory-based approach, young children have abstract representations of categories, such as biological kinds. When an entity is familiar, it is represented as a member of a familiar category, whereas when an entity is novel, it is represented as a member of a novel category. These novel categories are devoid of representational specifics; they rather exist as category "templates" or "placeholders" (see Gelman, Coley, & Gottfried, 1994; Gelman & Coley, 1991 for discussions), and linguistic labels point to this category placeholder. When a perceptual input indicates that compared novel entities are animals, a set of beliefs about "natural kinds" is activated. These include beliefs about growth, inheritance, reproduction, self-generated movement, and so forth (Gelman, Coley, & Gottfried, 1994). These beliefs in conjunction with the common category membership suggest that both entities belong to the same natural kind, and, therefore, they should share unobservable biological properties (Murphy & Medin, 1985; Gelman & Coley, 1991; Keil, 1994). Thus, according to the theory-based explanation, induction is category-based (i.e., it is a function of categorization) (Gelman & Coley, 1991), and the process underlying induction should be as follows. (1) The description of a single entity or multiple entities (e.g., This Gubla has biological property X or These Gublas have

biological property X) activates the essence placeholder "GUBLA." (2) Other members of the category GUBLA (this membership is denoted by the linguistic label) should have biological property X. (3) As indicated by the common label, this GUBLA is a member of the category GUBLA (or these Gublas are members of the category GUBLA), and therefore, it (or they) should have biological property X. Therefore, because both one-to-one and many-to-one induction follows from the category membership, there should be no primacy of one-to-one induction over many-to-one induction.

To test predictions derived from both approaches, we developed the following task. Suppose that the child is presented with a set of realistically looking novel animals having novel labels (e.g., "Look, these are Gublas"). Then, one Gubla is presented as a Target, another Gubla is presented as Test 1 and the rest of Gublas are presented as Test 2. The child is also told that this Gubla (Test 1) has biological property X, whereas these Gublas (Test 2) have biological property Y. Does the Target Gubla have biological property X or Y?

The putative processes that, according to each model, underlie the child's inference are as follows. According to the theory-based approach, the encounter with a group of novel biological objects that have the same linguistic label (i.e. Gubla) should activate the category placeholder GUBLA. Once the category is activated, the child should be equally likely to generalize from Test 1 (one Gubla) or from Test 2 (many Gublas) to the Target. On the basis of the theory-based approach, it should be inferred that in the task like this, young children should be at chance, or have a slight preference for many-to-one over one-to-one induction. The slight preference might stem from the fact that many identically looking Gublas should be more representative of the category than a single Gubla. Furthermore, normatively it is more appropriate to generalize from many Gublas than from a single Gubla, because a single entity is more likely to be an exception than many entities. Of course, we should not expect many young children to take into account this consideration, therefore, if any, only a small many-to-one preference should be predicted.

The similarity-based approach yields different predictions. As described above, all other things being equal, the computation of similarity between two entities should be simpler than computation of similarity between many entities and one entity. In addition, because similarity between two identical entities is the unity (Estes, 1994; Medin, 1975; Sloutsky & Lo, 1999), this similarity could not be less than similarity between several entities and one entity. Therefore, similarity between the Test Gubla and the Target Gubla should be no less than similarity between Test Gublas and the Target Gubla, and the former should be more easily computed. Based on these considerations, the similarity-based approach predicts a large preference of one-to-one induction over many-to-one induction.

These considerations led us to formulation of the following specific predictions. If young children base their induction on similarity between compared entities, they should generalize from a single Gubla to another single Gubla more often than chance. At the same time, according

to the theory-based account, young children should perform at chance (or with a slight preference of many-to-one induction).

## Experiment 1

### Method

**Participants** Participants were 31 children aged 4 to 12 years. The first group consisted of 16 four-to-five-year-old children enrolled in two daycare centers in an upper middle class suburb of Columbus, Ohio ( $M = 4.5$  years,  $SD = 0.6$  years, 11 boys and 5 girls). The second group consisted of 15 eleven-to-twelve year-olds selected from a public middle school located in an upper middle class suburb of Columbus, Ohio ( $M = 11.7$  years,  $SD = .31$  years, 8 girls and 7 boys).

**Materials** Eight sets of line-drawing pictures were used in the present experiment. Each set consisted of two single pictures and a stack of pictures (see Figure 1), with each picture measuring approximately 3" by 5". Both single pictures depicted realistically looking animals, whereas the stack was turned faced down such that pictures in the stack were not visible. The Target (a single picture) looked identical to Test 1. Materials also included artificial labels and a set of biological properties. The animals presented in each set of pictures were given the same artificial label (e.g., a Gubla). Children were taught that each of the Test stimuli had a particular biological property (e.g., has salt inside the body or has sugar inside the body). The task consisted of generalization of biological properties from one of the Test stimuli to the Target. The experiment had a between-subject design with age as a factor. The dependent variable of interest was the proportion of inductive generalizations from each of the Test stimuli, either one-to-one induction (choosing Test 1) or many-to-one induction (choosing Test 2). Each participant received eight trials.

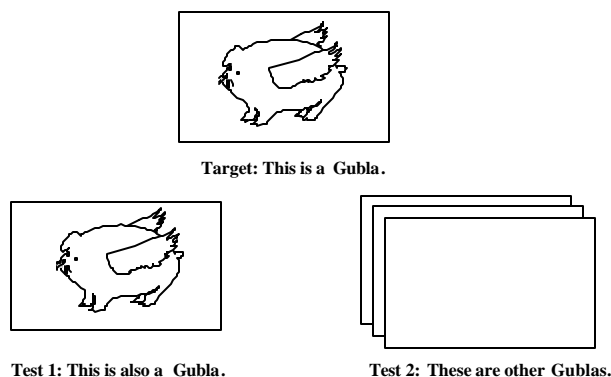

Figure 1: Layout of stimuli in Experiment 1.

**Design and Procedure** The experiment was conducted in a single 15-20 minute session that included three phases: stimuli presentation, comprehension/memory check, and inductive inference. Each participant was tested individually in a separate room at their daycare center or school.

**Stimuli presentation.** Each participant was presented with eight stimuli triads, one triad at a time. Each triad was

referred to using a two-syllable artificial linguistic label and was introduced as a group of animals (e.g., I will show you several Famos). The experimenter then presented participants with three stimulus items: (a) a single card depicting a single animal (the Target), (b) another single card depicting another single animal (Test stimulus 1), and (c) a stack of cards that were face down (Test stimulus 2). At this point, participants were asked to repeat the label. After presenting the stimuli items, the experimenter introduced two biological properties, one characterizing Test 1, and another characterizing Test 2 (e.g., This Famo has a lot of sugar inside the body. These Famos have a lot of salt inside their bodies). The order of presentation of the Test stimuli, their positions relative to the Target, and the order of introduction of biological properties were counterbalanced across trials. Stimuli items were randomly paired with biological properties.

**Comprehension/memory check and inductive inference phases.** After the stimuli items were presented, participants were asked to repeat the labels and biological properties. The labels and biological properties were reintroduced when participants failed to answer correctly. All participants successfully completed this comprehension/memory check phase. After repeating the labels and biological properties, children moved to the inductive inference phase, in which participants were asked which of the two biological properties was likely to be shared by the Target.

### Results and Discussion

In this section, we present proportions of generalizing from each of the Test stimuli across the two age groups. Results of this experiment are presented in Figure 2.

Figure 2: Proportions of one-to-one and many-to-one generalizations by age. Note: \*\* above chance,  $p < .0001$ ; \* below chance,  $p < .0001$ .

To determine the difference from chance, these results were subjected to one-sample t-tests. The analysis indicates that while 4-5 year-olds generalized from Test 1 (one animal) to the Target significantly above chance (81% of all responses),  $t(15) = 11.2$ ,  $p < .0001$ , 11-12 year olds generalized from Test 2 (many animals) to the Target,

significantly above chance (93% of all responses),  $t(14) = 9.4$ ,  $p < .0001$ . Percentages of one-one choices and percentages of many-one choices (both aggregated across the 8 trials) were subjected to a one-way ANOVA with age as a factor. The analyses indicate that 4-5 year-olds were significantly more likely to generalize from Test 1 (one animal) to the Target than 11-12 year-olds, whereas 11-12 year-olds were significantly more likely to generalize from Test 2 (many animals) to the Target than 4-5 year-olds,  $F_s(1, 29) > 97.1$ ,  $p_s < .0001$ . In addition, 10 out of 14 preadolescents explicitly pointed that the Target is more likely to share properties with a larger group of animals than with a single animal.

These results support our predictions describing inductive generalizations of young children and point to important differences in inductive generalizations of 4-5 year-olds and 11-12 year olds. While preadolescents' inductive generalizations conform to what should be expected when induction is category-based (they did in fact generalize in a category-based manner, thus both supporting predictions and validating the task), young children's inductive generalizations conform to what should be expected when induction is similarity-based. This experiment, however, constitutes a rigorous test of whether participants performed category-based induction, and a not so rigorous test of whether participants performed similarity-based induction. This is because one-to-one induction was supported by a picture, whereas many-to-one was not (see Figure 1).

Therefore, reported findings are indicative of the category-based induction of 11-12 year-olds, whereas they are ambiguous with respect to induction of 4-5 year-olds. Indeed, generalization in the latter group could point either to the primacy of one-to-one induction or to the preference of young children of depicted stimuli over non-depicted stimuli. Although such preference in itself might be indicative of similarity-based induction (indeed, category placeholders are not accompanied by pictures), we deemed it necessary to conduct a more rigorous testing of predictions generated by the similarity-based model. To this end, we conducted Experiment 2, where both Test 1 and Test 2 were both accompanied by pictures (Condition 1) or both were presented without pictures (Condition 2).

## Experiment 2

### Method

**Participants** A group of 30 children aged 4 to 5 years participated in the two conditions. These children were selected from daycare centers in an upper middle class suburb of Columbus, Ohio on the basis of permission slips returned by parents. The No-Picture condition group of 15 children consisted of 7 boys and 8 girls ( $M = 4.4$  years,  $SD = 0.48$  years). The Picture condition group of 15 children consisted of 9 boys and 6 girls ( $M = 4.4$  years,  $SD = 0.39$  years).

**Materials, design, and procedure** Materials, design, and procedure were identical to those in Experiment 1. The only

differences were that the design included an additional between-subject factor, the picture presentation condition that had two levels, Picture and No-Picture conditions, and that pictures were presented differently from those in Experiment 1. In the Picture condition, both Test stimuli were accompanied by pictures, whereas in the No-Picture condition neither of the Test stimuli was accompanied by a picture.

## Results and Discussion

Results of this experiment indicate that in both Picture and No-Picture conditions young children reliably generalized in a one-to-one manner. In the No-Picture condition in 78% of responses children generalized from Test 1, whereas in the Picture condition 77% of responses children generalized from Test 1, both above chance,  $t_s(14) > 6.2$ ,  $p_s < .0001$ . The response patterns in the Picture and No-Picture conditions were practically identical,  $t < 0.5$ .

These findings replicate those of Experiment 1 for young children, ruling out the possibility that young children's responses in Experiment stemmed from the fact that Test 1 (single animal) was accompanied by a picture, whereas Test 2 (many animals) was presented without a picture. Results of Experiments 1 and 2 also point to a difference in inductive generalization of young children and preadolescents: while the later perform inductive generalizations in a manner compatible with the category-based model, the former perform in a manner compatible with the similarity-based model.

The fact that young children equally frequently generalized from a single animal in both Picture and No-Picture conditions deserves special consideration. This finding could be indicative of several factors. First, it is possible that young children generalize from Test 1 (single animal) rather than from Test 2 (many animals) because they merely match quantifiers (e.g., one and one vs. one and many) or linguistic labels (e.g., Gubla and Gubla vs. Gubla and Gublas). Another possibility is that because computation of similarity is easier between single objects, young children are biased to compute similarity between single objects prior to computing similarity between a single object and multiple objects. Experiment 3 was conducted to distinguish between these possibilities.

## Experiment 3

### Method

**Participants** A group of 16 children aged 4 to 5 years ( $M = 4.1$  years,  $SD = 0.4$  years, 10 girls and 6 boys) participated in this experiment. These children were selected from daycare centers in an upper middle class suburb of Columbus, Ohio on the basis of permission slips returned by parents.

**Materials, design, and procedure** Materials, design, and procedure were identical to those in Experiment 1. The only difference was that the Target was presented as many entities, Test 1 as a single entity, and Test 2 as many entities. All stimuli were presented face up.

## Results and Discussion

Results of this experiment indicate that in 52% of responses young children generalized from Test 2, whereas in 48% of responses they generalized from Test 1; both types of generalization were indistinguishable from chance,  $t(15) < 0.3$ . Furthermore, the analysis of patterns of individual responses indicates that the chance-level performance does not stem from a bi-modal distribution where a part of the sample consistently generalized from Test 1, whereas the other part consistently generalized from Test 2. This performance rather stemmed from inconsistency within-participants. In particular, 2 out of 16 participants consistently (on 6 or more out of 8 trials) generalized from Test 2 (many entities), and another 2 out of 16 participants consistently (on 6 or more out of 8 trials) generalized from Test 1 (single entity), while 12 out of 16 participants were inconsistent in their choices of the two test items.

These findings allow us to rule out the matching hypothesis. Indeed, if participants were exhibiting matching, they should have generalized from Test 2 (many entities) to the Target (many entities) most often, which was not the case. Therefore, it seems plausible that patterns of responses observed in Experiments 1 and 2 (i.e., the tendency to generalize from a single entity to another single entity) stem from the fact that it is easier to compute similarity between several single entities than it is to compute similarity between a group of entities and a single entity.

## General Discussion

Results of the three reported experiments are as follows. Young children more readily generalize biological properties from one single entity to another single entity, whereas older children more readily generalize biological properties from many entities to a single entity. At the same time young children performed at chance when asked to generalize from many entities either to a single entity or to many entities. The latter finding undermines the possibility that young children's preference for generalization from one single entity to another single entity stems from their tendency to match quantifiers or label endings.

Taken together, these findings support predictions of the similarity-based approach. In particular, they indicate that when the computation of similarity is relatively simple (such as computation of similarity between single entities) young children more readily generalize biological properties than when computation of similarity is relatively complex (such as computation of similarity of many entities to a single entity). At the same time, when computation of similarity is comparably difficult (such as computation of similarity of many entities to many entities or a single entity to many entities), young children perform at chance.

These results point to the primacy of the one-to-one induction over the many-to-one induction in young children, an effect that has been predicted by the similarity-based position, but not by the theory-based position. Recall that in the case of category-based induction advocated by the theory-based position, there should be no primacy of the

one-to-one induction, and preadolescents, who supposedly perform induction in a category-based manner, did not exhibit the primacy of one-to-one induction.

Results also point to important developmental differences between young children and preadolescents. While preadolescents' inductive generalizations conform to what should be expected when induction is category-based, young children's inductive generalizations conform to what should be expected when induction is similarity-based. Therefore, it seems reasonable to infer that there should be a developmental transition from similarity-based to category-based induction. Such transition could be due to developmental and educational factors that lead to understanding that common category membership is a better predictor of unobservable properties than similarity (e.g., a whale looks more similar to a fish, but has internal structure similar to other mammals). However, additional research is needed to discern and tease apart these contributing factors.

The reported findings afford the differentiation between the theory-based and the similarity-based approaches to young children's induction, undermining the former and supporting the latter. Recall that according to the theory-based position, linguistic labels activate "essence placeholders" that should be equally applicable to all members of the category, independent of the quantity of these members. Therefore, if induction had been performed in a category-based manner, young children should have equally often generalized from a single animal and from a group of animals, or have a slight preference for many-to-one over one-to-one induction. In addition, the theory-based position does not predict dramatic differences between young children and preadolescents: both groups should perform induction in the category-based manner. At the same time, the similarity-based position (e.g., Sloutsky & Lo, 1999) predicts that while young children should generalize in a similarity-based manner (generalizing from a single entity to another single entity), preadolescents should generalize in a category-based manner. The primacy of one-to-one induction in young children and major differences between young children's and preadolescents' induction fit predictions of the similarity-based position, while not fitting predictions of the theory-based position.

Of course, the current results could not conclusively rule out the possibility of young children having representations of category templates, and it is hard to imagine any empirical findings capable of conclusively ruling out this possibility. The results of current experiments, however, support a parsimonious account of young children's induction that is based on a set of a priori predictions. We believe that a priori predictions are favored over post hoc accounts by both inferential statistics and philosophy of science, and, therefore, they should weigh more than post hoc accounts (cf. Barsalou, 1999).

In short, while the similarity-based approach is not capable of conclusively ruling out the proposal that young children rely on categories when performing inductive inference, it is capable of undermining such a possibility. In particular, the similarity-based approach is capable of predicting phenomena (such as those reported above) that

could not be predicted by the category-based position.

# Simulating Conditional Reasoning Containing Negations: A Computer Model and Human Data

Jacques Sougné (J.Sougne@ulg.ac.be)  
University of Liège  
Department of Psychology  
Bât B32, Sart Tilman

## Abstract

Modeling human conditional reasoning of the type “if p then q” containing negations poses a challenge for connectionism. A network of spiking neurons (INFERNET) was used to model this type of conditional reasoning. This model also provides insights on certain human limitations. The model is compared to empirical data, and classical explanations. Statistical analysis shows that the model’s performance not only surpasses classical explanations but also provides a very good overall fit to empirical data. INFERNET simulator results are also compared to human performance. The simulations compare well with both human performance and limitations.

## Introduction

INFERNET (Sougné, 1996, 1998a, 1998b, Sougné & French, 1997) achieves variable binding through temporal synchrony of node firing. In short, when one node fires in synchrony with another, they are temporarily bound together. It has a limited Working Memory (WM) span and the content of WM is maintained by oscillations. Once a node is activated, it tends to fire rhythmically at a particular frequency. This technique is used to represent n-ary predicates (Sougné, 1996), relational reasoning with multiple instantiation (Sougné, 1998a; Sougné, 1998b), working memory (Sougné & French, 1997) and conditional reasoning (Sougné, 1996). This paper shows how the model handles negated conditionals.

Many psychological studies in the area of deductive reasoning have focused on conditional reasoning of the type “if p then q.” Of course, some logicians would deny that material implication is really what humans mean by “if...then”. Nonetheless, here are transcribed rules related to material implication: modus ponens (MP) *If p then q; p; infer q* and modus tollens (MT) *If p then q; ~q; infer ~p* (~ stands for not). While most humans follow modus ponens, it is different for modus tollens. People also use two inappropriate rules related to material equivalence: Denial of the antecedent (DA) *If p then q; ~p; infer ~q*, and Affirmation of the consequent (AC) *If p then q; q; infer p*. Throughout this paper the “if p then q” form will be called the “major premise”, p the antecedent, q the consequent.

What happens when negations are introduced into the major premise? Negation can affect the antecedent or the consequent. It produces four forms of major premises.

Table 1 shows these four forms and the inferences resulting from the application of the four rules (MT, DA, AC, MT).

Table 1: Combination between form of major premises and the result of applying the four inference rules

	MP		DA		AC		MT	
	given	infer	given	infer	given	infer	given	infer
<i>If p then q</i>	p	q	not p	not q	q	p	not q	not p
<i>If p then not q</i>	p	not q	not p	q	not q	p	q	not p
<i>If not p then q</i>	not p	q	p	not q	q	not p	not q	p
<i>If not p then not q</i>	not p	not q	p	q	not q	not p	q	p

Empirical studies reveal that negations do modify the frequencies of rule application (Evans, 1977, Wildman & Fletcher, 1977, Pollard & Evans, 1980). Pollard & Evans (1980) explain these data with what they call “negative conclusion bias” which is a tendency to prefer accepting a conclusion in the negative form. This is effectively the case for DA and MT. This is not the case for MP, but one could invoke a ceiling effect. Finally the effect is not clear for AC. As stated by Evans, Newstead & Byrne (1993), this bias could be explained by people’s caution. Concluding that “the letter is not an X” would have a higher probability (25/26) than concluding that “the letter is an X” (1/26). Oaksford & Chater (1994) provide a similar explanation. There is also an interpretation of negation effect in terms of a “Matching bias”: a tendency to verify cases that are stated in the major premise. However, this bias concerns only certain procedures like the “Wason Selection Task”, the “Truth Table Task” or the “Evans construction task” in which participants have to test or verify a major premise instead of applying it. Moreover, matching bias is closely related to implicit negation (Evans, 1998). The present study focuses on explicit negation. While negation in conditionals is known to create difficulties (Oaksford & Stenning, 1992), little is said about double negation (for an exception, see Sperber, Cara, & Girotto, 1995 or Evans, Clibbens & Rood, 1995).

In this paper, the INFERNET simulator’s performance will be compared with human data. INFERNET suggests hypothesis related to the difficulty of removing double negations. An experiment was also done in order to collect reaction time data in a production task which were not available in previous studies.

## INFERNET

INFERNET is a network of spiking neurons (Maass & Bishop, 1999). In INFERNET, nodes can be in two

different states: they can fire (be on), or they can be at rest (be off). A node fires at a precise moment and transmits activation to other connected nodes with some time course. When a node activation or potential  $v_i^{(t)}$  reaches a threshold, it emits a spike. After firing, the potential is reset to some resting value  $V_r$ . Inputs increase the node potential, but some part of the node potential is lost at each time step. Spiking neuron models use a post synaptic potential function. Integration of input in INFERNET is a variation of standard input integration. In INFERNET there are two main types of connections: either they act on nodes (synaptic link) or on synapses (presynaptic link). Unlike most links, these latter links act on *connections* rather than nodes (French, 1995). Moreover each of these connections can be excitatory or inhibitory. There are six types of connections: synaptic excitation, synaptic inhibition, presynaptic amplification of an excitation, presynaptic inhibition of an excitation, presynaptic inhibition of an inhibition and presynaptic amplification of an inhibition (figure 1). In addition to the weight of a connection, there is a delay parameter associated with each connection. A delay of 10 means that the effect of the presynaptic node firing on the postsynaptic node will take 10 units of time. A unit of time has been taken to simulate 1 ms. In addition, connection weights are modified by a random factor that injects white noise into the signal propagation.

Figure 1: Example of synaptic and presynaptic connection in INFERNET. The node  $k$  inhibits the excitatory connection from  $j$  to  $i$

The potential of node  $i$  at time  $t$ ,  $v_i^{(t)}$  is:

$$V_i^{(t)} = \sum_{j \in \Gamma_i} \sum_{t_j^{(f)} \in F_j} \left[ w_{ij} + \sum_{k \in \mathcal{K}_{ij}} \sum_{t_k^{(f)} \in F_k} w_{k \rightarrow ij} \varepsilon_{k \rightarrow ij}(x) \right] \varepsilon_{ij}(x) - \eta_i(u) \quad (1)$$

The potential of node  $i$ :  $v_i^{(t)}$  is affected by connection weights coming from presynaptic node  $j$ :  $w_{ij}$  but also by the connection weights that modify this connection  $w_{k \rightarrow ij}$ . The set of presynaptic to node  $i$  is  $\Gamma_i = \{j | j \text{ is presynaptic to } i\}$ .  $F_j$  is the set of all firing times of presynaptic nodes  $j$ :  $t_j^{(f)}$ . The set of presynaptic to synapse  $ij$  is  $\mathcal{K}_{ij} = \{k | k \text{ is presynaptic to } ij \text{ synapse}\}$ .  $F_k$  is the set of all firing times of  $k$  nodes:  $t_k^{(f)}$ . These are the nodes from which start a connection acting on the connection  $ij$ . The connection weight linking node  $k$  to synapse  $ij$  is designed by  $w_{k \rightarrow ij}$ . The equations  $\varepsilon_{ij}(x)$  and  $\varepsilon_{k \rightarrow ij}(x)$  express the postsynaptic potential function. A value  $\eta_i(u)$  associated with the refractory state of nodes is subtracted. When  $v_i^{(t)}$  reaches the threshold  $\theta$ , node  $i$  fires and  $V_i$  is reset to a resting value  $V_r$ ,

## Representation in INFERNET

How does the brain represent the world? Two contrasting hypotheses are often presented in neuroscience: the code used by neurons is either a rate code or a pulse code. INFERNET relies on a pulse code, specifically, phase and

synchrony. In INFERNET, a symbol is represented by a cluster of nodes and is activated if its nodes fire in synchrony (the firing distribution is tightly concentrated around the mean: figure 2). Different symbols share nodes, so representations are distributed (see Sougné, 1998b), or more accurately, semi-distributed.

Figure 2: Symbols are represented as a set of nodes firing in synchrony.

There is considerable neurobiological evidence for considering synchrony as a possible binding mechanism in the brain (Roelfsema, Engel, König & Singer, 1996, Singer, 1993, Singer & Gray, 1995). In INFERNET, attributes are bound to an object and objects are bound to their roles by synchronous firing. For example, to represent “the red rose on the green lawn”, the attribute “red” must fire in synchrony with the object “rose” and they must fire synchronously with nodes belonging to the role “supported object” (Figure 3).

Figure 3: The “red rose on the green lawn” requires binding of symbols with their roles.

Discrimination is achieved by successive synchronies, for example, to discriminate a red rose on a green lawn. The nodes belonging to “red”, “rose” and “supported object” must fire in synchrony and those corresponding to “green”, “lawn” and “supporting object” must also fire in synchrony. Further, these two sets of nodes must fire asynchronously in different phases for “the red rose on the green lawn” to be perceived. Engel, Kreiter, König, & Singer (1991) provide evidence to show that if several objects are present in a scene, several groups of cells are clustered in distinct windows of synchrony.

A number of neurobiological parameters are involved in representations that rely on clusters of nodes firing simultaneously. The first is the frequency of oscillation. Certain specific oscillatory activities seem to facilitate synchronization (Roelfsema et al., 1996, Singer, 1993). In INFERNET once a node is activated, it tends to begin oscillating at a  $\gamma$  frequency range, whose lower limit is 30Hz and upper limit varies, according to various authors, from 70Hz (Abeles, Prut, Bergman, Vaadia & Aertsen, 1993), 80 Hz (MacKay, 1997) to 100 Hz (Wilson & Shepherd, 1995). The temporal gap between 2 spikes of a node is therefore from 10 to 33 ms. These  $\gamma$  waves have been observed to be associated with attention (Wang & Rinzel, 1995) and with associative memory (Wilson & Shepherd, 1995) and therefore seem to be a primary candidate for enabling synchronization and binding (Singer, 1993). The second key parameter is the precision of the synchrony at this frequency range. According to Singer and Gray (1995) this precision is between 4 to 6 ms., while for Abeles and al. (1993), it is about 5 ms, sometimes less, and depends on the oscillation frequency. This allows us to approximate the number of windows of synchrony that can be differentiated, i.e., approximately  $25/5 = 5$ , based on a typical frequency of 40Hz. If we assume that a window of synchrony corresponds to an item, a word, an idea, an object in a scene, or a chunk in working memory (WM), this puts WM span at approximately 5, with a small amount of variance since precision is proportional to oscillation frequency. This corresponds to current estimates of human WM span (see Cowan, 1998). The more the system needs to discriminate objects in WM, the more precise the synchrony should be. Since this parameter is bounded, it can lead to WM overload where windows of synchrony can no longer be distinguished. Therefore, the number of distinct items and the number of predicate arguments (Sougné, 1996) in WM is limited. Finally, following Lisman and Idiart (1995), the representation is maintained in WM by bursts of  $\gamma$  waves. Similar explanations for the brain's ability to store short-term memory items can be found in the literature (Hummel & Holyoak, 1997; Jensen & Lisman, 1998; Lisman and Idiart 1995; Shastri & Ajjanagadde, 1993).

### Inference in INFERNET

INFERNET implements logical gates sensitive to input timing. AND-gates require all inputs to reach the target at the same time. This is achieved by a set of excitatory and inhibitory links combined with presynaptic inhibition and facilitation (see Hawkins, Kandel, and Siegelbaum, 1993, for neurobiological evidence of this mechanism). Similarly, XOR-gates are only on when one of the inputs is active. These gates are related to the phenomenon of *coincidence detection* (Konnerth, Tsien, Mikoshiba, & Altman, 1996, Singer, Engel, Kreiter, Munk, Neuenschwander, & Roelfsema, 1997).

INFERNET has a Long Term Knowledge Base that is used for encoding premises and answering queries. Figure 4 shows the knowledge necessary to make conditional inferences with negations. Arrows represent connections; they are tagged with numbers that indicate the time required

to propagate activation. Specifically, in this example, a delay of 30ms corresponds to the lag between two spikes of a node oscillating at 33Hz. This delay ensures that these symbol-node spikes will synchronize after 30ms. The knowledge encoded, as shown in Figure 4, can correctly answer queries related to material implication.

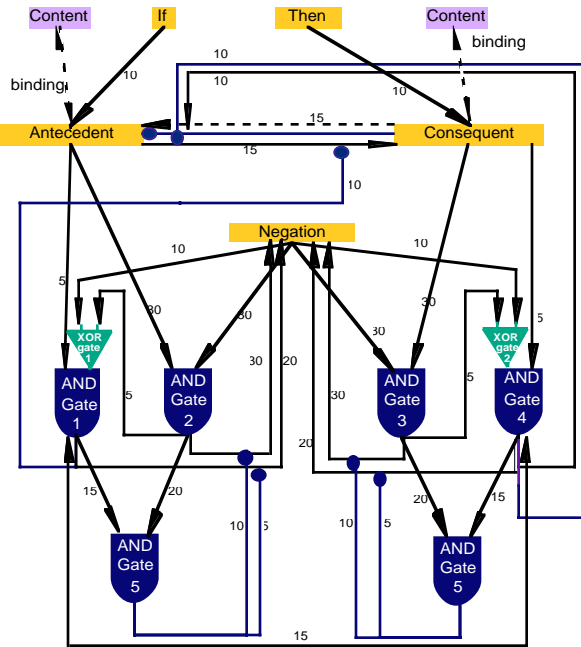

Figure 4: The encoded knowledge necessary to deal with negated conditionals

The first capacity that INFERNET must have is the ability to distinguish negations in the major premise. *AND-gate 2* detects when the antecedent is negated in the major premise and *AND-gate 3* detects a negated consequent. During the premise-encoding phase, if an antecedent is negated, for example: *If ~p then q*, the connection between the *AND-gate 2* and *p* will be strengthened as well as connections between *p* and *Antecedent*. After this phase, the firing of *p* nodes will be sufficient to induce the synchronous firing of nodes of *AND-gate 2*. The second ability of INFERNET is to detect whether in the question (minor premise) the antecedent or the consequent (as it occurred in the major premise) is negated and that is done by *AND-gate 1* and *AND-gate 4*. By following the diagram carefully, one can see that *AND-gate 1* detects the denial of the antecedent, and *AND-gate 4* detects the denial of the consequent. If the antecedent and the consequent has a negative form in the major premise (e.g. *If ~p then ~q*), and if the minor premise is in the affirmative form (e.g. *p*), *AND-gate 1* will be activated by *AND-gate 2* by the means of an *XOR-gate*. The same principle activates *AND-gate 4*. The role of *AND-gate 5* is to detect double negations. This gate will be active whenever *AND-gate 1* and *2* or *AND-gate 3* and *4* are active. This gate prevents nodes representing *negation* from firing. In order to do correct inferences, *Antecedent* and *Consequent* must be linked. The detection of the antecedent in the question

must enable firing of *consequent* nodes, unless *AND-gate 1* is active (thereby avoiding Denying the Antecedent). The detection of the consequent in the question must enable firing of *antecedent* nodes if *AND-gate 4* is not active (it avoids Affirming the Consequent). Finally, if *AND-gate 1* is active, *AND-gate 4* will be activated, and vice-versa.

## Hypotheses

Classical explanations of negation effects in conditional reasoning rely on the notion of “negative conclusion bias”: a tendency to prefer inferences in the negative form with the exception of MP (Pollard & Evans, 1980).

The first hypothesis that follows from INFERNET is that it should be easier to apply Modus Ponens than any other rule. This effect is attributed to the stronger links from antecedent nodes to consequent nodes. The second hypothesis states that whenever *AND-gate 5* (see figure 4) is needed, a decrease in performance should occur. This effect is due to an increase of the number of steps required to propagate the activation and to this gate’s role of blocking the oscillation of *negation* nodes. *AND-gate 5* is required to treat double negations. Therefore this hypothesis predicts a decrease in DA errors for major premises *If p then ~q* and *If ~p then ~q* and a poorer MT performance for major premises *If ~p then q* and *If ~p then ~q*.

In order to contrast classical and INFERNET hypotheses frequencies of inference and reaction times will be used.

## INFERNET Simulation Results

Normalized correlation between obtained data and different possible answers was computed for the 40 trials. This is a correlation between data observed and data for perfect answers. The proportion of correct responses was obtained by combining the correlations obtained on different trials, taking care to ensure that correlations are not additive (see Sougné, 1999 for computation details). INFERNET simulator results are reported in figure 5.

As expected, MP is more often applied than any other rule. There is also an effect of double negation which is responsible for the low frequencies of DA when the consequent is negated and of MT when the antecedent is negated.

Response times for the simulator are measured by monitoring the encoding phase. After each  $\gamma$  wave burst, the questions are presented and responses are collected. Since the INFERNET simulator has a resolution of 1ms, the response time is determined by the time (in ms) for the normalized correlation to reach a threshold. INFERNET simulator mean reaction times are reported in figure 6. The reaction times show that MP responses are faster than others and that a double negation results in slower reaction times.

An experiment was conducted to provide data that could be compared with INFERNET. Normally, data about negation effects on conditional reasoning do not provide reaction times and are collected with forced choice responses. The comparison between machine and human data will allow us to test INFERNET.

## Experiment and comparison with INFERNET simulator

### Participants and Design

The experiment has a within-subjects design. Forty participants received four major premises in a random order and had to answer four questions for each major premise in a random order. The 40 participants were undergraduate psychology majors, 31 females 9 males, mean age was 21.3 and SD was 2.1.

### Material

Four major premises were constructed, alternating positive and negative antecedents and consequents. Positive antecedent, positive consequent: *If the number is 3 then the letter is X*, Positive antecedent, negative consequent: *If the number is 3 then the letter is ~X*, Negative antecedent, positive consequent: *If the number is ~3 then the letter is X*, and Negative antecedent, negative consequent: *If the number is ~3 then the letter is ~X*. Each major premise presentation was followed by four questions: *The number is 3, what do you conclude?*, *The number is ~3, what do you conclude?*, *The letter is X, what do you conclude?*, *The letter is ~X, what do you conclude?*.

### Procedure

Each participant was seated approximately 50 cm in front of the monitor. One of the randomly chosen major premises appeared on the screen. Participants were asked to read it and to indicate when they understood it. The major premise stayed on the screen when the subsequent questions were displayed. Questions then appeared on the screen, one at the time and in random order. Participants had to answer each question. The computer recorded the time required to respond. The experimenter recorded the response. When the participant answered the four questions, the next major premise appeared on the screen with the same procedure until the four major premises had been presented. Before presenting the experimental material, participants received training exercises with the same procedure, but with an arithmetic content.

### Results

Frequencies of stating each inference are shown on figure 5. According to the “Negative Conclusion Bias” hypothesis, there should be more DA type inferences for major premises *If 3 then X* and *If ~3 then X*, more AC type inferences for major premises *If ~3 then X* and *If ~3 then ~X*, more MT type inference for major premises *If 3 then X* and *If 3 then ~X*, and finally more MP. According to the INFERNET prediction, there should be more MP type inferences than any other, fewer DA type inferences for major premises *If 3 then ~X* and *If ~3 then ~X*, and fewer MT type inferences for major premises *If ~3 then X* and *If ~3 then ~X*.

Data were analyzed by a Loglinear analysis which provides a means to analyze multi-way frequency table. Loglinear analysis evaluates the effect of each variable and

of their interaction<sup>1</sup>. Moreover, loglinear analysis evaluates each model that could explain the data, this gives us a way to compare INFERNET and the classical “Negative Conclusion Bias” model.

Figure 5: Graph of comparison between human and INFERNET simulator frequencies of inference.

In addition to the effect of the conclusion sign (i.e. with or without “not” in the conclusion) being significant (194 positive and 265 negative conclusions,  $G^2_{(1)}=44.135$ ,  $p<.0001$ , other effects are also. The effect of expected sign is significant, which means that DA + MT (188 inferences) are less often applied than MP + AC (271 inferences),  $G^2_{(1)}=59.358$ ,  $p<.0001$ . Forward inferences (MP+DA) are more often done (247 inferences) than backward inferences (AC+MT) (212 inferences),  $G^2_{(1)}=11.092$ ,  $p<.001$ . The interaction between the expected sign and the conclusion sign is also significant: among the positive conclusions those which involve a double negation are less often inferred (65 inferences) than others (129 inferences) while for negative conclusions cases, expected positive cases (142 inferences) are more comparable with expected negative cases (123 inferences),  $G^2_{(1)}=4.893$ ,  $p<.03$ . There is also an interaction between the expected sign and Forward and backward inferences. MP are more often applied (155 inferences) than AC (116 inferences) while DA (92 inferences) and MT (96 inferences) are sensibly equal,  $G^2_{(1)}=30.226$ ,  $p<.0001$ . The INFERNET model is the best fitting model  $G^2_{(20)}=12.88$ ,  $p=.88$ , while Negative Conclusion bias with the exception of MP cases provides a poor fit:  $G^2_{(22)}=21.92$ ,  $p=.46$ . The difference between these two models is significant:  $G^2_{(2)}=9.04$ ,  $p<.01$ .

The INFERNET data are not significantly different from these results. The comparison with human data can be done by adding one group factor to the analysis (Human vs INFERNET simulator). The effect of group is not significant, none of the interactions are significant.

Figure 6 shows mean reaction times for the 4 major premises and the four questions. The two hypotheses to compare are the same as above. The use of ANOVA<sup>2</sup> with

4 within-subject factors reveals a significant effect of the variables “Positive or Negative Conclusion”:  $F(1,9)=11.02$   $p<.01$  (negative conclusion bias). However, a Post Hoc Tukey test reveals that cases in which the conclusion is negative are only faster than those involving double negation. The double negation effect is significant:  $F(1,9)=12.79$   $p<.01$ . A post hoc Tukey reveals that reaction times for cases of “Double Negation” are significantly longer than others. INFERNET reaction times are faster than those of humans, but INFERNET does not account for the time of reading the question and producing an utterance.

Figure 6: Graph of comparisons between human and INFERNET simulator mean reaction times.

## Conclusions

Connectionist modeling of human reasoning is a difficult challenge. Even though Holyoak & Spellman (1993) have described human reasoning in terms of constraint satisfaction, few connectionist systems has been designed for modeling reasoning. INFERNET shows how reasoning might be possible based on certain low-level neurobiological mechanisms. These properties constrain the reasoning process and explain human limitations. People are sensitive to negated conditionals. INFERNET’s account of the phenomenon involves the type of inference and double negation effects and challenges classical explanations that rely on the notion of “Negative Conclusion Bias”. It was predicted that the number of steps required to perform an inference constrained the reasoning process. Removing double negations requires a long chain of gates opening. The longer the chain of successive gates, the higher the number of errors, and the less opportunity for binding fixation. This paper presented INFERNET’s predictions and results. These results confirmed that INFERNET is sensitive to double negations. A similar experiment has been conducted on human participants. Results confirmed INFERNET’s prediction and showed that the INFERNET explanation is better than classical explanation in terms of “negative conclusion bias”. Finally, INFERNET and humans data were compared and there is a high degree of qualitative similarity between the two.

## Acknowledgments

This research was supported by the Belgian PAI Grant p4/19 Special thanks to Robert French for his assistance in the work presented here.

<sup>1</sup> All the following  $G^2$  are underestimated because data were analysed with a between subjects design. A method for analysing within designs exists but in this case, it would require a  $2^{16}$  table to analyse. However, this would not be feasible. Note, however, that a within-subjects ANOVA gave the same results.

<sup>2</sup> In this analysis, degrees of freedoms have been corrected because of violation of the sphericity assumption: Box correction  $\hat{\epsilon} = .23$

## Abstract

One of the fundamental questions in cognitive science is how people remember the locations of important objects in the world with enough accuracy to find these objects when they are no longer in view. Evidence from a variety of studies suggests that people rely on visible reference axes—streets, walls, the edges of a table—to help them remember the locations of target objects. Use of such perceptual information can help stabilize memory, but there is a cost: when people are asked to reproduce the location of a hidden object, they exaggerate the distance between the reference axis and the actual location of the object. These memory errors increase in magnitude as memory delays increase. Thus, errors away from reference axes may provide a window into the second-to-second processes that serve to maintain location information in memory. In the present report, we describe a dynamic field model that captures in quantitative detail how information is maintained in memory near reference axes. This model explains the time-dependent integration of memory and perceptual processes, thereby moving beyond current models of location memory.

## Introduction

To interact successfully with the world, people must remember the locations of important objects with enough fidelity to find these objects when they are no longer visible. This is relatively easy when the target object shares a clear relationship with a visible landmark (e.g., under the landmark). In more challenging situations, however, there may be long delays between perception of the location and action toward it, and the target object may be hidden within a continuously varying scene or a field of view with relatively few perceptual landmarks. In these situations, how do people accurately maintain location information in memory?

Research on the short-term characteristics of location memory has generally focused on what people represent in memory when asked to remember the location of a hidden object. For instance, Smyth and colleagues have demonstrated that people represent locations relative to both egocentric body position and an allocentric reference frame (Smyth, Pearson, & Pendleton, 1988). Other data suggest that humans and non-human primates encode locations in retinotopic coordinates, head-centered coordinates, and shoulder or body-centered coordinates (e.g., Feigenbaum &

Rolls, 1991; Graziano, Hu, & Gross, 1997; Woodin & Allport, 1998).

Although the question “what is represented” is central to the study of location memory, it is equally important to understand how represented information is maintained in memory over short-term delays. In the past decade, this issue has been the focus of several neurophysiological studies (e.g., Constantinidis & Steinmetz, 1996; Rao, Rainer, & Miller, 1997). These studies have demonstrated that the sustained activation of neurons in prefrontal cortex, premotor cortex, and posterior parietal cortex underlie the maintenance of location information over short-term delays. Nevertheless, there have been relatively few behavioral studies investigating the short-term characteristics of location memory. The small number of behavioral studies is surprising given that virtually all of the studies examining what people represent in memory ask participants to reproduce remembered locations following a delay. A prerequisite for understanding the effects in many of these studies, then, is to understand how information about one location is maintained for several seconds.

The relative lack of behavioral data on maintenance processes has also led to a de-emphasis on time-dependent models of location memory. The goal of the present report is to introduce a dynamic model of location memory. This model represents the first attempt to explicitly capture how location information is maintained in memory over short-term delays.

## How Is Location Information Maintained?

One way to help maintain an accurate memory of location over delays is to encode locations relative to visible reference cues in the environment. People might, for instance, encode locations relative to salient perceptual landmarks. This can help stabilize memory, particularly if the landmark is visible from a variety of vantage points (e.g., the Eiffel Tower).

Although the use of landmarks has been well documented (e.g., Sadalla, Burroughs, & Staplin, 1980), the present report emphasizes people’s use of a different, but equally prevalent type of reference cue—visible reference axes. The environments in which people typically act are naturally sub-divided by visible reference axes. Reference axes such

as streets, rivers, and walls sub-divide far spaces, while axes such as the edges of tables, the edges of a computer screen, and the edges of a counter top sub-divide near spaces. Data from a variety of spatial memory studies suggest that, as with visible landmarks, people use reference axes to help them remember locations (e.g., McNamara, Hardy, & Hirtle, 1989). However, the use of reference axes may have a cost. Specifically, when people are asked to reproduce the location of a target object near a reference axis after different delays, responses become systematically distorted away from the reference axis on a second-by-second basis (Spencer, 2000). These delay-dependent effects are central to the present report because they provide insights into the processes that serve to maintain location information in memory.

### Location Memory Biases Near Reference Axes

Spatial priming and free recall studies have shown that adults use reference axes to help them remember locations. Specifically, adults group locations in memory relative to reference axes. McNamara and colleagues, for example, asked adults to learn the locations of multiple objects in a room subdivided by tape on the floor (McNamara et al., 1989). After the layout of objects was learned, participants read pairs of object names presented sequentially on a computer screen and judged if the second object was present in the original layout of objects. Adults responded more quickly when the two objects were in the same spatial region than when they were in different regions. This occurred even if the objects in different regions were physically closer than the objects in the same region. Similarly, free recall of objects and places is ordered relative to reference axes (McNamara et al., 1989). For example, adults use reference axes such as streets and rivers, recalling buildings and businesses from one region before recalling items in adjoining regions.

Although these data demonstrate that people use reference axes to organize location memory, it is difficult to isolate how such axes are used in these tasks because people are asked to remember multiple locations in the presence of many reference cues. Other studies have used much simpler tasks in which people remember a single location on each trial in the context of simple reference cues. In these studies, participants are typically shown a dot inside a geometrical figure. The dot is then covered up, there is a short delay, and participants are asked to reproduce the dot's location in a second, blank figure (e.g., Huttenlocher, Hedges, & Duncan, 1991; Huttenlocher, Newcombe, & Sandberg, 1994).

These studies allow a more complete view of the processes that maintain location information in memory, because factors central to these processes can be directly manipulated. For instance, the length of memory delays and the separation between the target location and the axes of the geometrical figure can be manipulated across trials. In addition, two types of error can be measured—the mean or constant error across responses to the same location, and the variability of these responses. These two measures provide complementary views of how location information is maintained. Constant error indicates both the direction and

magnitude of memory biases. Variable error indicates how stably location information is maintained.

Data from several location reproduction studies demonstrate that location memory is systematically distorted near reference axes. Specifically, memory is biased away from visible reference axes when the to-be-remembered locations are close to these axes. Huttenlocher and colleagues (1994) asked children and adults to reproduce the locations of dots within a rectangular frame. Responses in this study were biased away from the left and right edges of the frame. Similarly, when older children and adults were asked to reproduce the locations of dots within a circle, they made errors away from the edges of the circle (Huttenlocher et al., 1991; Sandberg, Huttenlocher, & Newcombe, 1996). Finally, Engbretson and Huttenlocher (1996) asked adults to reproduce the direction of a line within a “V” frame. Responses were once again biased away from the edges of the frame (see also, Schiano & Tversky, 1992).

In addition to biases away from visible reference axes, responses in these studies were biased away from “mentally imposed” axes. For example, participants made errors away from the vertical midline axis of the rectangular and V frames (Engbretson & Huttenlocher, 1996; Huttenlocher et al., 1994). Similarly, in the circle task, adults made errors away from both vertical and horizontal axes, suggesting they mentally sub-divided the circle into quadrants (Huttenlocher et al., 1991; Sandberg et al., 1996).

Finally, data from a recent study demonstrate that biases away from reference axes increase systematically over short-term delays. Spencer and Hund (2000) asked adults to reproduce the location of targets at different angular distances from the midline axis of a large, homogeneous task space. Participants moved to these remembered locations after delays that ranged from 0 to 20 s. As the delay increased, participants' responses were biased away from midline and became more variable. These delay-dependent effects suggest that errors away from reference axes may be a product of the processes that maintain information in memory. As such, these errors may offer unique insights into how location information is maintained over short-term delays.

### Perceptual Processes and Reference Repulsion

Although delay-dependent results from Spencer and Hund (2000) indicate that memory decay plays a key role in response biases near reference axes, data from several studies suggest that memory processes are not the sole cause of these biases. Instead, perceptual processes contribute to biases near reference axes. Specifically, perceptual judgements of dot location and line orientation are biased away from reference axes. Importantly, these biases occur even though, in many studies, reference and target displays are presented simultaneously. Thus, errors away from reference axes in these studies cannot be caused by memory processes.

For instance, when a test line abuts a visible reference line forming an acute angle, people report the angle is larger than it actually is. This *acute-angle expansion* or *tilt contrast* effect is maximized at small angles and if the

reference line is horizontal or vertical (e.g., Blakemore, Carpenter, & Georgeson, 1970). Judgements of line orientation are also repelled from “virtual” reference axes (e.g., Beh, Wenderoth, & Purcell, 1971). Virtual reference axes result from the symmetry properties of geometrical figures. A square, for example, has four virtual reference axes—two diagonals and horizontal and vertical axes. Beh et al. (1971) showed that when adults are asked to judge the orientation of a rod in the context of a square frame, adults’ judgements are repelled from the closest axis of symmetry defined by the square frame. Such repulsion is particularly strong near horizontal and vertical axes.

Finally, adults’ judgements of dot position are repelled from visible reference axes. Rauber and Treue (1998) asked adults to judge if two sequentially presented locations were identical. When these locations were close to a vertical reference line, adults’ judgements were repelled from the reference line. This effect decreased as the separation between the target location and the reference line increased.

To summarize, data suggest that both memory processes and perceptual processes contribute to response biases near visible reference axes. Response biases increase systematically over delays, suggesting that these errors are caused, in part, by how location information is maintained in memory. However, responses are also biased away from reference axes when reference and target displays are presented simultaneously, suggesting that perceptual processes play an important role.

Here we present a formal model that brings together perceptual and memory processes to explain the origin of response biases near reference axes. Central to this account is the proposal that initial biases in perceptual processes are amplified in memory over short-term delays. Specifically, our model demonstrates how enhanced perceptual processing of visual information near reference axes can produce both biases in perceptual judgements and biases in how information is maintained in memory.

### Empirical Results to be Modeled

The model we propose here was designed to capture data from several experiments that have explicitly investigated the time-dependent processes that underlie reference repulsion (Spencer & Hund, 2000). In these experiments, participants pointed to target locations projected on a large, opaque tabletop. Pointing movements were tracked using an optical-electronic motion-analysis system (Optotrak, Northern Digital, Inc.). Importantly, the layout of all visible

**Figure 1.** Schematic of apparatus. Targets projected on tabletop from below. Movements recorded using an Optotrak motion analysis system. Inset shows sample target positions relative to starting point.

reference cues were explicitly controlled (Figure 1). The experimental table was quite large (4' x 5') and the surface was homogeneous. Experimental sessions were conducted in dim lighting in a room with black curtains covering the walls and ceiling. This prevented participants from using external landmarks. Nevertheless, the hand, body, and table were clearly visible. Participants sat in a chair positioned within an arc cut out from one edge of the table (Figure 1). This limited their ability to use the front edge of the table as a reference location. Thus, in this task setting, visible reference cues included the edges of the table and its axes of symmetry, the location of the participant’s body and hand, and any reference locations projected onto the surface of the table.

In the first experiment (Spencer & Hund, 2000), participants moved to three target locations—a left, center, and right location—15 cm from a starting position located on the midline axis of the table. The delay (0-20 s) between the offset of a target light and a “go” signal was varied as was the angular distance of the targets from midline (10°, 20°, 40°, 60°, 80°; see Figure 1). Based on the results of studies by Huttenlocher and colleagues, we expected participants to make errors away from the midline reference axis, particularly when targets were close to 0°. The key question was how these errors would change as a function of delay. As the delay increased in the 10°, 20°, and 40° conditions, constant directional errors to the left target became significantly more negative (larger counterclockwise errors), and errors to the right target became significantly more positive (larger clockwise errors) (Figure 2a). Errors to the center target remained small across all delays. At larger target separations, the magnitude

**Figure 2.** (a) Mean directional errors over delays for movements to the left, center, and right targets in the 20° condition. Inset shows a schematic of target locations and mean directional error. Error bars = ½ standard deviation. (b) Constant (mean) and variable (standard deviation) directional errors for movements to each target location across target separation conditions.

of the errors away from midline decreased (Figure 2b) and no longer depended on delay. Variable (standard deviation) directional errors also increased over delays (see errors bars in Figure 2a). As with the constant errors, this effect was larger for movements to the left and right targets than to the center. Variability was largest in the 20° condition and decreased significantly at the other target separations (Figure 2c).

Results from this study indicate that location memory decays over short-term delays. More importantly, however, these results reveal a specific pattern of decay near a reference axis. Both constant and variable error increased over delay when participants moved to the left and right locations, and both types of error remained small when participants moved to midline. In addition, errors were largest at 20°, and decreased as the left and right targets were moved farther from midline. Thus, reference repulsion decreased for targets far from midline. Finally, there was a reduction in both constant and variable error very close to midline (at 10°).

In a second experiment, we found similar delay-dependent effects near reference axes, demonstrating that decay effects generalize to conditions in which the three targets are not symmetrically positioned around the midline axis of the table (Spencer & Hund, 2000). Specifically, we rotated the three targets clockwise and counterclockwise around the midline axis. For example, in one condition, targets were located at -60°, -40°, and -20°, while in another condition, targets were located at -40°, -20°, and 0°. Across all modified layout conditions, participants' responses to non-0° targets were repelled from midline as delays increased. In addition, the magnitude of these errors decreased as the targets were rotated away from midline (e.g., from -20° to -40° to -60°). Finally, participants' responses to targets along the midline axis were accurate with low variability.

## The Model

To explain the pattern of memory decay near reference axes, we propose the following dynamic field model. This model specifies how perceptual and memory processes are integrated over delays to produce reference repulsion. Although this model represents a new approach to location memory, several of the concepts we discuss here have been used to capture how adults plan reaching movements to visually specified target locations (Schöner, Dose, & Engels, 1995).

The starting point for our dynamic field model is the concept of an activation field, where “activation” indicates the likelihood that a participant will move to a specific location at a particular moment in time. Plans to move to a target can be thought of as distributions of activation values across all possible target locations, with higher values indicating that a person is more likely to move to these locations than to others.

Two different types of information are integrated within the activation or action planning field. The first input—target input—captures the appearance and disappearance of the target light. The second input—P-ACT input—represents a participant's memory of previously activated

locations. The integration of these inputs in the planning field is governed by an interaction function that determines how activation at one site in the field influences activation at other sites. We use a local excitation and lateral inhibition interaction function. Thus, activation at one site increases the activation of its neighbors and decreases the activation of sites far away. One consequence of this function is that strong input can produce “self-sustaining” activation. Such patterns of activation maintain themselves, even after input is removed. In this way, *the planning field can maintain a memory of the input*.

The main concepts of the dynamic field model are captured in Equation 1. This equation specifies how activation in the planning field changes from time step to time step. Specifically, the change in activation at the next time step is a function of the current activation, the current inputs (target, P-ACT), and the way current above-threshold activation at each site enhances or suppresses activation at all other sites (local excitation/lateral inhibition function). Once computed, the change in activation is added to the current activation to produce the activation in the planning field at the next time step.

$$\tau \dot{u}(x, t) = -u(x, t) + h + \int dx' w(x, x') f(u(x', t)) + S_{tar}(x, t) + S_{pact}(x, t) + S_{noise}(x, t)$$

**Equation 1.** Rate of change in field activation =  
- current activation + base activation + sum(current thresholded activation weighted by the interaction function) + target input + P-ACT input + spatially-correlated noise

Central to our dynamic field model is the way the model integrates perceptual and memory processes. We propose that interaction is not identical across all sites in the field, i.e., interaction is inhomogeneous. Specifically, interaction is more precise at sites associated with visible reference axes due to enhanced spatial tuning of visual processes at these locations. Thus, local excitation will be narrowly distributed at sites associated with a reference axis—the focus of enhancement—and broadly distributed across sites associated with regions of “empty” space. This is depicted in Figure 3. This figure shows the local excitation/lateral inhibition functions (positive/negative values) at twelve different locations in a sample field. The focal point in this example is at location 150, reflecting the presence of a reference axis at this central location. Local excitation is

**Figure 3.** Sample modulation of local excitation/lateral inhibition function around the focal point  $x_0$  (location 150).

most narrow at location 150, and expands to the left and right of this location.

The type of inhomogeneity we propose is conceptually similar to a proposal made by Suzuki and Cavanagh to account for repulsion effects in visual processing (1997); however, according to our proposal, inhomogeneities in visual processes couple directly into the processes that maintain location information in memory (via the interaction function). This has two effects on activation in the planning field over memory delays. First, activation peaks situated on or near the focus of enhancement will be attracted toward this focal point and remain stably positioned over delays. Second, activation peaks further from the focus of enhancement will be repelled from this focal point, because peaks gravitate toward sites with broader local excitation.

The form of inhomogeneous interaction we use is shown in Equations 2 and 3. We use an exponential form of inhomogeneity centered at the focal point  $x_0$ —the site associated with the reference axis. The width of local excitation is modulated across the spatial range specified by  $\sigma_\sigma$ , and the magnitude of the modulation is specified by the amplitude parameter ( $A_\sigma$ ).

$$w(x, x') = \frac{G_{\text{int}}}{\sqrt{2\pi}\sigma_{\text{int}}} \left\{ -w_i + \exp\left[-\frac{(x-x')^2}{2\sigma(x)^2}\right] \right\}$$

Equation 2. The interaction function is specified by  $w(x, x')$ , a local excitation/lateral inhibition function.

$$\sigma(x) = \sigma_{\text{int}}(1 - A_\sigma \exp[-(x - x_0)/\sigma_\sigma])$$

Equation 3. The interaction function (Equation 2) is inhomogeneous because the effective width of local excitation,  $\sigma(x)$ , depends on the field location  $x$ .

## Model Results

Figure 4 shows a simulation of the dynamic field model that captures delay-dependent results from the 20° condition in Spencer and Hund (2000). Recall that in this condition, participants moved to three targets positioned symmetrically about midline. Figure 4 shows how activation in the planning field evolves from second to second during one trial in which the target is presented at -20°. The lower left

**Figure 4.** Simulation of the dynamic field model. “Input” axes are identical to axes in field graph. Numbers mark events during a single trial. See text for details.

panel of Figure 4 shows the P-ACT input. Activation in this panel is high near -20°, 0°, and 20°, reflecting a participant’s memory of activation at these sites on previous trials. For simplicity, we assume that this input is relatively constant during a 20 s trial. The upper panel shows the target input. Activation in this panel is zero at the start of the trial when the target is not visible, high at -20° when the target is turned on, and zero again when the target is turned off. The P-ACT and target inputs are integrated within the action planning field shown in the right panel. At the start of the trial, the planning field is slightly “pre-activated” at previously moved-to locations (1). This reflects the P-ACT input. Next, a target is turned on and a peak of activation builds up in the planning field at the target direction driven by the strong target input (2). This input generates a peak that is maintained even after the target is turned off (3). Finally, during the delay, the peak is repelled from the focus of enhanced interaction (0°) and drifts away from midline (4). This effect is partially counteracted by the P-ACT input which attracts the peak toward previously activated locations, in this case, toward 0° (5).

The model depicted in Figure 4 not only captures how information is maintained in memory on a single trial, but also the delay-dependent pattern of constant and variable errors reported in Spencer and Hund (2000). Figure 5 shows simulation results from 100 iterations of the model in which the location of maximal activation in the field was read-out at different delays. As can be seen in this figure, the constant and variable errors computed from simulations of the model capture the pattern of error shown in Figure 2 across both delays and target separations.

**Figure 5.** (a) Directional errors over delays for simulated trials to the left and center targets in the 20° condition. (b) Constant and (c) variable directional errors for simulated trials to these targets across target separation conditions.

## Discussion

The dynamic field model effectively integrates the perceptual and memory processes that the literature suggests underlie biases away from reference axes. This model moves beyond the capabilities of previous location memory models in three fundamental ways. First, the field model proposes a specific integration mechanism that captures how location information is maintained from second-to-second over short-term delays. No current models of location memory are explicitly time-based. Second, the field model effectively reproduces time-dependent changes in both constant and variable errors near reference axes. Most models of location memory account for biases near reference axes; however, we know of no models that capture patterns of both bias and variability. Third, due to the “intrinsic” properties of the planning field, this field can generate its own activation in the *absence of input*. Thus, the field model can generate behavior that does not directly mirror the characteristics of input. Consequently, our model moves beyond models of location memory that posit that response biases are due to the relative weighting of inputs (e.g., Huttenlocher et al., 1991).

Finally, it is important to note that response biases in the dynamic field model are not solely a function of inhomogeneous interaction. As noted in Figure 4, the localization of activation peaks in the field is caused by the relative strength of repulsion effects (inhomogeneous interaction) and attraction effects (attraction toward P-ACT input). This has two important consequences. First, the field model may account for a second class of response biases prevalent in the spatial memory literature—attraction toward “prototypical” locations. We are currently exploring this possibility. Second, by changing the relative strength of repulsive and attractive effects, we may be able to capture striking differences in the performance of individuals. Consequently, the dynamic field model may offer insights not only into group effects, but also into the origins of individual differences in memory performance.

# A Simple Categorisation Model of Anaphor Resolution

Andrew J. Stewart (Andrew.Stewart@Unilever.com)  
Frederic Gosselin (gosselif@psy.gla.ac.uk)

## Abstract

In this paper we examine the way in which approaching the task of anaphor resolution as a categorisation problem can shed light on the possible mechanisms underlying pronoun resolution. We formulate a model of anaphor resolution data within SLIP (Strategy Length & Internal Practicability) (Gosselin & Schyns, 1997, 1999), a general categorisation framework. We chiefly focus on pronominal anaphors in this paper but we also report the results of modelling repeat name anaphor reading time data collected by Stewart, Pickering and Sanford (in press). The success of adopting the redefinition of anaphor resolution as a categorisation problem suggests that problems faced by the cognitive system that have been considered unique to particular processing domains might be understood at a more cognitively general level.

## Introduction

In this article we bring together work on categorisation and work on psycholinguistics. We adopt a particular psycholinguistic phenomenon as a case study and examine it within a categorisation framework. We illustrate what a categorisation perspective can offer psycholinguistics in terms of theoretical apparatus. We examine the performance of a model formulated within the SLIP (Strategy Length & Internal Practicability) categorisation framework (Gosselin & Schyns, 1997, 1999), and show that it can account for human behaviour in pronoun resolution, a problem common in language processing.

We begin by reviewing existing work on pronoun resolution. Then we move on to our proposal which redefines the task of pronoun resolution as a categorisation problem. Following this we turn to outlining the SLIP framework. Finally, we discuss the consequences of redefining pronoun resolution as a categorisation problem and examine the correspondence between our model's predictions and experimental data.

## Existing Psycholinguistic Work on Pronoun Resolution

Anaphors are expressions that refer back to characters mentioned in a text. One example of an anaphor is a pronoun. Consider the fragment of sentence (A) up to but including the pronoun 'he'.

(A) John blamed Bill because he had damaged John's car.

This pronoun could refer to either character. Based on the information conveyed by the pronoun itself, the only restriction is that it refers to a singular male character. As both potential antecedents match on these features the sentence could plausibly continue like sentence (A) or (B):

(B) John blamed Bill because he didn't really like Bill.

In (A) the pronoun is coreferential with the character 'Bill', while in (B) it is coreferential with the character 'John'. There are a number of cues available in the text to facilitate the process of identifying the appropriate pronominal referent.

## Grammatical role cues

One cue is the grammatical positions occupied by the potential antecedents. The word 'John' occupies the grammatical subject position, while 'Bill' occupies the grammatical object position. A number of psychological theories, e.g. Subject Assignment Strategy (Stevenson, Nelson, & Stenning, 1995) and Parallel Function Strategy (Sheldon, 1974), predict a preference to interpret the referentially ambiguous pronoun in the above examples as coreferential with the grammatical subject (although for different reasons).

Note that in the examples discussed in this paper the character occupying the grammatical subject position is also the first mentioned character. Gernsbacher (Gernsbacher & Hargreaves, 1988; Gernsbacher, 1989) proposed that the first mentioned character occupies a privileged position in the reader's discourse model. A similar first mention privilege has been observed in other tasks (e.g. Neath, 1993; Neath & Knoedler, 1994). One of the consequences of the first mention preference found in language comprehension is that later in a sentence it is relatively easy to refer to the first mentioned character.

## Gender cues

In addition to grammatical position information, other cues may also be present. Consider sentences (C) and (D) below.

(C) John blamed Mary because she broke the window.

(D) John blamed Mary because he was in a bad mood.

The gender differentiation between the two characters serves as an additional (strong) cue as to which character the pronoun can refer. However, even under conditions where gender information can unambiguously identify the appropriate pronominal referent, there is much evidence to suggest that the system does not immediately take advantage of this (Stevenson & Vitkovitch, 1986; MacDonald & MacWinney, 1990; Tyler & Marslen-Wilson, 1982). It appears that gender information is treated simply as another cue, not in any way qualitatively distinct from other factors.

## Semantic cues

A particularly strong semantic cue known as implicit causality (Garvey & Caramazza, 1974) can also facilitate interpreting the pronoun. Implicit causality is a property associated with a particular set of verbs which influences processing of the pronoun in constructions such as 'John blamed Bill because he...'. It is manifested as a bias to interpret the pronoun as consistent with the implied locus of cause underlying the described event; such as the action of 'blaming' in this example. 'Blame' is classed as an NP2 biasing verb as it biases toward the character occupying the second Noun Phrase as the causal locus. Similarly there are also verbs such as 'fascinate' which bias toward the first Noun Phrase.

The explicit cause information contained in the subordinate clause (e.g. 'broke the window') is an important disambiguating cue. In Example (B) the fragment 'didn't really like Bill' indicates that the pronoun should be interpreted in a manner inconsistent with the implicit causality bias. The causality congruency effect (Garvey & Caramazza, 1974; McDonald & MacWhinney, 1995) is the finding that it takes longer to read a sentence where the implicit cause and explicit cause conflict than when they are consistent with each other.

So then, the cues available to aid identification of a pronoun's referent include order of mention, implicit cause, gender and explicit cause. Given the restriction that gender and explicit cause must agree, the set of all possible combinations of cues has a cardinality of 8. This total set is shown in Table 1 with example sentences exhibiting those features and with the mean reading times associated with reading the disambiguating fragment, i.e. the explicit cause (Stewart, Pickering & Sanford, in press).

Compared to the large body of work proposing and investigating possible parsing mechanisms, there are relatively few formal theories of pronoun resolution.

## Centering Theory

An adequate explanation of a process requires reference to a possible formal mechanism underlying that process and, for pronoun resolution, must take into consideration factors such as gender agreement and implicit causality verb biases. Centering Theory (Gordon, Grosz & Gilliom, 1993) is the best articulated theory in the literature. Centering proposes that utterances have associated with them a set of forward and a set of backward looking centres. The forward looking centre contains as its members entities, one of which forms the referential link between one utterance and the next. Factors such as the grammatical role of the characters in a text influence the ordering of the prominence of each of these entities. The backward looking centre of an utterance contains one member; the entity used to maintain reference between that utterance and the one preceding. Centering theory is a descriptive theory, rather than a processing theory, in as much as it describes the nature of the referential cohesion between units of a text. Although it describes what

information might be used to facilitate pronominal reference resolution, it doesn't formalise how that information is used. This is hardly surprising as the theory originally grew out of work in Artificial Intelligence and so was never designed as a psychological model. How might a formal psychological model of pronoun resolution be arrived at? We propose that a possible way in which to arrive at a formal model of pronoun resolution is to make the explicit analogy between the problem faced by the processor in pronoun resolution and the problem faced by the processor in tasks of categorisation. In fact, at an important computational level we believe these problems are one and the same. There are many formal categorisation models and we believe that one in particular can be reinterpreted as a formal model of pronoun resolution.

## Mapping the problem of pronoun resolution onto that of categorisation

Let us return to Example (A), repeated below,

(A) John blamed Bill because he had damaged John's car.

The problem upon encountering the pronoun 'he' in this sentence can be understood as one of deciding of which category it is a member: should it be interpreted as a member of the set of expressions referring to the character 'John' or as a member of the set of expressions referring to the character 'Bill'? Furthermore, as we have discussed in above, this decision process is guided by explicit cause (and by gender, when it is relevant) and, to a lesser extent, by first mentioned character and by implicit causality information; these cues can be treated as features because they are discriminable parts of sentences that may be diagnostic with respect to the pronominal referent. Thus, a strong analogy can be made between problems of pronoun resolution and problems of categorisation. We shall study this parallel more thoroughly in the next section.

## A Categorisation Mechanism

SLIP (Strategy Length & Internal Practicability) was originally developed to model the results of experiments examining basic-levelness (Gosselin & Schyns, 1997, 1999). In this section we informally describe the SLIP framework and suggest how it can be used to model performance when faced with the type of categorisation problem required in identifying a pronominal referent. We provide a more complete treatment of this model in the Appendix.

We believe that pronoun resolution can be construed as a two-stage categorisation process. In the first stage, a hypothesis as to which referent is the most likely is generated. This is followed by the testing of this hypothesis. In the first stage, a SLIP categoriser extracts features randomly from the first half of the sentence. As soon as one critical feature is selected, a hypothesis is formulated. We believe that the first stage is informed by

Table 1. Total set of feature combinations with example sentences, reaction times reported in Stewart, Pickering & Sanford (in press), Experiment 4 and theoretical predictions of our categorisation model.

Sentence	Features							RT	Prediction
	F	NP1	NP2	G1	G2	CH1	CH2		
	1	1	0	1	0	1	0	1695	3.511
(1)	John fascinated Mary because he was very interesting.								
	1	1	0	0	1	0	1	1980	9.851
(2)	Mary fascinated John because he was easily interested.								
	1	1	0	1	1	1	0	1983	7.146
(3)	John fascinated Bill because he was very interesting.								
	1	1	0	1	1	0	1	2234	20.864
(4)	John fascinated Bill because he was easily interested.								
	1	0	1	1	0	1	0	1769	6.681
(5)	John blamed Mary because he was in a bad mood.								
	1	0	1	0	1	0	1	1641	6.681
(6)	Mary blamed John because he broke the window.								
	1	0	1	1	1	1	0	1893	14.005
(7)	John blamed Bill because he was in a bad mood.								
	1	0	1	1	1	0	1	1919	14.005

the first mentioned character and the implicit causality information. Order of mention is relatively salient and trivially recovered from the input. Au (1986) demonstrated that implicit causality information is also a very salient property. Both order of mention information and implicit causality contain some degree of uncertainty but they are also both useful predictors as to which way a sentence is going to continue (Garvey, Carmazza & Yates, 1975). The first mentioned character feature (F) can lead only to hypothesis\_1, i.e. the hypothesis that the first referent is the pronominal referent. The implicit causality information, however, favours hypothesis\_1 if the NP1 biasing implicit causality feature (NP1) is present in the sentence and hypothesis\_2 (the hypothesis that the second mentioned character is the pronominal referent) otherwise.

Consider again the first portion of our example sentences (1) and (5) in Table 1:

- (1) John fascinated Mary because he...  
 (5) John blamed Mary because he...

In the first case, the probability that hypothesis\_1 will win is 1 because the two diagnostic features (first mention and implicit causality) both suggest that hypothesis\_1 is appropriate. This is true of the first four example sentences in Table 1. For sentence (5) however, the probability that hypothesis\_1 will win is only .5 as the two features contradict each other. This is true of example sentences (5)-(8).

The hypothesis that was adopted in the first stage and the diagnosticity of gender both influence which verification strategy will be adopted in the second stage.

Suppose, for instance, that a categoriser is presented example sentence (1) from Table 1:

- (1) John fascinated Mary because he was very interesting.

At the end of stage one, the categoriser knows that gender information is relevant and it makes the hypothesis

that 'John' is the correct referent (i.e. hypothesis\_1). The extraction of either feature G1 or feature CH1 in the rest of the sentence verifies this hypothesis.

SLIP postulates a categoriser with a feature-extraction mechanism with a stochastic component. It is thus very likely that some features that are picked up by the categoriser are noninformative. For sentence (1), hypothesis\_1 will ultimately be verified but this can take time. In the SLIP framework it is simple to compute the number of features, on average, that will be needed to be picked up for the categoriser to reach a decision (see Appendix). This is the measure reported in the simulation. The predictions of our model for all the sentences are shown in Table 1 together with reading time data reported in Stewart, Pickering and Sanford (in press).

Let us contrast the treatment of sentence (1) with one identical on all points except for gender diagnosticity. A categoriser is presented with sentence (3) from Table 1:

- (3) John fascinated Bill because he was very interesting.

At the end of the first stage, hypothesis\_1 is generated and gender information is known to be nondiagnostic. We thus have one nondiagnostic gender feature and one diagnostic CH1 feature in this case (i.e. CH1). In the terminology of the SLIP framework, this sentence has less redundancy than sentence 1. After a while, hypothesis\_1 is also verified, but it takes longer to verify it in sentence (3) than in sentence (1) because of the lower redundancy of diagnostic information.

We now compare the first two situations with a third one in which the hypothesis formulated at the end of stage 1 is rejected in stage 2. A categoriser is shown example sentence (2) from Table 1:

- (2) Mary fascinated John because he was easily interested.

At the end of stage 1, hypothesis\_1 is proposed and gender is known to be diagnostic. This is similar to the outcome of stage 1 for sentence (1). Either G1 or CH1

would verify the hypothesis. Neither is present in the second portion of sentence (2) as the explicit cause information points to the second mentioned character (CH2). Thus, hypothesis\_1 needs to be rejected and hypothesis\_2 accepted. In the SLIP framework it is possible to compute a stop criterion based on an acceptable error rate so that if this criterion is reached, a revision of the hypothesis is made, i.e. the alternate hypothesis is adopted. In our simulation we have set the stop criteria at 11%, the error rate observed by Stewart, Pickering and Sanford (in press) (Experiment 4). Rejection of a hypothesis takes longer than verification of that hypothesis.

For sentences (5)-(8) from Table 1, the situation is slightly more complicated. Half the time hypothesis\_1 is selected in stage 1; half the time, hypothesis\_2 is selected. The average number of features that will be needed to be extracted before a decision can be made is the mean of that measure for the two possibilities. Take, for instance, example sentence (5) from Table 1:

(5) John blamed Mary because he was in a bad mood.

When hypothesis\_1 is proposed, the treatment of sentence (5) becomes equivalent to example sentence (1) already discussed; when hypothesis\_2 is elected, however, its treatment becomes equivalent to example sentence (2). So, the average number of features extracted before a decision is reached in sentence (5) is the mean of that in sentences (1) and (2). Arriving at a decision for sentence (5) is slower than (1) but faster than (2).

Stewart, Pickering and Sanford (in press) report the results of three further experiments examining the processing of anaphors in the context of sentences containing cues identical to the ones present in Experiment 4. The most important difference between those experiments and their Experiment 4 is that, while the anaphors in Experiment 4 are all pronouns, those in the remaining experiments are a mixture of ambiguous pronouns and unambiguous repeat names. In this paper we argue that the case of anaphor resolution can be reformulated as one of categorisation. Our main focus has been on the processing of anaphoric pronouns. To strengthen our argument, we need to show that our model also accounts for the processing of other types of anaphor. In addition to modelling Experiment 4 from Stewart, Pickering and Sanford (in press), we also modelled their Experiments 2 and 3 (deep processing condition). The raw Pearson correlations between the models' best predictions and the experimental data are .884 ( $p < .05$ ; best predictions: 1.12286, 1.11834, 1.12060, 1.12060, 1.15261, 1.28229, 1.25107, 1.25107 in the order of Stewart, Pickering, & Sanford's Table 1), .817 ( $p < .05$ ; best predictions: 1.20796, 1.64386, 1.42591, 1.42591, 1.38960, 2.02429, 1.69340, 1.69340 in the order of Stewart, Pickering, & Sanford's Table 1), and .816 ( $p < .05$ ), respectively, for Experiments 2, 3, (deep-processing condition), and 4. So, not only can our model correctly predict the reading time data associated with processing pronouns reported in Stewart, Pickering and Sanford (in

press), it can also correctly predict the reading times associated with the processing of more general anaphoric expressions.

## Discussion

Our categorisation function explains the first mention effect (Gernsbacher & Hargreaves, 1988; Gernsbacher, 1989), the causality congruency effect (Caramazza, Grober, Garvey & Yates, 1977; Ehrlich, 1980; Garnham, Oakhill & Cruttenden, 1992), and the effect of gender diagnosticity (Caramazza et al, 1977; Garnham et al, 1992) reported in the psycholinguistic literature. As outlined above, the first mention privilege is the finding that the first mentioned character is easy to later refer to within the sentence in which it appears. By considering the first mentioned character as 'special', and by associating a feature with it, SLIP performs more quickly when this character is the pronominal referent than when it is the second mentioned character. In other words, our model predicts that pronoun resolution is relatively straightforward when a pronoun refers to the first mentioned character. Our model also accounts for the causality congruency effect. It predicts that pronouns are more difficult to resolve when they occur in a sentence containing an NP1 implicit cause and an NP2 explicit cause. Our model predicts that the causality congruency effect will not be found for NP2 implicit cause verb conditions where the explicit cause is NP1. This is because the first mention privilege allows some difficulty that arises as a result of the implicit causality inconsistency to be overcome. In other words, our model predicts that, all other things being equal, the causality effect is asymmetrical. Although the causality congruency effect has been widely reported in the literature (McDonald & MacWhinney, 1995), possible accounts of its asymmetrical nature have never been provided. Finally, our model predicts that it should be easier to identify a pronoun's antecedent when gender information differentiates between possible referents (Caramazza et al, 1977; Garnham et al, 1992). Additionally, it also offers a computational explanation for why this is the case. In light of the close correspondence between our model's predictions and well-established psycholinguistic phenomena it is clear that not only does our categorisation function successfully characterise human performance on tasks of anaphor resolution, it also provides an explanation at the level of categorisation with respect to why this pattern of performance arises.

The success of SLIP on tasks as (apparently) diverse as anaphor resolution and basic level categorisation suggests that other types of cognitive tasks may also benefit from their reinterpretation as categorisation problems. Understanding the degree to which computational problems faced by the cognitive system in specific processing domains can be interpreted as specific instances of more general problems allows for the proposal of mechanisms of greater explanatory power than those currently suggested in (for example) the literature on anaphor resolution.

## Appendix

The gist of SLIP is both simple and intuitively appealing: a classifier with an imperfect pick-up mechanism serially cycles through one or many strategies test by test in an attempt to verify one of them. A strategy gives the procedure required to check whether an object is a member of a given category. More specifically, a strategy is a series of sets of redundant features. For instance, take example sentence (1) in Table 1 :

(1) John fascinated Mary because he was very interesting.

At the end of stage 1, hypothesis\_1 (i.e. the hypothesis according to which the first mentioned character is the pronominal referent) is made and gender is known to be diagnostic. This translates into the following strategy: S1 = [{G1, NP1}]. This is a length 1 strategy because it has only one set of redundant features. All the strategies required for pronoun resolution are of length 1 although for SLIP this does not have to be the case (see Gosselin & Schyns, 1997, 1999). For the sake of simplicity our formal discussion is confined to length 1 strategies here. The set of redundant features in S1 contains all the features which can decisively verify hypothesis\_1 in example sentence 1. Three other strategies are also used for the set of example sentences in Table 1: S2 = [{NP1}], S3 = [{G2, NP2}], and S4 = [{NP2}]. S2 is used when hypothesis\_1 is made and gender is nondiagnostic; S3 is employed when hypothesis\_2 is made and gender is diagnostic; and S4 is used when hypothesis\_2 is made and gender is nondiagnostic.

In the SLIP framework, a strategy as a whole is verified whenever all sets of redundant features have been individually verified in a specific order. A set of redundant features has been verified as soon as a one of its features has been verified. For example, S1 is verified as soon as either G1 or NP1 is verified. Given that a SLIP categoriser has a stochastic feature-pick-up mechanism, this verification habitually happens after a succession of misses. The probability of having t-1 successive misses is given by  $(P-PQ)^{(t-1)}$  where  $P$  is the probability of a random slip and  $Q$  is the probability of a diagnostic slip, i.e. the cardinality of the set of redundant features divided by the total number of features in the shown sentence. We assume in this article that 10 features are present in sentences for the verification stage: gender information (sometimes diagnostic and sometimes not), explicit cause (always diagnostic), and eight nondiagnostic features such as verb tense (this number was arbitrarily chosen, but a different one would make little difference). The probability of a hit is simply 1 minus the probability of a miss. Thus, the probability that a certain strategy will be verified after t tests is:

$$(P-PQ)^{(t-1)}[1-(P-PQ)].$$

This expression gives the Special Response Time Density Function (SRTDF) of a SLIP categoriser. It describes a geometric density function. The best fit between the data and our predictions is obtained with  $P = 1$ , meaning that features are gathered randomly.

The global measure reported in our simulations is the average number of features that have to be picked up before the categoriser reaches a decision (i.e. to verify or reject a strategy). We begin with the rejection case. If a categoriser has failed to verify a strategy after  $t_{stop}$  ( $t_{stop} = 1$ ) feature pick-ups either the strategy does not apply, or the categoriser's extraction mechanism has until then slipped onto nondiagnostic features. As  $t_{stop}$  increases the second possibility becomes less and less likely. A classifier could thus conclude quite confidently that a strategy does not apply if it has reached  $t_{stop}$  pick-ups if beyond this point the probability that the strategy applies to the pronoun is smaller than some small constant probability  $D$ . Given  $P$ ,  $Q$  and  $D$ ,  $t_{stop}$  can be calculated easily:

$$t_{stop} = \log D / \log(P-PQ).$$

This equation is known as the inverse survival function of probability  $D$ . A categoriser using this method errs with a probability of  $D$  on negative trials (i.e. it rejects the hypothesis when it is correct with a probability of  $D$ ). For the simulations  $D$  was set at .111, the subjects' mean error rate in Stewart, Pickering and Sanford (in press, Experiment 4). Note: this is not a free parameter. Consider example sentence (2).  $Q = 2/10$ . It thus takes our categoriser an average of 9.851 pick-ups before rejecting hypothesis\_1 and thus accepting the alternative hypothesis\_2.

Now that we know how to compute  $t_{stop}$ , we can calculate  $t_{mean}$ , the mean number of pick-ups required to verify positive trials (i.e. when a strategy is correct):

$$t_{mean} = \frac{\sum_{t=1}^{t_{stop}'} t \cdot SRTDF}{\sum_{t=1}^{t_{stop}'} SRTDF}$$

where  $t_{stop}'$  is simply  $t_{stop}$  rounded up to the next integer. Consider example sentence (1).  $Q = 2/10$ . We can thus use the  $t_{stop}$  calculated for example sentence (2); once rounded up it becomes 10. So,  $t_{mean}$  is equal to 3.511; it takes an average of 3.511 pick-ups for hypothesis\_1 to be accepted in this case.

## Category Induction for Ordinary Facts

Roman Taraban (r.taraban@ttu.edu)

Matt Hayes

Department of Psychology  
Texas Tech University  
Lubbock, TX 79409-2051

### Abstract

Typically, research on category learning has examined the acquisition of correct responses for explicitly identified categories. A connectionist model developed by McClelland (1981) used an interconnected network of factual elements to show that it was possible for a network to correctly infer connections between knowledge representations that were not explicitly coded into the network. Two experiments were conducted with adults using facts from the McClelland model. Clustering related facts, presenting the full set of transfer probes, and providing intermittent feedback during learning, did not reliably amplify the induction of implicit categories that was necessary for the transfer of learning tasks. The data in both experiments revealed a wide range of individual differences suggestive of graded levels of category induction. A series of simulations using backpropagation with recurrent connections showed that individual differences could be accounted for by manipulating feedback connections, the number of hidden units, and their connectivity. The discussion considers the relation of these findings to related research involving correlated features.

The notion of similarity has been very compelling in explanations of category acquisition. Intuitively it makes sense that we group things together because they are similar to each other. The details of how similarity should be computed have changed as theories have replaced one another over time (Taraban, 1993). However, one essential idea has remained, that category acquisition is driven by the identification or weighting of features that signal membership in one category or another. What is important to note for purposes of the present paper is that these theories of the relation of features to categorical distinctions have largely considered cases in which the features are all present and immediately available in instances of the object, and the possible classifications are made explicit to the learner (e.g., Nosofsky, Gluck, Palmeri, McKinley, & Glauthier, 1994). Typically, experiments have involved *supervised* learning, in which the category labels are part of what a participant learns. However, category learning is sometimes *unsupervised*, as when children learn to use linguistic elements that have an underlying categorical structure in their native language without ever labeling those categories (MacWhinney, Leinbach, Taraban, & McDonald, 1989), when they learn unlabeled categories in artificial languages (Billman, 1989; Brooks, Braine, Catalano, Brody & Sudhalter, 1993; Frigo & McDonald, 1998), or when they learn to classify events

(Kersten & Billman, 1997). In these cases, properties that are correlated form the basis for categories. The categories remain unlabeled and outside of direct instruction, but still influence individuals' classifications of novel instances.

Ordinary communication often carries correlated information, but it presents special difficulties because information is dispersed over time due to the serial and temporal nature of speech and print. A body of correlated information may be communicated, but the individual must construct or induce these correlations against temporal constraints. The question of how categories are formed and processed when the characteristic or defining features of the category are not simultaneously available has received very little attention. One of the few explicit models for the dynamic induction of categories based on co-occurring properties was proposed by McClelland (1981; see also McClelland & Rumelhart, 1988), who proposed a mechanism that could form generalizations from stored representations. The model was unique in that the "probe" or initiating information did not provide all the relevant cues simultaneously (e.g., *large, white, triangle*, as in Nosofsky et al., 1994). Instead, categories of co-occurring properties could be induced from encoded facts through a process of spreading activation and inhibition along connected pathways in a connectionist network. The network was capable of filling in missing information about an individual who was represented in the network (e.g., a gang member called *Lance*) due to co-occurring properties between that individual and other individuals represented in the network. The network could also provide the most likely features associated with groups (e.g., a gang called the *Jets*) based on properties that generally co-occurred with that group. The model is plausible in the sense that ordinary circumstances often expose us to disparate facts, and it has important implications in that it suggests we may still induce useful categorical generalizations based on co-occurrence patterns within those facts.

### Experiments 1 and 2

In Experiments 1 and 2, participants learned facts about individuals. Part of the learning was supervised, consisting of a name (e.g., *Lance*) and a category (e.g., *education*), with feedback indicating the correct response (*high school*). These facts are labeled the *base learning* items in Table 1. The responses to base learning items clustered into two im-

## Category Induction

PLICIT categories (i.e., all the individuals sharing the properties *Jets*, *high school*, and *drug dealer*, and all the individuals sharing the properties *Sharks*, *junior high*, and *car thief*). If participants induced these connections, it was through unsupervised learning, because those connections were never directly brought to participants' attention. Further, induction of these implicit categories drew heavily on memory, as the correlated properties never appeared together on a learning trial. Participants' induction of the implicit categories was tested using two types of transfer questions, *base transfer* and *novel transfer* items. Base transfer items asked participants about individuals' properties that were not among the base learning items. For instance, participants learned about Lance's gang and education, but not his occupation. For novel transfer items participants were given a "hint" about a totally new person (e.g., *Moe has a junior high education*) and were asked about the remaining properties (his *gang* and *occupation*).

Consonant with connectionist learning principles, performance on the transfer items would depend on weighted interconnections between elements. Relatedly, the amount of transfer would not be all-or-none but could occur in varying degrees. The discovery of individual differences would be consistent with learning in connectionist models, which occurs incrementally at different learning rates.

Category features that are activated together become associated (Billman, 1989; Kersten & Billman, 1997). As has already been described, learning trials in Experiments 1 and 2 presented a single property. Experiment 1 examined whether learning the underlying pattern of connections between properties could be facilitated by presenting related properties on contiguous trials. In Experiment 2, two additional manipulations were tested in an attempt to amplify category induction. One involved providing intermittent feedback during learning. The other involved presenting transfer probes during learning, without feedback. Both were meant to encourage participants to think about the connections between the properties they were learning.

## Method

**Participants** The 40 participants in Experiment 1 and the 60 participants in Experiment 2 were recruited from introductory psychology courses at Texas Tech University and participated for course credit.

**Materials** The learning and transfer materials were based on the table of information in McClelland (1981), although considerably reduced. Each of 16 individuals was described along three binary-valued dimensions: his gang membership, his education level, and his occupation. The assignment of dimension values to individuals was fully reliable in the following sense. If an individual belonged to the Jets, then that individual was also a drug dealer with high school education. Likewise, a member of the Sharks always had a junior high education and made his living as a car thief. Forty probes and eight hints were constructed from the matrix of information in Table 1. Each probe consisted of two parts: a name and the category of information about the named person. Example probes were *Art's gang*, *Art's education*, *Art's occupation*.

**Procedure** In Experiment 1, participants were randomly assigned to one of two conditions. In both conditions, learning trials were presented one at a time in blocks consisting of 18 probes. In the *unclustered* condition, the 18 base-learning probes were randomized. In the *clustered* condition, probes were also presented in random order with the exception that all probes about a particular person were presented in sequential trials (e.g., trial<sub>n</sub>: *Lance's education*; trial<sub>n+1</sub>: *Lance's gang*).

In Experiment 2, participants were randomly assigned to one of three conditions. The conditions differed in the number of base items that appeared in the learning sets and in the amount of feedback provided to participants during learning. The *control* condition was identical to the unclustered condition in Experiment 1. Participants learned the 18 base learning items shown in Table 1. The *intermittent-control* condition was identical to the control condition, except that feedback consisting of the correct response was provided at random two thirds of the time. The *intermittent-base* condition was identical to the intermittent-control condition, except that the six base transfer probes were mixed in randomly in each block of learning trials. Participants never received feedback on the base transfer items. The final test was identical in all three conditions.

Participants worked individually at a computer. One or two meetings were provided for learning the base items to

Table 1: Base Learning, Base Transfer, and Novel Transfer Items

Base Learning and Base Transfer Items				Novel Transfer Items			
Name	Gang	Education	Occupation	Name	Gang	Education	Occupation
Art	Jets	high school	drug dealer	Chuck	*	~ high school	*
Lance	Jets	high school	*	Jake	~ Jets	*	*
Greg	*	high school	drug dealer	Zane	*	~ high school	*
Pete	Jets	*	drug dealer	Ed	~ Jets	*	*
Nick	Sharks	junior high	car thief	Moe	*	~ junior high	*
Earl	Sharks	junior high	*	Gene	*	*	~ car thief
Karl	*	junior high	car thief	Vick	~ Sharks	*	*
Bill	Sharks	*	car thief	Ron	~ Sharks	*	*

\* Base and novel transfer items are marked with an asterisk. ~ The hints used for novel items are marked with a tilde.

criterion and one meeting was provided for taking the final test. Learning was self-paced. A learning trial consisted of a screen displaying a probe about one of the individuals in the experiment. The participant typed in a response. Feedback (when provided) indicated whether the response was correct or incorrect, and the correct response was displayed on the screen. Participants initiated the next trial by pressing a key on the keyboard. When participants reached the criterion of 17 or 18 correct, they were dismissed until the next day when the final test was administered.

Test trials were identical to learning trials in the way probes were presented and responses were made, except that participants did not receive feedback. Test trials were presented in two sets. The first set consisted of the presentation of the full set of 24 base-learning and base-transfer probes in random order. Immediately after responding to the 24 probes, participants were instructed by the computer that they would be presented with new items, that for each trial they would be given a “hint,” and that they should give their best response. For all trials, participants’ responses and accuracy were automatically recorded by the computer.

### Results for Experiment 1

Participants took an average of 215 trials to reach criterion in the unclustered condition and 189 trials in the clustered condition. Mean accuracy for all the learning trials in the unclustered condition was 63.6% and in the clustered condition 66.7%. Although these means favored mastering the base learning items in the clustered condition, an analysis of variance using number of trials as the dependent variable failed to show that the effect of condition was significant [ $F(1, 38) = 0.58, MSE = 11769, ns$ ], and an analysis using percent correct as a dependent measure failed to show that accuracy rates were significantly different [ $F(1, 38) = 1.60, MSE = 59.26, ns$ ].

Table 2: Mean Percent Accuracy for Final Test

Item Type	Experiment 1		Experiment 2		
	UN	CL	CO	IC	IB
Base Learning	83	84	85	83	82
Base Transfer	57	50	55	67	52
Novel Transfer	59	67	63	67	55

Note. UN: unclustered; CL: clustered; CO: control; IC: intermittent control; IB: intermittent base

Table 2 summarizes the final test data. Participants’ accuracy was high on base learning trials (84%), lower on novel transfer trials (63%), and lowest on base transfer trials (53%). A 2 (Condition: clustered, unclustered) X 3 (Item Type: base learning, base transfer, novel transfer) analysis of variance showed a main effect for item type [ $F(2, 76) = 23.85, MSE = 409.19, p < .001$ ] but not for condition [ $F(1, 38) = 0.03, MSE = 628.92, ns$ ] nor interaction of the two factors [ $F(2, 76) = 1.31, MSE = 409.19, ns$ ]. Tukey HSD (alpha = .05) tests showed that base learning accuracy differed significantly from base transfer and novel transfer ac-

curacy; base transfer and novel transfer did not differ from one another.

The possibility of individual differences in these data warranted a closer examination of individual test outcomes. Indeed, the rationale for a *gamma* parameter in the McClelland (1981) model was to allow for individual differences in induction. The incremental nature of connectionist learning is also suggestive of individual variation. Participants did quite well on the base learning items, but differed noticeably in their performance on the transfer items (See Appendix). Assuming a binomial distribution ( $n = 16, p = .50$ ) of individual responses for the novel transfer items, 35% ( $n = 7$ ) of the participants in the unclustered condition and 50% ( $n = 10$ ) in the clustered condition had accuracy rates that were not likely to be due to chance (accuracy  $\geq 75\%, p < .03$ ). For base transfer items, 10% ( $n = 2$ ) of the participants in the unclustered condition and 5% ( $n = 1$ ) in the clustered condition scored better than chance (binomial:  $n = 6, p = .50$ ; accuracy = 100%,  $p < .02$ ) (These three participants also scored better than chance on the novel transfer items).

### Results for Experiment 2

Participants took an average of 250 trials to reach criterion in the control condition, 284 trials in the intermittent-control condition, and 222 trials in the intermittent-base condition. These differences were not reliable [ $F(2, 57) = 1.10, MSE = 17756.41, ns$ ]. The mean percent correct was 61.4 in the control condition, 63.7 in the intermittent-control condition, and 58.4 in the intermittent-base condition. These differences were significant [ $F(2, 57) = 4.26, MSE = 33.87, p < .02$ ]. Tukey HSD tests showed that mean accuracy in the intermittent-control condition was significantly higher than in the intermittent-base condition. The control and intermittent control conditions were not significantly different. The small advantage for the intermittent-control condition was due in part to the additional blocks of trials these participants needed to reach criterion. These late trials tended to be error free.

The test data are summarized in Table 2. A 3 (Condition: control, intermittent-control, intermittent-base) X 3 (Item Type: base learning, base transfer, novel transfer) analysis of variance showed a main effect for item type [ $F(2, 114) = 31.93, MSE = 362.67, p < .001$ ]. Tukey HSD tests showed that base learning accuracy differed significantly from base transfer and novel transfer accuracy; base transfer and novel transfer did not differ from one another. The effect of condition was not significant [ $F(2, 57) = 1.56, MSE = 834.38, ns$ ], nor was the Condition X Item Type interaction [ $F(4, 114) = 0.98, MSE = 362.67, ns$ ].

A closer look at individual performance was again undertaken. For the novel transfer items, 40% ( $n = 8$ ) of the participants in the control condition, 55% ( $n = 11$ ) in the intermittent-control condition, and 30% ( $n = 6$ ) in the intermittent-base condition had accuracy rates that were not likely to be due to chance (binomial:  $n = 16, p = .50$ ; accuracy  $\geq 75\%, p < .03$ ). On base transfer items, 15% ( $n = 3$ ) of the participants in the control condition, 20% ( $n = 4$ ) in the intermittent-control condition, and 5% ( $n = 1$ ) in the intermit-

tent-base condition scored better than chance (binomial:  $n = 6$ ,  $p = .50$ ; accuracy = 100%,  $p < .02$ ); all but one of these also scored better than chance on the novel transfer items.

Because the experimental manipulations in Experiments 1 and 2 failed to produce reliable differences, combining the data was warranted in order to increase statistical power. Across the 100 participants, mean accuracy on base transfer items was 56%, and on novel transfer items it was 62%. A one-sample  $t$ -test showed that base transfer performance was significantly greater than chance (50%) [ $t(99) = 2.55$ ,  $p < .02$ ]. A paired  $t$ -test showed that performance on novel transfer items was significantly higher than on base transfer items [ $t(99) = -2.06$ ,  $p < .05$ ]. Overall, participants did better on novel transfer items. Performance for both types of transfer items exceeded chance.

## Discussion

A knowledge base was organized around individuals, like Art and Lance, about whom participants learned properties (e.g., *Lance's gang is Jets*; *Lance's education is high school*). In order to transfer knowledge of these facts to new instances, participants had to use the learned facts to induce the categorical relations between them. There is no specific way in which this had to be done. A person might notice that *Jets* and *high school* always co-occur without noting the link with *drug dealer*. A person might induce some other connections or the complete set of connections. An examination of individual performances (see Appendix) suggests large discrepancies in induction. Some participants appeared to perform at chance on the transfer trials, others scored perfectly, and yet others were in between. These data suggest that individuals can evoke the appropriate categories even if these were not explicitly taught. As the McClelland (1981) model suggests, it is not necessary to develop explicit connections in order to exploit the existing connections in useful ways. The data also support the supposition that the level of induction is graded. This is consistent with connectionist models, which do not encode rules or *If-Then* productions, but which develop interconnections and internal representations (on a hidden layer) incrementally, or alternatively, which control the spread of activation and inhibition parametrically within a storage and retrieval mechanism like McClelland's (1981).

## Connectionist Simulations

In a preliminary set of simulations, the base learning items in Table 1 were interconnected as described in McClelland (1981) and McClelland and Rumelhart (1988). There were no direct connections for base transfer items (e.g., a link from *Lance* to *drug dealer*). For novel transfer items, the "hint" (e.g., *Jets*) was activated. The model was tested at three settings of  $\gamma$ , a parameter that controls the level of inhibition between units in the same pool of units in the network, and thereby changes the level of generalization (McClelland, 1981). With  $\gamma$  set to .1000, .1249, or .1500, the mean probability of a correct response to base learning items was .98. Probabilities for base transfer items were .97, .67, .50, respectively. For all three  $\gamma$  values

the probability of a correct response to novel transfer items was .98.<sup>1</sup> The first two findings are consistent with the findings in Experiments 1 and 2, that is, a range of individual differences on base transfer items when performance was high on base learning items. The third outcome of the simulation, uniformly high performance on novel transfer items, did not fit the data, which showed a wide range of individual differences on these items. It is generally impossible to salvage the McClelland (1981) model. When given a hint like *Jets*, the network needs to find only one member with that feature and will generalize from that member. The highest levels of inhibition leave at least one member to generalize from. Another shortcoming of the McClelland model for present purposes is that it uses fixed weights and thus does not account for individual differences based on learning.

The binomial analyses of individual performance presented earlier suggested that there were three major patterns of behavior (See the Appendix for representative data). The most predominant pattern, characteristic of 54% of the 100 participants, was above chance performance on the base learning items and chance performance on base transfer and novel transfer items, which will be labeled the HLL pattern. The next most predominant pattern, representing 29% of the participants, was above chance performance on the base learning, chance performance on the base transfer items, and above chance performance on novel transfer items (the HLH pattern). Ten percent of the participants achieved above chance performance on all items (the HHH pattern). Only one participant had a HHL pattern. Three participants had LLH patterns and three had LLL patterns. The connectionist solution presented next required the simultaneous manipulation of multiple connectionist factors, including network architecture, hidden unit resources, connectivity, and internal feedback. The model replicated all the patterns above except the LLL and the LLH patterns. Adding a decay factor would be necessary to account for human participants who reached the criterion on the day prior to the test but who scored at chance (L - -) on base learning items on the day of the test.

The model is depicted in Figure 1. The inputs, corresponding to probes, activated exemplars (*local* representations). Each input (e.g., *Art*) was linked to a single exemplar unit (e.g., *Art*). All other units between pools were fully interconnected. The output units had recurrent connections back to a hidden layer of units (*distributed* representation). The hidden layer also received connections from the exemplar units. A learning trial occurred in two

<sup>1</sup> All connections in the network were set to 1. Default values were used for the parameters  $\alpha$ ,  $\text{decay}$ , and  $\text{estr}$ . The remaining parameters were set to  $\text{max} = 1.10$ ,  $\text{min} = .01$ ,  $\text{rest} = .01$  for ease of interpreting the output. The probabilities were based on an application of the Luce (1959) choice rule to the activations from the relevant pool of units; e.g.,  $P(\text{Jets}) = \text{activation}(\text{Jets}) / \text{activation}(\text{Jets}) + \text{activation}(\text{Sharks})$ .

Table 3: Mean Probabilities (X100) for the Connectionist Simulations

Item Type	Feedback Connections Only										Feedback and Exemplar Connections										
	Number of Hidden Units										Number of Hidden Units										
	1	2	3	4	5	6	7	8	9	10	1	2	3	4	5	6	7	8	9	10	
Base Learning	90	92	91	91	91	91	91	91	91	91	90	94	96	97	97	97	97	97	97	97	97
Base Transfer	51	53	44	49	48	49	52	52	51	51	53	73	88	92	92	89	94	93	91	91	91
Novel Transfer	50	55	78	88	82	81	52	48	51	49	51	54	89	95	93	94	51	50	55	52	52

passes. During the first pass, the output units were activated by the inputs via the exemplar and hidden units. During the second pass, activation was passed back to the hidden units via the recurrent connections and only these units fed activation forward to the output units. Error on each pass was calculated and weight adjustment took place through the application of the backpropagation learning rule (Rumelhart, Hinton, & Williams, 1986) at the end of each epoch of training. An epoch of training consisted of one exposure to each base learning item.

For base learning and base transfer test trials, a name (e.g., *Art*) and category (e.g., *occupation*) were presented on the input layer, and the probability of a correct response was computed using the Luce (1959) choice rule for the relevant activations (see footnote 1). For novel transfer items, the “hint” (e.g., *gang*, *Jet*) was activated on the output layer, which functioned as the “teacher,” and fed back to the hidden units; the probe category (e.g., *occupation*) was activated on the input layer. Activation was fed forward to the output layer and probabilities were computed as described above. On test trials, there was a single pass through the network and no weight adjustments.

Activation and weight adjustment roughly corresponded to a trial in the human experiments. An explicit probe evoked an output, feedback was provided and all the weights were adjusted in order to improve performance on the base learning items. During the second pass, there was an implicit recirculation of the outputs through the hidden layer (cf., McClelland, McNaughton, & O’Reilly, 1995, for a discussion of consolidation in memory) and related weight adjustment. The first pass in learning corresponded to elements that could be observed in the experimental manipulation (e.g., probes, response, feedback). The second pass corresponded to unobservable processes for which some justification will be provided in the course of describing the simulation manipulations and results.

Each simulation outcome presented in Table 3 is the mean of 10 independent simulations. All the parameters in the simulations were fixed, except whether or not the exemplar units were connected to the hidden units, and the number of hidden units, which varied from one to ten. The learning rate for all trials was .01, momentum was .90, and each simulation consisted of 4000 epochs of training. Eleven input units were used to code base learning trials. One input was allocated to each of eight gang member names and one to each category of information (i.e., gang, education, occupation). Thus, the input layer mimicked a participant who was asked *Art’s gang*, for instance. Each of these input units connected to a single exemplar unit. These internal exemplar representations were necessary to guarantee high learning of the base learning items across all manipulations of the hid-

den units. The exemplar units connected fully to all the output units. The output units coded the same elements as the input layer and, additionally, the responses to the probes (e.g., *Jets*, *drug dealer*). These feedforward connections from input to exemplar units to output units were all that was required to learn base learning items.

Figure 1: The Simulation Model

Feedback connections from all the output units were fully connected to the hidden units. A practical benefit of the feedback connections is that they allowed the “hint” that was used for the novel transfer trials to originate from the “teacher” (output) units, where the responses were coded. Feedback connections like these, or an equivalent, were necessary to cross reference the probes and responses in the experimental manipulation. These feedback connections were primarily responsible for the gradations of performance, up to 88% correct, on novel transfer items depending on the number of hidden units (see Table 3). By varying the number of hidden units, base learning items were high (90%-92%) and base transfer items were near chance (48%-53%). In half of the simulations, the exemplar units also connected to the hidden units. These additional connections, along with the feedback connections from output units, allowed for gradations of performance on base transfer (53%-94%) and novel transfer items (50%-95%), depending on the number of hidden units. Near perfect performance on all three types of items occurred with four hidden units: base learning (97%), base transfer (92%), and novel transfer (95%).

The simulations were not intended to account for all the individual differences in the human data, but rather to uncover network organizations that produced variations comparable to those observed in the human performance. Doing well on base transfer items requires connections between the exemplar units and the hidden units. One account of participants’ better performance on novel versus base transfer items is that connections from exemplar units to hidden units were formed less readily than feedback (recurrent) connec-

tions. The pattern in Table 3 for the transfer trials also suggests that too few or too many hidden units is not ideal. This suggests that the hidden units control the dimensionality of the solution (cf., Hinton, 1992). The dimensionality of the solution determines how much induction takes place (cf., Landauer & Dumais, 1997).

### General Discussion

The experiments and simulations presented here were inspired by McClelland's (1981) connectionist model that was able to infer connections between stored "facts," even though the network was not explicitly trained to make those connections. Correctly making these inferences depends on uncovering the correlational structure between the facts. Further research is necessary to confirm that differences in the conditions of learning and retrieval are crucial to explaining the strong individual differences found in the human performance here and elsewhere. Two bodies of research currently suggest somewhat different conclusions on these points. Billman (1989) and Kersten and Billman (1997) contrasted learning and generalization for stimuli with many correlated features to those with only few correlated features and found that participants readily generalized from the former but not the latter. The features of the facts in Experiments 1 and 2 were also highly correlated, but participants did not readily form generalizations from them. The crucial difference, which remains to be tested more fully, is that Billman and Kersten explicitly displayed the correlations as part of their learning phase, whereas the connections in our experiments were implicit across learning trials. For instance, *Jets* and *drug dealer* are perfectly correlated, but participants never viewed those two features together. The present manipulations are more comparable to the "control" language in the artificial language experiments of Brooks et al. (1993). Their control language also had a rich correlational structure comparable to the ways in which noun gender in languages like Russian affects morphological and inflectional differences. In spite of the underlying correlations, participants found the control language difficult to learn, we surmise, because the correlational structure was implicit across trials as in the present study. However, the generally low performance for the control language presumably included a range of individual differences, as presented here, meaning that some individuals discover the correlational structure in spite of its dispersion over trials. Therefore, we believe that the present research begins to bridge several lines of existing research, that it uncovers the broad individual differences in performance, and offers a preliminary connectionist explanation for those differences. The counterpart to the "experimental" language in Brooks et al. and "high systematicity" in Billman needs to be tested for the current stimuli and integrated into the present connectionist architecture.

### Appendix

Each triple, separated by semicolons, is mean percent accuracy for each participant, for base learning, base transfer, and novel transfer items, respectively.

Boulevard du Rectorat, 5

4000 Liège BELGIUM

## Abstract

When subjects learn to categorize new stimuli adequately, they have to segment these stimuli into relevant features for categorization. In the experiments reported here, children had to discover a rule for categorization. Preliminary experiments have shown that depending on the nature of the irrelevant features, children could find the relevant features from age four or could not find them before the age of eleven or twelve. A central question is whether children aged four or six who have discovered the rule in a simplified version of the relevant features would generalize to a "complex" version (i.e., in which there is more background noise) of the relevant features, i.e., a version that they would be unable to learn before twelve without pre-training. Conditions promoting the generalization from the simple version to the complex version were also investigated. Two conditions were compared: relearning with or without feedback. Results showed that children aged 4 and 6 could generalize the "simple" version of the target concept to a more complex version of the same concept, either with and without feedback in the generalization phase.

## Introduction

Children have to learn to categorize stimuli according to adults' standards. In order to achieve this correctly, they have to find the relevant features for categorization. If the particular task is to learn to categorize a set of new stimuli into two new categories, they will have to find the features that characterize stimuli of each category and that distinguish them from stimuli of the other category. Imagine a traditional concept learning experiment in which participants have to discover one relevant feature that allows for perfect categorization. Stimuli are constituted of a number of dimensions, either relevant or irrelevant. Subjects are presumed to formulate and test simple hypotheses concerning the rule that define membership (Nosofsky, Palmeri, & McKinley, 1994). This means that participants will analyze stimuli into their dimensions and test whether each dimension partitions the set of stimuli. A number of characteristics of the stimuli contribute to the task difficulty. The salience of dimensions: a non salient relevant dimension among salient irrelevant dimensions presumably requires more systematic analyses of the stimuli than a salient relevant dimension among non salient irrelevant dimensions.

Variability in the perceptual manifestation of a relevant feature can hinder this relevant feature and impede its discovery. For example, compare Figure 1A stimuli with

Figure 1C stimuli which define two experimental conditions. In the two conditions, the stimuli come from two categories defined by the same relevant features. Each stimulus has four "legs", with one category being defined as "1 isolated leg and 3 connected legs" (1+3), the other category being defined as "two sets of two connected legs" (2+2). In Figure 1C the length, shape, size of the legs were made more variable than in Figure 1A. Preliminary results obtained by Thibaut (1999) indicate that the rule (1+3 vs. 2+2) could be discovered from the age of four in the case of Figure 1A stimuli whereas children under thirteen could not find the equivalent rule for Figure 1C stimuli. Figure 1B stimuli elicited intermediary results: most children aged ten discovered the rule.

Thibaut (1999) suggested that young children had problems either in screening the stimuli, or inhibiting irrelevant features, or plan systematic comparisons between stimuli. The purpose of the present contribution is to assess to what extent young children (four- or six-year olds) who discovered the relevant features for categorization 1+3 vs. 2+2 in the simplified version (Figure 1A) would be able to generalize to more complex versions of the same features (Figure 1B and 1C). In other words, once he/she has learned to apply a classification rule in a low variability context (such as Figure 1A stimuli), is a child able to apply it in a high variability context ?

It has been emphasized in the developmental literature that there are differences between adults' and children's in processing abilities. According to Kemler (1989), children are more holistic processors than adults. She suggested that holistic processors would run into more difficulties when only one of many attributes is relevant for categorization than when categories are defined by overall similarity relationships, i.e., when stimuli share many characteristic features. Other authors consider that property-specific information is accessible to young children, even those aged 4 or 5 years. This means that children can analyze stimuli in terms of their constituent features, even if they do not analyze the stimuli in the same way older children and adults do. Ward (1989), Ward and Scott (1987) have argued that the difference between young learners and older learners is that younger learners may have rigid attribute preferences.

Following the holistic view, one can hypothesize that if young children perceive stimuli holistically, they should be unable to analyze the complex stimuli into their constituents and, thus, should also be unable to isolate specific aspects of the legs in order to generalize the simple version of the rule to the complex version. In the same

way, if young children have rigid attribute preferences it might be that, when confronted to the complex stimuli, they will focus their attention on the salient irrelevant properties and be unable to analyze the legs in terms of less salient properties.

Studies on generalization generally take a different perspective from the one followed here. Usually, children first learn a given concept, then they are presented with a set of new stimuli, the purpose being to analyze to which among these new stimuli they generalize the concept. Here the issue is to analyze to what extent children who discovered a rule for categorization in a simplified context will be able to generalize it to more complex objects for which they would be unable to discover the rule if they had to discover it without being first presented with the simple version. This is important because a positive answer would mean that an appropriate learning sequence can lead to an understanding of concepts which, otherwise, would remain out of the conceptual world of the child. Two generalization conditions will be compared. In the first one, children will be given feedback when they will learn to apply the simple rule to the complex stimuli. In the second condition, there will be no such feedback. It is believed that feedback will promote the understanding of the equivalence between the known simple version of the rule and its complex version. This is because, if young children do not perceive this equivalence at first glance, they can test different translations of the simple rule in terms of the complex rule and get feedback at each trial. In the no feedback condition, successive trials do not bring any information about children's successive hypotheses. If a child does not find the correct way to generalize the simple version of the rule after a limited number of trials, the absence of feedback increases the probability that his/her attention will be caught by salient irrelevant features.

### Experimental Design

Preliminary results (Thibaut, 1997) have shown that children under thirteen could not parse Figure 1C stimuli adequately. In the same way, most of children under eight could not find the relevant feature for categorization in the stimuli displayed on Figure 1B. On the other hand, the majority of children aged four could find the relevant features 1+3 and 2+2 in stimuli such as the ones displayed in Figure 1A. The purpose of the experiment was to assess whether children aged four and six who are able to find the relevant features for categorization for the simple stimuli (Figure 1A) would be able to generalize them to the stimuli displayed in Figures 1B or 1C.

The design of the experiment is summarized in Table 1.

### Methods

**Participants.** Fourteen 6-6.11-year-olds participated in the complex transfer items with feedback condition, eleven 6-

6.11-year-olds participated in the complex transfer items with NO-feedback condition, fourteen 6-6.11-year-olds participated in the semi-complex transfer items with feedback condition, fifteen 6-6.11-year-olds participated in the semi-complex transfer items with NO feedback condition, eleven 4-4.11-year-olds participated in the complex transfer items with feedback condition, twelve 4-4.11-year-olds participated in the semi-complex transfer items with feedback condition and nine 4-4.1-year-olds participated in the complex transfer items with NO feedback condition. All children were tested individually.

Table 1 : design of the experiment.

Age	Aged 4	Aged 6
Conditions		
Training condition and transfer with complex stimuli, NO feedback	x	
Training condition and transfer with complex stimuli, with feedback		
Training condition and transfer with semi-complex stimuli, with feedback		
Training condition and transfer with semi-complex stimuli, NO feedback		

Note. Cell marked "x" was not run.

**Materials.** The two categories (1+3 and 2+2) of eight stimuli were the ones used by Thibaut (1997). The learning stimuli (simple version) are presented on Figure 1A. The 16 stimuli were composed of four legs which were thin and vertical. There were eight 1-3 stimuli and eight 2-2. In this condition, the purpose was to remove salient irrelevant features for categorization. There were two sets of transfer stimuli, complex and semi-complex. The complex transfer stimuli were outlines of unknown shapes composed of two parts, the upper part (the body) and the lower part (four legs). The two categories had the same structure. In five out of the eight stimuli, the body had a mushroom-like shape that was slightly distorted over the stimuli in the case

Figure 1A: two "simple" stimuli used in the training phase.

Figure 1B. Four semi-complex stimuli. Both categories (2+2 and 1+3) contain an equivalent proportion of thin and large stimuli.

Figure 1C. Four complex stimuli from categories 1+3 and 2+2. The first stimulus has the body (upper part) characteristic of category 1+3 and the third stimulus has the body characteristic of category 2+2. The UP1 stimuli are neutral stimuli.

of category 1+3, and an angular shape in the case of category 2+2 stimuli. These two shapes were selected for their distinctiveness and perceptual saliency. The three remaining stimuli from each of the two categories were constructed with three different bodies (UP1, UP2, UP3). Since UP1, UP2, and UP3 were present in both categories

they could not be considered as cues for categorization (see Figure 1C). For each stimulus, the lower part consisted of four legs which were spatially grouped either as one leg on the left and three legs on the right in category 1+3, or two pairs of legs in category 2+2 (see Figure 1C). These

distinctive features (1-3 vs. 2-2) were the only ones available in order to categorize all the stimuli correctly.

For the semi-complex transfer stimuli, a set of 16 stimuli was constructed. The irrelevant cues "thin" "vertical", "the rightmost leg pointing to the right", and "large" were crossed with the cues "one leg plus three legs" (1+3) and "two pairs of legs" (2+2) according to four types of stimuli. There were four 1-3 stimuli and four 2-2 stimuli with "thin" legs and "the rightmost leg pointing to the right", and four 1-3 stimuli and four 2-2 stimuli composed of "broad and vertical legs" (see Figure 1B for examples of the 4 types of stimuli).

### Procedure

**Familiarization phase.** The entire set of training stimuli (Figure 1A) was presented once to the subject. Each stimulus was shown for five seconds. Then, it was removed and followed by a new stimulus. There was no feedback during this phase, and when it was over, participants were then told that they would have to learn to sort the stimuli into two categories, the name of which was provided, "bollo" for the 1-3 category, "tipi" for the 2-2 stimuli.

**Learning phase.** A first stimulus (simple version, Figure 1A) was presented for approximately five seconds

and the subject had to guess its name. The experimenter gave the appropriate feedback and presented the second stimulus in the same way, followed by the other stimuli. Feedback was provided after each answer. The order of presentation of the stimuli was random. Once the entire set of stimuli had been presented to the subject, it was presented a second time. The learning phase was stopped when children made no mistake during two successive presentations of the set of stimuli or if they were still making errors after the ninth presentation of the set. Subjects were tested individually. A session lasted for 10 to 25 minutes, depending on the number of trials necessary to complete the task.

**Transfer phase.** Children who had learned the rule for categorization had to categorize the transfer stimuli. Children were told that they would have to classify new "tipi" and "bollos" different from the ones they had seen before. In the complex stimuli with feedback condition, children were presented with the complex stimuli (Figure 1C) in the same way as in the learning phase. They received a feedback after each trial. In the semi-complex with feedback condition, children were presented with the semi-complex stimuli and received a feedback after each trial. In

Table 2. Number of subjects who reached the criterion in the two age groups and the various experimental conditions: with or without training with simple stimuli and with or without feedback in the transfer phase

Condition	Four-year-olds		Six-year-olds	
	Correct	Failure	Correct	Failure
Complex stimuli (no training with simple stimuli)	0	10	0	10
Semi complex stimuli (no training with simple stimuli)	0	10	6	8
Training condition and transfer with complex stimuli and no feedback	x	x	6	5
Training condition and transfer with complex stimuli and feedback	4	7	9	5
Training condition and transfer with semi-complex stimuli and with feedback	9	3	12	2
Training condition and transfer with semi-complex stimuli and NO feedback	8	6	11	4

Note. Cells marked "x" were not run.

the complex with NO feedback condition, complex stimuli were presented, and children never received a feedback after their classification. In the semi-complex with NO feedback condition, semi-complex stimuli were presented, and children never received a feedback after their classification. In all these experiments, the learning criterion was the same as in the learning phase.

## Results and discussion

The purpose of the experiment was to assess whether children who had first learn the rule for categorization with simple stimuli would be able to generalize it to semi-complex or complex stimuli when a feedback was provided or not. Results are summarized in Table 1. Khi square comparing data obtained in the control condition (no training with simple stimuli, Thibaut, 1997) with the new data (training with simple stimuli) revealed a significant difference in the majority of cases ( $p < .05$ ). The only exception was the case of the "generalization to complex stimuli with feedback" condition with children aged four. In this condition, a majority of children failed to generalize correctly. In sum, in a majority of conditions, training with simple stimuli influenced generalization positively. This is important because it suggests that people can generalize what they have learned to new situations that would have been beyond their understanding without this pre-training. The results obtained in conditions with feedback were compared with the equivalent results in conditions with no feedback. Comparisons revealed no significant difference (Khi square,  $p > .05$ ).

A number of authors have described children's concept learning in terms of attentional capacities (capacity to focus on specific dimensions) or of sensitivity towards dimensions (see introduction). The present results indicate that one has to include other dimensions in any model of concept learning. First, provided that exemplars of a given dimension can be highly variable (compare the simple and the complex versions of the rule), the notion of a "sensitivity to a dimension" cannot be assessed independently of the variability across instances of this dimension. This means that the probability that a relevant dimension will be discovered also depends on the presence and the structure of the other dimensions (irrelevant) that compose the stimuli. Second, in order to understand whether or not a particular instance of a dimension will be discovered by children, one has to include participants' history of categorization. By history of categorization, I mean the categorizations already performed by an individual (see Schyns, Goldstone, & Thibaut, 1998; Thibaut & Schyns, 1995). The present data suggest that the history of categorization influenced positively the way children generalized the rule. To summarize, a model of categorization and generalization has to take selective sensitivity to a particular dimension into account, provided that this notion incorporates the notion of variability in the instantiation of the dimension across stimuli. It must also

incorporates the history of categorization with a particular category in order to understand whether or not children are able to generalize a given dimension to new instances of this dimension. The present data show that knowing the history of categorization, one can predict whether a set of new stimuli is learnable. Complementarily, one can predict which history of categorization is necessary to promote generalization to subsets of highly variable stimuli. This is particularly important given that, in a majority of cases, we do not encounter identical instances of the same category.

The results presented here are important because the status of the transfer stimuli is controlled *a priori* more systematically than in traditional category learning experiments. In these latter studies, participants are confronted with transfer items of which the "intrinsic complexity" is not known. Here, the stimuli complexity in terms of learnability was independently assessed before the experiment. This is important for the control of the "paths of generalization". Following the learning strategy used here, one can bypass the role of the salient irrelevant features that would mask the relevant features for categorization whereas starting with the complex stimuli would lead to the incorrect conclusion that young children are unable to abstract the rule for categorization.

## Abstract

A significant part of everyday learning occurs incidentally — a process typically described as implicit learning. A central issue in this and germane domains such as language acquisition is the extent to which performance depends on the acquisition and deployment of abstract rules. In an attempt to address this question, we show that the apparent use of such rules in a simple categorisation task of artificial grammar strings, as reported by Shanks, Johnstone, and Staggs (1997), can be simulated by means of a simple recurrent network, and may thus turn out not be incompatible with the acquisition of statistical regularities rooted in the processing of exemplars of the presented material.

## Introduction

Over development and learning, we acquire a considerable amount of information incidentally. Natural language offers perhaps the most striking example of such incidental learning: Infants do not need to be explained grammar rules in order to be able to communicate effectively and are presumably unaware of the fact that they are learning something at all. Adult speakers likewise “know” whether expressions of their native language are grammatically correct but can seldom explain why.

## Implicit Learning

The notion of “*implicit learning*” (IL) usually designates cases in which a person learns about the structure of a fairly complex stimulus environment, without necessarily intending to do so, and in such a way that the resulting knowledge is difficult to express (Berry and Dienes, 1993). In short, IL is the ability to learn without awareness (Cleeremans, Destrebecqz, and Boyer, 1998), as opposed to explicit learning, which is strategy- and/or hypothesis-driven, and of which one tends to be consciously aware.

IL can produce *implicit knowledge*. According to Cleeremans (1997), “at a given time, knowledge is implicit when it can influence processing without possessing in and of itself the properties that would enable it to be an object of representation, and implicit learning is the process by which we acquire such knowledge.” (p.199) As for the notion of “representation”, we agree with Perruchet and Vinter (submitted), who state that a representation has to *represent* an entity in the real world and has to be in and of itself manipulable *as* that entity (Perruchet and Vinter talk about

its “function within a causal system”). Therefore, an entity that is an *object of representation* has to exist independently from the “hardware” of the system by which it is represented, making it available for information-processing operations in a variety of contexts (Cleeremans, 1997) — such as a rule that is applicable to different instances of a certain problem.

Inherent to this issue is the question of whether the mechanisms through which implicit and explicit knowledge are acquired are best viewed as being subtended by separate processing systems. This is exactly what has been suggested by Shanks and colleagues (Shanks and St John, 1994; Shanks, Johnstone, and Staggs, 1997; St John and Shanks, 1997), who proposed to abandon the distinction between Implicit and Explicit Learning in terms of conscious awareness being present or not, and instead suggested that the distinction is one of rule-based versus memory-based learning processes. Before going any deeper into this matter, let us consider two different ways of looking at learning in general, to illustrate how they can possibly account for Implicit Learning.

## Computational Modelling of IL

Two views come forth when considering the mind in general, and implicit learning in particular: the symbolic and the connectionist approach. Each has its own view on how knowledge is represented and how it might be manipulated. The symbolic metaphor is usually associated with rule-based learning, while the connectionist metaphor is associated with memory-based learning based on the statistical characteristics of the stimuli.

**The Symbolic Metaphor.** Cleeremans & Jiménez (submitted) point out that a symbol system leaves no room for a concept like IL. In a symbol system, expressions that are formed are static representations of (real-world) entities or relations, stored in the system’s memory. These symbols, be it of objects or of rules, have to be interpreted by something — a processor — when they are to be used by the system to augment its knowledge base (memory), that is, to learn. From this perspective, IL can only exist if one assumes the existence of a *cognitive unconscious*, i.e. a subset of the mind that can basically process all the information that the conscious system can process, only minus consciousness. Consequently, consciousness is purely

epiphenomenal in this framework. It is exactly the fact that all symbols have in and of themselves the property of being an accessible representation, independent of the processor, which makes them unsuitable as a metaphor for implicit knowledge. For it is impossible to conceive of any knowledge that could influence processing while remaining unavailable to outside inspection. Importantly, this perspective also makes it possible to assume the existence of *abstract* knowledge that remains inaccessible to conscious inspection.

**The Connectionist Metaphor.** By contrast, in a connectionist network, there is no external processor engaged in learning, that is, learning does not consist of augmenting a distinct knowledge base. Instead, learning in a connectionist network is the *result* of changes that occur in the network (weight-change between units). These changes are themselves *caused by* information processing, i.e. the coupling of a certain input with a desired output. Thus, this processing also changes the process of learning (through for example back-propagation of the error between the actual and the desired output). Furthermore, as transient knowledge in a connectionist network consists of activation patterns, instead of symbols, a piece of knowledge does not have to be "interpreted" by the central processor before it can influence processing. These properties make it possible for a connectionist network to possess knowledge that can influence behaviour despite failing to be represented as such. It makes it possible to consider implicitness as something more than simply a property of the database or a property of the processor.

From the connectionist point of view, subjects are said to base their judgements on the basis of exemplar information, without explicitly extracting abstract generalities, or rules – the abstract processing is performed online during the test, when necessary. The episodic account provides a refined version of mere instance-based processing (e.g. Neal & Hesketh, 1997). One of the most popular instances of traditional connectionist networks is the Simple Recurrent Network (SRN), as proposed by Elman (1990). Here, judgements are no longer based on instances, but on instances *within their context*. Learning is nothing more than a byproduct of the processing itself (weight-change), while retrieval results from the overlap between processes operating during study- and test-phases. Several variations on this basic principle have been proposed, but the main point remains as stated: no abstract rules in implicit learning. Instead, more fragmentary knowledge is used to gradually and dynamically build up representations of the stimulus environment. This leaves room for implicitness, not in the way of equating the existence of representations with accessibility to consciousness (as do for example Perruchet and Vinter, submitted; O'Brien and Opie, 1999), but in virtue of the dynamical aspects of representation building. For example, it might be possible to conceive of conscious representations as being structured differently than unconscious ones, or as being of lower quality.

## Experimental Research on IL

Recently, some of the processes involved in word segmentation have been described as rooted in the same mechanisms as implicit learning and frequency estimation. For instance, Saffran et al. (1997) conducted an experiment on word segmentation in artificial speech. They exposed children (6-7 years old) and adult subjects to a continuous speech flow such as *bupadapatubitutibudutabapidabu*. Subjects were told that the experiment was about the influence of auditory stimuli on creativity (to make sure learning was incidental and not intentional). The only cues to word boundaries were the transitional probabilities between pairs of syllables (e.g., *bu-pa*), which were higher within words than between words. Afterwards, subjects heard two sets of sounds, each consisting of three syllable pairs, and were told to decide which one sounded more like the tape they had heard. Both adult and child subjects managed to perform well above chance, suggesting that learning might proceed in the absence of attention and the intention to do so, even despite the brevity of the exposure (one or two times a 21' tape). The fact that children did as well as adults suggests a robust phenomenon that might play a role in natural language acquisition.

In another interesting artificial language experiment, Marcus et al. (1999) claim to have showed that 7-month-old infants can "represent, extract, and generalise abstract algebraic rules." In short, the infants were exposed to artificial "sentences" during a training phase, and subsequently were presented with a few test items, some of them belonging to the same language, while others introduced some structural novelty. For example, when an infant had been habituated to *gatiti* or *linana* (both having an ABB structure), it was subsequently presented with test sentences such as *wofefe* or *wofewo* (the last one being of ABA structure). The basic set-up is similar to the Saffran et al. (1997) experiment, with the important difference that there where the Saffran et al. test items were composed of the same material as the training items, Marcus et al. introduced a change in the sensory content of the material. That is, prior to hearing the above illustrated test items, the infants had never heard */wo/*, or */fel/*. Still, infants tended to listen more to the sentences containing a structural novelty. As a result, since this task could not be performed on the basis of mere transitional probabilities, Marcus et al. concluded that infants had the capacity to represent algebraic rules. However, Marcus et al.'s claim that an SRN could not model the observed effect was disputed by Elman (Seidenberg & Elman, 1999; Elman, 1999) and McClelland and Plaut (1999), basically on the account that an overlap need not be present in the "raw input" itself. Instead "the relevant overlap of representations required for generalisation [...] can arise over internal representations that are subject to learning." (McClelland & Plaut, 1999, p.2) Transfer and generalization remain precarious issues, however, when it comes to computational modelling in a connectionist network. An experiment by Shanks et al. (1997) clearly illustrates this point.

## Biconditional AGL: Shanks et al. (1997)

As mentioned before, Shanks and St John (1994) proposed to abandon the idea of the conscious/unconscious dichotomy in favour of a rule-based/instance-based dichotomy. The basic idea is that humans possess two learning systems capable of creating distinct forms of mental representation, one system consisting of symbolic rule-abstraction mechanisms and the other involving subsymbolic, memory-based, connectionist mechanisms (see Shanks, 1998, for a discussion). In this context, Shanks et al. considered transfer in AGL tasks to be at least to some extent mediated by abstract (rule-) knowledge and claimed that people systematically become aware of the relevant regularities in AGL tasks where only rule learning is possible. To demonstrate, Shanks et al. exposed subjects to artificial grammar strings generated by a biconditional grammar (see also Mathews et al., 1989). Biconditional grammars involve cross-dependency recursion (see Christiansen & Chater, 1999) such that letters that appear at each position before and after a central dot depend on each other. An example is given in Figure 1, where letter D is paired with F, G with L, and so on.

**Figure 1.** A biconditional grammar string as used by Shanks et al. (1997). Possible letters in each position before the dot are linked biconditionally with the letters that may appear after the dot.

Shanks et al. constructed biconditional grammar training strings as well as a set of grammatical and nongrammatical and test strings, in such a way that grammatical and nongrammatical test items could not be distinguished on the basis of their overlap with the training strings in terms of bigrams or trigrams (or any other  $n$ -gram). During training, two groups of subjects were shown strings one a time on a computer screen and had to perform one of two tasks on each trial. One group (the match group) had been told that the task was about memory, and had to select the correct string among five strings presented on screen. The other group (the edit group) was told that the strings had been constructed according to rules and that their task was to find them. On each trial, edit subjects had to indicate which letters they thought violated or confirmed to the rules, and were subsequently given feedback. All subjects then performed a classification test in which they were asked to decide which strings were grammatical or not. Shanks et al. showed a dissociation between the two groups: While the edit group performed well and most subjects extracted the rules, the match group performed at a chance level, thus suggesting that "instance-memorisation and hypothesis-testing instructions recruit partially separate learning processes." (Shanks et al., 1997, p.243)

The basic claim is thus that, in order to perform the biconditional grammar task, it is necessary to conceive of some abstract (symbolic) rule-like knowledge of the

grammatical structure, and that, subsequently, the distinction made between grammatical and nongrammatical strings cannot be simulated by a connectionist network making use of simple frequency statistics. The goal of this paper is to demonstrate that in fact no such abstract rules are necessary and that, at least under some conditions, biconditional grammar learning can be accomplished by a network developing representations based on frequency statistics.

## A Simulation of Shanks et al.

### Simulation Parameters and Procedure

**The Simple Recurrent Network (SRN)** is a connectionist network especially designed to predict the next step in a sequence. Its design allows it to "keep in memory" the earlier steps in that sequence, by using what preceded as a *context*. This context is a copy of the learning-state at time  $t-1$ , which is fed back into the network at time  $t$ , together with the new input. In this way, the network is able to integrate the new input with what it has already learned in earlier stages, and will predict on this basis the sequence step at  $t+1$ . A typical example of an SRN is given in Figure 2.

**Figure 2.** The Simple Recurrent Network as conceptualised by Elman (1990).

Importantly, on each time step the context units contain a copy of the *patterns of activation* that existed over the *hidden units* at  $t-1$ . As described in Servan-Schreiber, Cleeremans and McClelland (1988, 1989; see Cleeremans, 1993), learning progresses in a continuous fashion through three stages, during which more and more temporal contingency information is incorporated in the context, and hence in the hidden unit representations. The statistical regularities the SRN uses to predict the next letter are thus gradually "stored" in the hidden unit representations of the network. As a consequence, the network becomes able to behave in a rule-like manner and to predict the next element in the sequence *as if* it knew the grammar rules.

**Network Architecture and Parameters.** The SRN had 9 input and output units, necessary for representing the information that was available to the subjects in the Shanks et al. experiment. (The six letters of which the strings were composed, D, F, G, L, K and X, as well as the beginning and end of each string, together with the dot in between the first and the last four letters of a string.) The number of hidden units (and hence context units) was 100, which made use of logistic adjustment. The learning algorithm was error backpropagation, with a learning rate of .15 and the context

being reset to zero after each complete string presentation. Weight adjustment was not applied on the connections from context to hidden units (1 on 1 relation). Momentum was set at .9.

**Training Material.** The basic training material consisted of a set of 18 strings as designed by Shanks et al. (List 1). Based on these strings, they created 18 grammatical and 18 nongrammatical strings.

The items were to meet four objectives: (1) Grammatical strings had to conform to the biconditional grammar: Letter position 1 is linked to 5, 2 to 6 and so on, with the linked letters being D-F, G-L, and K-X. (2) The use of the 6 letters was balanced, so that each letter appeared 3 times in each of the 8 letter locations. (3) Each training string differed from all other training strings by at least 4 letter locations. (4) Each training item had a grammatical similar item and an ungrammatical similar item that each differed from the training item by only 2 letter positions. Each training item was different from all other test items by at least 3 letter locations. The basic simulation was carried out on exactly these strings. A training epoch consisted of all 18 strings being presented once to the network, in a random fashion.

**Measurement of Accuracy.** Different measurements of accuracy exist, of which we used the *Luce ratio* (Luce, 1969) — a simple measure of relative strength in which the activation of the target output unit is divided by the sum of the activations of all output units. To assess network performance, we considered the average Luce ratios for all strings. In addition, we also considered the Luce ratio on a letter-by-letter basis for more detailed analyses.

### Simulation Results

**Learning.** In order to assess learning, the network was tested before and during training on seven occasions. On each test, the network was tested on the 18 grammatical training strings, the 18 new grammaticals, and 18 nongrammaticals. Results were obtained over 9 simulations and averaged. As described before, the Luce ratio of the output was computed for each element of each string. Subsequently, the ratios were compared over the two conditions of interest (grammatical test/nongrammatical test) by means of an ANOVA, for each learning step.

As can be seen in Figure 3, the SRN was indeed able to discriminate between grammatical and nongrammatical strings. Original training strings were learned almost perfectly from 100 epochs onwards. Further, the network clearly discriminates between novel grammatical and nongrammatical strings (i.e., better predictions for grammatical strings), even *before* it is completely successful in mastering the training strings. ANOVA measures are, at 50 epochs,  $F(1,161)=24.1$ ,  $p<.001$ ; at 100 epochs,  $F(1,161)=36.3$ ,  $p<.001$ ; at 300 epochs,  $F(1,161)=33.5$ ,  $p<.001$ . From 1000 epochs onwards, the network gets a little 'overtrained' on the original strings, causing it to do somewhat less well on the unseen strings; at 1000 epochs  $F(1,161)=13.3$ ,  $p<.001$ ; at 3000 epochs  $F(1,161)=8.34$ ,

$p<.005$ . The figure also makes it clear that the main effect is not due to some initial biasing since initial performance is identical for the three types of strings (prior to training,  $F(1,161)=1.13$ , ns; at 10 epochs,  $F(1,161)=.048$ , ns).

**Figure 3.** Network learning, measured with the Luce ratio. Error bars are shown for novel G and nonG strings.

Based on these findings we can therefore conclude that contrary to what Shanks et al. claimed, the SRN can in fact distinguish between grammatical and nongrammatical strings generated by a biconditional grammar without making use of explicit rules. In order to rule out the possibility of the SRN merely having learned to predict the dot and/or the end of a string, we computed the mean Luce ratios on a letter-by-letter basis, as presented below in Table 1. Shown are the important ratios, belonging to the letters after the dot (ratios for training strings had value 1). When the difference exceeds .05, the highest ratio is in bold.

Table 1 clearly shows the mean Luce ratios on a letter-by-letter basis to be higher in grammatical than in nongrammatical strings. This indicates that the network has learned something other than merely the dot or the end of the string.

**Table 1.** Mean Luce ratios on a letter-by-letter basis, in each position, after 3000 epochs, for grammatical and nongrammatical test strings (included is the frequency of occurrence of the letter in each position).

## GRAM

	5th	#	6th	#	7th	#	8th	#
D	.25	(2)	.89	(2)	.01	(4)	.69	(4)
F	.70	(4)	.50	(4)	.55	(1)	.18	(3)
G	.71	(2)	.49	(2)	.26	(5)	.38	(3)
K	.41	(2)	.72	(5)	.09	(3)	.99	(2)
L	.58	(4)	.99	(3)	.11	(3)	.68	(3)
X	.43	(4)	.56	(2)	.33	(2)	.01	(3)

## NGRAM

	5th	#	6th	#	7th	#	8th	#
D	.19	(2)	.70	(2)	.72	(4)	.13	(4)
F	.39	(4)	.87	(4)	.20	(1)	.75	(3)
G	.37	(2)	.37	(2)	.17	(5)	.01	(3)
K	.46	(2)	.32	(5)	.19	(3)	.33	(2)
L	.74	(4)	1.00	(3)	.00	(3)	.50	(3)
X	.50	(4)	.38	(2)	.50	(2)	.00	(3)

**When the network fails to learn.** In order to illustrate exactly when a network can learn, we include a simulation of a situation in which it *fails to learn*. We created two (grammatical) strings with a high degree of similarity, FG GG.DLLL and KG GG.XLLL, and presented them to the network in the same way as was done in the main simulation. Figure 4 shows the activation values of the 9 output nodes for one string (the other showed the same evolution in activation values), as well as the evolution of the Luce ratios.

**Figure 4.** Left Panel: Evolution of output unit activations after presentation of the dot in the FG GG.DLLL string. Right Panel: Evolution of the Luce ratio after presentation of the dot for the two strings FG GG.DLLL / KG GG.XLLL.

Here, the network fails to reach a decision: it gets stuck at a "post-dot" activation value of 0.5 for both D and X (exactly the same plot is produced for the other string). The reason why learning fails in this case is addressed in the discussion.

## Discussion

What had to be shown *was* shown, namely that a connectionist network, more precisely a Simple Recurrent Network, is able to make a distinction between grammatical and nongrammatical letter strings, generated from a biconditional grammar as used by Shanks et al. (1997). These strings were designed so that, according to them, subjects *had* to make use of abstract rules in order to

accomplish the categorisation task. This paper clearly demonstrates that this is not the case, and that judgements of grammaticality using biconditional grammars can be made by extracting statistical features out of the material.

One of the major challenges in working with connectionist networks is how to probe the hidden units in order to "unfold" the complex representation of the stimulus material. Cluster analysis or principal component analysis performed on the hidden unit activations are standard ways of doing so, but may not always provide insight into how the representations enable the network to solve the task. The fact that cluster analysis does not reveal a clear structure does not necessarily imply that there *is* no structure. It may simply mean that the representational aspect needed to accomplish the most important aspect of the task, is *not* the most important aspect. Thus, clustering will not be carried out on that aspect — which, importantly, does not necessarily entail that the network is unable to use the relevant information successfully (see Cleeremans, 1993).

Biconditional grammars are difficult to master because they require maintaining information across intervening irrelevant items. Servan-Schreiber et al. (1991) explored the conditions under which the network can carry information about distant sequential contingencies (e.g. 1–5) across intervening elements, to distant, to-be-predicted elements. It appeared that this information is retained as long as it is in some way relevant to predicting each intervening item (the *prediction-relevance* criterion). When it is not, the relevant information tends to be lost as training progresses, as a consequence of the way in which representations of the temporal context are only gradually built up. Indeed, for different predictions to be achieved at any point in a sequence, the network needs to have developed different internal representations of the sequence so far. When two sequences are identical for a number of time steps so that the relevant information for making different predictions has to be retained over these intervening elements, each training trial actually induces the development of increasingly similar internal representations of the two sequences (because they require similar predictions)— exactly the opposite of what would be required for the network to master the material. Hence, the network fails to predict the fifth letter in the example above because the first letter of each string fails to be prediction-relevant when processing the intermediate Gs and ends up, as a result, with internal representations that fail to be sufficiently distinctive of each string to enable it to make different predictions about the fifth letter when presented with the dot.

Shanks et al. however, could not present the extremely simple (and for the network, extremely difficult) material to their subjects, for everyone would have discovered the rule in that case. Importantly however, the way in which their material is constructed results, for instance, in all the training strings to be determined by their *first two* elements — something that enables the network to learn the construction paths of each training string very quickly. In addition, in most cases, sequential information was in fact prediction-relevant on each step, which makes it easy for the network to distinguish between grammatical and nongrammatical strings. These findings suggest that the

Shanks et al. material was in fact inadequate to test for the rule based versus memory based distinction. As mentioned before however, it is clearly impossible to conceive of easy strings like KGGG.XLLL for which the rules are not discovered by subjects.

Insofar as simulations are concerned, while the SRN fails on such degenerate cases (unlike human subjects), the issue of whether this failure reflects a principled limitation of connectionist networks in general remains an open issue. Servan-Schreiber et al. showed that even very slight adjustments to the statistical structure of otherwise identical sequences could greatly enhance the prediction accuracy of the SRN. Thus, embedded information, as in recursive structures, need only be prediction-relevant in terms of the statistical distribution of the embedded elements for such structures to be successfully mastered by an SRN. There is also accumulating evidence that the pattern of failures observed with models like the SRN closely mimic that observed with human subjects (e.g., Christiansen & Chater, 1999) in the domain of natural language learning.

Empirically, we would like to suggest that experiments be carried out on a slightly different basis than used in Shanks et al., since their 'match' group showed no sign at all of having learned the material. One possibility would consist of changing the instructions of the match group so that attention is not *drawn away* from certain properties that might allow subjects to become sensitive to the structural properties of the material.

To conclude, we have demonstrated that a simple connectionist network can in fact master material previously considered to *require* the acquisition of rule-based knowledge for mastery of novel instances to occur. This outcome does not entail that rule-based learning never occurs (as it obviously does for some subjects in Shanks et al.'s experiments), but simply that biconditional grammars might not address all the issues involved in efforts to dissociate rule-based vs. memory-based learning processes in the implicit learning literature. Further simulation work will attempt to explore these issues in greater depth.

# Representational Scaffolding During Scientific Inquiry: Interpretive and Expressive use of Inscriptions in Classroom Learning

Eva Erdosne Toth (etoth+@andrew.cmu.edu)  
Department of Psychology; 5000 Forbes Avenue  
Pittsburgh, PA 15213

## Abstract

External representations (inscriptions) such as tables, visualizations, graphs and diagrams have been widely studied to determine their cognitive effects. However, a research-based pedagogy for their classroom use is yet to be offered. The two independent studies presented here are conceived from the same standpoint: the cognitive effects of inscriptions are influenced by the mode of their use (interpretive or expressive). The results of these studies indicate that the interpretive and expressive use of different external representations during scientific inquiry influenced students' (1) understanding the logic of designing experiments and their (2) ability to coordinate experimental data with theories. Representational scaffolding with collaboratively shared evidential-consistency maps helped students overcome traditional "inquiry traps" such as confirmation bias. These results show that representational scaffolding can provide an effective pedagogy for cognitively-based instructional interventions to teach scientific inquiry skills.

## Introduction

Representing knowledge with inscriptions such as pictures, diagrams and maps is a pivotal aspect of scientific practice. These external representations can be tools to think with for the clarification of ideas while designing experiments, analyzing data, and formulating theories. They can also be tools to talk with, aiding communication between a community of scientist-peers. Increasingly, everyday decisions are based on information presented with external representations found in textbooks, newspapers and even on breakfast cereal boxes. Today it is considered part of basic education to be able to understand and communicate with external representations. Arguably, external representations are at the center of both scientific and everyday reasoning. Thus a study of how one learns to make sense of and reason with representations has great significance.

For the purpose of research on learning, external representations should be differentiated from the internal products of one's thinking, often also described with the terminology "representations" (Kotovsky & Simon, 1990). I use the word "inscriptions" (Latour & Woolgar, 1979; Lehrer & Schauble, 1998) interchangeably with "external representations" and with both I refer to artifacts of thinking existing outside of one's head. My primary aim with this article is to describe the potential use of these external representations of thinking to scaffold learning. First, I describe the theoretical grounding of my overall approach to the understanding and use of inscriptions in classroom

learning. Next, I detail two studies, which describe the effects of inscriptions on two crucial aspects of scientific inquiry: (a) the logical process of setting up informative (unconfounded) experiments and (b) the reasoning associated with making sense of empirical observations by building evidential-consistency relationships between experimental data and theories. Finally, I describe the implications of these results for learning and teaching scientific inquiry skills and outline future research to further develop a cognitively-based pedagogy built on representational scaffolding.

## Theoretical grounding

My analysis of the educational benefit of various forms of external representations starts with a framework outlining the cognitive value of inscriptions. Developed by Collins and Ferguson (1993), this framework states that each form of external representation carries with it a methodology or heuristic for its use. External representations function through two mechanisms. They can (a) narrow the space of information search by localizing the most important message into perceptually salient, jointly displayed chunks (Larkin & Simon, 1987). They can also (b) provide a way for previously obscured information to become available (to "emerge") during the development and interpretation of inscriptions (Koedinger, 1992). That is, external representations scaffold activity by making certain aspects of inquiry salient (Stenning & Oberlander, 1995) and by constraining the user to certain activities (Suthers, 1999). With such mechanisms external representations provide representational scaffolding during classroom learning.

For example, students provided with the table shown in Figure 1a can clearly see that the most important variables to consider when determining what makes balls roll farther down ramps are the steepness of the ramp, the length of run, the surface of the ramp and the type of ball. No other variable is deemed important by the developer of this table, thus students' thinking is constrained to these essentials. One salient piece of information from this table is that all four of these variables should be considered for each apparatus of a simultaneous comparison (for both ramp A and ramp B).

Another salient component of experimental design emerges when students fill this table out. If students neglect to pay attention to any of the variables on one of the ramps the missing information becomes salient – as indicated by

the empty cells in Figure 1b. Thus, representational scaffolding can provide an innovative instructional methodology to teach students how to design informative (un-confounded) experiments.

VARIABLES	RAMP A	RAMP B
Surface		
Steepness		
Length of run		
Type of ball		

Figure 1a. Representational scaffolding by constraining students' thinking to the focal elements of experimentation.

VARIABLES	RAMP A	RAMP B
Surface	Smooth	Rough
Steepness	High	High
Length of run	Long	
Type of ball	Golf	

Figure 1b. Representational scaffolding by the salience of empty cells drawing students' attention to variables that may have been ignored during experimental testing.

With few exceptions (Lehrer & Schauble,1998) however, the full potential of the use of inscriptions in classroom science learning environments has not been examined.

There are two modes of using inscriptions: interpretive and expressive. These two modes are inherently combined during the development and the use of external representations in scientific practice. In classroom environments, however, students usually use inscriptions interpretively: they are given a teacher-developed external representation to make sense of by observing parts or by completing, "filling it out" – as shown in Figure 1. Expressive use of inscriptions entails the active generation of a form of external representation with the aim of communicating an idea. While students' active generation and manipulation of their own knowledge is considered important under the currently dominant constructivist pedagogy, inscriptions are rarely used expressively by students during classroom learning.

The study of inscription use in classroom learning environments is best approached by the examination of students' difficulties with each of these modes of using inscriptions. The first study described here shows how students used inscriptions both interpretively and expressively while designing and conducting scientific experiments and recording data results. The second study describes the effects of a software tool that eases students' way into working with external representations. Both of these studies illustrate the value of learning with inscriptions and indicate which student difficulties should be considered

in the further refinement of an instructional methodology that is built on representational scaffolding.

## Representational scaffolding during scientific experimentation

### Subjects and Procedures

Two classrooms of 28, 4<sup>th</sup> grade students experimented in small groups of 3-4 to determine what makes balls roll farther down on ramps. The instructional goal was to teach valid experimentation skills, specifically the control of variables strategy or CVS. The task of each student group was to design experiments with a pair of physical ramps and record their experiments in laboratory notebooks. The outcome of the research-based methodology to teach valid experimentation skills from this study was detailed in Toth, Klahr & Chen (in press). The present paper focuses on the effects of using inscriptions during scientific inquiry in the classroom. Two slightly different procedures were employed by the classroom teacher, each allowing a focused view at either the interpretive or the expressive use of inscriptions.

During the first week of instruction student groups learned how to create controlled comparisons with pairs of ramps and filled out a teacher-specified table of dependent and independent variables to indicate their experimental setup. This table representation was similar to that in Figure 1, with the exception that the two possible values for each of the four variables were already provided in the cells of this table. The students' role was simply to circle the variable value of their choice to map their ramp setup onto the table. Prior to experimentation, students were specifically taught how to conduct this mapping activity. This interpretive use of inscriptions was intended to help students as well as the teacher keep track of the experimental designs used over time. The researcher's classroom observation notes recorded student's activities and their difficulties.

During the second week of the study - after two weeks of spring break – the students applied the previously learned skill of designing controlled experiments to learn more about ramps. This time they designed experiments using one ramp at a time. They were asked to record each of their experiments into any external representations of their choice (expressive use). Data sources included videotapes of classroom experimentation, laboratory notebooks recorded by students and the researchers' observation notes. Students' expressive use of inscriptions was scored using a modified version of a quantitative coding scheme suggested by Kosslyn (1989). The scoring included attention to how the inscription communicated the logical design of experiments and the clarity of reasoning inherent in it.

### Results and Discussion

**Interpretive use of inscriptions** Classroom observations of the interpretive use of inscriptions (first week) indicated that

as soon as students looked at the teacher-developed table and tried to fill it out, they wanted to go back to the physical ramps and make changes to the setup of the variables. They indicated that they wished to set their tests up "better" or "differently." While this intent of the students created a slight problem for the experimenters – who at the time were interested in documenting students' developing knowledge of experimentation strictly adhering to a prior protocol developed during laboratory studies (Chen & Klahr, 1999) – this observation soon led to the realization that the interpretive use of the pre-developed table representation may have helped students abstract the overall structure of the experiment and thus aided their understanding of the design of un-confounded experiments. I hypothesize that as students filled out their teacher-defined table an important characteristic of scientific inquiry may have become salient to them: the criteria that all important variables of an experimental setup should be considered during experimental design. As outlined above (Figure 1) this table constrained students' thinking to the most important variables, but also made student errors in designing informative (controlled) experiments salient to them. If one of the variables was not attended, this omission became obvious ("emerged") during the work with the representation. Similarly, if two variables were changed instead of one between experiments (a confounded experiment was created) this oversight was made perceptually salient. Thus information previously not available to students became obvious through the representational scaffolding provided by the use of this inscription.

After a week of focused experimentation and instruction, students learned the strategy of creating controlled experiments from which they could tell with certainty the effect of any focal variable under investigation (Toth, Klahr & Chen, in press). Having learned to overcome systemic error with the use of the control of variables strategy (CVS) during experimentation, students were presented with a new challenge: to record their experiments with inscriptions of their own choice (expressive use) while they continued applying CVS to learn more about variables associated with ramps. The subsequent analysis of the student-developed inscriptions from this second week of study revealed various student difficulties.

**Expressive use of inscriptions** Two characteristics of the expressive use of inscription were noticeably difficult for students: (1) using the common techniques of developing inscriptions (using labels and data correctly in a coordinated way) and (2) reasoning scientifically with inscriptions. Various problems resulting from the lack of experience with a common representational technique were identified. Common problems included missing labels, missing data content and insufficient alignment of data with labels.

Students' laboratory notebooks fell into three specific patterns in terms of reasoning scientifically about

experiments through inscriptions: (a) showing incorrect CVS only, (b) showing a combination of correct and incorrect CVS over time, (c) indicating a possible search for interaction of variables without clear CVS design

These effects were found even after students were documented to have learned the control of variables strategy (Toth, Klahr and Chen, in press). That is the effect found here can be attributed to either students' inability to use external representations or the lack of transfer of the CVS strategy to situations slightly changed from the condition of learning.

Overall it appears that the interpretive use of a well-selected external representation (Figure 1) can positively influence student's understanding of skills associated with scientific inquiry. This effect is due to the representational scaffolding inherent in any form of inscription. This characteristic makes certain inscriptions especially fitting for a learning task while not appropriate for others. In this example, a table representation appears to be fitting for the interpretive task of abstracting and combining the logical components of scientific experimentation. However, the expressive use of inscriptions is more problematic as it should consider the structure of the domain, the goal of the activity as well as the cognitive state of the interpreter. It is hypothesized that innovative pedagogies such as collaborative reflection and discussion conducted through external representations may help students learn the skills of developing effective inscriptions.

The next study describes a software tool called Belvedere (Suthers et al., 1997) that eases students' way into working with external representations. It also details the effects of representational scaffolding by different forms of representations and suggests a reflective methodology to support the use of inscriptions in classroom learning environments.

## **Representational scaffolding while coordinating data with theories**

### **Subjects and Procedures**

Four classrooms of 9<sup>th</sup> grade students (N = 73) participated in a 2X2 research design in which the effects of two different external representations (evidence mapping vs. prose writing) was studied. As part of their science class—taught by their regular science teacher—the students participated in problem-based-learning. They were presented with a set of scientific challenges to which no known solutions existed at the time. Their task was to explore web-based information sources – a set of researcher developed<sup>1</sup>, hypertext materials – and to find a solution to a scientific challenge such as mass extinctions, the evolution of marine iguanas or the sudden appearance of a mysterious

---

<sup>1</sup> The materials used in this study were developed primarily by Arlene Weiner with assistance from the author.

disease. Evidence mapping entailed using a shared, whiteboarding software tool, BELVEDERE, to diagram evidential consistency relationships between hypotheses and data. BELVEDERE's main menu provided epistemological categories that included object-shapes for hypotheses (rounded rectangle shapes in Figure 2), data (rectangle shapes in Figure 2) and links to indicate consistency ("for" links), inconsistency ("against" links) and conjunction ("and" links) between data and hypotheses (Figure 2).

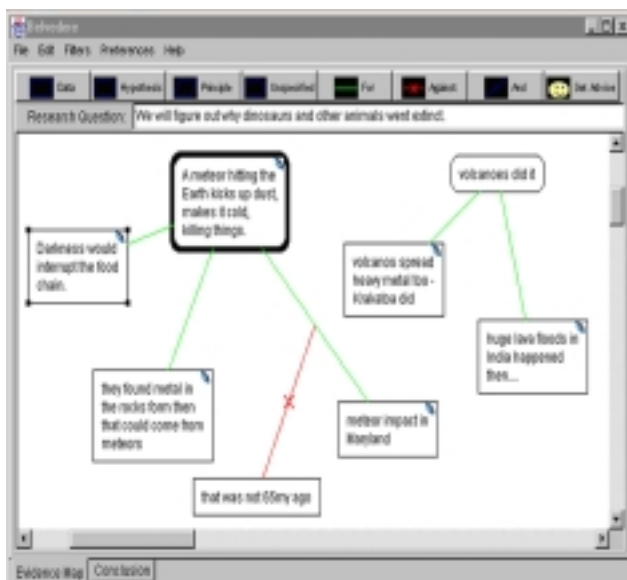

Figure 2. Example evidence map created with the BELVEDERE software tool.

The diagramming activity started with exploring the web-based materials for information and continued with recording ideas using the software tool. In order to make this record with the mapping tool students needed to categorize the currently considered information as data or hypothesis, select from the appropriate shape from the menu pallet and copy the information being considered into the selected object-shape. Similarly students could choose links from the menu to indicate evidential consistency relationships between data and hypotheses (Figure 2.)

Students not using the software tool for mapping used prose writing to record their thinking during inquiry. Prose writing consisted of using a word-processor to write a prose-based account of exploring the web-based materials and solving the challenge problem. Students were instructed to record the main aspects of their inquiry: both data and hypotheses and detail how they decided on a conclusion. In addition, one of the classrooms in each condition (mapping and prose) was given a method of explicitly reflecting on the process of their inquiry by using a paper-based handout of specific inquiry criteria detailing optimal performance during inquiry. These so-called “reflective assessment rubrics” were used from the beginning of inquiry for

reflection as well as during final assessment of performance. Students who did not use the explicit reflection were only implicitly prompted about the criteria by which their work will be evaluated. It was expected that this implicit prompting would result from the structure of the challenge materials and the nature of the inquiry activity.

Thus each of the four classrooms was randomly assigned to one of the following treatments: Map&Reflect, Map-NoReflect, Prose&Reflect, Prose-NoReflect (Figure 3).

Treatment	Materials	Representation	Reflection
Map & Reflect	Hyper-Media	Mapping	Reflection
Map - NoReflect	Hyper-Media	Mapping	No-Reflection
Prose & Reflect	Hyper-Media	Prose	Reflection
Prose - NoReflect	Hyper-Media	Prose	No-Reflection

Figure 3. Elements of experimental design for study two.

The effects of representational scaffolding on students' inquiry skills was analyzed from students' inquiry artifacts - the products of their work (maps or prose). Though students conducted many units of problem-based-learning, the results discussed here are from the first unit only. This unit was chosen with the expectation that the use of inscriptions in the early stages of inquiry would provide intricate details of representational scaffolding inherent in these inscriptions. It was expected that this software tool will ease students' into reasoning about data and hypotheses with inscriptions, as it scaffolds the development of evidence-map representations with pre-defined categories that can be flexibly used to allow students' to actively generate and manipulate their own scientific knowledge.

As an indicator of students' effectiveness during inquiry three scores were analyzed: (1) the number of information units (hypotheses and data) recorded and correctly categorized, the (2) number of inferences recorded (indicating correct relationships between data and hypotheses) and the (3) the quality of final conclusions drawn by students in each condition.

## Results and Discussion

Groups in the prose writing condition recorded about the same number of hypotheses and data as groups in the evidence mapping condition. However, analysis of the amount of information that was correctly categorized by students revealed that the mapping groups categorized significantly more of their recorded information as hypothesis and data compared to the prose writing groups. Since in either condition (mapping or prose) the percentage of incorrectly categorized information units was minimal

(<10%) it is reasonable to argue that it was the effect of the mapping representation that scaffolded students' categorization efforts. That is, the evidential consistency mapping, with its pre-defined epistemological categories, prompted students to consider the meaning of these categories and to organize the outcome of their investigations based on these categories. Unlike the mapping activity, the prose writing was a familiar mode of communication for students. However, the prose representation did not make the categories of scientific inquiry perceptually salient throughout students' investigation, resulting in the lower number of information pieces categorized by the prose writing groups. There was no significant effect of the type of reflection on either the number of information units recorded nor on the categorization of these records.

Interesting representational scaffolding effects were found during the analysis of the inferences recorded by student groups in the different conditions. The mapping groups recorded significantly higher number of inferences describing relationships between data and hypotheses compared to the prose writing groups (Figure 4).

Figure 4. The effects of representational scaffolding and explicit reflection on the number of inferences between data and hypotheses recorded by students

The use of explicit reflection also significantly influenced student's ability to express inferences indicating the relationship of their data and hypotheses. The Map&Reflect groups performed significantly higher than any other group, including the Map-NoReflect group on this measure.

Analysis of the types of inferences (consistency, inconsistency and conjunction) revealed that the difference between the Map&Reflect groups compared to the Map-NoReflect groups was in the frequency of inconsistency ("against") relationships recorded (Figure 5). This is a crucial finding that indicates the value of both mapping and explicit reflection and their combined effect helping students overcome confirmation bias during the evaluation of scientific hypotheses based on empirical data.

Figure 5. Sub-scores of information evaluation by groups in the four treatment condition.

Furthermore, when students' final reasoning with prose conclusions were analyzed there were no significant differences between prose and mapping groups in the quality of the final conclusions. Since these conclusions were written in prose by students in both conditions (mapping or prose), this finding indicates the lack of efficiency in transferring the inquiry skills learned by the mapping groups from the mapping activity to prose writing. Further instructional interventions are necessary to ensure a more effective transfer.

Overall it appears that the evidence mapping provide better scaffolds for students during scientific inquiry when the goal of activity is to categorize information and evaluate scientific hypotheses based on evidence. Explicit reflection on the specific criteria of scientific inquiry was found to support the evidence mapping activity, but not traditional prose writing.

## Conclusion and Educational Significance

External representations of thinking can play a pivotal role in the learning of scientific inquiry skills. The studies presented here detailed the effects of inscriptions during two important processes of scientific inquiry: (1) designing and conducting experiments and (2) coordinating experimental evidence with domain theories. The classroom studies described here yielded evidence for two methods of using inscriptions: interpretive and expressive. Interpretive use of a teacher-developed table representations was found to scaffold students' progress of inquiry by making the variables of an experiment salient and by perceptually constraining the students' attention to abstract the characteristics of correct experimentation. However, during the expressive use of inscriptions students were found to have difficulty with using the common techniques of

developing inscriptions and with indicating their reasoning during experimentation. While the lack of transfer of CVS skills has been clearly documented since this study (Toth & Klahr, 2000) further instructional interventions and studies can reveal how a reflective pedagogy based on representational scaffolding may help with this transfer difficulty. The results of study two indicate that such methodology may be very effective.

While evaluating experimental data against theories, the representational scaffolding effect provided by evidential consistency mapping (compared to prose writing) was confirmed. Evidence mapping was found to be a successful instructional methodology to teach how to categorize and label scientific information and to teach students how to evaluate hypotheses based on empirical data. The findings also suggested that reflective assessment (by the use of the explicit criteria for maximum performance in rubrics format) was an effective instructional manipulation to support the scaffolding effect of external representations.

In collaborative classroom learning environments there has been a need for a methodology that combines cognitive effectiveness with the social circumstances of collaborative learning. The effects of collaborative reflection over shared representations seem to be promising and should be further refined. One such study is currently under way by the author to explore how the social circumstances of the anticipated peer-interpretation of inscriptions influence students' expressive use. Further research should also consider the use of software tools in the shared activity of expressively and collaboratively using various forms of inscriptions.

### Acknowledgements

Funding for study one was provided by the James S. McDonnell Foundation to David Klahr and Zhe Chen of the Department of Psychology, Carnegie Mellon University. Funding for study two was provided by the Presidential Technology Initiative to Dan Suthers, Eva Toth and Arlene Weiner who worked under the leadership of Alan Lesgold at the University of Pittsburgh Learning Research and Development Center (LRDC). ## Abstract

This paper investigates the change in scientists' representation of phenomena of interest during the exploratory analysis of visual data. The scientists initially represented expected findings in formal, scientific terms, whereas they represented anomalies in informal terms. Over time, these representations shifted from informal to formal. We propose that this shift in representation is the result of an increased understanding of the individual phenomena, rather than of greater understanding of the data at a global level.

## Introduction

A strong and perhaps foundational theme in cognitive science is the issue of representation. From both empirical and computational perspectives, performance has been found to depend heavily on how information is internally represented (Kotovsky, Hayes, & Simon, 1985; Larkin & Simon, 1987; Newell & Simon, 1972; Zhang & Norman, 1994).

One area in which representation is likely to be especially important is scientific discovery (Schunn & Klahr, 1995). There are many formal and informal methods for representing data, even within the same discipline and narrow sub-area. The choice of representation of the data is likely to have a large impact on what can and will be discovered.

An additional twist on the issue of data representations in science is the difference between goals of scientific discovery and goals of communication of the discoveries. The external representations that are best for discovery are not necessarily the representations that are best for communication of the discovery to others. For example, issues of historical convention are likely to be more important in communication, whereas issues of ease of generation and manipulation are going to be more important for the original discovery.

The goal of this paper is to examine how scientists represent data internally to themselves while they are analyzing their data. In particular, do they tend to think of their data in formal, discipline-specific terms, or do they rely on more informal and simple perceptual terms? One might expect them to use formal terms because of their expertise and extensive domain knowledge. On the other hand, they may use perceptual terms because in many areas of science, the data are presented in fairly complex visual displays that make heavy use of spatial metaphors—or indeed represent spatial dimensions directly (Trafton et al, under review).

One dimension that we hypothesize would influence the choice of internal representation is the degree to which the

data are as the scientist expects. That is, perhaps scientists are more likely to represent apparently anomalous data in informal, perceptual terms and expected data in formal, conceptual terms.

Another related dimension that we investigated was time: How do scientists' representations of their data change over time as they explore their data? One might imagine that the representations become more formal as scientists develop an understanding of the dataset as a whole. Alternatively, the changes in representation may occur at a more item-specific level—the representation of each item changes separately as understanding of the item changes.

A wide variety of methodologies has been used to study scientific reasoning and scientific discovery, each with their advantages and disadvantages (see Klahr & Simon, 1999, for a review). For this research project, we adopted a modified form of Kevin Dunbar's "in vivo" methodology (Dunbar, 1995, 1997, in press). The "in vivo" methodology involves observing scientists as they are doing their research. Dunbar focused on the activities that occur in lab group meetings. Because we were interested in the processes of data analysis, we focused, instead, on pairs of scientists working at their computers, analyzing their data. Like Dunbar, we perform a form of protocol analysis (Ericsson & Simon, 1993), analyzing the speech produced by the scientists to make inferences about the underlying cognitive processes.

The reason for focusing on pairs of scientists rather than on an individual scientist is that dyads produce speech naturally as part of their data analysis activities. By contrast, forcing an individual scientist to give a think-aloud protocol may change the very representations that we seek to study. For example, the individual scientist may change her focus to aspects of the data that are more easily verbalized, or she may change her representations from visio-spatial representations to more verbal representations.

Our methodology also contrasts with the retrospective analyses of historical cases from science (e.g., Gentner et al., 1997; Nersessian, 1985; Thagard, 1999). By focusing on the activities of non-famous (albeit expert) scientists working on a problem that may or may not lead to an important discovery, we may obtain a more representative view of how scientists reason.<sup>1</sup>

---

<sup>1</sup> Of course, if one's goal is to understand how large conceptual leaps are made in science, the historical case-study approach may be more fruitful.

Because our methodology is extremely labor-intensive, it lends itself most readily to case studies. However, the use of case studies always raises the question of generalizability: does the pattern found with these scientists at this particular time in this particular domain generalize to other scientists in other domains? To address this issue, we gathered data from two sets of scientists working in different disciplines on different kinds of problems. The first set of scientists was a pair of astronomers examining radio and optical data of distant galaxies. The second set of scientists was a pair of neuropsychologists examining fMRI imaging data of brain functioning under different experimental conditions. Thus we included both observational and experimental research from disciplines differing widely in types of training and age of the discipline. One should note, however, that both situations involved preliminary examinations of complex data visualizations presented on computer screens.

## Method

### Participants

The participants in the first domain were two expert astronomers, one a tenured professor at a university, the other a fellow at a research institute. The astronomers had earned their Ph.D.s six years and ten years respectively before this study; one has approximately 20 journal publications and the other approximately 10 in this area. One of the astronomers, hereafter referred to as A1, focuses on conducting and analyzing astronomical observations, and has an expertise in ring galaxies; the other, hereafter referred to as A2, combines teaching with primarily theoretical astronomical research and model construction. The astronomers have been collaborating for some years, although they do not frequently work physically alongside one another (i.e., work simultaneously at the same computer screen to examine data).

The participants in the second domain were two scientists in neuropsychology, one a postdoctoral researcher (B1) who has been in the field over 3 years, the other a graduate researcher (B2) who has been in the field for 1 year. The scientists work in a renowned national US research institute and are involved in developing a new methodology for analyzing fMRI brain data. They frequently work simultaneously at the same computer screen to examine data.

### Procedure

In both studies, the scientists were video- and audio-taped as they explored computer-generated visual representations of a new set of data. For the first study, A1 was in charge of the keyboard and mouse and sat directly in front of the screen; A2 sat slightly to his left. For the second study, B2 was in charge of the keyboard and mouse and sat directly in front of the screen while B1 sat slightly to her right. In both studies, all scientists had the shared monitor in their clear line of sight. They were instructed not to explain or interpret their comments to the researchers, but to carry out their work as though no camera were present. For each study, the relevant part of the session lasted about 1 hour. The scientists' interactions were transcribed and coded as described below. At a later date, we interviewed the scientists in both domains in order to obtain clarification of some domain-related issues.

### The Tasks and the Data

The astronomical data under analysis were optical and radio data of a ring galaxy. A ring galaxy forms as the result of a collision between two galaxies, and such collisions are relatively frequent cosmic events; consequently, ring galaxies *per se* are not uncommon. Both astronomers had conducted research and published scholarly articles on other ring galaxies, but this particular galaxy was relatively new to them. Nor had they examined this data set before; consequently, they considered this session exploratory.

The astronomers' high-level goal was to understand the evolution and structure of the ring galaxy, by a complex sequence of inferences that began with interpreting contour lines on the display in terms of the 3-dimensional flow of gas in the galaxy. The astronomers' task was made difficult by two characteristics of the data: First, the data were one- or at best two-dimensional, whereas the structure they were attempting to understand was three-dimensional. Second, the data were noisy, and there was no easy way to distinguish between noise and real phenomena. Figure 1 shows a screen snapshot of the type of data they were examining.

Figure 1. Example of data examined by astronomers.  
Radio data (contour lines) are laid over optical data.

The fMRI data were obtained to understand how activation patterns inside the brain would change when people are anticipating some events to happen. There were two experimental conditions and one control condition. The scientists had to examine the data and compare them across the three conditions. This was the first time they had conducted the experiment and examined the data. The session was considered exploratory. Figure 2 shows an example of the fMRI data that they were analyzing. Similar to the astronomical data, fMRI data are inherently noisy and can only be displayed in two dimensions although the activation patterns under analysis were mostly three dimensional.

Figure 2. Example of fMRI data (color removed).

### Coding Scheme

The protocols were divided into 829 (astronomy) and 370 (fMRI) segments. As each scientist spoke in turn, a new segment was established. Then the scientists' individual utterances were further segmented by complete thought.

A coding scheme was developed to examine how the scientists explored the data. The entire astronomy protocol was coded independently by 2 different coders in order to establish the reliability of this scheme. Inter-rater reliabilities for each code are reported below. Because we found high agreement in coding the astronomy protocol, we expect the agreement in the neuropsychology protocol to be high also.

**On/Off Task** In order to allow us to focus our analysis only on those utterances that were relevant to the scientists' task of data analysis, we coded each segment as on-task or off-task. All segments that addressed matters external to the data analysis were coded as off-task; these segments included external interruptions (e.g., the telephone ringing), extraneous comments by the scientists (e.g., jokes or banter between them), comments relating to the software, specific details about plans for future observations, and so on. All segments that addressed issues of data analysis were coded as on-task. These included comments relating to the selection of a display type (as opposed to comments about how to implement that display) as well as decisions about obtaining additional data in the future (as opposed to details about how to obtain those data). Initial agreement between the coders was 90%. All disagreements were resolved by discussion.

**Noticings** In order to establish which phenomena the sci-

entists attended to, we first coded for the scientists' *noticing* phenomena in the data or features of the display. A noticing could involve merely some surface feature of the display, such as a line, shape, or color, or it could involve some interpretation by the scientists, for example, identifying an area of star formation or concentration of gas for the astronomers or activation in a particular area of the brain (e.g. thalamus) for the neuropsychologists. Only the first reference to a phenomenon was coded as a noticing; coding of subsequent references to the same phenomenon is discussed below. Agreement between the coders was 95%. Disagreements were resolved by discussion.

Because our investigation focused on the change in representation of anomalies in the data, we further coded these noticings as either "anomalous" or "expected," according to one or more of the following criteria: a) in some cases the scientists made explicit verbal reference to the fact that something was anomalous or expected; b) if there was no explicit reference, domain knowledge was used to determine whether a noticing was anomalous or not; c) a phenomenon might be associated with (i.e., identified as either like) another phenomenon that had already been established as anomalous or not; d) a phenomenon might be contrasted with (i.e., identified as unlike) a phenomenon that had already been established as anomalous or not; e) the scientists might question a feature, thus implying that it is unexpected. Table 1 illustrates these codes. Agreement between the coders was 87%. Those noticings for which disagreement could not be resolved were excluded from further analysis.

**Subsequent References** Our investigation focused on the astronomers' representation of phenomena over time. Whereas the coding of the noticings captured the first reference the astronomers made to a phenomenon of interest, we also needed to establish how they made subsequent reference to each noticing. Consequently, all subsequent references to each phenomenon were also identified.

Because the scientists were sharing a computer monitor, frequently the first interaction between them after a noticing was to establish that they were both looking at the same thing. Subsequent references that served purely to establish identity were *not* included in the analyses.

Not all subsequent references immediately followed a noticing; frequently, the scientists returned to a phenomenon of interest after investigating other features of the data. The

**Table 1.** Noticings (italicized) coded as unusual or expected.

Criterion	Code	Example - Astronomy	Example - fMRI
Explicit	Anomalous	What's that <i>funky thing</i> ...That's odd	Bunch of <i>stuff here</i> ... Yeah, that's weird
Domain Knowledge	Expected	You can see that all the <i>H1</i> is concentrated in the ring	So there is a <i>subcortical activation</i> that is probably caudate.
Association	Anomalous	You see similar kinds of <i>intrusions</i> along here	So there's the <i>thing</i> we've been seeing consistently.
Contrast	Expected	That's odd...As opposed to <i>these things</i> , which are just the lower contours down here	So <i>it's lateral</i> , which means its not in the midline... on our incentive task we see midline, but not lateral, so that's why that's not a spot.
Question	Anomalous	I still wonder why we don't see any <i>H1</i> up here in this sort of northern ring segment?	[None found]

scientists made frequent gestures to the feature of the image under discussion; by constructing a map of the noticings, and cross-referencing it with these gestures, the coders were able to determine the specific noticing to which a subsequent reference referred. Tables 2a and 2b illustrate the coding scheme for subsequent references in each domain.

**Entity Coding** To investigate the initial and changing representations of the phenomena the scientists noticed, we first identified what characteristics of each noticing (anoma-

Table 2a. Subsequent references in astronomy domain.

Noticing: First reference to phenomenon  
 Establish identity: Reference excluded from analysis  
 SR: Subsequent reference included in analysis

Code	Utterance
Noticing (N9)	A1: What's that funky thing...
Establish identity	A2: Left center, you mean...
Establish identity	A2: This stuff? [points to screen]
Establish identity	A1: Yeah
Establish identity	A2: Yeah
SR to N9	A1: What is that? A2: You can see there is some gas here [points to different area] inside the ring, but not much...
Noticing (N10)	
SR to N9	A1: Except for that little knot there.

Table 2b. Subsequent references in neuropsychology domain.

Code	Utterance
Noticing (N23)	B1: There, did you see that?
Establish identity	B2: Yah did you see that? [points to screen]
SR to N23	B1: That was near the thalamus.
SR to N23	B1: That might be spurious.
Noticing (N24)	B2: So the z-score of that one is 4.22.
SR to N24	B1: It's right up there [points to the threshold on screen]

lous and expected) first caught the scientists' attention. We then noted what characteristics the scientists attended to in their subsequent references to each noticing. We coded each noticing and subsequent reference as either "formal" or "informal" as follows. Formal references are those for which the scientists referred to the underlying phenomenon, using the terminology of the domain—for example, to a specific gas, star formation, the stellar continuum, or the like in the astronomy domain, and to the thalamus or caudate nucleus, for example, in the neuropsychology domain. Informal references include references to some generic feature of the display, such as a blob, a bulge, or a "dipsy-doodle" in the astronomy domain, and a neuron "lighting up" in the neuropsychology domain. They also include references to a phenomenon by its location (e.g., "lower right," "northwest") and anaphoric references, (e.g., pronouns). A few references combined characteristics of more than one code (e.g., "big blob of H1" combined the informal reference to a "blob" with the formal reference to H1 gas). Such references were coded as "mixed" references, and were excluded from subse-

quent analysis. Coder agreement on this coding was 100%.

## Results and Discussion

There were 619 (75%) (astronomy) and 317 (85%) (neuropsychology) on-task segments. Subsequent analyses do not include off-task segments.

### Noticing Anomalies and Expected Phenomena

There were 27 (astronomy) and 35 (fMRI) noticings. In the astronomy data, 9 (33%) were anomalous, 13 (48%) were expected, and 5 (19%) were uncoded because either the astronomers or the coders disagreed. In the fMRI data, 13 (37%) were anomalous, 19 (54%) were expected, and 3 (9%) were uncoded. Figure 3 shows that the proportion of anomalous and expected noticings was similar in each dataset. Uncoded noticings were excluded from subsequent analysis.

Figure 3. Percentage of anomalous and expected noticings.

### Representation of Noticings

Our first question concerned how the scientists initially represented the phenomena they investigated. In the astronomy domain, 8 of the 13 (62%) expected phenomena were first identified by formal references and the remaining 5 (38%) by informal references. In contrast, most of the anomalies (78%) were initially identified by informal references, with only 2 of the 9 anomalies (22%) identified formally. Interestingly, both formal references were negative—they referred to the *absence* of the astronomical phenomenon (e.g., "I still wonder why we don't see any H1 up here.") A similar pattern was observed in the neuropsychology domain. Ten of the 19 (53%) expected phenomena were first identified by formal references, and 9 (47%) by informal references. Ten of the 13 (77%) anomalies were identified informally, with 3 (23%) identified by formal references. Again, 2 of the 3 formal references were negative (e.g. "There's nothing on the thalamus either, that's surprising"). Figure 4 shows the percentage of formal references to these initial noticings.

Thus it appears that in general, the scientists initially represented the expected phenomena in the formal, scientific terminology of that domain. However, their initial representations of unexpected or anomalous features of the data were

highly informal. Recall that these informal references were based primarily on irregular features of the display rather than the underlying phenomena that these features represented. Occasionally, it was the *absence* of a phenomenon that first drew the scientists' attention to these anomalies.

Figure 4. Percentage of formal references to initial noticings (anomalous and expected) in two domains.

### Local Changes in Representation

Next, we examined whether the scientists' representation of these phenomena changed as their investigation of the data progressed. The analyses that follow depend on the subsequent references to the noticings. In order to ensure a sufficient basis on which to judge change, we include only those noticings that received more than the mean number of subsequent references (i.e., more than 8 subsequent references for the astronomy and more than 3 for the fMRI data).

Five of the noticings in the astronomy data and 15 in the fMRI data received more than the mean number of subsequent references. In the astronomy data, the subsequent references to these 5 noticings account for 66% of all segments that made any reference to a phenomenon noticed by the astronomers. In the fMRI data, the subsequent references to these 15 noticings account for 69% of all such segments. Thus by confining our analyses to these 20 noticings, we focus on the majority of the data. It should also be noted that, because in general expected phenomena received little further attention, especially in the astronomy domain (Trickett, Trafton, & Schunn, 2000), most noticings included in these analyses are anomalies.

In order to examine change over time, we divided the period of attention to each individual noticed object into two phases, early and late. We tallied the total number of subsequent references for each and divided it by 2. For noticed objects with an odd number of subsequent references, we discarded the midpoint reference, to insure an even split. We then compared the numbers of formal and informal references in the early and late phases of the scientists' investigation.

In the astronomy data, in the early phase of investigation, 17 of the 63 (27%) subsequent references were formal compared with 30 (48%) in the later phase. By contrast, 39 (61%) of the subsequent references were informal in the early phase compared with 25 (39%) in the later phase,  $\chi^2(1) = 6.65, p < .01$ . (These percentages do not sum to 100% because of the mixed references excluded from the analysis.) In

the fMRI data, in the early phase of investigation, 18 of the 45 (40%) subsequent references were formal compared with 29 (64%) in the later phase. By contrast, 27 (60%) subsequent references were informal in the early phase compared with 16 (36%) in the later phase,  $\chi^2(1) = 5.39, p < .05$ . Thus, in both domains, the number of formal representations increased, while the number of informal representations decreased. Figure 5 shows the increase in formal references in the later phase.

Figure 5. Changes in representation of noticed objects.

These results show that the scientists' representations changed significantly over time, as they investigated these anomalies. In the early phase of analysis, their representations were informal and display-based, most likely because they did not have a precise understanding of the phenomenon under investigation. The scientists needed a label by which they could identify, discuss, and refer to the phenomenon, and this label tended to be based on the visual appearance of the feature. As their investigation proceeded, however, these visually-based labels decreased. The reduction in display-based and anaphoric references suggests that the scientists became more specific, and points to an increased understanding of these anomalous phenomena.

### Global Changes in Representation

It is possible that the shift toward a formal representation occurred not because the scientists' understanding of individual anomalies increased, but because their global understanding of the data increased over time. In order to investigate this possibility, we divided each entire analysis session into early and late phases, based on overall time spent. Thus, in this analysis, there were unequal numbers of reference in each phase, but the time spent on each phase was the same.

We counted the number of formal and informal references to these well-referenced phenomena in each phase. In the astronomy protocol, 63% of the references in the early phase were informal, compared with 45% in the late phase; 35% of the early references were formal, compared with 39% in the late phase. This difference was not significant,  $\chi^2(1) = 1.4, p > .2$ . Although the proportion of informal references did drop off, the number of formal references remained constant. In the fMRI protocol, 53% of the references in the early phase were informal, compared with 52% in the late phase; 47% of the early references were formal, compared with 48%

in the late phase. This difference was also non-significant,  $\chi^2(1) < 1$ . Thus, it does not appear that the shift toward a more formal representation occurred as a result of a more general, global understanding of the data.

### General Discussion

Our results show that both groups of scientists initially represented expected and anomalous phenomena quite differently. Whereas they represented the expected phenomena in the formal terms appropriate to their domain of expertise, they represented the anomalous phenomena in highly informal terms that referred to salient features of the visual data. These results also show that these internal representations changed over time, shifting from informal to formal representations. However, this shift in representation did not appear to be caused by a global increase in understanding of the data under analysis, but was instead local, and associated with the individual phenomena under investigation. This shift in representation appears to have affected primarily the scientists' representation of anomalous or unexpected findings in their data. We have investigated elsewhere the key role of anomalies in the exploratory stages of data analysis (Trickett, Trafton & Schunn, 2000).

Our focus in this study has been on the exploratory stages of data analysis. We believe that including two independent data analysis sessions in quite different scientific domains strengthens our claims about these changes in representation. However, clearly we need to ascertain whether our results generalize to other situations and scientific domains.

In this paper we examined fairly small changes in representation at the item-specific level. Much research in cognitive science on the topic of conceptual change has focused on relatively larger scale changes in representation (e.g., Chi, 1997; Thagard, 1999). One may wonder what the relationship is between the micro-level changes that we have reported in this paper and the more macro-level changes reported in the conceptual change literature. Some researchers (e.g., Chi, 1997) have speculated that some macro-level changes are not the result of many small changes; instead Chi has argued that some macro-level changes are the result of a complete conceptual reorganization. Similarly, some historians of science have noted that some scientific changes appear to be more radical or revolutionary than others appear to be (e.g., Kuhn, 1967). We believe that the relationship between the micro-level changes in representation and the macro-level changes that are thought to constitute conceptual change remains an open question, and that this question could be fruitfully studied by observing the same scientists over a much longer time scale than we have done so far. We are currently planning such longitudinal studies.

### Acknowledgments

This research was supported in part by student fellowships from George Mason University to the first and second authors and by grant number 55-7850-00 from the Office of Naval Research to the Naval Research Laboratory. We thank Georgia Seeley and Audrey Lipps for assistance with coding.

## Abstract

This study investigates the role of anomalies in the exploratory analysis of visual scientific data. We found that anomalies played a crucial role as two experts analyzed astronomical data. Not only did they pay significantly more attention to anomalies than expected phenomena, both immediately and over time, but also anomalies provided a framework within which they investigated the data.

## Introduction

Attention to the unexpected may be an important component of scientific discovery. Exploring anomalies can lead to theory development and even conceptual change. Philosophers of science (e.g., Kuhn, 1962) have argued that unusual findings play a key role in scientific revolutions, and scientists themselves have claimed that investigating anomalies lies at the heart of scientific innovation (e.g., Knorr, 1980).

Within cognitive psychology, response to anomalous data during scientific inquiry has been noted in a variety of studies, including historical reconstructions of actual scientific discoveries (e.g., Kulkarni & Simon, 1988), on-line studies of scientists (e.g., Dunbar, 1997), laboratory studies in which participants “rediscover” a scientific phenomenon (Dunbar 1993), and studies of those with little scientific training as they perform abstract scientific reasoning tasks (e.g., Tweney, Dowerty, & Mynatt, 1982; Klahr & Dunbar, 1988). These studies have not yielded a consistent pattern of response to unexpected data, possibly because of the range of scientific training and knowledge among the participants.

Recognizing this variety of responses to anomalous data, Chinn and Brewer (1992, 1993), propose a taxonomy of seven reactions to unusual findings, from ignoring the data and upholding the theory to accepting the data and changing the theory. This taxonomy is derived from anecdotal examples from the history of science and from empirical studies of scientific reasoning in the psychological literature. Although Chinn and Brewer propose that this taxonomy applies to scientists and non-scientists alike, they have tested it only among undergraduates with little scientific training.

Thus, despite the general belief that anomalous data is important in scientific discovery, no clear picture has emerged of how scientists (as opposed to laypersons performing scaled-down scientific discovery tasks) respond to unexpected findings. On one hand, there is a well-established tradition in studies of scientific thinking that shows people overlook data inconsistent with their hypothesis, looking

only for support for their theories (e.g., Wason, 1960). Within this tradition, scientists have been found to be as susceptible to this confirmation bias as laypeople (e.g., Mahoney & DeMonbreun, 1977; Mitroff, 1974.) Similarly, studies of complex visualization usage have shown that expert meteorologists do not pay much attention to unusual or anomalous features. Instead, they seem to extract information in a very goal directed manner, rarely following up on features that are not directly relevant to their immediate task (Trafton et al., under review). This evidence—of confirmation bias, even among scientists, and of the goal-directed nature of complex visualization usage—suggests that scientists may overlook unexpected results or anomalies.

On the other hand, however, Dunbar has recently questioned the validity of the studies of confirmation bias on the grounds that they employ arbitrary experimental tasks that involve no scientific knowledge and therefore bear little relationship to tasks that real scientists perform (Dunbar, 1997). Dunbar has argued that in order to investigate how scientists reason, one must observe scientists as they perform their scientific tasks.

Using an “in vivo” methodology that involves observing actual scientists at work, Dunbar has suggested that scientists do attend to unusual results (Dunbar, 1997). He found not only that scientists attended to unexpected results more than they did to expected findings, but also that individual scientists were quick to discard a hypothesis when faced with results that were inconsistent with it. Furthermore, he noted that in lab meetings, the group of scientists tended to focus on a surprising result until they had constructed a plausible hypothesis to account for it. Dunbar concluded that attending to anomalous findings is an important strategy that contributes to successful scientific inquiry (Dunbar 1997). Similarly, Kulkarni and Simon (1988) identified an “attend to surprising result” heuristic as crucial to Hans Krebs' discovery of the urea cycle.

Both Chinn and Brewer's and Dunbar's studies have involved participants, whether trained scientists or not, who were evaluating data to test a specific theory. However, there are many phases of scientific inquiry, and response to anomalous data might be quite different during an exploratory phase from when a theory is firmly established. During exploratory data analysis, theories may be only partially defined. Nonetheless, given their extensive domain knowledge, scientists doubtless have general frameworks which lead to expectations that may or may not be met by the data. They may therefore pay more attention to unusual results,

because such framework anomalies may provide insights for interpreting data and developing theories.

Similarly, there are many forms of data, but previous studies have focused on data that were either presented textually or required direct, relatively simple perceptual judgments. However, scientists in many domains employ complex visualization techniques in order to inspect their data. Little is known about the role of unusual or unexpected findings in either exploratory or scientific visualization.

Our goal is to investigate the role of anomalies during early, primarily exploratory phases of visual data analysis. Specifically, we investigate whether scientists notice anomalies in this type of data and, if so, the extent to which they attend to them, both immediately and over time. We also investigate how the visual nature of the data affects the detection of and attention to anomalies.

There are many methodologies available by which to examine the processes of scientific inquiry, and there are strengths and weaknesses associated with each (see Klahr & Simon, 1999 for a review). Our approach has been to combine features of several methodologies in order to take advantage of their respective strengths.

First, we have chosen to conduct a case study of actual scientists at work because this methodology offers an extraordinarily rich set of observations of high face validity. Most case studies of scientific inquiry have focused on famous scientists who have made discoveries of great historical importance (e.g., Gentner et al, 1997; Kulkarni & Simon, 1988). We have chosen instead to focus our investigation on more “ordinary”—albeit expert—scientists, the ultimate significance of whose work is currently unknown. We believe this focus on the more mundane aspects of scientific inquiry may yield results that are more representative of scientists’ everyday activities.

Second, we collected verbal and visualization data of the scientists working together and conducted a verbal protocol analysis of these data in order to gain insight into the scientists’ concurrent thought processes (Ericsson & Simon, 1993). Verbal protocols have frequently been collected in laboratory studies of non-scientists performing scientific discovery tasks; however, this methodology has rarely been used with practicing scientists. Furthermore, because we collected a protocol of a work session involving two scientists, there was no need for an experimenter to prompt the participants to keep talking. By focusing on a dyad, we were able to obtain a more natural account of the scientists’ thinking than is possible with an individual.

Finally, we have adopted Dunbar’s (1995, 1997) “in vivo” methodology because, as Dunbar points out, it affords a unique opportunity to observe “how scientists really reason.” Instead of observing a lab group as Dunbar did, however, we chose to study a dyad, for two reasons. First, the two scientists we observed were of equal professional status, thus we avoid social issues that might make junior scientists reluctant to question the interpretations of a senior colleague. Second, we think that the verbal protocols of a dyad might represent each scientist’s thinking more completely than those of a group. In a group setting, with more people “jumping into” a discussion, individuals may be less likely to pursue lines of thought in significant depth.

## Method

### Participants

The participants in this study were two expert astronomers, one a tenured professor at a university, the other a fellow at a research institute. The astronomers had earned their Ph.D.s six years and ten years respectively before this study; one has approximately 20 publications in this general area and the other approximately 10. One of the astronomers, hereafter referred to as A1, focuses on conducting and analyzing astronomical observations, and has an expertise in ring galaxies; the other astronomer, hereafter referred to as A2, combines teaching with primarily theoretical astronomical research and model construction. The astronomers have been collaborating for some years, although they do not frequently work physically alongside one another (i.e., work at the same computer screen at the same time to examine data).

### Procedure

The astronomers were video- and audio-taped as they explored computer-generated visual representations of a new set of observational data. They were working in one astronomer’s office at a shared computer monitor. One astronomer was in charge of the keyboard and mouse and sat directly in front of the screen; the other astronomer sat to his left, with the monitor clearly in view. They were instructed not to explain their comments to the researchers, but to carry out their work as though no camera were present. The relevant part of the session lasted about 53 minutes and generated 7676 words. The astronomers’ interactions were later transcribed and coded as described below. At a later date, we interviewed A2 to obtain clarification of domain-related issues.

### The Task and the Data

The astronomical data under analysis were optical and radio data of a ring galaxy. A ring galaxy forms as the result of a collision between two galaxies: one galaxy is thought to have passed through another, leaving both a doughnut-shaped ring of stars and gas (the ring galaxy) and a smaller galaxy nearby. Such galactic collisions are relatively frequent cosmic events; consequently, ring galaxies *per se* are not uncommon. Both astronomers had conducted research and published scholarly articles on other ring galaxies, but this particular galaxy was relatively new to them. Nor had they examined this data set before; consequently, they considered this session exploratory.

The astronomers’ high-level goal was to understand the evolution and structure of the ring galaxy. This understanding emerges from an understanding of where, how, and why star formation occurs within the galaxy, which rests on an understanding of the flow of gas in the galaxy. In order to understand the flow of gas, the astronomers must understand the kinematics (the velocity and position) of the system, by inferring the 3-dimensional streaming motions of the gas. They make inferences about streaming motions by interpreting the velocity field, represented by contour lines on the 2-dimensional display. Examining the velocity contours is thus the lowest level task in this chain of inferences.

The astronomers’ task was made difficult by two characteristics of their data. First, the data were one- or at best two-

dimensional, whereas the structure they were attempting to understand is three-dimensional. Second, the data were noisy, and there was no easy way to distinguish between noise and real phenomena. Figure 1 shows a screen snapshot of the type of data the astronomers were examining. In order to make their inferences, the astronomers used different types of image, representing different phenomena (e.g., different forms of gas), which represent different information about the structure and dynamics of the galaxy. Some of these images could be overlaid on each other. In addition, the astronomers could choose from images created by different processing algorithms that result in different weightings of the data, each with advantages and disadvantages (e.g., more or less resolution). Finally, they could adjust different features of the display, such as contrast or false color.

Figure 1: Example of data examined by astronomers. Radio data (contour lines) are laid over optical data.

### Coding Scheme

The protocol was divided into 829 segments: as each astronomer spoke, a new segment was coded; then their utterances were further segmented by complete thought.

A coding scheme was developed to examine the astronomers' attention to anomalous phenomena in the ring galaxy. The protocol was coded independently by two different coders. Inter-rater reliabilities for each code are reported below.

**On/Off Task** In order to allow us to focus our analysis only on those utterances relevant to the scientists' task of data analysis, we coded each segment as on- or off-task. All segments that addressed matters external to the data analysis were coded as off-task; these segments included external interruptions (e.g., the telephone ringing), extraneous comments by the astronomers (e.g., jokes or banter between them), comments relating to the software, specific details about plans for future observations, and so on. All segments

that addressed issues of data analysis were coded as on-task. These segments included comments relating to the selection of a display type (as opposed to comments about how to implement that display) as well as decisions about obtaining additional data in the future (as opposed to details about how to obtain those data). Initial agreement between the coders was 90%. All disagreements were resolved by discussion.

**Episodes** Next, we divided the protocol into discrete, non-overlapping episodes that would allow us to study the astronomers' shifting focus of attention. The protocol was segmented into 19 exhaustive episodes. An episode began with the astronomers' focus on a feature or point of discussion and lasted until their attention switched to another phenomenon or theoretical point; at this switch of attention, a new episode was coded. Although the focus of most episodes was a feature of the galaxy, this was not necessarily the case; for example, one episode consisted of a discussion about a future observation session and the data to be obtained from it. Agreement between coders was 98%.

A new episode frequently coincided with a display change, but did not necessarily do so. Sometimes the astronomers switched their focus of attention to another galactic feature visible on the same display, thus beginning a new episode without changing the display. At other times, they changed the display in order to explore another representation of a feature, thus changing the display within the same episode.

**Noticings** In order to establish which phenomena—unusual or not—the astronomers attended to, we first coded for the astronomers' *noticing* phenomena in the data. A noticing could involve merely some surface feature of the display, such as a line, shape, or color, or it could involve some interpretation by the astronomer, for example, identifying an area of star formation or concentration of gas. Only the first reference to a phenomenon was coded as a noticing; coding of subsequent references to the same phenomenon is discussed below. Agreement between the coders was 95%. Disagreements were resolved by discussion.

Table 1: Noticings (in italics) coded as unusual or expected

Criterion	Code	Example
a) Explicit	Anomalous	What's <i>that funky thing...</i> That's odd
b) Domain Knowledge	Expected	You can see that <i>all the HI</i> is concentrated in the ring
c) Association	Anomalous	You see <i>similar kinds of intrusions</i> along here
d) Contrast	Expected	That's odd...As opposed to <i>these things</i> , which are just the lower contours down here
e) Question	Anomalous	I still wonder why <i>we don't see any HI up here</i> in this sort of northern ring segment?

**Subsequent References** One of our questions was the

extent to which the astronomers continued to investigate anomalies. Whereas the coding of the noticings captured the first reference the astronomers made to a phenomenon of interest, we needed to establish how frequently they made subsequent reference to each noticing. Consequently, all subsequent references were also identified and coded.

Because the astronomers were sharing a computer monitor, frequently the first interaction between them after a noticing was to establish that they were both looking at the same thing. Subsequent references that served purely to establish identity were *not* included in the analyses.

Table 2: Coding of subsequent references  
 Noticing: First reference to phenomenon  
 Establish identity: Reference excluded from analysis  
 SR: Subsequent reference included in analysis

Code	Utterance
Noticing (N9)	A1: What's that funky thing...
Establish identity	A2: Left center, you mean...
Establish identity	A2: This stuff? [points to screen]
Establish identity	A1: Yeah
Establish identity	A2: Yeah
SR to N9	A1: What is that? A2: You can see there is some gas here [points to different area] inside the ring, but not much...
Noticing (N10)	
SR to N9	A1: Except for that little knot there.

Not all subsequent references immediately followed a noticing; frequently, the astronomers returned to a phenomenon of interest after investigating other features of the galaxy. The astronomers made frequent gestures to the feature of the image under discussion; by constructing a map of the noticings on the galaxy, and cross-referencing it with these gestures, the coders were able to determine the specific noticing to which a subsequent reference referred. Table 2 illustrates the coding scheme for (sequential) subsequent references.

## Results and Discussion

There were 619 on-task segments (75%). Subsequent analyses do not include off-task segments.

### Noticing Framework Anomalies

Our first question was did the astronomers notice anomalies in the data? Recall that a "noticing" is a first-time reference to a phenomenon of interest. There were 27 noticings during this session. Of these, 9 (33%) were anomalous, 13 (48%) were expected, and 5 (19%) were uncoded, because the astronomers themselves or the coders disagreed. This analysis shows that at least one-third of the phenomena the astronomers identified were unusual in some way. It appears then that the astronomers *did* notice anomalies in this dataset.

Interestingly, most of the anomalies (78%) were identified in highly informal terms or by features of the display, rather than by underlying astronomical phenomena. Thus, the astronomers usually identified anomalous phenomena as "blobs," "bulges," or "dipsy-doodles" rather than in formal astronomical terms (such as a specific type of gas). Not only

were anomalies important to the astronomers, but their attention to these anomalies appears to be drawn primarily by visual features of the data. We investigate the relationship between representation and anomalous/expected results elsewhere (Trickett, Fu, Schunn, & Trafton, 2000).

### Relationship between Episodes and Noticings

Next, we investigated whether the anomalies played any part in guiding or structuring this exploratory session, that is, whether there was any relationship between the noticings and the episodes, and if so, whether this relationship was different for the anomalies than for the expected phenomena.

In order to investigate this relationship, we noted how each episode began. Nine of the 19 episodes began with a noticing, 7 began with a subsequent reference, and 3 episodes began with something other than a noticing or subsequent reference to a noticing. Thus, out of 19 episodes, only 3 were initiated by theoretical or other similar considerations. Noticing and subsequent references, while common, only account for 61% of the segments. Thus episodes are more likely to start with a data-driven event (noticing or SR) than one would expect from the base rates,  $X^2(1) = 3.88$ ,  $p < .05$ . This result suggests that the most likely focus of attention was some feature of the data rather than some theoretical or other matter. This exploratory session analyzing visual data appears to have been driven primarily by the data themselves rather than theoretical considerations.

What features of the data were likely to attract the astronomers' attention? Of the noticings that sparked an episode, an equal number (3) were anomalous and expected. But whereas *no* episodes began with a subsequent reference to an expected phenomenon, 6 subsequent references to anomalies launched a new episode. This analysis suggests that at a first pass, the astronomers were equally likely to attend to expected as to anomalous phenomena in the data. However, as they explored the data further, it was the anomalies, not the expected phenomena, that directed their investigations. Table 3 summarizes these results.

Table 3: Noticings and subsequent references beginning an episode

	Notice	SR
Anomalous	3	6
Expected	3	0

### Initial Attention to Anomalies

Once the astronomers had identified something unusual in the data, what did they do with this observation? There are several possible reactions: they could pursue the anomaly in order to try to account for it, they might temporarily disregard it but return to it later, or they might move on to explore some other, better understood, aspect of the data. A related question is whether their response to anomalies was different from their response to expected phenomena.

First, we investigated this issue by considering the extent to which the astronomers made subsequent reference to a noticing immediately upon identifying it. If anomalies and expected phenomena are of equal interest, we would expect

them to make a similar number of subsequent references to both the anomalous and expected patterns. However, if anomalies play a more important role in their efforts to understand the structure of the galaxy, we would expect them to pay more attention (measured by the number of subsequent references) to anomalies than to expected observations.

Although there were fewer anomalies identified in this session, collectively these anomalies received over 3 times as many subsequent references within the same episode as the expected phenomena. The total number of subsequent references to anomalies was 68 (mean = 7.6), compared with 19 (mean = 1.5) for expected phenomena. A t-test on these data was significant,  $t(20) = 2.27$ ,  $SE = 2.69$ ,  $p < .05$ . These results show that the astronomers did pay more attention to the anomalies immediately upon noticing them, or soon thereafter, than they did to the expected phenomena. This in turn suggests that the anomalies were more important to the astronomers than those phenomena they expected to find. Table 4 summarizes the results of this analysis.

Table 4: Subsequent references (SRs) within episodes

	Total SRs	Mean SRs	Range
Anomalous (N=9)	68	7.6	1 - 30
Expected (N=13)	19	1.5	0 - 4

Furthermore, as Table 4 shows, the range of subsequent references was also much greater for the anomalies than for the expected phenomena. *All* the anomalies received at least one subsequent reference soon after the astronomers noticed it. In contrast, 5 of the 13 expected phenomena (38%) received no subsequent references, i.e., no immediate further attention. In addition, 5 of the 9 anomalies (56%) received more than 5 subsequent references; none of the expected phenomena was referred to so frequently. This analysis provides further support for our claim that overall, the anomalies were more important to the astronomers' goals than the expected phenomena. In addition, it suggests that the anomalies themselves were not of equal importance, with some anomalies receiving much more attention than others.

### Long-Term Attention to Anomalies

It appears, then, that as the astronomers explored the data about the ring galaxy, they paid more attention immediately to the anomalies in this data than they did to expected phenomena. These results say nothing, however, about the continuing role of the anomalies in the astronomers' analysis. Possibly, having explored an anomaly, the astronomers might "consider the matter closed" and switch their attention to another phenomenon. As with the astronomers' immediate attention to phenomena, we compare their treatment of anomalies with their response to the expected phenomena.

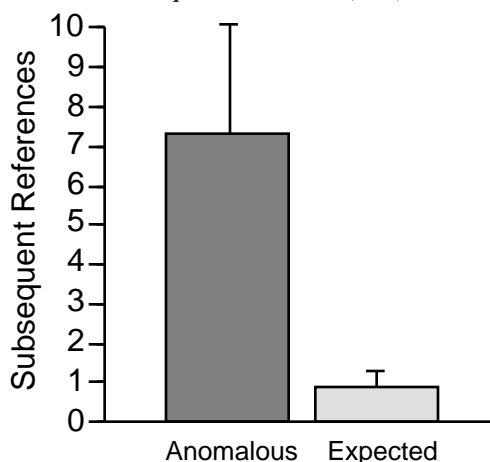

In order to investigate the extent to which the astronomers revisited the phenomena they noticed, we examined the number of subsequent references to both anomalies and expected findings *across* episodes. Recall that an episode ended when the astronomers switched attention to another feature or point of discussion. Thus, a reference to a feature across an episode indicates a switch of attention *back* to that fea-

ture, after having focused attention on something else.

One of the expected phenomena was first noticed in the last episode; because it was not possible for it to be referenced in a later episode. Thus the number of expected phenomena for these analyses is reduced from 13 to 12.

Seven of the 9 anomalies (78%) were referenced across episodes, compared with 6 (50%) of the expected phenomena. Overall, the total number of subsequent references across episodes to anomalies was 66 (mean = 7.3), compared with 11 (mean = 0.9) to expected phenomena. A t-test on these data was significant,  $t(19) = 2.66$ ,  $SE = 2.41$ ,  $p < .05$ . This result shows that the astronomers continued to pay more attention to anomalies than to expected phenomena, revisiting them even after switching their attention to other features of the data. Figure 2 summarizes these results.

Figure 2: Mean subsequent references (SRs) across episodes

Five of the 9 anomalies (56%) received more than 5 subsequent references across episodes. None of the expected phenomena was referenced so frequently. Furthermore, the astronomers persisted in returning to some anomalies, in 3, 4, 5, or even 6 episodes. The spread of episodes during which subsequent references were made was quite extensive and in several cases spanned almost the entire session. For example, Noticing 2 was first identified in episode 1 and was further referred to in episodes 2, 5, 6, 13, 15, and 17. Noticing 11 was first identified later in the session, in episode 9, and was further referenced in episodes 11, 13, 15, and 17. These results suggest that some anomalies were very puzzling to the astronomers and that they were sufficiently important to the exploration of the data that they returned to them repeatedly, even long after they had first noticed them.

### General Discussion and Conclusion

This study was conducted to investigate the role of anomalies in the exploratory stages of visual data analysis. We found that the astronomers did notice and pay attention to anomalies. They paid significantly greater attention to the anomalies in the data than to the expected phenomena. Furthermore, they found some anomalies sufficiently intriguing that they returned to them later in their exploration, in some cases repeatedly and over relatively long stretches of time. None of the expected phenomena received this type of prolonged attention. We conclude, therefore, that anomalies

played an important role in the exploration of these data.

In addition, we found that the astronomers' attention was initially drawn by features of the data rather than theoretical considerations. Although at first an expected phenomenon was as likely as an anomaly to become the focus of attention, as the analysis proceeded, the anomalies were more likely to hold the astronomers' attention. Furthermore, attention to the anomalies was initially drawn by irregular features of the visual representation rather than by the underlying phenomenon itself. This suggests that their approach was highly perceptual, because they identified anomalies primarily on the basis of unusual curves, lines, etc.

It is possible that anomalies played a significant role in this data analysis session *because* of the visual nature of the data. The anomaly was visible on the display at all times; consequently, it is possible that the astronomers were cued primarily by the display rather than memory to revisit the anomaly. However, this does not seem to be the case. If the display were the only means by which the astronomers were cued to make subsequent reference to the anomaly, we would expect them to make subsequent references to *all* anomalies. As our results indicate, though, they were selective in the anomalies they continued to investigate. Although visibility on the display may have helped to keep a particular anomaly activated in the astronomers' memory, this alone does not seem to have been sufficient to prompt them to revisit it. Rather, it appears that some anomalies were "tagged" as worthy of further investigation, and that the astronomers continued to search for a satisfactory way to explain them.

In contrast to the widely-held belief that scientists are susceptible to confirmation bias and seek chiefly to confirm what they already expect, our results present a picture in which investigating framework anomalies is a central activity in exploratory data analysis. We propose that the anomalies were instrumental in guiding the structure and content of the data analysis session.

We acknowledge that this is a case study of particular scientists in one domain, working at a specific phase of their research. However, our results are part of a growing body of evidence that attention to anomalies may be an important component of scientific inquiry (cf. Dunbar, 1997). Moreover, the scientists in this study were engaged in a task—exploratory data analysis—that is undertaken in all scientific domains. They neither employed unusual techniques nor used specialized equipment unique to their domain. We therefore expect our results to generalize to scientists in other domains. Whether or not they apply to later stages of data analysis (such as hypothesis-testing) remains an open question. We are currently extending this research by applying our methodology to a variety of scientists working with scientific visualizations in several domains. We are also planning to conduct longitudinal observations of scientists, in order to investigate the role of anomalies in their work at different stages of data analysis.

### Acknowledgments

This research was supported in part by a student fellowship from George Mason University to the first author and by grant number 55-7850-00 from the Office of Naval Research to the Naval Research Laboratory. We thank Georgia Seeley

and Audrey Lipps for coding assistance and Erik Altmann, Melanie Diez, Anthony Harrison, William Liles, and Lelyn Saner for comments.

## Abstract

In the simple recurrent network (SRN) model, proposed by Cleeremans and McClelland (1991) to describe implicit sequence learning, the distinction between reaction time and prediction of the next trial is somewhat blurred. That is, the reaction time of the network is taken to be inversely proportional to the activation value of the corresponding node. In a prediction task the prediction would also be directly derived from the activities of the output nodes. In order to investigate the difference between ability to predict following stimuli and reaction times, we study implicit sequence learning in a similar vein as done by Cleeremans and McClelland (1991), using a slightly less complex grammar than they did. In addition we ask subjects to guess where the next stimulus will be at randomly chosen trials during the learning process. Results show a direct correspondence between fast reaction times and correct predictions.

## Introduction

Implicit learning has been studied for over thirty years starting with Reber (1967). Only recently attention has been given to modeling this kind of learning behavior in detail, mainly using neural networks. Specifically simple recurrent networks have been used successfully by Cleeremans and McClelland (1991) to model subjects' behavior on learning sequences that are generated by a finite state automaton, in fact the very same automaton that was used by Reber (1967).

Many different paradigms have been developed for studying implicit learning behavior. One characteristic that divides those paradigms is the way in which they assess the possession of implicit knowledge. In this paper two such measures, reaction times and predictions, are studied. In implicit learning research the sequential implicit learning paradigm has become increasingly popular and with that the use of reaction time as the primary measure of performance (see for example Nissen & Bullemer, 1987; Cleeremans & McClelland, 1991; Seger, 1997). We used an augmented sequence learning paradigm in which a direct comparison between reaction times and predictions was possible.

---

<sup>1</sup>The authors wish to thank their students Sander van Duyn, Wanda Toxopeus, Stijn Gooskens, Thijs de Jongh & Edibe Tali for valuable help in setting up this experiment and collecting and analyzing the data.

## Sequence learning

One of the more recent paradigms to study implicit learning is so-called sequence learning. Subjects are typically offered sequences of stimuli that are formed according to some (formal) rule(s). The only thing subjects have to do is press some key that corresponds to the current stimulus. For example when the stimuli are just zeros and ones, the current stimulus could be formed by taking the xor of the preceding two stimuli. It is now interesting to see if subjects implicitly learn this rule. This is measured by comparing RTs on correct trials, that is trials on which the current stimulus is in fact the xor of the two preceding trials, with RTs on incorrect trials, where the current stimulus is *not* the xor of the two preceding trials.

Cleeremans and McClelland (1991), using this paradigm, had their subjects learn an endless sequence of stimuli generated by a finite state grammar. To determine the effects of implicit learning, they assessed reaction times, and found these to be decreasing as subjects got more training. Similar studies have been done where, instead of measuring reaction times, performance was assessed by asking subjects to predict the next stimulus after having seen an initial segment of a string. However, few studies have investigated the exact relation between RTs and prediction performance in implicit learning. The present study aims to gain insight into this relation by analyzing RTs and prediction performance simultaneously.

In this context the work of Cleeremans and McClelland (1991) on the SRN model for implicit learning, is of interest. They use the SRN model to predict RT performance of subjects by taking the reaction time of the network to be inversely proportional to the activity of the output unit corresponding with the correct response<sup>2</sup>. The activity of the 'correct' output unit can thus be interpreted as a measure of anticipation of the position of the next stimulus. This anticipation in turn can be used to make *predictions* of the next stimulus as well; in this case the position corresponding with the output unit with the highest activity has the highest probability of being predicted. This means that the

---

<sup>2</sup>Note that this doesn't leave the possibility for incorrect responses. This is not a big problem, however, since typically incorrect responses are very seldom because of the simplicity of the task.

SRN model predicts a negative relation between prediction performance and RTs, with the RTs decreasing as prediction performance gets better. The aim of the present study is to test this hypothesis empirically.

## Experiment

To assess the relation between RTs and prediction of stimuli directly we did a sequence learning experiment in which the standard series of RT trials was interspersed with prediction trials at which subjects had to guess where the next stimulus would come. A similar procedure is proposed by Jimenez, Mendez, and Cleeremans (1996) which they named the *continuous* generation task. The main difference between this procedure and other generation tasks is that no feedback is given on the correctness of the prediction; rather, after subjects have made their prediction the next stimulus of the sequence is presented with the same response-stimulus interval as between consecutive RT trials.

Subjects were given a four-choice RT task, consisting of a total of 4800 trials divided in twenty blocks of 240 trials each. The blocks were split into two sessions that were presented on two consecutive days. Unknown to subjects the sequence of stimuli followed a pattern that was generated using the finite state grammar which is described below. Because of the rather complex structure of the sequences generated with such a grammar subjects were presented with 4800 trials. There were two types of stimuli: RT trials and prediction trials. At the RT trials subjects were asked merely to reproduce the current stimulus by pressing the appropriate key. At the prediction trials subjects were asked to predict the next stimulus by pressing the appropriate key. Each block of 240 trials was divided into subblocks of four types: grammatical RT, random RT, grammatical prediction and random prediction. The switch from one subblock to the next was not marked so subjects were unaware of the existence of these subblocks. The sequence of stimuli in the random subblocks was unrestricted but for the fact that no two consecutive stimuli could be the same, which would lead to undesired speed-up of responses due to priming.

The random trials are used as a control condition, accommodating for possible effects of motor training, as well as for additional effects of subjects gaining implicit knowledge of the grammar. This design provides the possibility to assess the effects of implicit learning, by comparing RTs and prediction performance in the grammatical trials to those obtained in the random trials. Note that this is a within subjects design, so that each subject is his own control group (i.e., the performance of each subject on the grammatical trials is compared with that same subject's performance on random trials). The prediction of an inversely proportional relation between RTs and prediction performance, as derived from the SRN model (Cleeremans & McClelland, 1991), translates into three statistical hypotheses. The first is an interaction effect of condition and time on the RTs: If implicit learning occurs, RTs should decrease more for the grammatical trials than for the random trials. The

second is an interaction effect of condition and time on prediction performance: over time, prediction should improve for the grammatical trials, but not for the random trials. Finally, on trials leading to correct predictions, RTs

## Method

**Subjects** Twenty-four subjects, undergraduates at the Department of Psychology of the University of Amsterdam, participated in this experiment. They received both course credits and money for participation. On top of that they could earn bonuses for fast and accurate responses.

**Procedure** At the start of the experiment subjects were told that in this task both accuracy and speed were important. The experiment started with two small blocks of trials that were not recorded to familiarize the subjects with the task. Each block consisted of four subblocks: 20 random RT trials, 100 grammatical RT trials, 100 grammatical prediction trials and 20 random prediction trials. In the RT subblocks only reproduction of the stimuli was asked of the subjects; in the prediction subblocks RT trials were interspersed with prediction trials. At the end an extra block was added in which the order of the random and grammatical trials was reversed to test whether the order of the subblocks could influence the results.

To enable a more direct comparison between prediction and reaction times, an extra block was added in which the series of trials for both the RT subblock and the prediction block was identical. In this way it is possible to directly compare the RT on a given trial with the prediction made on the very same trial.

**Stimulus material** The sequence of stimuli in the grammatical subblocks was generated from the finite state grammar in figure 1. Sequences are produced by this grammar in the following manner:

1. Start in state #1 and randomly choose one of the arcs leaving that state while noting the letter corresponding to the followed arc.
2. In the next state repeat this process of choosing an arc and noting the corresponding letter
3. The process ends when state #7 is reached and the process starts over again to create strings of unbounded length.

**Display** As can be seen in figure 1 the alphabet of the grammar consists of four letters. The letters were translated into screen positions as shown in figure 2. In the grammatical RT subblock subjects were exposed to 100 trials; in each trial the  $\times$ -symbol appeared in one of the quadrants of the computer display and the subjects had to press the corresponding key on the numerical keypad on the keyboard. The keys 1,2,4 and 5 on the numerical keypad were used to ensure that the spatial configuration of the response keys matched the spatial configuration of the stimulus positions

Figure 1: Finite state automaton used to generate strings for sequence learning experiments. A string is formed by starting in state #1 and then randomly choosing one of the arcs leaving that state meanwhile noting the letter corresponding to that arc. Continue stepping from state to state until the end state #7 is reached; from there the process starts over again from state # 1.

on the display. Subjects were instructed to hold their index finger over the middle of the four keys and press the appropriate key only with the index finger.

**Exit interviews** All subjects were asked a series of questions after the experiment was completed to assess whether subjects had acquired any explicit knowledge of the grammatical sequence.

### Results

The data of one of the subjects was not included in the analyses, because the subject had too many errors in three consecutive blocks due to misplacing the index finger over the numerical keypad. Comparison of the last two blocks revealed that the order of the subblocks, random before grammatical or vice versa, did not significantly influence reaction times.

**RT trials** Grammatical RTs decreased from 404.7 ms at the beginning of the experiment to 342.6 ms at the end; random RTs decreased from 414.2 ms to 370.3 ms. The mean RTs are displayed in Figure 3.

The first hypothesis predicts that RTs decrease more for the grammatical trials than for the random trials. In order to test this hypothesis, RTs were averaged over subjects and over two consecutive blocks. A repeated measures ANOVA with two within factors, block (10 levels)  $\times$  grammaticality (2 levels), indicates a significant interaction between grammaticality and blocks: as predicted, grammatical trial RTs decreased more over time than did random trial RTs,  $F(9, 198) = 3.87; p < 0.001$ . The analysis also yielded significant main effects for grammaticality and training: grammatical trial RTs were significantly smaller than the random trial RTs,  $F(1, 22) = 59.49; p < 0.001$ , and RTs became faster over blocks for both grammatical

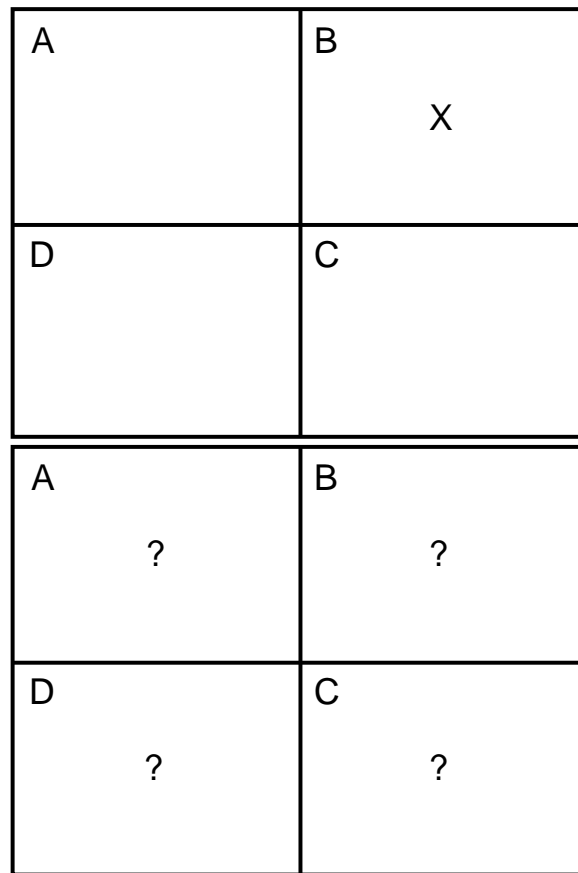

Figure 2: The top panel shows the computer display for the RT trials. Subjects have to press the key corresponding to the quadrant of the screen where the  $\times$  is shown. In the bottom panel the screen lay-out for a prediction trial: all quadrants have a question mark and subjects have to choose whatever letter they think will occur next. The letters in the top-left corner of the quadrants were not part of the actual display.

and random trials,  $F(3.78, 198) = 25.75; p < 0.001$  with Greenhouse-Geisser correction for non-homogeneous variances.

**Prediction trials** The percentage of correct predictions in grammatical subblocks increased from 33.6 % at the beginning to 52.2 % at the end of the experiment. The corresponding percentages for the random predictions are 30 and 34 % respectively. The proportions of correct responses on predictions for both random and grammatical subblocks are displayed in Figure 4.

The second hypothesis states that prediction performance should improve over time for the grammatical trials, but not for the random trials. In line with this prediction, a significant interaction between blocks (time) and

Figure 3: Mean reaction times for grammatical and random trials. Means are averaged over two consecutive blocks,  $N = 23$ .

grammaticality was found,  $F(7.9, 198) = 2.25$ ;  $p = 0.027$ , showing that the grammatical predictions did show more improvement over time than did the random predictions. More specifically, there was no improvement over time for the random trial predictions when analyzed separately,  $F(1, 228) = 0.845$ ;  $p = 0.359$ , as was to be expected.

**Prediction and RT trials: comparison** To compare performance on prediction and RT trials directly we added a block of trials in which the strings used for the RT trials and for the prediction trials were identical. Table 1 shows the mean RTs for correctly and incorrectly predicted items in this added block of trials. An anova with one within factor (correct vs. incorrect) confirms that correct predictions correspond to fast RTs,  $F(1, 22) = 6.44$ ;  $p = 0.019$ .

Table 1: Mean reaction times for correctly and incorrectly predicted trials.

Prediction	mean	sd
correct	360.96	49.64
incorrect	389.97	30.30

**Exit interviews** Subjects were asked whether they noticed anything particular in the sequence of stimuli. Although some subjects felt there was some ‘regularity’ in the sequence, none of the subjects could specify this, except for three subjects that said that the subsequence  $AB$  occurred rather frequently. This is the subsequence in the grammar which corresponds with the loop between the two top right nodes in Figure 1.

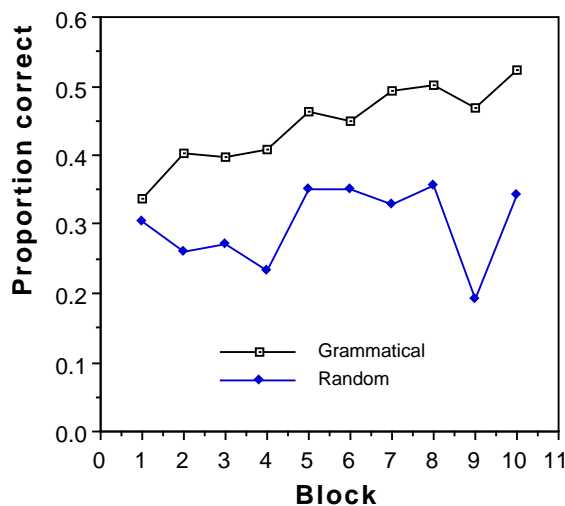

Figure 4: Proportion correct predictions of grammatical and random prediction trials,  $N = 23$ .

## Discussion

The results show that implicit learning occurs: subjects give faster responses on grammatical trials than on random trials and this effect becomes larger towards the end of the experiment. Secondly, subjects gradually get better at predicting following stimuli due to training as well. Thirdly, as expected, smaller RTs correspond with a better ability to predict the following stimulus.

## Models of sequence learning

Cleeremans and McClelland (1991) applied the SRN to implicit sequence learning. The SRN successfully describes subjects’ growing sensitivity to dependencies between successive stimuli. The success of the SRN model is due to its ability to capture the ‘statistical constraints’ inherent in the sequence of stimuli. The SRN model also correctly predicts, at least in a qualitative manner, the inverse relation between RTs and the proportion of correct predictions as we have shown above. A drawback of the SRN model is that it is not very well suited for describing individual differences. The SRN model construes implicit sequence learning in subjects as statistical learning. Subjects first grow sensitive to first order frequencies of symbols, then to second order frequencies, that is bigram frequencies, then third order frequencies et cetera. Individual differences in both the learning process and the resulting implicit knowledge base, that is knowledge of frequency constraints, are not brought out by the model. Below we will describe how hidden Markov models can be used to model individual behavior of subjects.

## The hidden Markov model

Hidden Markov models, henceforth HMMs, are also called stochastic finite automata since they are equivalent to finite

automata where the arcs between states have probabilities corresponding to them. The only restriction is that the probabilities on the arcs leaving a particular state should sum to one. This resemblance to finite automata is the reason for exploring the possibility of applying HMMs to implicit learning. Before presenting results of fitting HMMs to subjects' data we give a short introduction to HMMs.

Hidden Markov models have mainly been used in speech recognition applications such as Schmidbauer, Casacuberta, Castro, and Hegerl (1993), Chien and Wang (1997) although recently more psychologically oriented applications have come up as well such as in action learning (Yang, Xu, & Chen, 1997). The main reason that HMMs are used in speech recognition is that they are especially well suited for capturing temporal dependencies in a series of utterances which then helps in identifying phonemes. This feature can be used to model the temporal dependencies that are inherent in the series of stimuli that are typically used in implicit learning.

More formally a HMM consists of the following elements (notations adapted from Rabiner (1989)), also see figure 5 for clarification:

1. a set of states  $S_i, i = 1, \dots, N$
2. a set  $V$  of observation symbols  $V_k, k = 1, \dots, M$
3. a matrix  $A$  of transition probabilities  $a_{ij}$  for moving from state  $S_i$  to state  $S_j$
4. a matrix  $B$  of observation probabilities  $b_j(k)$  of observing symbol  $V_k$  while being in state  $S_j$
5. a vector  $\pi$  of initial state probabilities  $\pi_i$  corresponding to the probability of starting in state  $S_i$  at  $t = 1$

The equations describing the dynamics of the model are as follows:

$$S_{t+1} = A S_t + \zeta_{t+1}$$

$$O_{t+1} = B S_t + \xi_{t+1},$$

where  $S_t$  is the hidden process and  $O_t$  is the observed process;  $\zeta_{t+1}$  and  $\xi_{t+1}$  are zero mean martingale increment processes, cf. Elliott, Aggoun, and Moore (1995, p. 20) for further details. A hidden Markov process then is a Markov process with multiple indicators for each (hidden) state. By substituting  $S_t$  by its definition in terms of  $S_{t-1}$  in the defining equation for  $O_{t+1}$  it is easily seen that in fact  $O_{t+1}$  is dependent on all foregoing observations back to  $O_1$ . Hence, at any given point observations can depend on all foregoing observations. This is in contrast with a normal Markov model where the next observation only depends on the current observation.

### Characterizing sequence learning behavior

Fitting a hidden Markov model is in fact the inverse of producing a sequence of stimuli from a finite state automaton:

Figure 5: Representation of a hidden Markov model. This model produces exactly the same sequences as the grammar we used in the experiment with equal probabilities. Sequences are generated in the same manner as in FSAs: start in one of the states on the left with letter A or B, then follow the arcs leading from those states. A sequence ends when one of the accepting states is reached, that is the two states with the double circle around them. From there the process continues by going to one of the starting states again. For the accepting state with the letter D the arcs are drawn to the start states. For reasons of clarity the arcs from the accepting state with the C are left out. The arcs leading from one state to the next have probabilities corresponding to them which are given in the figure for some of the arcs.

finding the best automaton to describe a given sequence of observations. This procedure can be applied to any kind of sequence of categorical observations and hence also to a sequence of responses in a sequence learning experiment. In simulation studies we have shown that in fitting a HMM the right automaton can be induced from the data (Visser, Raijmakers, & Molenaar, accepted for publication). That is, having generated a sequence from the grammar used in the experiment we found the HMM in Figure 5 exploratively.

**Sequence learning data** In the prediction subblocks of the experiment subjects were presented with question marks on the screen at random points in the sequence of stimuli. In between the prediction trials normal RT trials were presented. For each subject this resulted in a sequence of responses consisting of the trials that were presented on the screen interspersed with their own predictions about the position of the next stimulus.

In order to characterize sequence learning we fitted HMMs on these sequences of responses. To bring out the learning we fitted separate HMMs on the initial and final segments of the sequence of responses. Both segments consisted of 500 trials. We expected to see a rise in number of hidden states of the model from beginning to end; that is,

we expected subjects to gradually build a more complex model of the grammar underlying the sequence of stimuli. A rise in number of states would reflect subjects' growing sensitivity to the structure of the sequence. For two subjects we indeed found such a rise in the number of states from two states at the start of learning to four states at the end of learning. Overall however, results were inconclusive. This is, we think, mainly due to the fact that only a small proportion of the series of responses that were analyzed were actually produced by the subject. Of the series of 500 trials that the HMMs were fitted on, only 125 were produced by the subjects, the others were generated by the finite state automaton and only *reproduced* by the subjects. As a consequence, of all the responses only a quarter could be useful in discriminating between beginning and end of the learning phase. Hence the low power of the test. In future research it would be useful to have longer sequences of freely generated responses to which HMMs can be fitted more reliably.

### Conclusion

In sequence learning both RTs and prediction have been used as a measure of performance. The results of this experiment show that when measured simultaneously it is possible to relate directly improvement in prediction performance and improvement in RT performance on grammatical trials. The direct comparison shows what is to be expected: fast RTs are indicative of the subjects' level of anticipation of the next trial and on the same count result in correct predictions. With this study it is also shown that prediction is possible even in a fairly complex rule system, that can not be verbalized by subjects.

The SRN model has proved to be a valuable model for describing the learning processes inherent in implicit sequence learning. However the model does not seem especially suitable to describe individual subjects' behavior. Therefore we introduced the hidden Markov model as a stochastic counterpart of the FSA to characterize individual learning behavior. Since hidden Markov models are an excellent means of describing temporal dependencies between responses they are in principle well suited for describing implicit learning behavior. Our results with fitting HMMs are promising in that we can reliably estimate them on the kind of sequences that are generally used in implicit sequence learning. It would be interesting to do experiments where subjects generate longer sequences of responses instead of the single predictions they made in the experiment described in this paper.

# A Constructivist Dual-Representation Model of Verb Inflection

Gert Westermann (gert@cogsci.ed.ac.uk)

Institute for Adaptive and Neural Computation, Division of Informatics  
University of Edinburgh, 2 Buccleuch Place  
Edinburgh EH8 9LW, Scotland UK

## Abstract

A constructivist neural network is presented that models impaired inflectional processing in German agrammatic aphasia. The model is based on a single mechanism and develops two types of representation through a constructivist learning process. The model accounts for data that has been taken as evidence for a dual mechanism theory of inflection, and it suggests an inflectional processing system that is based not on a distinction between regular and irregular cases, but between inflections that are easy and hard to learn. The model represents a successful single-mechanism neural network account of verb inflections.

## Introduction

The debate between rule-based and association-based theories of inflection has been continuing for many years and has moved from the initial focus on the English past tense to other languages such as the German participle (e.g. Clahsen, 1999; Marcus *et al.*, 1995). The reason for this shift is that in English, the issues of “regularity” and “high frequency” are confounded which makes it difficult to distinguish between the different theories. By contrast, in the German participle the regular case does not apply to the majority of all verbs, making it a so-called “minority default” (Marcus *et al.*, 1995).

A popular recent theory of how inflections are formed is the *Dual Mechanism Theory* (DMT) that postulates two qualitatively distinct mechanisms for the production of regular and irregular cases (e.g. Clahsen, 1999; Pinker, 1991, 1997; Marcus *et al.*, 1995). According to the DMT, regular inflections are produced by a mental symbolic rule, whereas irregulars are stored in an associative lexicon. Based on these mechanisms, the DMT claims to account for differences in the processing of regular and irregular inflections: whereas regular forms are applied productively to novel forms independently of their similarity to existing forms (e.g., *faxed*), irregular inflections show similarity effects both in existing “families” (*read* → *read*, *lead* → *led*, *breed* → *bred*) and in the extension to novel forms (*cleed* → *clad*).

However, while considerable empirical research has established processing differences between regular and irregular forms on many different levels from acquisition over psycholinguistic and ERP studies to impaired adult processing (see Clahsen, 1999, for an overview), little progress has been made in the specification of the DMT. Particularly problematic is the question in which way the

two mechanisms interact to produce the inflected form. Marcus *et al.* (1995) proposed the *Blocking Principle* which states that a lexical entry (indicating an irregular verb) blocks the application of the rule, but an implementation of this principle (Nakisa *et al.*, 1997) showed that in practice it involves parameters for which a useful setting cannot be found. Therefore, the DMT remains highly underspecified and thus hard to falsify. However, even in its underspecified form, the DMT is contradicted by some empirical data, e.g., frequency effects for regular English past tense (Stemberger and MacWhinney, 1986) and regular Dutch plural (Baayen *et al.*, 1997) forms, and similarity effects for regular German participles in agrammatic aphasia (Penke *et al.*, 1999).

In this paper I present a neural network model of inflectional processing in German agrammatic aphasia that accounts for dissociations between regular and irregular forms without postulating two qualitatively distinct mechanisms. Instead, the model develops two types of representations in a constructivist process, driven by the structure of the training data, and it displays emerging areas of functional specialization that correspond largely, but not completely, to the distinction between regular and irregular forms. The trained model is lesioned in different ways and it accounts for empirical data better than the DMT. Based on these results I propose a new theory of inflectional processing that is based on a distinction not between regular and irregular, but between “easy to learn” and “hard to learn” forms.

The rest of this paper is organized as follows: first, the structure of the German participle and the impairment profiles observed in agrammatic aphasia are reviewed. Then, the network model, the data, and the training regime are described, followed by a detailed analysis of the performance of the model in comparison with agrammatic aphasics. Finally, the resulting new theory of inflectional processing is presented and related to the DMT.

## The German Participle

German participles are comparable in usage to the English past tense in describing an event in the past. There are three groups of participles: *Weak* participles are formed by a (prosodically determined) prefix *ge-*, the verb stem, and the ending *-t*, e.g., *sagen* (say) → *gesagt* (said). *Strong* participles take the ending *-en*, e.g., *geben* (give) → *gegeben* (given) and they may also change the

verb stem, e.g., *gehen* (go) → *gegangen* (gone). A few strong verbs have idiosyncratic participle forms, e.g., *sein* (be) → *gewesen* (been). The third group are *mixed* verbs that take the weak ending *-t* but change their stems like strong verbs, e.g., *wissen* (know) → *gewusst* (known). It is generally claimed that the weak verbs form the regular class, while strong verbs are irregular, and the terms regular and irregular will here be used in this sense.

In contrast to English, German does not have a majority of regular tokens (each verb counted according to how often it occurs in a corpus), and the majority of types (each verb counted just once) is less pronounced than in English.

The CELEX database (Baayen *et al.*, 1993) lists 3015 German participles. After cleaning out some obvious errors and homophones and choosing the more frequent of different participle forms of one stem, 2992 participles remain. However, German verbs are often formed by modifying other existing verbs with a prefix or separable particle, e.g., the simplex verb *fahren* (drive) occurs in CELEX in 28 composite forms such as *hinausfahren*, *losfahren*, *fortfahren* etc. (drive out, drive off, continue). Since a prefix or particle do not alter the way in which the participle of a simplex verb is formed, all composite forms were combined into one simplex form.

For the simulation experiments described below, 20,000 verb tokens were randomly extracted from this corpus according to their frequency. To ensure that each verb occurred at least once, all verb types which had not been randomly selected were added onto the resulting corpus with a token frequency of one (this applied to 18 verbs).

The structure of the resulting training corpus is shown in table 1.

	type	token
Regular	518 (78.01%)	9306 (46.49%)
Irregular	134 (20.18%)	9717 (48.54%)
Mixed	12 (1.81%)	995 (4.97%)
Sum	664 (100.00%)	20018 (100.00%)

Table 1: The structure of the training corpus.

## Agrammatic Aphasia

Agrammatic (Broca’s) aphasia is a language disorder that is generally caused by a stroke predominantly affecting anterior parts of the left hemisphere. One of the characteristic symptoms of Broca’s aphasia is the tendency to omit or confuse inflections. Investigating the precise nature of these deficits can therefore lead to insights into the internal representation of inflectional morphology. Penke *et al.* (1999) analyzed data from eleven aphasic subjects who each produced 39 regular and 39 irregular participles in a sentence completion task with respect to regular and irregular errors, overregularizations and irregularizations, frequency effects, and effects of ablaut-patterns on error rates. They found irregular inflections to be selectively impaired in six of the subjects, and three showed no significant difference between regular

and irregular participles (the remaining two made more irregular errors but their total number of errors was too small to establish a significant difference between regulars and irregulars). Penke *et al.* (1999) concluded that irregular inflection can be selectively impaired in agrammatic aphasia.

## The Network Model

For the simulations described in this paper, a constructivist neural network (CNN) model was developed that builds the hidden layer of a radial basis function (RBF) network. Each hidden unit has a Gaussian activation function and thus acts as a *receptive field* for an area of the input space. The problem in building RBF networks is to decide on the number and positions of these receptive fields. The CNN algorithm solves this problem by constructing the hidden layer during learning, adding units when and where they are needed. The network starts with just two units in the hidden layer, each covering roughly half of the input space (see figure 1). The network tries to learn the task with this architecture (by adjusting the weights with quickprop), and when learning no longer improves the performance, a new unit is inserted. The place where the new unit is inserted is determined by the classification error resulting from treating inputs within one receptive field as similar: the receptive field that previously caused the highest error is shrunk and the new unit is inserted next to it. The idea here is that a unit which produces a high output error is inadequate, and therefore more structural resources are needed in that area. A similar network has already been successfully used to model the acquisition of the English past tense (Westermann, 1998).

Figure 1: Receptive fields covering the input space at the beginning (left) and the end (right) of learning.

Figure 1 shows a hypothetical start and end state in a two-dimensional input space. While initially only two units cover the whole of the space, later hidden units have been inserted with different densities across the space to account for the specific learning task.

Figure 2 shows the network architecture. The input layer takes a phonological representation of the verb infinitive, and the output layer has one unit for each possible output class (see below). The hidden layer initially consists of only two units but is grown during learning. There are direct connections from the input to the output layer, and each hidden unit is fully connected to the output layer.

Figure 2: The initial architecture of the network.

## Data

The 664 German verbs were classified according to the way in which their participles are formed, resulting in a total of 22 classes, one of which was the “stem+*-t*” (regular) class, 6 were for mixed verbs, and 15 for irregular verbs.

The verbs were represented phonologically, and each phoneme was encoded by a 7-bit feature vector with features such as *fricative*, *plosive*, *voiced* etc. for consonants, and *front*, *high*, *open* etc. for vowels. Presence of a feature was encoded with 1 and absence with -1.

For the training of the network, the phonological representation of the infinitive of each verb was then inserted into a template consisting of three syllables: XCCCVCVCC-XCCCVCVCC-XCCCVCVCC; C stands for consonant, V for vowel, and X for whether the syllable is stressed or not. Since the endings of verbs are significant for the determination of the participle class, the verbs were right-aligned in this template so that the endings occurred in the same slots.

The resulting network had 150 input units (three syllables with seven phonemes each represented by seven features, plus one stress-bit per syllable), and 22 output units for the 22 inflection classes.

## Training

The task to be learned by the network was the mapping from the phonological representation of the verb infinitive to the class of its participle. Viewing the learning of the participle as a classification task avoids confounding it with phonological details such as different pronunciation of regular forms depending on the last stem phoneme (e.g., *holen* → *geholt* vs. *landen* → *gelandet*).

Five CNN models were trained on this corpus with different random initial weight settings. The networks were tested before the insertion of a new hidden unit. An output class was counted as correct when the corresponding unit, but no other unit, had an activation value over 0.7.

## Results

In order to model agrammatic aphasia, the CNN was lesioned in different ways. It was assumed that the removal of weights in the model corresponds to the destruction of neural tissue in the brain by a stroke.

## Localized Lesioning

The output in the CNN model is produced through two sets of connections: the direct connections between the input and the output layer that the network started out with, and the connections from the growing hidden to the output layer. A localized lesioning of these pathways in the CNN resulted in a double dissociation between regular and irregular verbs for four out of the five runs. The further analyses were conducted with these four networks.

Figure 3: Double dissociation between regular and irregular (and mixed) verbs after lesioning the two pathways in the networks.

Figure 3 shows the results of lesioning the hidden-output (HO) and the direct input-output (IO) connections. Lesioning the HO connections resulted in a marked decrease of the performance of irregular and mixed verbs, with regular inflections remaining nearly fully intact. By contrast, lesioning the IO connections resulted in the opposite profile: performance of regulars was significantly more impaired than that of irregular and mixed verbs. It is important to note that this double dissociation emerged as a result of the structure of the training data together with the constructivist development of the model and was in no way prespecified.

Removing the HO connections in the network thus modeled the basic deficit in the inflection of agrammatic aphasics, namely, the breakdown of irregular and selective sparing of regular participles. Based on this result, the performance of the HO-lesioned CNN models was investigated with respect to the more detailed results reported by Penke *et al.* (1999).

Penke *et al.* (1999) found that all subjects who made more errors on irregulars than on regulars overgeneralized the regular ending *-t* to irregular verbs, but they only rarely irregularized regular verbs (i.e., their regular errors consisted mainly in using a wrong suffix or none at all). Testing the four corresponding CNN models for this behavior showed a good match of the aphasic profiles: the networks over-applied the regular class to 73.7% of all wrong irregulars (aphasics: 63.3%), but only 6.5% of all regular errors were irregularizations (aphasics: 14.3%). The other errors that can be made by the CNN models are no output, or ambiguous output when two (or more) output units are simultaneously activated.

Based on the assumption of two qualitatively distinct processing mechanisms for regular and irregular inflections, Penke *et al.* (1999) predicted and found a frequency effect in the aphasic production of irregulars, but not of regulars: there were significantly more errors for infrequent irregulars than for frequent ones, but no such effect occurred for regulars. When tested on the same verbs as the aphasic subjects, the CNN models equally showed a small frequency effect for irregulars but not for regulars: the error rate for low frequency irregulars (93.3%) was significantly higher than for high frequency irregulars (89.0%) (Wilcoxon,  $p = 0.068$ ), but error rates for regulars did not differ statistically (1.7% for low frequency and 2.4% for high frequency regulars,  $p = 0.273$ ).

Alternatively to a qualitative distinction, regulars and irregulars might represent two ends of a continuum: a regular verb can be said to be “very regular” if it is similar to other regulars and dissimilar to irregulars. It is “less regular” if it is dissimilar to other regulars but similar to irregulars. The reverse is true for irregulars (see also Daugherty and Seidenberg, 1992).

This assumption is attractive because it integrates mixed verbs which fall between regulars and irregulars in that they combine an irregular stem with the regular ending. Mixed verbs are generally ignored in the DMT because they are hard to consolidate with the proposed qualitative distinction between regulars and irregulars.

A regularity continuum would predict that “less regular” regulars, being more similar to irregulars, should be more error prone than “very regular” regulars in agrammatic aphasics. Penke *et al.* (1999) analyzed the distribution of verbs with respect to stem vowels and found that for the stem vowel <e>, irregulars outnumber regulars, making regulars with this stem vowel less regular. Therefore, regular verbs with <e> should have a higher error rate because they are similar to irregulars.

This prediction was confirmed in the analysis of the aphasic data: all regular suffixation errors occurred with <e>-stems. While Penke *et al.* (1999) interpreted their results within the framework of a qualitative distinction between regulars and irregulars (allowing grading effects for both mechanisms with the qualitatively distinct verb groups influencing each other), a more plausible interpretation is that of a regularity continuum where a single mechanism underlies the production of both forms.

Testing the CNN model, which is based on such a single mechanism, for this effect yielded the same pattern of results as in the aphasic subjects: when tested on the same verbs, 4 out of 5 of the regular errors were for the stem vowel <e>, indicating that these verbs are treated more like irregulars.

In summary, by lesioning the HO connections in the CNN model, detailed aspects of the performance of agrammatic aphasics on German participle inflections could be modeled. These results comprise both those that have been claimed to be evidence for the dual mechanism theory (double dissociations; frequency effects only for irregulars) and those that contradict the predictions of the dual mechanism theory (regularity continuum effect).

## Global Lesioning

As shown in the previous section, the lesioning of the HO pathway in the CNN model can account for a selective impairment in the inflection of irregular verbs and thus model the performance of agrammatic aphasic subjects. This selective and total lesioning of one pathway might suggest that the processing of regular and irregular verbs is subserved by locally different brain structures that can be selectively affected by a stroke. To establish whether the observed profile could be modeled without this assumption, the effects of globally lesioning the network to different degrees was investigated, without making a distinction between the IO and the HO connections. Over 200 trials, the network was lesioned in 5%-steps by randomly removing weights from both sets of connections.

Figure 4: Performance on regulars vs. irregulars for 200 lesioning trials at 20 lesioning steps each (in 5%-steps). Greyscale indicates degree of lesioning (from dark to light). Data for the aphasic subjects are marked by circles.

The result of this global lesioning is shown in figure 4. The 4,000 lesioned networks showed some variety of regular vs. irregular errors, but, like with the aphasic subjects, there was never a selective sparing of irregulars with a breakdown on regular participles (top left of the plot). Instead, in most cases impairment of irregulars was stronger than of regulars (below the diagonal).

The data for the eleven aphasic subjects from (Penke *et al.*, 1999) are also displayed in figure 4. All aphasic data are within the range of performance predicted by the simulations, showing that although there is variability in the performance of agrammatic aphasics, differently lesioned CNNs can model the performance of each of them. The model is not over-general, however: like in aphasic subjects, a selective sparing of irregulars with a breakdown of regular inflections did not occur in any of the lesioning trials.

Why does global lesioning in the CNN lead to a profile in which irregular participles are more impaired than

regulars? An answer to this question can be found by analyzing the connections in the model. Many of the IO connections are inhibitory, suppressing the activation of the wrong inflection class by other IO connections. This profile is due to the distributed representation of the input: overlapping representations between classes make the inhibition of wrongly activated classes necessary, and with increased lesioning this inhibition is lost, resulting in the activation of wrong output classes for regular and irregular verbs equally. By contrast, the HO connections from one receptive field usually contain only one strongly excitatory weight to the correct output class. Therefore, the HO weights do not tend to activate a wrong output class. This different weight structure can be explained by the localist nature of the receptive fields: due to the constructivist growth process, receptive fields tend to cover only verbs from one class. Therefore, representations for different classes do not overlap and inhibition is not required. An analysis of the distribution of the receptive fields over the verbs showed that they had been preferentially allocated for the difficult-to-learn irregular verbs. Therefore, a partial lesioning of the HO connections affected predominantly irregulars. Taken together, irregulars were impaired by the removal of weights in both the IO and the HO connections, while regulars were affected only by lesioned IO connections. Together, a global lesioning therefore led to a more pronounced breakdown for irregulars than for regulars.

A global lesioning profile in which regular inflections are selectively impaired could only arise from a total lesioning of the IO connections together with no or weak lesioning of the HO connections. Based on the CNN model therefore the prediction is made that a selective impairment of regular inflections in aphasics would be evidence for a locally separate processing of regular and irregular inflections in the brain, whereas the selective impairment of irregulars cannot be taken as evidence for such a separation.

## A Dual-Representation Theory of Verb Inflection

The results described in this paper show that the CNN can account for detailed empirical results from agrammatic aphasic inflectional processing. At the same time, the CNN avoids the problems of the DMT, namely, underspecification and contradiction to some empirical data.

Whereas the DMT proposes two mechanisms operating on a single representation of a verb stem, the CNN develops so that a single mechanism operates on two representations of the verb. Initially, the direct phonological input is used in the IO pathway to produce the output class. For verbs for which the output cannot be learned based on this structural representation alone, the CNN develops through a constructivist process additional representations in the hidden layer. In contrast to the structure-based input representations, these new representations are identity-based and localist: the activation of a hidden unit receptive field only indicates the presence of a certain input, without information about

its structure. The CNN is therefore a single mechanism, but dual representation model. This dual representation view sheds a different light on the dissociations between regular and irregular forms. The DMT does not assume that any regular verbs are produced by the irregular mechanism, or vice versa. The common aphasic profile where both regular and irregular cases are partially impaired (albeit to different degrees) is therefore often attributed to performance errors or the unpredictability of aphasic impairment.

A more compelling explanation is offered by the CNN: here, the dissociations that become visible in the lesioning trials do not run clearly along the lines of regulars vs. irregulars. Instead, all verbs for which the inflection class cannot be learned in the direct IO pathway are shifted to the developing hidden layer and the HO pathway. This shift concerns regular, irregular, and mixed verbs, to different degrees. The dissociation between verbs is thus better described as *easy to learn* vs. *difficult to learn*, with the difficult forms relying on the hidden layer, whereas easy forms are produced in the IO pathway alone. This distinction can account better for the data such as mixed verbs, a regularity continuum, or the different aphasic profiles.

But what factors determine whether a form is easy or difficult to learn? The degree of difficulty is determined by several interacting distributional factors that can be derived from the principles of associative learning:

1. Frequency: a frequent transformation is easier to learn than an infrequent one. Therefore, inflection classes with a high summed token frequency will be easier to learn than those that only apply to rare verbs.
2. Class size: a transformation that applies to many different verbs is easier to learn than one that just applies to one verb. Therefore, inflection classes with many members (counted in types) are easier to learn than those confined to only a small group of verbs.
3. Similarity of class members to members of other classes: the inflection class of a verb is easier to learn if other similar verbs share the same class.
4. Ambiguity of inflectional morpheme: an inflection is easier to learn if it applies uniquely to members of its class, i.e., if it does not exist in other context as well. For example, the *-ed* suffix in English is highly indicative of the past tense: an analysis of the CELEX corpus showed that 99.6% of all word types in English that end in *-ed* are past tense forms. By contrast, the German irregular participle ending *-en* is much more ambiguous: it also occurs in verb infinitives (*gehen*, to go), noun plurals (*Wiesen*, meadows), and as part of noun singulars (*Drachen*, kite).

These factors influence each other, and further research will be needed to establish in detail how they interact. Nevertheless they show that the *regular—irregular* distinction is a good first approximation of the *easy—difficult* distinction: the regular inflection, although it does not apply to the most frequent individual

verbs, is the single most frequent inflection in both English and German: 57.2% of English past tense tokens and 46.89% of German participle tokens are regular. At the same time, these classes are also the biggest in type size (88.4% and 64.7%, respectively). However, the third point, similarity of class members to members of other classes, does not separate along the lines of regular and irregular verbs: many regular verbs are similar to irregulars which should make them harder to learn in this view. And in fact the regularity continuum that has been shown for aphasics indicates that regulars that are similar to irregulars are more prone to impairment than others, that is, they rely more on storage in the lexicon.

A similar analysis of factors influencing errors in past tense formation has been conducted with school children (Marchman, 1997), where their errors on an elicited past tense production task were determined by frequency, the number of similar sounding stems in the same and in different inflection classes, and the phonological characteristics of the stem and past tense forms.

Taken together, although the dissociations of verbs into easy and difficult corresponds largely to the regular-irregular dissociation, it nevertheless suggests that the regular case is a post-hoc extraction and idealization of the developed structure of the inflectional processing system.

## Discussion

The results presented in this paper suggest a novel account of inflection learning and processing: it is a single mechanism system in which dual representations emerge from a constructivist learning process together with the structure of the environment. The system separates verbs along the lines of easy vs. hard to learn and can thus better explain empirical results that have so far been taken as evidence for the Dual Mechanism Theory. The qualitative distinction between regular and irregular inflections that lies at the core of the DMT, is a projection of formal linguistic analysis onto the human data. Because according to formal linguistics, human language data does not correspond to the abstract “competence” but is instead corrupted as “performance”, any data that does not correspond to the predictions of the formal theory (i.e., regulars that behave like irregulars and vice versa) can therefore be attributed to performance. This method makes the DMT hard to falsify based on such data. By contrast, the CNN model is fully specified, and it shows how the actual human data can be modeled without recourse to a competence-performance distinction. Whereas the abstract category of “regularity” remains a good formal description of language structure, the fallacy is in drafting it into service as a *processing* category, as done in the DMT.

A way to test the validity of the CNN model empirically is to abandon the regular/irregular distinction in favour of an easy/hard distinction, by identifying “hard” regulars and “easy” irregulars. Such a distinction should then better predict impairment profiles in agrammatic aphasics and other aspects of dissociations in inflectional systems. More research along these lines will be needed

to empirically verify the dual-representation model of verb inflection.

While connectionist, single-mechanism models of inflections have been rejected by proponents of the DMT (e.g. Clahsen, 1999; Pinker, 1997; Marcus *et al.*, 1995), the CNN model presents evidence that such models can account for inflectional processing more successfully than theories that rely on qualitatively distinct processing mechanisms.

## Abstract

This paper proposes that abstract concepts are represented as contextually derived structures. According to this *abstract structure theory*, abstract concepts are related to mostly temporal and spatial structures that underlie and can be extracted from concrete situations. Linguistic context elements of abstract concepts, such as verbs and prepositions, express these structures, and can thus aid in the acquisition of such concepts. The paper presents results from a corpus study that supports the hypothesis, and discusses implications.

We propose that abstract concepts, such as *faith* or *notion*, are represented as abstract structures, which represent particular contexts in which they occur. Abstract concepts are not directly perceivable, but are often used in verbal descriptions of situations, or in utterances related to a situation. Such utterances have to unambiguously point out the entity that is referred to by the abstract noun. We argue that the relevant abstract structures can be inferred from their linguistic context, in particular, from verbs and prepositions used with the abstract nouns.

## Concept Constraints and Contextual Similarity

Similar concepts occur in similar linguistic contexts. Miller and Charles (1991) report that contexts of similar concepts are more often classified as belonging to the same concept. For example, the sentences *the patient rang for the \_\_\_\_\_* and *the \_\_\_\_\_ gave the patient an injection* both suggest that the word *doctor* or *nurse* would complete the sentence well. We found that a neural network could be trained to correctly select one out of seven abstract concepts based on linguistic context information in 72% of test cases (Wiemer-Hastings, 1998). An approach to learning verbs from context was described by Wiemer-Hastings, Graesser, and Wiemer-Hastings (1998; see also Hastings, 1994). This work shows a close link between context of use and concepts.

## Acquisition from Contexts

The relationship between concept and context similarity has implications for language acquisition: Unknown words can be learned from context. Berwick (1989) discussed a system that acquired word meaning based on contextual similarity of the word to the contextual representation of

familiar words. Sternberg and Powell (1983) have shown experimentally that human participants could infer unknown word meanings from the context of a short text passage.

So, linguistic context provides useful information for language acquisition. In the acquisition of concrete concepts, this information is a "bonus" added to more directly useful information that the learner has access to, that is, information about perceptual or functional characteristics, as well as uses of the objects in situations. It is not even clear to what extent the linguistic information actually *adds* to this perceptual information. It might instead just reflect the information contained in the perceptual context of use, thus being redundant with it.

Linguistic context (in particular, syntactic context) has been shown to facilitate the acquisition of verbs (e.g., Fisher, 1994). Levin (1993) has provided a classification of semantic verb classes based on syntactic verb frames. Thus, much critical lexical information can be extracted from the linguistic context. This is important when the available information is largely *confined* to linguistic information. This is the case for abstract noun concepts, which refer to complex situations and relationships within these situations. If linguistic context is informative for verbs, it should be helpful all the more to acquire abstract concepts, such as *ignorance* or *strategy*. Indeed, Quine (1960) has argued that abstract concepts must be acquired on the basis of linguistic information alone. In support of this hypothesis, we found that abstract concepts can be distinguished pretty reliably based on semantic and syntactic aspects of their context (Wiemer-Hastings, 1998). If the hypothesis holds, then it should also be possible to identify linguistic context elements that are related to abstract concept meanings, thus that they co-occur with similar frequency with similar abstract concepts, and do not co-occur with dissimilar abstract concepts.

## Context Dependence

Clearly, the characteristics of entities systematically constrain contexts in which they can occur. However, this statement implies that entities are something that is given a priori, and contexts are selected based on the entities. This may be true for concrete entities, such as furniture items. Concrete entities exist independent of aspects of particular

contexts. A chair is still a chair if it occurs in a new context. Concrete concepts have characteristics that put concrete constraints on how we interact with them. Their characteristics thus determine, to some extent, their use. In this sense, concrete entities are to some extent independent of contexts.

With respect to abstract concepts, it seems that the relationship between context and concept constraints is reversed: their use is not determined by their characteristics, but their characteristics are inferred from their use. It seems that the context is the a priori given in this case, whereas abstract concepts are used to describe and make sense of complex situations and processes. Abstract concepts do not exist independently. They can only "happen" in particular contexts. An *idea*, for example, is conceived mentally, and can be expressed in words. Its consequences can be observed in context. It has the pragmatic function of overcoming some obstacle. In a slightly different context, one may call the concept a *suggestion* or *recollection*, instead of an *idea*. Similarly, *truth* is a characteristic ascribed to a statement that describes a particular state of affairs correctly (see Barsalou, 1999). If the state of affairs is different from a statement, the concept truth does not apply anymore.

This difference in the relation between abstract and concrete concepts and their contexts also affects language acquisition. We first acquire words for concrete entities. Later, we learn that there are abstract concepts, but we need to infer their characteristics from the contexts in which they are used. That is, the context is processed before the abstract concept can be understood. For abstract concepts, we could accordingly postulate that they are understood to be similar to the extent that they are used in the same linguistic contexts.

### **Operationally Defined Context**

Context is a complex notion. In contrast to verbs, there are no particular syntactic frames associated with abstract concepts. However, if abstract concepts put constraints on admissible contexts of use, then some of their contextual elements should reflect important semantic aspects of the concepts. Are there any indications as to what context elements may play a role?

### **Explaining Contextual Effects with Scripts**

Context effects on concept processing (e.g., on the speed in word recognition) have been shown in many studies. A series of experiments showed that such effects are mostly due to global context rather than local context elements (Hess, Foss, & Carroll, 1995). Sharkey and Mitchell (1986) suggested that context effects on lexical processing are mediated by scripts (Schank & Abelson, 1977). Scripts are schemata of actions, such as seeing a doctor, or eating out in a restaurant. According to Sharkey and Mitchell, associated words activate target words not through associations (i.e., through strong connections in a semantic network), but by activating a script that in turn activates the target word.

This hypothesis has received empirical support. However, it cannot easily be applied to abstract concepts. Consider, for example, the difficulty in selecting a script for *idea*. One would likely assign the concrete concept *menu* to the *restaurant script*, but concepts like *idea* can occur in a wide, almost arbitrary, variety of concrete situations such as represented by scripts. Yet, there are particular aspects of contexts that must be true for an abstract concept to apply. In the case of *idea*, for example, the concept typically occurs in a context where there is a problem or obstacle of some kind; an agent who reflects or discusses possible ways to overcome the obstacle; and a thought or utterance (the *idea*) that leads to the problem-solving action. A temporal sequence with causally related elements emerges from this scenario. We collectively call such sequences and structures for other kinds of abstract concepts *abstract structures*.

### **Abstract Structures**

Abstract structures represent integrated processes, events, or particular relationships in situations. They are *abstract*, in that they apply to situations with different concrete aspects. They are *structures*, in that they organize sets of entities in a situation with respect to the causal, temporal, spatial and other relations that hold between them. The concept is similar to schemata or scripts. However, abstract structures are more abstract than scripts, so we opt to use a different term here, to avoid the association with concrete situations.

Abstract concepts have a temporal and spatial dimension. The temporal dimension is critical, because it represents the ontological class of a concept (i.e., whether the concept is a point-like event, a process, or a state), and the sequencing of events within a structure. The representation of many abstract concepts requires information about their time course, for example, *discussion* or *sequence*. Causal aspects usually depend on temporal information as well. For example, concepts like *effect*, *consequence*, *impact* etc. require some temporally preceding entity or event. In principle, this suggested representation format is compatible with a perceptual approach, which integrates perceptual aspects beyond vision. One such theory has recently been proposed by Barsalou (1999). He proposes a combination of situation percepts with introspective information to represent abstract concepts. Our approach does not challenge this view, but approaches the representation from a linguistic point of view, and focuses on dynamic aspects of the concepts within context.

This paper describes first results of an investigation of this *abstract-structure* hypothesis. If linguistic context serves as a basis for abstract concept acquisition, then it is necessary that it reflects critical relationships in the situation context, and thus directs the learner's attention to the relevant aspects in this situation to identify the referent of the abstract noun. In relation to this reasoning, in particular we test the following prediction: Temporal, spatial and other aspects of the abstract structure related to an abstract concept are expressed in, and can be inferred from, its linguistic context.

## Context Elements

According to the abstract structures hypothesis, there should be linguistic context features that express causal, temporal, and other information. With this in mind, we examined the linguistic contexts of abstract concepts selectively with respect to such elements. What context elements are likely to reflect spatial, temporal and other relationships between the agents and entities in a situation?

This paper discusses two elements of context: verbs, and prepositions. Selecting two groups of lexical items clearly does not follow the view that it is global context that is critical with respect to concept representation. However, it appears worthwhile to examine context elements that can be easily identified and test these first, instead of attempting to identify more complex structures in text. The selection of verbs and prepositions follows directly from our hypothesis that abstract concepts are represented as contextual structures. Both verbs and prepositions express the relationships pertinent to abstract concepts, according to our hypothesis.

Verbs describe the way in which agents interact with each other and with entities, and convey aspects relevant to abstract concepts, such as events and causality (Basili, Pazienza, & Velardi, 1996). They express causal (e.g., *cause, evoke, produce, lead to*, etc.), temporal (e.g., *follow, end, begin*, etc.) and spatial information (e.g., *leave, hide, bring, remove*). Verbs also express other important aspects of abstract concepts related to agent - object relations, such as evaluations (e.g., *like, want*, etc.), verbal expression (e.g., *announce, explain, suggest*, etc.), and others. The central role of verbs with respect to the processing and identification of agents and objects has been shown in a lot of research, even if not specifically for abstract concepts. Altmann and Kamide (1999), for example, show that verbs guide our attention to particular aspects of a situation, because they lead us to expect what particular kinds of entities will be made reference to subsequently. Whereas this finding generalizes to entities outside the visual domain is an open question, but it is a possibility.

Prepositions can explicitly be classified with respect to the same dimensions (see Table 1). Considering these two context elements in the linguistic context of abstract concepts, we examined the question if the verbs and prepositions that occur in the contexts of particular abstract concepts express semantic aspects of the abstract concepts. We predicted that if they do, then similar abstract concepts should co-occur with similar kinds of verbs and prepositions with similar frequency.

## Corpus Analysis of Abstract Concept Contexts

In order to test what kinds of verbs and prepositions occur with abstract concepts, one has to consider a representative number of context samples. For example, one would expect that very general predicates (such as *think about, talk about*) occur with all kinds of concepts, and to provide little basis for differentiation. In order to get at the systematic relationships between verb and preposition context and

abstract concepts, we must therefore look at a variety of contexts and record two aspects: a) patterns of co-occurrence between abstract concepts and verb / preposition classes, and b) the frequencies of the co-occurrences.

We conducted a corpus analysis to obtain both measures. Corpus analyses have been used frequently since large databases of naturally occurring text have become available electronically. Boguraev and Pustejovsky (1996) express the power of corpus analyses proposing that "Text corpora reflect language as it is used and evolves; by studying regularities of use and patterns of behavior of words, which only emerge from analysis of very large samples of text and / or speech, it is possible to induce (among other things) lexical properties (...)" (p. 5). The power of co-occurrence patterns in text for representing semantic aspects of concepts and texts has been demonstrated by the success of systems such as Latent Semantic Analysis (LSA; Landauer & Dumais, 1997) and HAL (e.g., Burgess & Lund, 1997). However, since LSA uses co-occurrence information among all elements of text, it does not tell us much about *which* elements of context play a role in relation to individual kinds of concepts.

## The Corpus

A sample of thirty abstract nouns was selected randomly, but so that different ontological classes (e.g., state, process, event, emotion) were represented. The sample included the words *accident, agreement, approach, aspect, attempt, effect, decision, discovery, discussion, essence, fear, freedom, goal, idea, ignorance, impression, indifference, invention, miracle, notion, plan, pride, principle, recollection, result, silence, strategy, surprise, truth, and wisdom*. We collected our corpus from NexisLexis, an online database that contains full texts from newspapers, magazines and other sources, representing a wide range of topics. For each abstract noun, 250 sentences were collected that contained the particular abstract noun. The sampling was principally random. However, we made sure that no sentences were repeated, and that a variety of topics was represented. Altogether, we collected a corpus of 7500 sentences.

## Encoding Co-occurrence

For each noun, we looked at every sentence and recorded the verb and preposition that occurred in direct relation to the abstract noun. Verbs and prepositions were recorded with information about whether they preceded or followed the abstract noun. We additionally counted the frequency with which each verb and preposition occurred<sup>1</sup>.

This method yielded a large number of verbs and prepositions (about 1700). The raw data would have yielded long context vectors with very low average frequencies. Analyses based on such vectors would

---

<sup>1</sup> Verbs and prepositions were not recorded in combination. In many sentences, only one of the two occurred. Further, the combinations may lead to an enormously extensive data space that would be hard to reduce by classification.

presumably be distorted by noise. Therefore, we classified our recorded verbs and prepositions into semantic classes. Verbs were classified into the semantic classes constructed by Levin (1992). Her system contains 37 semantic verb classes that occurred in our corpus. They include verbs of *occurrence* (e.g., *happen*), *possession* (*give*, *obtain*), *communication* (*describe*, *announce*), and *psychological verbs* (*amaze*, *disturb*). We only considered verbs that could clearly be classified consistent with these classes.

Prepositions were classified into spatial, temporal, causal, modal, propositional, referential and possessive information, and further sub-classified within these groups (see Table 1).

Table 1  
Classification of prepositions

Preposition class	Subclass	Examples
Spatial location	distance	near, by, far from
	relation to 1 object	on, in, behind
	relation to 2 objects	between, amidst
Spatial motion-direction	related to origin	from, out of
	related to destination	into, towards
	related to path	through, across
Temporal	related to future	until, prior to
	related to past	after, since
	related to presence	during, while, at
Temporal	expressing time-range	after (time-range)
	expressing point-in-time	on, at
Causal	related to factor	due to, because of
	related to effect	in order to
	related to means	through, whereby
Modal / concomitative		with
Propositional Referential		about, on
	inclusive	with regard to
	exclusive / adversatives	
Possessive		except, contrary to
		of, from

### Abstract Concept Context Vectors

A noun-context element matrix was constructed that listed abstract nouns against context element classes (Table 2). The context elements contained the verb classes  $1$  to  $n$  after Levin (1992) that had non-zero occurrences in the corpus, followed by preposition classes  $1$  to  $n$ . The cells in the matrix contained the co-occurrence frequency in the corpus. Context elements were represented twice. The first time, the co-occurrence data only count times that the abstract noun *preceded* the particular context element class in context. The second time counted the times the context elements were followed by the abstract noun, respectively.

Table 2  
Co-occurrence matrix for context elements

	Verb class $1$	...	Preposition class $n$
Abstract noun 1	5	...	0
...	...	...	...
Abstract noun 30	0	...	58

### Evaluation

Thirty context-vectors were constructed based on the co-occurrence matrix, one for each abstract concept. Each vector represents how often a particular abstract noun occurs with different kinds of verbs and prepositions in context. These vectors were used to evaluate the hypothesis that linguistic context, in the form of verbs and prepositions, reflects semantic aspects of abstract concepts. If this hypothesis is correct, then the contexts of similar abstract concepts should be similar, resulting in a significant correlation of the cosines of the context vectors with human similarity judgments of the corresponding abstract concept pairs.

We tested what context information is related to abstract concepts in particular. Six different vectors were constructed to represent various aspects of context. We built vectors to represent only prepositions, only verbs, or both. For each of these, there were two versions: an extended, "ordered" version that contained word order information, and a short, "unordered" version that ignored word order information. For the ordered version, we counted co-occurrence separately for context elements preceding versus following the target noun. For the unordered vectors, co-occurrence counts within the verb and preposition classes were collapsed to disregard word order. This vector version thus represents merely how frequently which kinds of verbs and prepositions can in general co-occur with the abstract noun.

To test whether the verb and preposition context relates to abstract concepts, we compared the similarity of the context vectors to similarity judgments of the corresponding abstract concept pairs, provided by human raters. The 30 abstract concepts resulted in 435 vector / abstract concept pairs. Correlations were computed between two similarity measures: human similarity judgments of the concept pairs, averaged across 33 raters, and vector cosines for the context vector pairs. Both measures range from 0 (maximally dissimilar) to 1 (maximally similar).

### Results

Table 3 shows the correlation coefficients. The cosines of the full vectors, containing verb and preposition co-occurrences and word order information, were significantly correlated with the human ratings ( $r = 0.22$ ,  $p < 0.01$ ).

Table 3  
Correlation coefficients between the vectors and human similarity judgments

	Ordered Vectors	Unordered Vectors
Verbs and prepositions	0.22	0.17
Verbs only	0.22	0.18
Prepositions only	0.20	0.13

This correlation is modest, but highly significant. It indicates that more similar abstract concepts tend to have

similar co-occurrence patterns with verbs and prepositions. This coefficient is higher than the average human interrater correlation coefficient, computed for a random sample of 100 coefficients (mean  $r=0.18$ ,  $SD=0.16$ ).

To estimate the relative relevance of verbs and prepositions, we computed the vector cosines separate for verbs and prepositions. The cosines for both were significantly correlated with the human ratings ( $r_{prep} = 0.20$ ,  $p < 0.01$ ;  $r_{verb} = 0.22$ ,  $p < 0.01$ ). Thus, the co-occurrence patterns of both context elements, verbs and prepositions, are significantly related to abstract concept similarity.

Further analyses tested the relevance of word order information. The question here is whether the correlation is due to the information which verb and preposition classes can co-occur with an abstract concept in general, or whether the word order is critically important. Word order information may play an important role in abstract concept representation. For example, in the phrases "due to the discussion" versus "the discussion due to (...)" the prepositions express very different information about discussion. In the first example, the discussion causes some effect; in the second example, the discussion itself was caused by something.

We computed the cosines for the vectors that just represent co-occurrence with verb or preposition classes without separating co-occurrence counts according to word order. The cosines were correlated with the human ratings. The resulting correlations were significant ( $p < 0.01$ ), but the correlations were smaller than the ones obtained before. The correlation for the verb-only vectors was  $r=0.18$ ; the preposition-only vectors yielded a correlation of  $r=0.13$ . The combined verb and preposition vectors led to a correlation of  $r=0.17$ . Thus, word order does increase the correlation, especially in the case of prepositions.

We compared our results to correlations of the human similarity judgments with cosines from LSA for the same concepts. Since LSA takes into account all words in context, and for a lot more text, it is a good model to compare our vector matches to. In particular, if verbs and prepositions cover the important aspects of context related to abstract concepts, then the correlations of human ratings with LSA cosines should be comparable to the ones obtained in our study. If however the match with LSA cosines is substantially higher than our correlations, then verb and preposition context conveys only part of the relevant context information and other word classes should be included. We found that the correlation between human judgments and LSA cosines was significant ( $r_{LSA} = 0.23$ ,  $p < 0.01$ ), but not much higher than the correlations we obtained for our selective context vectors. This might mean that the correlation obtained from LSA is mostly due to the verbs and prepositions in the underlying text corpus. At least, the verb and preposition co-occurrence patterns can account for as much of the similarity ratings as LSA.

## Correlations of Verb and Preposition Context

In addition to these correlations with human ratings, we looked at a few correlations among the vector cosines. We found that the cosines of preposition vectors and verb vectors were significantly correlated ( $r=0.13$ ), but only if the vectors separated co-occurrence counts with respect to word order. In other words, similar abstract concepts tend to be preceded and followed by similar types of verbs and prepositions. This means that contexts with similar patterns of verb occurrence also resemble each other in the patterns of prepositions they contain.

## The Role of Ontological Information

It was mentioned before that verbs and prepositions convey ontological information (such as states, processes, events). To what extent can the human similarity judgments and context vectors be explained by two concepts being of the same as opposed to different ontological kinds? To test this, we created a Boolean variable that was "1" when both concepts in a pair were of the same ontological status, and "0" otherwise. We correlated this variable with the human similarity judgments, and with the context vector cosines.

The ontological status was significantly correlated to the human ratings,  $r=0.23$ ,  $p < 0.01$ . That is, the ontological status of two concepts may play a role in how people judge concept similarity. The ontological status was also related to the context vector cosines, but only to a selective group. First, it was correlated to the combined verb and preposition vectors. Interestingly, the correlation coefficient was exactly the same for the vectors containing information about word order and those not containing this information ( $r=0.13$ ,  $p < 0.01$ ). Furthermore, ontological status was correlated with the preposition-only vector cosines that did *not* contain word order information ( $r=0.10$ ,  $p < 0.05$ ).

This interesting result suggests that word order matters with respect to abstract concepts, but may be irrelevant, or even provide misleading information, with respect to the ontological status of the abstract concepts. The information represented by the preposition-only vectors without word order information simply reflects the frequency with which abstract concepts co-occur with the different kinds of preposition classes (Table 1). It makes sense that *statehood*, *eventhood*, etc. would be reflected in the kinds of verbs and especially prepositions that co-occur with the concepts. For example, event concepts may be surrounded by temporal prepositions such as *before* and *after*, whereas process nouns may be marked by prepositions such as *while* or *during*. Ontological status was also significantly correlated to the LSA cosines ( $r=0.12$ ) to a similar extent.

## Discussion & Implications

We have proposed that abstract concepts are represented by abstract structures that contain causal, temporal, spatial and other information pertinent to the abstract concept. Assuming that these contextual aspects are reflected by the verbs and prepositions that co-occur with particular abstract concepts, we have conducted a corpus study that examined

whether similar abstract concepts co-occur with similar patterns of verbs and prepositions. We found that the similarity of context vectors based on these word classes were significantly correlated with the similarity of the abstract concepts occurring in these contexts. That is, similar abstract concepts have similar co-occurrence patterns with verb and preposition classes. We found that the correlations of abstract concept similarity was not much higher with cosines of LSA vectors, indicating that verbs and prepositions may indeed be the most informative context elements with respect to abstract concepts. We did find a pretty substantial correlation between the verb and preposition vectors, however. This correlation suggests an alternative interpretation, namely, that different aspects of context are related to abstract concepts but that they are interrelated, thus that they do not add any further information to distinguish abstract concepts.

In future work we plan to examine to what extent a particular set of verb and prepositions can be used to identify the abstract structure corresponding to an abstract concept, and to kinds of abstract concepts (e.g., *states* versus *events*). Another interesting question is how many verb and preposition classes are most informative in relation to abstract concepts. Perhaps the correlations could be improved by choosing more classes with finer distinctions, or conversely, by reducing the class space even further.

Another interesting question is whether our abstract structure theory can explain context effects as reported by, for example, Schwanenflugel and Shoben (1983). Contexts preceding abstract concepts may instantiate the particular abstract structure underlying their representation and thus mediate priming effects. This could be tested by setting up contexts that differ in the amount of information they provide with respect to the relevant abstract structure.

# Adding syntactic information to LSA

Peter Wiemer-Hastings

Peter.Wiemer-Hastings@ed.ac.uk

School of Cognitive Science / ICCS, Division of Informatics  
University of Edinburgh, Edinburgh EH8 9LW Scotland

## Abstract

Much effort has been expended in the field of Natural Language Understanding in developing methods for deriving the syntactic structure of a text. It is still unclear, however, to what extent syntactic information actually matters for the representation of meaning. LSA (Latent Semantic Analysis) allows you to derive information about the meaning without paying attention even to the order of words within a sentence. This is consistent with the view that syntax plays a subordinate role for semantic processing of text. But LSA does not perform as well as humans do in discriminating meanings. Can syntax be the missing link that will help LSA? This paper seeks to address that question.

## Introduction

In the beginning, there was syntax. And it was good. But it did not give us what we really want to know about a text — what it means. Then there was latent semantic analysis (Deerwester, Dumais, Furnas, Landauer, & Harshman, 1990, LSA), which provided a means of comparing the “semantic” similarity between a source and target text, and thereby giving some idea of meaning of the source. That was good too, almost as good as humans in a simple task, but not quite. Because LSA pays no attention to syntax at all — not even word order — one promising approach to improving LSA is by giving it some of the information that is provided by syntax. Knowledge about the syntactic structure of a sentence provides information about the relationships between the words: which words modify which other words, and the relationships between verbs and their arguments or thematic roles. The research presented here is an attempt to evaluate the benefits of providing LSA with thematic role information which comes from syntactic knowledge.

## Previous work

The primary goal of the AutoTutor project (Graesser, Franklin, Wiemer-Hastings, & the Tutoring Research Group, 1998; Wiemer-Hastings, Wiemer-Hastings, & Graesser, 1999) is to model human tutorial dialogue. It is based on studies of the discourse patterns of human tutors during tutoring sessions (Person, Graesser, Magliano, & Kreuz, 1994). These analyses have shown that human tutors do not have complete understanding of their students’ answers to questions, but they do get an approximation. For AutoTutor, LSA provides such

approximate understanding of student inputs by comparing them to expected answers, and using the LSA cosines as a metric of the extent to which the student entered what was expected.

We evaluated this approach by randomly selecting a set of 8 student answers to each of 24 questions in our domain of computer literacy (Wiemer-Hastings, Graesser, Harter, & the Tutoring Research Group, 1998). We asked human raters to evaluate these answers by providing an aggregate measure of the percentage of student answer propositions that “match” some expected answer proposition. Proposition was defined loosely as an atomic sentence. Match was left to the human raters to define. Then we performed the same analysis with LSA, modeling the match function by adjusting the cosine threshold. The best performance was realized with a 200-dimensional space with a cosine threshold of 0.5. This provided a correlation of  $r = 0.49$  with the average rating of the human judges. Because the distribution of ratings was skewed, we also calculated Cronbach’s alpha. The average alpha score between human raters was  $\alpha = 0.76$ . The alpha score between LSA and the average human rating was  $\alpha = 0.60$ . These results were very encouraging. LSA provided much of the discrimination shown by human raters, enough to use in the AutoTutor system. It could however, be improved.

The obvious information source that LSA ignores is syntax. It is a “bag-of-words” approach, simply adding together term vectors to make a vector for a text. This paper is an attempt to identify whether the addition of syntactic knowledge can strengthen LSA judgments.

## Related work

Partially as a result of the Behaviorist movement in psychology, linguistics and natural language processing focused for a long time primarily on the syntactic structure of sentences (Chomsky, 1981, for example). In the 70’s and 80’s, Schank sought to change this by claiming that semantics alone was sufficient (Schank & Riesbeck, 1981, for example). More recently, researchers from psychology have championed LSA as both a technique for determining the meaning of texts and as a model of human language.

Much of the recent interest (and controversy) regarding LSA can be traced to Landauer, Kintsch, and colleagues. They imported LSA from the realm of information retrieval and hailed it as part or parcel of a psy-

chological model of language understanding. Landauer and Dumais (1997) described LSA as a model of human language acquisition, using it to explain how the pace of lexical acquisition apparently outstrips the exposure to new words. Landauer has gone on to claim that LSA is a complete model of language understanding (Landauer, Laham, Rehder, & Schreiner, 1997). He explains away the existence of syntax by suggesting that it is only there to simplify the computational complexity of getting the words into an LSA-like representation in the first place.

Other psychologists have stressed the role which syntax can play in lexical acquisition. The syntactic bootstrapping (Gleitman & Gillette, 1994) theory shows how pre-verbal children can use their knowledge of syntax to help guide their acquisition of verbs.

Kintsch (1998) has appended LSA to his Construction/Integration model of text understanding as the semantic component. LSA provides a sort of spreading activation-like inclusion of related concepts when new information is integrated into a knowledge structure. This allows the system to perform a type of inference, making, for example, “driver” and “computer” available when “bus” is mentioned in a text.

In other related psychological approaches, MacDonald has proposed a used a variant of LSA to predict semantic priming (McDonald, 2000). And Ramsar and colleagues have used LSA to model analogical reasoning (Packiam-Allaway, Ramsar, & Corley, 1999).

The HAL system (Burgess & Lund, 1997) is similar to LSA in the sense that it is based on co-occurrences, but word order information enters the representation space through a weighting mechanism: A co-occurrence is weighted more heavily the fewer words intervened between the two words, within a window of usually ten words. So, two words that co-occur in immediate adjacency are weighted most strongly. This is not syntax, but it does grant some sensitivity to word order.

Burgess and Lund replicated earlier work by Finch and Chater (Finch & Chater, 1992) which showed that by applying a high-dimensional method to clustering the co-occurrences of words in a corpus, it is possible to infer lexical categories that correspond well with standard syntactic theories. Finch and Chater also showed that you could use these categories to infer basic grammatical rules (see also (Siskind, 1996; Christiansen & Chater, 1999) for other corpus-based approaches to acquiring such information). Thus, there seems to be sufficient information in a corpus of text to statistically infer something about the syntactic structure of that corpus.

This does not mean, however, that a technique like LSA already has the type of syntactic information that we are attempting to incorporate here. For any particular sentence, LSA creates a vector just based on the bag of words that are in that sentence. It has no information about the word order within that sentence or about the relationships between the words.

## Approach

Our initial success with LSA and the potential for improvement led us to examine how additional information

could be provided. One obvious possibility is to use more classical natural language understanding techniques as a pre-filter for LSA. The idea is to use parsing, anaphora resolution and other dialogue-processing techniques to prepare chunks of text for LSA to process semantically. Alternatively, this could be viewed as using LSA as the semantic component of a classical natural language understanding system.

We preprocessed the student sentences and the expected answer sentences in the following way: First, we performed a basic syntactic segmentation of the sentences. Although there are surface-level parsing methods generally available (Abney, 1996, for example), their grammars must be modified to conform to the application. If this approach is successful, we will move to automated methods. For this test, we simply separated the sentences into atomic clauses or propositions, and then segmented them by hand, breaking them down into strings which corresponded to:

- subject noun phrase
- verb, including adverbs and adverbial phrases
- object noun phrase (when applicable)

This provides two types of additional information:

1. the grouping of words which belong together into “components”
2. the pseudo-semantic role of the components as derived from syntactic argument structure

Second, we resolved anaphora in the sentences, replacing pronouns by their antecedents. Finally, when there was a conjunction, we distributed the arguments. For example, if there was a sentence like, “Subject verb object1 and object2”, it was broken into (“verb” “Subject” “object1”) and (“verb” “Subject” “object2”), using a verb-prefix notation.

We made no attempt to do any other processing based on discourse relations for two reasons. First, LSA normally ignores “stop words” like “if” and “because” anyway. Second, extracting any more complex discourse relations would require the use of semantic understanding which is the goal of this process. Table 1 gives some examples of sentences and their representations in this scheme.

There are three competing hypotheses of the effect on similarity judgments of using this additional information along with LSA:

1. Component grouping will increase discrimination because it adds information — the role of different components.
2. Component grouping will hurt discrimination because LSA works better on longer strings.
3. Component grouping will hurt grouping due to some complexity of combining individual component similarity scores.

Table 1: Example sentences and their representations

RAM stores the instructions to your programs.	(“stores” “RAM” “the instructions to your programs”)
If the new motherboard uses the same type of RAM, you can just take the SIMMs out of your old motherboard and install them in your new motherboard.	(“if uses” “the new motherboard” “the same type of RAM”) (“can just take out of your old motherboard” “you” “the SIMMs”) (“and install in your new motherboard.” “you” “the SIMMs”)

The following section describes our first attempt to test these hypotheses using a straightforward combination of the between-component cosines.

## Experiment 1

Given this type of representation, there remain a variety of ways to calculate the overall similarity between propositions based on the similarities of the components. In experiment one, we took the most straightforward approach, simply averaging the cosines of the respective components. In other words, we calculated the LSA cosine between the verb string from a student proposition and the verb string from an expected answer. We repeated this for the other sentence components. If there was an object string for one sentence and not for the other, a component score of zero was recorded. Then we averaged across the (normally two or three) components of the propositions.

Next, we aggregated the scores for each student answer proposition by taking the maximum average cosine across the different expected answer propositions. As in the previous experiment, the final score was the percentage of student answer propositions that achieved a score above the empirically-determined threshold. We tested thresholds between 0.05 and 0.95 in 0.05 increments. We measured the correlation between the LSA scores with the human ratings.

The best correlation was  $r = 0.18$  (not significant), with the threshold at 0.10.<sup>1</sup> This is far below the performance of the previous approach which used LSA to compare entire sentences. Thus, these findings do not support hypothesis 1.

The decrease in the overall performance could potentially be due to the difference between comparing sentences (as in the original experiment) and comparing propositions. But the aggregate score essentially factors that out to the extent that length of string does not affect LSA discrimination. String length does affect LSA discrimination however. Rehder et al (1998) used LSA to assess the domain knowledge of essay writers. To determine the effect of essay length on LSA discrimination, they truncated each essay after 10 words, 20 words, and so on. Below 60 words, they found fairly poor perfor-

mance. The performance steadily increased from there up to their 200 word maximum. Despite this finding, we have found performance approaching human abilities on our tutoring texts which have an average length of 16 words. Thus, we thought that any minor reduction in performance due to length would be offset by increased information provided by the pre-processing.

Analysis of cases of disagreement between LSA and the human raters showed that some items got very bad scores because one component consisted only of a “stop word” — a member of a list of 440 common words that includes prepositions, pronouns, and some very common adjectives, adverbs, verbs, and nouns. For example, one student proposition has a verb component group consisting of the string, “stores”, and the expected answer has the verb string, “has”. In this case (“RAM stores information being worked with”), the meanings of these two verbs are quite similar. But because “has” is on the stop word list, it has no representation in the LSA space, and the cosine comparison returns a value of 0.

On the other end of the spectrum, there was often an exact match between the subjects. For example, “RAM” and “CPU” are frequent subjects which, if they match at all, tend to match exactly, getting a 1.0 cosine. Because average “good” cosine matches are often in the 0.4 to 0.6 range, this tends to inflate the cosine average. This is especially the case for intransitive sentences where there are only two components. At the threshold that provided the best correlation with human raters, 0.10, the verb string only had to match at the 0.20 cosine level to put the entire proposition over threshold.

Another factor which seemed to affect the ratings was the fact that there are so different ways in which the same content can be expressed in natural language. For example, “RAM stores things being worked with” should have a fairly high semantic match for “The CPU uses RAM as a short-term memory storage” (whole string LSA cosine = 0.48). But because the components do not line up at all in this approach, the cosine average score is 0.03.

Based on these analyses, and under the hope that hypotheses 3 was the case instead of hypothesis 2, the approach was modified as described in the next section.

## Experiment 2

As previously mentioned, the shortness of the subject components seemed to have an inordinate effect on the overall scores. The average number of words in subject components was 1.6, and many subject strings include stop words like “the” which do not contribute to LSA

<sup>1</sup>Due to the tediousness of pre-processing the sentences by hand, these results were only calculated on the first third of the test set. Analyses of the correlations on the original task on this part of the test set showed that it had lower performance ( $r = 0.32, p = .01$ ), but not as low as the results of experiment 1. Immediate future work will be to process the rest of the test set.

cosines. Because of this, we tested in experiment two, an alternative scoring strategy. In this strategy, the score between two propositions was calculated as follows:

If there is a suitable match between the subjects, then return the average of the cosines of the other components.

Here, “suitable match” was defined as either a cosine of  $0.7^2$ , or a cosine of zero. In theory a zero cosine means a complete lack of semantic similarity. In practice, however, the cosine is only exactly 0 when one of the strings is empty modulo stop words. Thus, this allows the matching of vague subjects like “you”.

There are psychological theories of discourse which (vaguely) support this approach. One is the Given-New distinction of referents in discourse (Clark & Haviland, 1977; Brennan, 1995). The theory includes a discourse processing strategy in which the hearer searches the prior discourse context for an antecedent for Given information which is commonly the syntactic subject of a sentence. The rest of the sentence is New information which is attached to the antecedent. In our approach, we filter out expected answers which do not have matching Given information. Then we rate the similarity with the remaining items based on the similarity of the New information.

For this approach, the results were better than for experiment 1. The maximum correlation between the system and the human raters was  $r = 0.24$ , ( $p = 0.06$ ). This still does not approach the level of performance of the original system, however. This led us to attempt to address the other concerns raised above in experiment 3.

### Experiment 3

In experiment 3, we built on the Given-New approach presented above. This time, however, we joined the verb component of each proposition with its object component into one larger component. This corresponds to the VP in the basic  $S \rightarrow NP VP$  sentence, or to the predicate in the Subject/Predicate description of a sentence. Obviously this is a partial reversal from our previous approach of adding more information derived from syntax. The justification was to make the LSA comparisons less brittle with respect to distinctions between information in the verb and in the object.

The results for this approach were better than for experiment 2. The maximum correlation was  $r = 0.40$  ( $p < 0.01$ ), with a cosine threshold of 0.3. (The Cronbach's alpha score was  $\alpha = 0.49$ .)

Although this is an improvement, it is still not as good as the 0.49 correlation achieved by matching the entire sentence strings. Thus, these results do not support hypothesis 1. And taken together, their support for hypothesis 3 is ambiguous at best. This leaves us with the question: Why, when getting more information, does the discrimination still suffer?

### Discussion and Future work

In some ways our approach has been to find the best formula for combining the similarity ratings between the different components. The one which worked best, the one used in experiment 3, is non-linear. Perhaps a further search of combination methods can out-perform the basic LSA approach.

Taking the cue from other statistical NLP approaches and neural networks, perhaps we just have to find the right weight space which gives the best correspondence between the parameters (components) and the training data (human judgments). Ideally, if we were to attempt such an implementation, instead of aggregate human judgments over a set of items, we would have a rating for each pair of items. That would be much more demanding on the human raters, but would give more data to train the approach on.

Future work will focus on two fronts. First, we will acquire more data on which to evaluate this approach, both by adding more test items, and by getting additional human judgments as outlined above. Second, we will explore other methods of combining the added syntactic-derived information into LSA.

## Abstract

Many formal models of categorization adhere to two basic principles. First, the extent to which a stimulus is subjectively characteristic of a particular category can be represented by a single number. Second, the probability with which people choose a particular category label for a stimulus can be derived from these numbers via the Ratio Rule a.k.a. the Luce choice axiom (Luce, 1959). A categorization experiment employing artificial visual stimuli is presented and is shown to be problematic for these two principles. We demonstrate that, for the data presented here, the first principle can be retained if one replaces the Ratio Rule with a simple connectionist model.

## Introduction

Category learning is the task of acquiring the correct category label for each of a set of presented stimuli. The ability to categorize is central to cognition, and it has been the subject of a large number of studies. Over the last thirty years, these studies have typically involved abstract stimuli grouped into categories not necessarily definable in terms of a simple rule (e.g. Homa, Sterling, & Trepel, 1981; Medin & Schaffer, 1978; Posner & Keele, 1968). Psychologists have proposed a variety of formal models of our ability to learn and make decisions about such categories. The models differ in many respects - for example, the Generalized Context Model (Nosofsky, 1986) proposes the memorization of presented examples, whilst a number of other theories propose the formation of feature-category associations (e.g. Gluck & Bower, 1988; Kruschke, 1996; McClelland & Rumelhart, 1985). Despite such diversity, a great many theorists seem to agree on two fundamental principles. First, the extent to which a stimulus is subjectively characteristic of a particular category can be represented by a single number. We will refer to such numbers as *category magnitude terms*. Second, the probability with which a participant decides that a stimulus belongs to a particular category is determined by the Ratio Rule, a.k.a. Luce's Choice Axiom (Luce, 1959). In the current context, the Ratio Rule can be stated

$$P(i) = \frac{v_i}{\sum_{j=1}^n v_j}$$

where  $P(i)$  is the probability of choosing category  $i$  from  $n$  alternative categories and  $v_j$  is the category magnitude term for the  $j$ th alternative.

Theorists seldom justify their adoption these principles. Of greater concern is the fact that, as far as we are aware, there have been no direct tests of the Ratio Rule in the context of categorization. The evidence for the Ratio Rule, such as it is, comes from pair-comparison experiments and identification experiments (Bradley, 1954; Clarke, 1957; Hopkins, 1954). The evidence provided by such studies is equivocal at best, and some studies provide direct evidence against the Ratio Rule (e.g. Burke and Zinnes, 1965; Lamming, 1977).

Previously, we had made an unsuccessful attempt to disprove the Ratio Rule in the context of two-choice categorization decisions (Jones, Wills, & McLaren, 1998). The reason for this might have been that the Ratio Rule was basically correct for categorization decisions, but we suspected that it was because the predictions made by the Ratio Rule in a two-choice situation tend to be numerically close to the predictions of a number alternative accounts. Therefore in the experiment described here we tested a property more characteristic of the Ratio Rule - its predictions about probability ratios.

A long appreciated feature of the Ratio Rule is that it predicts that the ratio in which two alternatives are chosen is unaffected by the addition of a third alternative. For example, in a taste preference test between Coke and Pepsi, participants might choose Coke with a probability of 0.8. The Ratio Rule predicts that whilst the addition of lemonade might change the probability with which either Coke or Pepsi is chosen, it does not change the 4:1 ratio of probabilities.

The ratio we concentrate on in the current study is directly related to this property. It is the ratio between 1) the probability with which a particular response is made to a stimulus when three category labels are available and 2) the probability with which the same response is made to an equivalent stimulus when only two of the labels are available. For example, let's call the three labels A, B, and C, and say that A is the option which is disallowed in the two-choice example. Under the assumption that category magnitude terms for allowed alternatives are not affected by the number of alternatives available, it can be shown that the Ratio Rule predicts

$$\frac{P(B : B, C)}{P(B : A, B, C)} = \frac{v_A}{v_B + v_C} + 1 \quad \text{Measure 1}$$

This is not much use as it stands because we do not have any direct way of measuring the category magnitude terms, and different theories of categorization do not generally agree on how one might estimate the terms from observable data. The utility of Measure 1 lies in the fact that the Ratio Rule's predictions for the probability with which category A is chosen (when it is allowed) are similar in form. Specifically

$$P(A : A, B, C) = \frac{v_A}{v_A + v_B + v_C} \quad \text{Measure 2}$$

This correspondence means that, in situations where  $v_a$  is constant, any given change in  $(v_B + v_C)$  will produce the same direction of change in these two measures. One no longer needs to know what values the magnitude terms take. Instead one just needs to set up a situation where it is reasonable to assume  $v_A$  is constant across a set of stimuli. Then, to the extent different stimuli result in different values of  $P(A:A,B,C)$  and the 2 choice to 3 choice ratio (Measure 1), these differences must be in the same direction for both measures if the Ratio Rule is correct.

A number of similar correspondences can be set up, but we employ just one further here. Consider a second set of stimuli which are comparable to the first, except in their relative similarity to one of the three categories. In this situation it may be reasonable to assume that the magnitude terms for these two sets of stimuli differ only in respect to that category. Taking the category on which they differ as A, and the two magnitude terms as  $v_A$  and  $v_{A'}$ , the ratio of probabilities with which category B (or C) is chosen in response to these otherwise comparable stimuli is

$$\frac{P(B : A', B, C)}{P(B : A, B, C)} = \frac{v_A + v_B + v_C}{v_{A'} + v_B + v_C} \quad \text{Measure 3}$$

Note that in a situation where the two magnitude terms for category A can be assumed to be constant, and  $v_A > v_{A'}$  this third measure must exhibit the same direction of change as the other two. We investigated whether all three measures do indeed show the same direction of change in the context of a simple categorization task.

## Experiment

The experiment had two phases. In the training phase, all participants learned about the category membership of a set of novel, artificial stimuli. Each training stimulus belonged to one of three categories - A, B or C. In the transfer phase which followed participants were asked to determine the category membership of a set of test stimuli. Some participants were allowed to respond A, B or C, whilst for others the option A was disallowed. The stimuli presented in the transfer phase were designed to vary smoothly from being characteristic of category B and uncharacteristic of category C through to being characteristic of C and uncharacteristic of B. They were designed in this way so that (hopefully) the

three measures we were interested in comparing would be relatively smooth functions of the number of category B (or category C) elements. If reliable functions were found for our measures and these functions all exhibited the same direction of change then we would have evidence in support of the Ratio Rule. If the functions found exhibited different directions of change then this would be strong evidence against the Ratio Rule.

Participants with three response alternatives were presented with one of two sets of test stimuli. The members within a set were designed to be equally characteristic of category A. For one set they were somewhat characteristic of category A, whilst for the other they were uncharacteristic. All participants with two response alternatives received the test stimuli somewhat characteristic of A.

## Method

**Participants and Apparatus.** 36 Cambridge University students participated. They were tested individually in a quiet cubicle on a Acorn Risc PC microcomputer with a 14" color monitor. The computer's screen was at eye level, approximately 90 cm directly in front of where the participant sat. Responses were recorded via the "X", "B" and "M" keys of a standard PC keyboard. For this experiment the keys were re-labeled "A", "B" and "C" using bold red letters against a white background.

Figure 1: An example stimulus.

**Stimuli.** Each stimulus was a collection of twelve different small pictures (hereafter elements), arranged on an invisible four-by-three grid inside a 4.5 cm by 3.5 cm rectangle outline (see Figure 1 for an example). Every stimulus contained twelve elements drawn from a pool of 40 that we have used in a number of previous experiments (see Jones et al., 1998). No stimulus contained more than one copy of any particular element. At the beginning of the experiment, and separately for each subject, 12 elements from the pool were randomly designated as category A elements, a different 12 as category B elements, and a different 12 again as category C elements. The remaining four elements were designated as novel elements and were not employed in the training phase. Each training stimulus for each category was constructed by starting with all 12 elements characteristic of that category (e.g. category A elements for a category A training stimulus). Each element in the training stimulus then underwent a 10% chance of being replaced by a randomly chosen element from one of the other two sets (e.g. replaced by a B or C element in the case of a category A training stimulus). It was these modified stimuli that were

presented to subjects as training stimuli. This procedure produces training examples which are composed predominantly of elements characteristic of a particular category but also exhibit considerable variability in terms of the specific elements they contain. Ninety training examples were created for each subject, thirty from each of the three categories.

Participants received one of two sets of test stimuli - a *familiar-elements* set or a *novel-elements* set. Each stimulus in a familiar-elements set contained four A elements,  $x$  B elements and  $(8-x)$  C elements where  $x$  could be 0, 1, 2, 3, 4, 5, 6, 7 or 8. Ten examples of each of these nine types of test stimulus were created for each participant receiving a familiar-elements test set. The specific elements used to create each test stimulus were chosen randomly within the constraints provided by the number of A, B and C elements the stimulus was to contain. Ten examples of each of four dummy stimuli were also created, these stimuli being (8 A, 0 B, 4 C), (8 A, 4 B, 0 C), (0 A, 4 B, 8 C) and (0 A, 8 B, 4 C). The purpose of the dummy stimuli was to obscure from the participants that all test stimuli of interest (from the perspective of the experimenter) were constant in terms of the number of elements from category A they contained. Stimuli in the novel-element test sets were constructed in the same manner as familiar-element stimuli, except that the four novel elements (see above) were used instead of four randomly selected A elements.

The position of elements within a stimulus was randomly determined for each stimulus presented, with the constraint that exactly one element occurred at each location in the four-by-three grid. Where stimuli were accompanied by a category label, this was presented as a large sans-serif capital A, B or C in an outline rectangle (4.5 by 3.5 cm) immediately to the right of the stimulus itself.

**Procedure.** Participants were allocated to one of three groups such that an equal number (12) participated in each. The three groups, referred to hereafter as the *two-choice*, *three-choice* and *novel-elements* groups, differed in the number of response alternatives available in the test phase and the stimuli presented during the test phase.

The training phase was the same for all participants. After some general instructions the ninety training stimuli were presented sequentially and in a random order. Each training stimulus was presented for five seconds in the center of the monitor, accompanied by the appropriate category label. Two seconds of plain mid-gray mask in the stimulus and label rectangles preceded the next example. Participants were not required to respond during the training phase. They were simply asked to concentrate on the examples shown as they would later be asked to classify new, unlabelled examples. This training procedure had proved effective in a number of previous experiments (Jones et al., 1998; Wills & McLaren, 1997).

The training phase was followed by a test phase. There were 130 stimuli in the test phase (90 target stimuli and 40 dummy stimuli) which, again, were presented sequentially and in a random order. Test stimuli were not accompanied by a category label. Participants in the two-choice and three-choice conditions received a familiar-elements test set whilst participants in the novel-elements condition received a

novel-elements test set (see *Stimuli*). On the presentation of each test stimulus, participants were asked a question. Participants in the two-choice condition were asked "Is this a B or a C?". Participants in the three-choice and novel-elements conditions were asked "Is this an A, a B or a C?". In all conditions they responded by pressing the appropriate key on the computer keyboard. They then pressed the "Y" key, whereupon the next stimulus was immediately presented. There was no time limit for these decisions, and participants were put under no pressure to respond quickly.

The allocation of the category labels "A", "B", and "C" to the logical categories A, B and C was counter-balanced.

## Results

Figure 2a shows the probability with which participants responded with the category A label to test stimuli (Measure 2) as a function of the number of category B elements they contained (the conclusions of this study are unaffected if one plots against category C elements instead). The functions for the three-choice and novel elements conditions both appeared to show an inverted-U trend. The significant fit of a second-order polynomial to the nine mean data points confirmed this appearance for the three-choice condition,  $F(2, 6) = 5.6$ ,  $p < 0.05$ , but not for the novel-elements condition,  $F(2, 6) = 3.2$ ,  $p > 0.1$ . The quadratic co-efficient for the three-choice condition was significantly different from zero,  $b^2 = -0.006$ ,  $t(7) = 2.4$ ,  $p < 0.05$ .

The data points in Figure 2b are the average of the probability with which participants responded with their category B label to stimuli with  $x$  category B elements and the probability with which they responded with their category C label to test stimuli with  $x$  category C elements. In other words, it shows response probability as a function of the number of *category-appropriate* elements. Averaging these two probabilities is appropriate because, across subjects, there is no factor that determines which of the two categories providing variable numbers of elements to test stimuli should be described as category B and which as category C. A replication of this experiment with non-counterbalanced category labels failed to reveal any significant response bias. Number of category-appropriate elements in Figure 2 reduces from left to right in order to follow the convention that generalization functions (such as those shown in Figure 2b) are plotted as slopes with negative gradients.

For our current purposes it is not the data presented in Figure 2b which are of central interest, but the ratios calculated from the mean points it displays (Measures 1 and 3). These ratios are presented as a function of category-appropriate elements in Figure 2c. Inspection of this figure shows that the 2 choice to 3 choice ratios (Measure 1) appear to exhibit an increasing, accelerating trend whilst the 3 choice novel-elements to 3 choice ratios (Measure 3) exhibit a decreasing, accelerating trend. The significant fit of a second-order polynomial to the nine points of Measure 1,  $F(2, 6) = 803$ ,  $p < .0005$ , with a best-fit line for which all three co-efficients were significantly different from zero,  $b^2 = 0.049$ ,  $t(7) = 14$ ,  $p < .005$ ;  $b = -0.674$ ,  $t(7) = 24$ ,  $p < .0005$ ;  $a = 3.48$ ,

Figure 2: **a)** Probability of producing a category A response. **b)** Mean response probability (see text). **c)** Two ratios calculated from the data in Figure 2b. Plot symbols = empirical data. Lines = predictions of the winner-take-all model presented in the Modeling section.

$t(7) = 2.5, p < .05$ , supports this conclusion. The nine points of Measure 3 were also a significant fit to a second-order polynomial,  $F(2, 6) = 17, p < .005$ , and all three coefficients differed significantly from zero,  $b^2 = -0.021, t(7) = 3.0, p < .05$ ;  $b = 0.244, t(7) = 4.3, p < .005$ ;  $a = 0.632, t(7) = 3.8, p < 0.01$ .

## Discussion

Our results pose two central problems for the Ratio Rule as it is currently employed in many formal models of categorization.

First, the Ratio Rule predicts that the two ratios represented in Measures 1 and 3 should show the same direction of change over any interval of category-appropriate elements. However, the best-fitting quadratics for the corresponding functions show opposite directions of change (Figure 2c). Second, the Ratio Rule predicts that the probability of choosing category A in the three-choice condition (Measure 2) should show the same direction of change over any interval of category-appropriate elements as the other two measures. However, the best-fitting quadratics for measures 1 and 2 are of opposite shape (compare Figure 2a with Figure 2c). One might argue that these findings are of relatively little consequence because the discrepancies are in derived measures with no straightforward psychological interpretation, rather than in the response probabilities themselves. Such a position is disingenuous. The predictions under test arise naturally and unavoidably from a central (some would say defining) feature of the Ratio Rule - the fact that the ratio in which two alternatives are chosen is unaffected by the addition of a third alternative. These data provide evidence against that central tenet and hence bring the formulation into question.

If any one step in a chain of inferences is incorrect then the conclusions drawn from that process must be brought into question. Consequently, theoretical conclusions about the nature of categorization must be re-examined if our conclusion is found to be generally valid. Conversely, if the assumptions we have made in coming to our conclusions can be shown to be invalid then the Ratio Rule is not necessarily incorrect. Below we briefly consider some possible criticisms of our conclusion.

First, one could argue that we have disproved the Ratio Rule for means across participants, but this does not disprove the formulation for individual participants. This is a valid point, but as most formal theories of categorization have been applied to group means our conclusion still stands for these theories. Second, it is true that our stimuli are rather more complex than those typically used in category learning experiments. It may be the case that our results do not generalize to simpler stimuli, or that our stimuli are unusual in some other way. This seems to be an empirical matter, and one which is worthy of investigation. A third, substantial criticism is that we have assumed that category magnitude terms are, for our stimuli, univariate functions of the number of category-appropriate elements the stimulus contains (i.e. the magnitude term is determinable solely from this property). There are at least two distinct ways in which this assumption could be incorrect.

First, for specific models of categorization it may be possible to show that the category magnitude term for category A is not invariant under changes in the magnitude terms for categories B and C. For example, one might be able to demonstrate for the GCM model (Nosofsky, 1986) that the test stimuli were not at a fixed distance (in psychological similarity space) from category A examples. The difficulty here is that the procedure which Nosofsky uses to derive the psychological similarity space assumes that the Ratio Rule is correct. Some way around this circularity would have to be devised.

Second, one could quite reasonably argue that category magnitude terms are importantly affected by what response alternatives are available (as a number of theorists outside of the categorization literature have argued e.g. Restle, 1961; Tversky, 1972). If this were the case in our experiment then the derivation of Measure 1 would be invalid because it is directly based on this assumption.

Therefore one response to our results might be to retain the Ratio Rule but introduce a mechanism by which category magnitude terms can be affected by the alternatives available for decision. However, for most formal models of categorization this would require considerable revision of the basic principles upon which they were based. We wondered whether there was a direct replacement for the Ratio Rule that could accommodate our results without having to modify the rest of the theory.

Figure 3: The winner-take-all model.

### Modeling

Previously we have proposed that response probabilities in categorization might be modeled by a simple winner-take-all connectionist system employing category magnitude terms as input activations (Wills & McLaren, 1997). Such a system is illustrated in Figure 3. In addition to the magnitude-term inputs, each unit has a fixed excitatory connection to itself and fixed inhibitory connections to the other units. These connections can cause the units to “compete” with one another until only one has a non-zero activation. In our system a decision is deemed to have been made when the highest activation exceeds its nearest competitor by some threshold value,  $S$ . This general architecture has been proposed previously by Grossberg (1976) amongst others, and has been employed in the modeling of a number of other

psychological phenomena (e.g. Houghton, 1990; Usher & McClelland, 1995).

For the purposes of this simulation we assume that category magnitude terms are defined by the function  $v = 0.047c + 0.012$ , where  $c$  is the number of category-appropriate elements the stimulus contains. The exact form of this equation is not critical. It was chosen because it describes the behavior of a simple localist delta-rule network with a learning rate of 0.0025. This learning rate was previously found to be successful in modeling the rate of learning in similar experiments (Wills & McLaren, 1997). The important thing to note is that we are preserving the assumption that category magnitude terms are independent of the response alternatives available.

The magnitude term input activations ( $r$ ) are assumed to be noisy and, for simplicity, this noise is assumed to be rectangular, have a mean of zero, and a range from  $-N$  to  $+N$ . Magnitude input activations are also constrained to lie between 0 and 1. The specific shape of the noise distribution is not critical and similar mean behavior could be produced with a Gaussian distribution. The output activations of the units are governed by the equations

$$o = \frac{o + En}{1 + En + D}, \text{ if } n > 0 \text{ and } o = \frac{o + En}{1 - En + D} \text{ otherwise,}$$

where  $n$  is the total input the unit, and  $E$  and  $D$  are excitation-rate and decay-rate constants respectively. These are standard activation equations with properties similar to those used by, for example, McClelland & Rumelhart (1985). Output activations in our model are constrained to be non-negative. Total input ( $n$ ) for a given unit is the sum of  $r$  and  $o$  for that unit, minus the sum of the outputs ( $o$ ) of the other units. For the current simulation  $E = 0.2$ ,  $D = 0.1$  and  $N = 1.1$ . The threshold parameter  $S$  was set to 0.18 for the two-choice condition, 0.65 for the three-choice condition and 0.72 for the novel-elements condition.

In the two-choice condition of our experiment, participants were not allowed to make category A responses. In our WTA model this was simulated by fixing the output activation of the category A unit at zero.

The results of our simulation are shown as lines in Figure 2. Note that the model respects all the major trends in the experiment and is numerically close to the observed data. A detailed discussion of the principles underlying the success of this model is not possible here, but it is important to note that the exact details of the implementation are not critical. Indeed, not even the expression in connectionist terms is essential. The model simply provides a mechanism by which a decision similar in principle to Thurstonian choice (Thurstone, 1927) can be made. We have demonstrated in other analyses that simply choosing the noisy alternative which is instantaneously the biggest does reasonably well in predicting the trends in Measures 1 and 2 (whether one employs Gaussian or rectangular noise).

However, only the connectionist system correctly predicts the trend in Measure 3. This is because it employs different decision thresholds in the three-choice and novel-elements conditions, which allows it to predict that Measure 3 falls below unity without having to make the counter-intuitive

assumption that the category A magnitude term for a stimulus containing no category A elements is greater than for a stimulus containing four category A elements (the only way a simple Thurstonian choice process could predict ratios smaller than one).

## Conclusion

The Ratio Rule as generally applied in formal models of categorization was shown to be incorrect for the experiment presented. Whilst further investigation is necessary, we suggest that our results may indicate a need to replace the Ratio Rule as currently employed with an alternative system (perhaps still based around the Ratio Rule). One possibility would be to substantially revise existing models so that they provided a mechanism by which category magnitude terms could be affected by the alternatives available for decision. We have shown that our results do not require that this modification be made. Rather, one simply needs to directly substitute the Ratio Rule with a decision mechanism based on the principles of Thurstonian choice. The noise employed in this mechanism may have one of a number of distributions. As a caveat, one distribution it is unlikely to have is a double exponential distribution because this would make it indistinguishable from the Ratio Rule (Yellott, 1977).

## Acknowledgments

The authors would like to thank Fergal Jones, Koen Lamberts, Donald Laming and Thomas Palmeri for their helpful comments. Thanks are also due to Stian Reimers and Neil Stewart who helped out with similar studies for which there was insufficient space in this article. This research was supported by a grant from the ESRC to I.P.L. McLaren.

## Abstract

We propose a theory of the spontaneous reasoning strategies that individuals develop. These strategies depend on component tactics based on mental models. Reasoners vary their use of tactics in ways that are not deterministic. This variation leads different individuals to assemble different strategies, which include constructing incremental diagrams corresponding to mental models, and pursuing the consequences of a single model step by step. The number of models required by the premises predisposes reasoners towards certain strategies, e.g., multiple models tend to elicit incremental diagrams. Similarly, the connectives in premises also bias reasoners towards certain strategies, e.g., conditional premises tend to elicit reasoning step by step from a single model.

## Introduction

Psychologists have tended to neglect the strategies that individuals develop spontaneously to make complex inferences (cf. Schaeken, De Vooght, Vandierendonck, and d'Ydewalle, 2000). By a *strategy*, we mean a systematic sequence of elementary mental steps, i.e., tactics, that an individual follows in making an inference. Pioneering studies of strategies examined relational reasoning in which the task is, say, to infer who is tallest in a series of individuals. The results suggested that reasoners develop a variety of strategies (e.g. Wood, 1969; Quinton and Fellows, 1975). However, there has been a dearth of studies of strategies in sentential reasoning, which hinges on negation and connectives such as "if", "or", and "and". Some theorists have argued that sentential reasoning relies on a single deterministic strategy based on formal rules of inference (cf. Rips, 1994; Braine and O'Brien, 1998). We suspect that theorists have postulated a single deterministic strategy because their experiments have used too simple premises for strategies to differ, and because they have failed to gather evidence about reasoner's strategies. Indeed, we and our colleagues have proposed that naïve reasoners generally develop a variety of strategies (e.g. John-

son-Laird and Byrne, 1990; Byrne and Handley, 1997; Bucciarelli and Johnson-Laird, 1999).

## Experiment 1: A taxonomy of strategies

How can experimenters best observe the strategies that reasoners use in sentential reasoning? In our view, studies of strategies should examine inferential problems that are sufficiently time-consuming to force the participants to think, but not so difficult that they make many errors. We therefore used sentential problems based on three premises, but each set of premises was compatible with only two alternative possibilities. The task was to evaluate a given conclusion and to think aloud (cf. Ericsson and Simon, 1984). Here is a typical example of a problem:

Either there is a blue marble in the box or else there is a brown marble in the box, but not both. Either there is a brown marble in the box or else there is white marble in the box, but not both. There is a white marble in the box if and only if there is a red marble in the box. Does it follow that: If there is a blue marble in the box then there is a red marble in the box?

Henceforth, we use the abbreviations: "iff" for biconditionals of the form "if and only if", "ore" for exclusive disjunctions of the form "either \_ or else \_, but not both", and "or" for inclusive disjunctions of the form "\_ or \_, or both".

Our theory of strategies is based on mental models (Johnson-Laird and Byrne, 1991), and each mental model represents a possibility. All the problems in the experiment called for two mental models. The premises of the example above yield the following two models of the possible contents of the box, shown on separate lines:

blue	white	red
brown		

As the models show, the putative conclusion follows from the premises.

*Method.* Eight Princeton undergraduates, who had no training in logic, carried out twelve inferences, which each had a conclusion to be evaluated. The problems were based on three or four premises. Half of them had valid conclusions and half of them had invalid conclusions. The premises were mainly biconditionals and exclusive disjunctions, and the conclusions were conditionals except for two problems, which had exclusive disjunctions as conclusions. As in the example above, the contents of the problems concerned different colored marbles. The problems were presented in a different random order to each participant.

The participants were allowed to use pencil and paper. They were told to think aloud as they tackled each inference, and we video-recorded what they said, wrote, and drew. The camera was above them and focused on the paper on which they wrote, and they rapidly adapted to its presence.

*Results.* None of the participants made any errors in evaluating the given conclusions, though they were not always right for the right reasons. We transcribed the tapes verbatim apart from repetitions of words, filled pauses, and hesitations. These protocols also included a record of the step by step drawings of diagrams. We were able to make sense of almost all of what the participants said, drew, and wrote. Most participants used two or more distinct strategies, but two of them stuck to the same strategy throughout the experiment. What the protocols did not reveal were either the processes in developing a strategy, or the mechanisms underlying the tactical steps. We were able, however, to categorize the protocols from every participant for every problem into one of the strategies in the taxonomy in Table 1 below.

The taxonomy distinguishes five main strategies. It is based on all our experiments, but it may be necessary to add further strategies: no-one can ever know when the classification is complete. The five strategies were:

1. The incremental models strategy. Reasoners draw a diagram that integrates all the information from the premises. The diagram corresponds to a set of models (see the example above). Some participants drew the models in vertical columns down the page. Others arranged them horizontally. One participant merely drew circles around the propositions in the premises themselves to pick out one of the two models. Participants work through the premises in an order that allows them to increment their diagrams.

2. The step strategy. Reasoners pursue the step by step consequences of either a categorical proposition or a supposition. They accordingly infer a sequence of what logicians refer to as “literals”, where a *literal* is a proposition that does not contain any sentential connectives: it may be an atomic proposition, *A*, or its negation, *not A*. Consider the following problem, stated in an abbreviated form:

- Pink iff black.
- Black ore gray.
- Gray iff blue.

Does it follow that if not pink then blue?

One participant's complete verbatim protocol, illustrating the strategy, is:

Assuming we have no pink:  
 There is no pink. [He crosses out “pink” in premise.]  
 So there is no black. [Crosses out “black” in premises.]  
 There is gray. [Circles “gray” in premise.]  
 There is blue. Yes. [The conclusion follows.]

3. The compound strategy. Reasoners take two compound assertions, i.e., assertions containing a sentential connective, and draw a compound conclusion from them, e.g.:

Pink ore brown. [Reads premise]  
 Pink and white. [Points to diagram of premise:  
 pink → white]

If brown then not white.[A compound inference.  
 Writes: brown, ~~white~~]

White ore brown. [The required conclusion]

The strategy consists in a sequence of such compound inferences that yield an ultimate conclusion.

4. The chain strategy. Reasoners construct a chain of *conditionals* leading from one constituent of a compound conclusion to its other constituent. They make an immediate inference from any premise that is not a conditional to convert it into an appropriate conditional (see Richardson and Ormerod, 1997). Here is an example of a protocol:

[Crosses out terms in diagrams:

If not pink then not green. ~~pink~~ = ~~green~~  
 If not green then red. ~~green~~ or red  
 If red then white. red = white

Yes. [I.e. If not pink then white]

The valid use of the strategy to prove a biconditional or exclusive disjunction calls for two chains, but reasoners usually rely on just a single chain.

5. The concatenation strategy. Reasoners sometimes concatenate the premises to form a complex intermediate conclusion. They then draw an immediate inference from it to the required conclusion. For example, one participant concatenated the premises:

A and B.  
 B iff C.  
 C iff D.

to yield : A and (B iff C iff D). She then made an immediate inference to the required conclusion: A and D.

For the twelve problems in Experiment 1, we calculated the total number of times each strategy occurred in the protocols, and then expressed these numbers as percentages of the total number of occurrences of strategies. The results were as follows:

Incremental models strategy:	34% of overall use.
Supposition and step strategy:	21% of overall use.
Compound strategy:	19% of overall use.
Chain strategy:	25% of overall use.
Concatenation strategy:	0% of overall use.

The most salient feature of the protocols was that different participants used different strategies.

### A theory of reasoning strategies

A *deterministic* process is one in which each step depends solely on the current state of the process and whatever input it may have (Hopcroft and Ullman, 1979). Following Harman (1973), however, we assume that reasoning is not a deterministic process that unwinds like clockwork. Our first assumption is accordingly:

1. The principle of *nondeterminism*: thinking in general and sentential reasoning in particular is governed by constraints, but there is seldom just a single path it must follow. It varies in a way that can be captured only in a nondeterministic account.

Experiment 1 corroborated the principle of nondeterminism, and it did so at two levels. At a high level, the participants developed diverse strategies. At a low level, there was considerable variation within strategies.

Our second assumption is:

2. The principle of *strategic assembly*: naïve reasoners assemble reasoning strategies bottom up as they explore problems using their existing inferential tactics. Once they have developed a strategy, it can control their reasoning in a top-down way.

A corollary of the principle is that individuals are most unlikely to develop a reasoning strategy working “top down” from a high-level specification. Granted the principle, it also follows that the space of possible strategies is defined by the different ways in which inferential tactics can be sequenced in order to make inferences. Hence, an exhaustive enumeration of tactics provides the recursive basis for all possible strategies.

If the mechanism underlying reasoning depends on mental models, then each inferential tactic must be based on models. We therefore postulate a third assumption:

3. The principle of *model-based tactics*: inferential tactics are based on mental models.

The mechanisms for constructing models are, in turn, constrained by the nature of the human mind, which reflects innate constraints and individual experiences.

Our first test of the three principles was to show that mental models can underlie all the strategies and tactics in our taxonomy. The *incremental models* strategy is isomorphic to the cumulative construction of a single set of models based on the premises. The *step* strategy is based on a categorical premise or a supposition. Although the strategy is similar to the one strategy that Rips (1994) proposes, the model theory allows a greater freedom in the use of suppositions – a freedom that corresponds to their use by naïve reasoners. The main inferential step is to use a literal to update a set of models based on a premise in order to draw another literal as a conclusion. A premise, such as: Black ore gray, yields two models:

black  
gray

and the supposition, Not black, eliminates the first model and yields the literal conclusion: gray. The *compound*

Table 1: The model-based tactics underlying each of the five strategies: + indicates the use of a tactic, and (+) indicates its optional use.

Tactics	The five strategies				
	Increment models	Step	Compound	Chain	Concatenation
Make a supposition	(+)	+			
Concatenate premises		(+)	(+)		+
Construct models	+	+	+	+	+
Update models	+	+	+		
Immediate inference from models	(+)		(+)	+	+
Formulate intermediate conclusion from models		+	+		
Evaluate or formulate a conclusion from models	+	+	+	+	+

strategy relies on a series of compound inferences based on models. The *chain* strategy depends on the construction of a chain of conditionals. The chain has one explicit mental model and one implicit mental model. To prove a conditional of the form:

If A then D.

individuals can construct a chain leading from D to A, e.g.:

If D then not-C.  
If not-C then B.  
If B then A.

Such a strategy is invalid. So, why do reasoners construct this chain? The answer is that the conclusion holds in the mental models of the chain:

d     ¬c     b     a

Hence, mental models underlie the strategy. The *concatenation* strategy appears at first sight to rely on purely syntactic operations, and therefore to violate the principle of model-based tactics. In fact, the strategy depends critically on mental models. Given a pair of premises of the form:

A iff B.  
B ore C.

there are two ways in which to concatenate a conclusion:

1. (A iff B) ore C.
2. A iff (B ore C).

Which of these two conclusions follows from the premises? In fact, neither conclusion is valid. Yet, eight out of the eight participants in Experiment 3 who concatenated conclusions from the relevant premises generated conclusion 2. It is the one conclusion that has the same mental models as the premises. Ten participants in Experiment 2 used the tactic of concatenating a conclusion on one or more occasions. On 82% of occasions, the resulting conclusions were compatible with the mental models of the premises, and nine of the ten participants concatenated more conclu-

sions of this sort than not (Sign test,  $p < .02$ ). Concatenation is not blindly syntactic. It tends to be accepted only if it yields the same mental models as the premises. Table 1 presents the taxonomy of strategies and their underlying model-based tactics.

**Experiment 2: Development of strategies**

The theory predicts that the nature of the inferential problems given to reasoners should influence their development of strategies. According to the principle of strategic assembly, the characteristics of particular problems should trigger certain strategies “bottom up”. One instance of this prediction concerns the effects of number of models. Problems that include a categorical premise or a conjunction of them yield a single model. Hence, individuals can use a categorical premise as the starting point of their reasoning, and the step strategy is the easiest way to proceed because it places a minimal load on working memory. With multiple-model problems, the optimal way to keep track of the possibilities is to use the incremental models strategy. Multiple models, however, should also yield a greater number of errors. The aim of the present experiment was to test these predictions.

*Method.* Twenty Princeton undergraduates acted as their own controls and evaluated given conclusions to 36 problems presented in three blocks: twelve one-model inferences, twelve two-model inferences, and twelve three-model inferences. Typical problems were of the form:

<i>One-model</i>	<i>Two-model</i>	<i>Three-model</i>
A and B.	A iff B.	A iff B.
B ore C.	B ore C.	B iff C.
C iff D.	C iff D.	C or D.
A and not D?	A iff D?	A or D?

The participants evaluated the conclusions, and we used the same think-aloud and video-recording procedure as before.

Table 2: The percentages of the different strategies for the three sorts of problems in Experiment 2. The balances of the percentages (5%) were uncategorizable strategies.

	The strategies		
	Incremental models	Step	The other strategies
One-model premises	21	69	3
Two-model premises	26	56	15
Three-model premises	49	45	2

*Results.* As the model theory predicts, errors increased with the number of models: there were 8% of errors with one-model problems, 15% of errors with two-model problems, and 20% of errors with three model problems (Page’s  $L = 251.5$ ,  $p < 0.05$ , one-tailed). Table 2 presents the percentages of the different strategies for the different sorts of problem. The participants were sensitive to the properties

of the particular problems. As the theory predicts, they relied increasingly on the incremental models strategy as the problems required a greater number of models (Page’s  $L = 254.5$ ,  $p < .05$ , one-tailed). They tended to use the step strategy with one-model problems, but the use of the strategy declined with an increasing number of models. The results accordingly corroborated the principle of strategic assembly: reasoners develop strategies “bottom-up” depending on the sort of problem that they encounter.

**Experiment 3: Formulating conclusions**

This experiment was similar to Experiment 2, except that the participants had to draw their own conclusions.

*Method.* Twenty four Princeton undergraduates acted as their own controls and carried out four one-model inferences, four two-model inferences, and four three-model inferences, in counterbalanced orders. For each problem, they wrote down their answer to the question, “What, if anything, follows?” and we used the same procedure as before.

*Results.* The participants developed diverse strategies, and the realization of any particular strategy varied from trial to trial even for the same participant. As the model theory predicts, the percentages of invalid conclusions, modal conclusions about possibilities, and conclusions that failed to take into account all the premises, each increased significantly with the number of models. Table 3 presents the percentages of the different strategies in the experiment. As predicted, the use of the incremental models strategy increased with the number of mental models required by the premises. With one-model problems, the participants were likely to use the step strategy, but there was an increase in the use of the incremental models strategy with multiple-model inferences. This trend was reliable (Kendall’s coefficient of concordance,  $W = 0.228$ ,  $X^2 = 10.94$ ,  $p < .01$ , two-tailed).

Strategies should influence the form of the conclusions that reasoners draw. With incremental models, it is difficult to see what is common to a number of alternative possibilities, and so reasoners should tend to describe each possibility separately and to combine these descriptions in a disjunction. The other strategies, however, are unlikely to yield conclusions of this sort. These strategies focus on a single possibility, such as a supposition. We examined this prediction by dividing the participants in Experiment 3 into two post hoc groups. In the *model* group (9 participants), more than half of the participants’ identifiable strategies yielding conclusions were the incremental models strategy. In the *non-model* group (15 participants), more than half of the participants’ identifiable strategies yielding conclusions were some other sort. For the model group, 63% of the problems solved with the model strategy had a conclusion that was a disjunction of possibilities, but for the non-model group only 11% of the problems solved with a non-model strategy had such a conclusion (Mann-Whitney test,  $z = 2.87$ ,  $p < .005$  one-tailed). Different strategies do yield different sorts of conclusion.

Table 3: The percentages of the different strategies for the three sorts of problems in Experiment 3. The balances of the percentages (11% overall) are uncategorizable strategies.

	The strategies			
	Incremental models	Step	Compound	Chain
One-model premises	14	80	5	3
Two-model premises	33	22	20	9
Three-model premises	36	25	14	7
Overall	28	41	13	7

### Experiment 4: Strategies and premises

The principle of strategic assembly implies that the form of the premises should influence the development of strategies. A way to elicit the incremental models strategy should be use to disjunctive premises, which are naturally represented as sets of possibilities. A way to elicit the step and chain strategies is to use conditional premises, which have only a single explicit model required by these strategies. These effects should occur even when the premises are otherwise logically equivalent. Once individuals have developed a strategy, it should have a “top down” residual effect on their subsequent performance. It should be used for problems that would not normally trigger its use. The experiment tested these predictions.

*Method.* Twenty Princeton undergraduates acted as their own controls and drew their own conclusions to two sets of problems: four disjunctive problems and four logically equivalent conditional problems. Half the participants received the four disjunctive problems in a random order followed by the four conditional problems in a random order; and half the participants received the two blocks of problems in the opposite order.

*Results.* Table 4 presents the percentages of the different strategies for the two sorts of problems, and it gives the data separately for the two blocks of trials. As the theory predicts, the participants were more likely to use the incremental models strategy (56%) for the disjunctive problems than for the conditional problems (23%; Wilcoxon test  $T = 66, n = 11, p < .0005$ ). The table shows that the participants who first carried out the conditional problems rarely developed the incremental models strategy (10% of these problems), but their use of the strategy increased reliably for the disjunctive problems (55% of problems, Sign test,  $p < .02$ , two tailed). In contrast, those who first carried out the disjunctive problems often developed the incremental models strategy, and did not reliably reduce its use with the conditional problems. This difference between the two groups was reliable (Mann-Whitney  $U = 21, p < .05$ , two tailed). An obvious explanation for the differential transfer is that the incremental models strategy is simpler to use with any sort of sentential connective, whereas the step and chain strategies call for additional immediate inferences to convert

Table 4: The percentages of the different strategies for (a) the disjunctive problems and (b) the conditional problems in Experiment 4. The balances of the percentages are trials with erroneous responses or uncategorizable strategies.

(a) Disjunctive problems	The strategies	
	Incremental models	Step, Compound, and Chain
Presented first	58	35
Presented second	55	35
Overall	56	35

(b) Conditional problems	The strategies	
	Incremental models	Step, Compound, and Chain
Presented first	10	90
Presented second	35	60
Overall	23	75

disjunctive premises into conditionals.

The experiment corroborated the principle of strategic assembly. The nature of the sentential connectives biases reasoners to adopt particular strategies. The incremental models strategy, though it places a greater load on working memory, is more flexible than the other strategies, which are more finely tuned to conditional premises.

### General Discussion

Unlike some cognitive domains, such as arithmetic (Lemaire and Siegler, 1995), accounts of sentential reasoning have neglected strategies (for reviews, see Evans, Newstead, and Byrne, 1993; Garnham and Oakhill, 1994). Studies have failed to use appropriate methods to discover strategies; and in consequence theorists have often assumed that reasoners rely on a single deterministic strategy. We have tried to remedy the neglect and to advance a new theory of strategies in reasoning. Naïve reasoners use at least five distinct strategies. As the theory predicts, each strategy is built from tactical steps that rely on the manipulation of models (see Table 1). The *incremental models* strategy keeps track of all the mental models compatible with the premises. The *step* strategy pursues the step by step consequences of one model – either one derived from a categorical assertion in a premise or one created by a supposition. The *compound* strategy combines the models of compound premises to infer what is necessary or possible. The *chain* strategy pursues a model in a sequence of conditionals, which may be inferred from the premises, leading from one constituent of a conclusion to another. The *concatenation* strategy forms a conclusion by concatenating the premises, but normally only if the resulting conclusion has the same mental models as the premises. Because it relies on mental models, it gives rise spontaneously to illusory inferences (cf. Johnson-Laird and

Savary, 1999; Goldvarg and Johnson-Laird, 2000; Johnson-Laird et al., 2000; Yang and Johnson-Laird, 2000).

The model theory explains how people develop reasoning strategies. They are equipped with a set of inferential tactics. As they reason, the variation in their performance, leads them to assemble these tactics in novel ways so that they yield a reasoning strategy. As a result, they develop different strategies. All their strategies, however, depend on tactics based on mental models. The properties of inferential problems can accordingly influence the development of particular strategies. The problems in Experiments 2 and 3 called for one, two, or three models. As the theory predicts, the participants tended to use the conjunction in one-model problems as the starting point for the step strategy, which places a minimal load on working memory. As the number of models increased, they were more likely to use the incremental models strategy, which keeps track of the different possibilities compatible with the premises. Experiment 4 also bore out the theory's account of strategic assembly. Disjunctive premises, as predicted, tended to elicit the incremental models strategy, whereas conditional premises tended to elicit other strategies. The participants increased their use of incremental models on switching to disjunctive premises, but they did not decrease its use on switching to conditional problems. Although incremental models load working memory, the strategy is more flexible than those that are optimal for conditional premises.

What would have refuted our theory? At the lowest level, that of inferential mechanisms, the theory would have been refuted if there had not been an increase of difficulty with the number of models required by the problems. This phenomenon has been observed in previous studies (see Johnson-Laird and Byrne, 1991), but not before in inferences based on three sentential connectives. At the tactical level, the theory would have been refuted if reasoners used tactics incompatible with manipulations of models. Suppose, for example, that the concatenation had not been sensitive to the mental models of the premises, then a tactic would have been controlled purely by syntactic considerations, and it would have been contrary to the theory. At the strategic level, the theory would have been refuted if reasoners had uniformly developed a single deterministic strategy (cf. Rips, 1994). The moral of our results is clear. They support the three principles of the model theory of reasoning strategies.

## Abstract

Two experiments examined the content of novice and expert representations for both surface and deep structural elements of arithmetic equations. Experiment 1, which used a forced-choice categorization task in which surface features of equations (e.g., digits) competed with deep structural principles of mathematics (associativity and commutativity), found that experts were more likely to focus on principles in their judgments than were novices, who focused more often on surface elements. Experiment 2, using a similar task, introduced trials in which only principled elements varied. Novices were able to focus on principled elements in this case, but failed to transfer these representations when surface features were re-introduced. These findings indicate that novices had knowledge of the principles, but that they did not attend to them when competing surface features were present.

## Introduction

It has been well established that in various knowledge domains (e.g., physics, mathematics, or chess) experts approach problems in a manner different from that of novices (Chase & Simon, 1973; Chi, Feltovich, & Glaser, 1981; Larkin, 1983; Simon & Simon, 1978; Reed, Ackinclose, & Voss, 1990). In particular, while experts are more likely to focus on hidden relational properties of a problem, novices are more likely to focus on less important surface features of a problem. However, while there is some understanding of the content of mental representation (i.e., of which aspects of information are likely to be represented and which are likely to be left out), the process of construing the representation remains largely unknown. Do people attend to and encode those aspects that are left out, but then discard them, or do they fail to attend to and encode these "irrelevant" aspects?

The current paper (Part 1) focuses both on establishing differences in content of representation for experts and novices within a simple domain (arithmetic) and testing a number of viable explanations that could account for these differences. A subsequent paper (Part 2) focuses on examining differences in the process of construing representations for experts and novices.

There is a large body of literature indicating that in problem solving, reasoning, learning and transfer, and problem

categorization, novices tend to focus on surface features rather than on deep relational properties. These effects have been demonstrated in a variety of knowledge domains, including chess (Chase & Simon, 1973), mathematics (Blessing & Ross, 1996; Schoenfeld & Herrmann, 1982; Bassok, 1996, 1997; Novick, 1988; Reed, et al, 1990; Silver, 1981), physics (Chi, et al 1981; Simon & Simon, 1978; Larkin, 1983; Larkin, McDermott, Simon, & Simon, 1980), and computer programming (Adelson, 1984). Similar effects have been observed in a variety of knowledge-lean domains, such as deductive and inductive inference. When presented with deduction problems, untrained reasoners often tended to ignore the argument's logic (i.e., its deep structure) while relying on the argument's surface features, such as content and believability (Evans, Newstead, & Byrne, 1993; Johnson-Laird & Byrne, 1991). When presented with induction and analogy problems, novices and young children also often ignored deep relational structure while relying on the surface features (Gentner, 1989; Holyoak & Koh, 1987).

While there is little disagreement that novices focus on surface features, it remains unclear why novices tend to focus on surface features and not on deep relational properties. One possible explanation of novices' tendency to represent surface features is that novices merely have little knowledge of deep structural relations. However, while this possibility is capable of explaining expert-novice differences in extremely knowledge-demanding domains, such as medical diagnostics, chess, or advanced physics, it falls short of explaining these differences in fairly simple domains, such as elementary mathematics and physics. For example, researchers examining novices' representations in mathematics and physics often drew examples from students' textbooks, thus reasonably assuming that students should be familiar with the deep structure underlying these problems (Chi, et al, 1981; Larkin, 1983; Novick, 1988). The credibility of the lack of knowledge explanation is further undermined by findings that even those novices who receive instruction in a domain often continue to focus on surface features rather than the deep structure of a problem. These has been demonstrated across a variety of knowledge domains, including mathematics (Morris & Sloutsky, 1998) and physics (Kaiser, McCloskey, & Proffitt, 1986; McCloskey, 1983). Finally, the fact that findings on novices' representations in knowledge-lean domains are compatible with those in knowledge-

rich domains makes the low knowledge explanation even less plausible. At this point, however, lack of knowledge cannot be ruled out as an explanation for differences in problem construal by experts and novices. It is also possible that surface features are used more frequently by novices, and, as a result, they are more available than deep relational properties (cf. Anderson, 1990). Henceforth, we will refer to this possibility as the availability explanation.

Another possibility that appears more credible is that even when novices know about deep relations and are capable of extracting these relations, they still fail to represent these relations because surface features are more prominently present in the problem. In failing to represent relational features, they may either fail to encode relations, or these relational features may lose attentional competition to more salient surface features. However, this representational processing explanation can only be tested if the above-described explanations are eliminated as possibilities. In the current paper, then, the focus is on establishing difference in content of representations of experts and novices within the domain of arithmetic, and then testing the knowledge and availability explanations. If differences between experts and novices are found, and the data are inconsistent with the predictions of the alternative explanations, then the way is cleared to test the representational process explanation.

The goal of the current studies, then, is to establish why experts and novices differ in the content of their problem representations. To achieve this goal, we deemed it necessary to control for knowledge factors, while manipulating representational factors. In controlling for knowledge factors, we (a) used simplified tasks and (b) selected only those deep properties that were well familiar to a wide range of participants. In particular, we selected the commutative and associative properties of arithmetic, because these principles are learned in the elementary school and revisited in the beginning of the middle school (Everyday Mathematics: Teacher's Reference Manual, 1998), and therefore are likely to be familiar to the majority of middle school students and college undergraduates.

In this paper, we present two experiments. In Experiment 1, experts and novices in mathematics were asked to group arithmetic equations. These groupings could be based either on the commonality of surface elements (e.g., digits used, the number of constituent elements in the equations) or on the commonality of a deep mathematical relation (principles of commutativity or associativity). In Experiment 2, we introduced a two-phase grouping task. During the first phase, deep relations were "unmasked," such that surface elements were not varied among the compared equations. During the second phase, the deep relations were "masked" again by reintroducing competing surface elements.

## Experiment 1

The goal of this experiment was to validate the principles in question and to eliminate the possibility that expert-novice differences stem from differences in overall intelligence (or age) between novices and experts.

## Method

**Participants** Five samples were selected for the current experiment. The first group, which will be referred to as the "younger children", contained 20 first- and second-graders taken from an elementary school ( $M = 7.26$  years,  $SD = 0.59$ ; 8 girls and 12 boys). The second group, which will be referred to as the "older children", contained 16 sixth-graders taken from a middle school ( $M = 12.10$  years,  $SD = 0.38$ ; 5 girls and 11 boys). Both of these groups were selected from schools located in an upper middle-class suburb of Columbus, Ohio.

The third group of participants consisted of 25 undergraduates in an introductory psychology course at a large Midwestern university who participated for course credit. This group had an average age of 19.78 years ( $SD = 1.38$ ), with 11 women and 14 men.

These three groups of mathematics "novices" were contrasted with a group of mathematics "experts". This group consisted of 20 graduate students in a Mathematics department at the same university who participated for payment of ten dollars. This group had an average age of 28.88 years ( $SD = 6.05$ ), with 7 women and 13 men.

However, differences between "experts" and "novices" were not limited to expertise. Experts were also older and they might represent a self-selected group with respect to an overall ability. Therefore, we deemed it necessary to select a matching group that would be similar to experts in terms of age and overall ability, while differing in the level of expertise. This matching group consisted of 16 graduate students in a History department at the same university who participated for a payment of ten dollars. This group had an average age of 29.93 years ( $SD = 4.67$ ), with 8 women and 8 men.

**Materials** Five features of arithmetic equations were used in Experiment 1. Two of these features were considered "principled properties", in that they represented deep, relational principles of mathematical operations: the associativity and commutativity principles. The former states that for addition, subtraction, and multiplication, constituent parts can be decomposed and recombined in different ways (e.g.,  $a + b = [a - c + c] + b$ ). The latter states that the order of elements is irrelevant for addition and multiplication (e.g.,  $a + b = b + a$ ). The other three features were nonprincipled surface features that occur in arithmetic equations: (1) digits (e.g., 6, 3); (2) sign (e.g., -, +); and (3) the number of constituent terms in an equation. The numerical solutions of equations were controlled for by making these solutions either all equal or all equivalently different for each trial.

A forced-choice similarity paradigm was used in this experiment. Participants were presented with three cards at a time, a target card and two test cards, each which had printed on it an arithmetic equation. Participants were instructed to match the problem on the target card to one of the test problems with which they believed it was most similar. Each of the two test problems shared one feature with the target problem, and differed on the feature that the target shared with the other test problem, with all other fea-

tures held constant. All five features were pitted directly against each other, with the exception of the two principled features, yielding a total of nine feature comparisons. For example, on one of the trial in which commutativity competed with digit, the Target problem was  $6 + 3 + 4 = 3 + 4 + 6$ , the digit test problem was  $6 + 3 + 8 = 3 + 4 + 10$ , and the commutativity test was  $7 + 2 + 8 = 8 + 2 + 7$ .

There were four exemplar arithmetic equations representing each of the nine comparison sets, resulting in a total of 36 trials presented to participants. The numbers used in the arithmetic equations ranged from 1 to 15, and the operations used included addition, subtraction, and multiplication.

**Procedure** All participants were run individually by a male experimenter into a small, quiet room. Participants were instructed that they would be presented with math problems for which they were to group together problems that were similar. A warm-up trial was used to acquaint participants with the task. For the warm-up trial, the participant was presented with cards containing Gelman and Markman’s (1986) blackbird-flamingo-bat figures. The target card, which depicted a blackbird that looked similarly to the bat and dissimilarly from the flamingo, was placed equidistantly below the flamingo and bat cards, which were the test items. The experimenter pointed to each of the two test items, and asked the participant “which of these is more like this,” after which the experimenter pointed to the target item. After participants chose one of the test items, the experimenter asked the participant “why did you choose that one?” After the participant’s verbal explanation (either based on physical similarity or the commonality of species), the experimenter pointed out that the other test item could have also been chosen based on the other attribute, and made the point that similarity can simultaneously occur across multiple dimensions. All participants showed understanding of this concept and of the task.

Four trials for each of the nine features-principle comparisons resulted in a total of 36 trials, which took approximately 30 minutes. Trial order was determined using a block randomization procedure. The positioning of the test items in relation to the target (i.e., left or right) was counterbalanced across comparison type.

## Results and Discussion

The main goal of this experiment was to examine participants’ knowledge of principles in question. To achieve this goal, we considered as choices indicating knowledge only those for which the participants’ explanation of the choice was consistent with the principle. This was done because participants could select principled test stimuli for a reason that might have nothing to do with the principle in question. Only explanations *directly* referring to the principle in questions were considered choice-consistent. The proportion of consistent choices for each principle is the dependent variable used in the forthcoming analyses.

The degree to which participants in each sample made explanation-consistent principled choices was analyzed using a one-way ANOVA for each principle across samples. Table 1 presents overall percentages of explanation-consistent prin-

cipled choices aggregated across trials by principles and age groups. The ANOVA for explanation-consistent associativity choices yielded a significant difference among the samples in the proportion of choices made,  $F(4, 92) = 30.72$ ,  $MSE = .07$ ,  $p < .001$ . The percentage of explanation-consistent associativity choices increases monotonically across the five samples. The ANOVA for explanation-consistent commutativity choices also indicated that there was a significant difference among the samples in the proportion of choices made,  $F(4, 92) = 23.61$ ,  $MSE = .08$ ,  $p < .001$ . As shown in Table 1, the percentage of explanation-consistent commutativity choices also increases monotonically across the five samples.

Table 1: Means and standard deviations (in parentheses) for percentage of explanation-consistent principled choices in Experiment 1.

Sample	Principle	
	Associativity	Commutativity
Younger children	0.00 (0.00)	0.00 (0.00)
Older children	2.08 (6.04)	9.03 (17.32)
Undergraduates	10.66 (26.15)	20.44 (30.71)
History grads	26.39 (38.89)	36.81 (35.54)
Math grads	80.00 (36.34)	77.22 (35.95)

Bonferroni post-hoc tests (with  $\alpha = .05$ ) were used to compare the mean proportion of explanation-consistent principled choices for each sample. These tests yielded identical patterns for both the associativity and commutativity principles, indicating that there were not significant differences in the proportion of explanation-consistent principled choices by younger children, older children, and undergraduates, that History graduate students made significantly more explanation-consistent principled choices than younger children, and that Mathematics graduate students made significantly more explanation-consistent principled choices than each of the other four samples.

Results from Experiment 1 point to several important regularities. First, experts were found to consistently represent principles when categorizing arithmetic equations, whereas novices were more likely to focus on surface features rather than on principles; even when novices did focus on principles, they did so inconsistently. Second, very few younger children exhibited knowledge of principles in question. Third, expert-novice differences were not limited to age or general intelligence: history graduate students and math experts, equally aged groups with similar levels of overall intelligence, exhibited large differences in using deep principled features. Thus the experiment allows us to eliminate the possibility that general ability or development account for expert-novice differences.

However, Experiment 1 left an important question unanswered: it remains unknown why many novices failed to focus on deep principled features. One possibility is that novices merely lack knowledge of these principles. A sec-

ond possibility is that surface elements are more available than deep relational features due to a more frequent use of the former. The goal of Experiment 2 is examine the two possibilities.

## Experiment 2

To accomplish the main goal of this experiment (i.e., to distinguish among the above mentioned possibilities), it was necessary to observe whether novices represent principled features when these features do not compete with surface elements. In the current study, then, participants were given a number of trials in which the target problem shared a principled feature with one of the test problems, and shared no unique surface features with the other test problem. We refer to these trials as “unmasked” since principled features are no longer attentionally “masked” by surface elements.

In addition, in the current experiment the “unmasked” trials are followed by “masked” trials equivalent to the trials in Experiment 1, in which the surface elements are reintroduced to compete with principled features in participants’ similarity judgments. This will enable the examination of the degree to which representations of principled features will be maintained, or whether the surface features will draw attention away from principled features, such that there is no transfer of representation due to the positive learning set. If the former is true, then it is expected that participants’ explanation-consistent principled choices will be more frequent for the subsequent “masked” trials than they were in Experiment 1; if the latter is true, then there should be no difference between the frequency of these choices.

If novices are more likely to make explanation-consistent principled choices in “unmasked” trials, it indicates that they have knowledge of the principles in question, thus undermining the lack of knowledge explanation. If novices are more likely to represent principles in “unmasked” trials but there is no transfer to “masked” trials, this finding would undermine the availability explanation.

## Method

**Participants** Three samples were selected for Experiment 2, each representing a different age group. Two of the groups, the “younger children” and the “older children” used the same participants from Experiment 1; Experiment 2 was conducted approximately four months after Experiment 1 for both samples. The third group of participants consisted of 19 undergraduates in an introductory psychology course at a large mid-western university who participated for course credit. This group had an average age of 21.79 years ( $SD = 6.49$ ), with 12 women and 7 men.

**Materials and Procedure** The same principled features (i.e., associativity and commutativity) and surface features (i.e., digit, sign, and number of elements) used in Experiment 1 were used in Experiment 2. The same nine comparisons used in the previous experiment were again used here for the last 27 trials (three trials for each of the nine comparisons). In addition, in the current experiment, the first

eight trials consisted of ‘unmasked’ comparisons, thus leading to a total of 35 trials.

For the “unmasked” trials, each of the two principled features (i.e., commutativity and associativity) was compared four times against ‘control’ problems. For these trials, the two test problems were equivalently similar to the target on nonprincipled features, while one test problem shared a principled feature with the target problem. For example, for an unmasked-commutativity trial, the target equation was  $2 + 6 + 8 = 6 + 8 + 2$ , the commutativity Test equation was  $11 + 1 + 5 = 5 + 1 + 11$ , and the control Test equation was  $3 + 9 + 5 = 12 + 4 + 1$ .

## Results and Discussion

We first analyze performance in “unmasked” and “masked” trials across the three groups of novices. For purposes of clarity, we will refer to “masked” trials in Experiment 1 as *Masked 1*, whereas “masked” trials in Experiment 2 will be referred to as *Masked 2*. Again, when analyzing performance, we will focus on the proportion of choices made by participants for only the trials in which mathematical principles were present, and we will consider only those choices for which the participants’ explanation of the choice was consistent with the principle. We first present the analyses of Unmasked and Masked 2 trials, followed by comparisons across Masked 1, Unmasked, and Masked 2 conditions.

The degree to which participants in each sample made explanation-consistent principled choices in the Unmasked comparisons was analyzed using a one-way ANOVA for each principle across the three samples. The ANOVAs for explanation-consistent associativity and commutativity choices revealed significant differences among the samples in the proportion of choices made,  $F_s(2, 51) > 5.42$ ,  $ps < .01$ . As evidenced in Table 2, the percentage of explanation-consistent principled choices increased monotonically with age.

Table 2: Means and standard deviations (in parentheses) for percentage of explanation-consistent principled choices in Experiment 2.

Sample	Trial Type	
	Unmasked	Masked 2
Associativity		
Younger Children	0.00 (0.00)	1.17 (5.10)
Older Children	20.31 (29.18)	6.94 (15.11)
Undergraduates	27.63 (36.22)	18.13 (27.27)
Commutativity		
Younger Children	15.79 (30.29)	1.75 (7.65)
Older Children	67.19 (29.89)	15.28 (22.18)
Undergraduates	90.79 (20.77)	35.09 (36.71)

Bonferroni post-hoc tests (with  $\alpha = .05$ ) were used to compare the mean proportion of explanation-consistent principled choices for Unmasked trials for each sample. For associativity trials, this test indicates only one statistically

significant difference among samples, that undergraduates made more explanation-consistent associativity choices than younger children. However, for commutativity trials, all between-sample comparisons were statistically significant. Aggregated across both principles, less than 10% of the younger children's responses were principle-based, while almost 50% of older children's responses and over 60% of undergraduate students' responses were principle-based.

It should be noted that there were large differences in the proportion of participants focusing on commutativity and associativity, with the former being greater than the latter. However, even for associativity, where effects were smaller than for commutativity, around 50% of older children and undergraduates provided at least one explanation-consistent principled choice, thus exhibiting knowledge of the principle in question.

The degree to which participants in each sample made explanation-consistent principled choices in the Masked 2 comparisons was also analyzed using a one-way ANOVA for each principle across samples. The ANOVAs for explanation-consistent associativity and commutativity choices yielded a significant difference among the samples in the proportion of choices made,  $F_s(2, 51) > 4.1$ ,  $p_s < .05$ . Again, as evidenced in Table 2, the percentage of explanation-consistent principled choices increases monotonically with age.

Bonferroni post-hoc tests (with  $\alpha = .05$ ) were again used to compare the mean proportion of explanation-consistent principled choices for Masked 2 trials for each sample. For both principles, this test indicates only one statistically significant difference among samples that undergraduates made more explanation-consistent principled choices than did younger children. These data in conjunction with the results of the Unmasked condition suggest that even when participants knew the principle in question, they often focused on surface features.

Overall proportions of explanation-consistent principled choices in Masked 1, Unmasked, and Masked 2 trials aggregated across the principles and broken down by sample are presented in Figure 1. Participants' explanation-consistent principled choices on Unmasked trials generally increased in comparison to their choices on Masked 1 trials. Younger children gave more explanation-consistent commutativity choices for Unmasked trials than for Masked 1 trials ( $t = 2.27$ ,  $p < .05$ ), though there was not a significant difference in the amount of explanation-consistent associativity choices, which is due to a floor effect. Older children gave more explanation-consistent principled choices for Unmasked trials than for Masked 1 trials for both principles ( $t = 2.65$ ,  $p < .02$  for associativity, and  $t = 9.8$ ,  $p < .001$  for commutativity). Undergraduates gave more explanation-consistent commutativity choices for Unmasked trials than for Masked 1 trials ( $t = 8.59$ ,  $p < .001$ ), though there was a marginally significant difference in the amount of explanation-consistent associativity choices ( $t = 1.81$ ,  $p = .078$ ). These differences indicate that unmasking increased the proportion of principled choices in all samples.

Figure 1. Percentage of explanation-consistent principled choices for each sample for unmasked” and “masked” trials in Experiment 2, and “masked” trials in Experiment 1.

Participants' explanation-consistent principled choices on Masked 2 trials generally decreased in comparison to their choices on Unmasked trials. Younger children gave more explanation-consistent commutativity choices for Unmasked trials than for Masked 2 trials ( $t = 2.37$ ,  $p < .05$ ), though there was not a significant difference in the amount of explanation-consistent associativity choices, which is due to a floor effect. Older children gave more explanation-consistent principled choices for Unmasked trials than for Masked 2 trials for both principles ( $t = 2.74$ ,  $p < .02$  for associativity, and  $t = 8.15$ ,  $p < .001$  for commutativity). Undergraduates gave more explanation-consistent commutativity choices for Unmasked trials than for Masked 2 trials ( $t = 7.23$ ,  $p < .001$ ), though there was a marginally significant difference in the amount of explanation-consistent associativity choices ( $t = 1.81$ ,  $p = .078$ ). These differences indicate that there was not pure transfer of representations from Unmasked to Masked 2 trials: once principled features had to compete again with surface features, the number of explanation-consistent principled choices decreased markedly.

An important question is whether the transfer led to a significant increase of explanation-consistent principled choices compared to when participants were never exposed to Unmasked trials. That is, whether being exposed to a positive learning set significantly increased subsequent attention to principles. To answer this question, we compared participants' explanation-consistent principled choices on the Masked 1 and Masked 2 trials. While the proportions of explanation-consistent principled choices are somewhat larger for each sample and each principle on Masked 2 trials than for Masked 1 trials (as evidenced in Figure 3), t-tests for each comparison revealed that none of these differences are statistically significant. Thus, the positive learning set of the Unmasked trials had a nonsignificant effect on the degree to which participants represented principled features of mathematics problems.

Overall, results of Experiment 2 indicate that 94% of the middle school participants and 100% of the undergraduate participants exhibited knowledge of principles in question

(i.e., provided an explanation-consistent principled choice on at least one trial), focusing on these principles in Unmasked trials. This finding severely undermines the lack of knowledge explanation. At the same time, the increase in younger children's principled choices due to "unmasking" was rather small, which points to a lack of knowledge. However, even in the two older groups, once nonprincipled features were reintroduced, representation of principled properties attenuated to levels similar to Experiment 1, a finding that undermines the availability explanation.

## Conclusion

The results of the two reported experiments establish a difference in the content of expert and novice representations for arithmetic problems. These results suggest that the observed differences do not stem from a lack of knowledge of deep principles by novices. The results further suggest that differences in content of problem representations in experts and novices may stem from different processing mechanisms underlying the construal of problem representations in experts and novices. The research presented in Part 2 will focus the examination of the processes of construal of problem representations by expert and novices.

# Accentuation of category differences: Revisiting a classic study

Janet K. Andrews (andrewsj@vassar.edu)  
Kenneth R. Livingston (livingst@vassar.edu)  
Vassar College Program in Cognitive Science  
124 Raymond Avenue, Poughkeepsie, NY 12604 USA

## Background

In 1963, Tajfel and Wilkes reported a study using as stimuli simple lines that were either unlabeled or were labeled with a letter A or B. Participants simply estimated how long the lines were, and the dramatic finding was that when the attachment of letter labels was systematically related to line length, such that A essentially meant "short" and B "long," participants significantly overestimated the difference between the longest A line and the shortest B line. This effect came to be known as the accentuation of intercategory difference, and Tajfel and Wilkes (1963) proposed that this basic cognitive/perceptual bias could explain the exaggeration of perceived differences between members of different social groups, thereby explaining an aspect of stereotyping. In the decades since the Tajfel and Wilkes (1963) study an extensive body of cognitive social psychology has been built on their results.

There is, however, reason to be doubtful of the strength of Tajfel and Wilkes' original findings. Recent research in the literature on basic perceptual and cognitive processes has also been exploring the operation of effects like those that Tajfel and Wilkes described as accentuation (e.g., Goldstone, 1994; Livingston, Andrews, and Harnad, 1998). One of the discoveries from this work is that it is extraordinarily difficult to demonstrate such effects when stimuli vary in only one dimension, a conclusion that seems to apply specifically to the case of lines varying only in length.

We think that Tajfel and Wilkes' results are consistent with an alternative explanation based on the demand characteristics of the task situation, rather than genuinely altered perceptual processing. In particular, when a category distinction is imposed on a continuous variation in the stimuli, it may have the effect of telling participants that they are supposed to treat within-category items as more similar or even as identical. While this is a real effect of category information on judgment, it is very different from the kind of basic, perceptual, and essentially involuntary process that these accentuation results have been taken to represent. We believe that it is very important to determine which interpretation of these line-length accentuation effects is correct. We therefore performed a series of studies intended to clarify the status of Tajfel and Wilkes' classic and much-cited results.

## Experiments and Results

Three replications of the Tajfel and Wilkes study were done, two using their original procedures with lines drawn on cards (Experiments 1 and 3), and one using computerized

presentation (Experiment 2). Experiment 1 produced results very similar to those of Tajfel and Wilkes, namely, a statistically significant overestimation of the difference in length between the longest A line and the shortest B line. However, surprisingly, Experiments 2 and 3 produced no such effects, but instead, accurate line length estimates across all stimuli. A re-examination of the data from Experiment 1 revealed that the group results were due to a very small subset of participants giving *identical* length estimates of the four lines in each labeled class. When their data were removed, the Tajfel and Wilkes' accentuation effect completely disappeared. Line length estimation was essentially accurate whether the lines were labeled or not.

## Conclusion

We believe that our results show that the original finding of intercategory difference accentuation reported by Tajfel and Wilkes is both extremely fragile and almost certainly the result of demand characteristics rather than altered perception of stimuli. This raises the question of how to interpret the accentuation effects found in the many studies using explicitly social stimuli that came after Tajfel and Wilkes. It is possible that these, too, reflect demand characteristics. However, they may be reflecting processes similar to those that produce real effects of categorization on the perception of nonsocial multidimensional stimuli. Work by Goldstone (1994), Livingston et al. (1998), and others has demonstrated both accentuation of intercategory differences and accentuation of intracategory similarity, but only with *multidimensional* stimuli and only when the categories require *learning* (as opposed to the simple attachment of labels to known categories, as in Tajfel and Wilkes). This suggests that it may be possible to explain social psychological accentuation effects in terms of more basic perceptual/cognitive processes after all, a possibility that further research can and should examine more fully.

# Training and Transfer of Foreign Word Identification at Three Speeds

**Anita R. Bowles** (bowlesa@psych.colorado.edu)

Department of Psychology, Campus Box 345, University of Colorado, Boulder, CO 80309-0345

**Alice F. Healy** (ahealy@psych.colorado.edu)

Department of Psychology, Campus Box 345, University of Colorado, Boulder, CO 80309-0345

It is unclear whether slowing one's speech rate when talking to foreign language students improves their comprehension and ability to segment spoken input into separate words. Although some studies have found that slowed speech facilitates understanding (Flaherty, 1979), others showed either no effect (Blau, 1990) or an effect only for beginning foreign language students (Griffiths, 1992). The current series of experiments adds to this literature by examining the relationship between speech rate and beginning learners' foreign word identification in sentences.

## Method

### Subjects

In Experiment 1, 72 subjects participated; in both Experiments 2 and 3, 36 subjects participated. These subjects had no previous knowledge of Spanish; they were assigned to conditions in a pseudorandom order.

### Procedure

In each experiment, during training, subjects listened to 12 Spanish sentences containing words included in a beginning Spanish textbook pronounced by a native speaker. The sentences were presented one at a time through a computer. After each sentence was presented, the subjects attempted to type it and then received feedback in the form of the correctly spelled sentence. The sentences were presented in blocks of 12, with each subject trained for eight blocks.

In Experiment 1, subjects were assigned to one of four training lists. One third of the subjects given each list trained with sentences presented at a normal conversational rate (145 words per minute). Another third trained on sentences slowed to 104 wpm. The last third trained on speeded sentences presented at 203 wpm. SoundEdit software was used to expand or compress the normal speech used for the medium speed to create stimuli at the slow and fast speeds. Subjects were then tested on 48 Spanish sentences (the 12 sentences in each of the four training lists). One third of the sentences from each list were presented at the slow speed, one third at the medium speed, and the last third at the fast speed.

In Experiments 2 and 3, only two of the lists were used at training, but all four lists were used at test. Three slower speeds were used (70, 97, and 134 wpm). The stimuli in these experiments were produced at all three speeds by the native speaker. No computer expansion or compression was used. In Experiment 2, before the beginning of training, half of the subjects were given visual pretraining on the spelling

of the Spanish words in their training list, and half received no pretraining. During pretraining, subjects saw each word and copied it three times. In Experiment 3, half of the subjects were given visual pretraining, and half were given both visual pretraining and auditory pretraining on the sound of the words in isolation.

## Results

Subjects in all three experiments who trained at the fast speed had a significantly lower proportion of correct responses during training than did subjects who trained at either the slow or medium speeds. There was also a main effect of testing speed, with subjects scoring worse for sentences tested at the fast speed than at the slow or medium speeds. Importantly, in Experiments 1 and 2, subjects trained at the fast speed did significantly worse at test than did those trained at the slow or medium speeds, but there was no difference between the slow and medium speed groups. In contrast, in Experiment 3 (in which all subjects received some form of pretraining), there was no effect of training speed on accuracy at test.

## Conclusions and Implications

These experiments show that words in rapid speech are difficult for beginning foreign language learners to identify within sentences. However, with pretraining on individual words, the negative effects of training at a rapid rate are reduced. More importantly, the results suggest that slowed speech is not better for word identification than is normal conversational speech, even for novice foreign language students. These findings imply that slowing speech is not necessary for beginning foreign language instruction.

# Temporal Tuning in the Acquisition of Cognitive Skill

Richard A. Carlson (racarlson@psu.edu)

Lisa M. Stevenson (lms152@psu.edu)

Department of Psychology, The Pennsylvania State University

University Park, PA 16802

Fluent cognitive performance depends on concurrent activation of appropriate representations of goals, procedures, and data. This observation is reflected in a number of current theories such as Anderson's ACT-R (Anderson & Lebiere, 1998). Together with the observation that part of the improvement with practice of many skills can be attributed to better coordination of actions with the environment (e.g., Neisser, 1992), this suggests what we call the *temporal tuning hypothesis*: As a consequence of practice, individuals will adjust the timing of their mental and information pickup activities so that the activation of information to be processed is optimally synchronized with ongoing mental activity. Previous research has demonstrated the learning of timing constraints in perceptual-motor (Dominey, 1998) and cognitive tasks (Carlson, Shin, & Wenger, 1994). We examined this hypothesis in three experiments in which participants performed computerized multiple-step arithmetic or spatial tasks.

We examined the possibility of temporal tuning by allowing subjects to control the pacing of their problem-solving performance by pressing keys to briefly display part of the information required for each step. Experiments 1 and 2 used a running arithmetic task in which subjects updated a total at each step. Subjects practiced solving 8-step problems for 10 blocks of 10 trials. In Experiment 1, operators for all steps were visible throughout each trial, and a new operand was displayed in response to a keypress at each step. In Experiment 2, both operator and operand appeared sequentially in response to the keypress. In both cases, the new information was displayed briefly, then masked. We manipulated constraints on timing by varying between subjects the delay between each keypress and the display of the available information. Delays ranged from 200 to 1100 ms. Experiment 3 used a spatial path-construction task with procedures and design similar to Experiment 2, to provide generality across task domains. In all experiments, we changed the timing constraints in final test blocks to verify that the practiced constraints had been learned.

If the structure of mental processes for performing each step allows temporal tuning, with practice subjects should learn to anticipate when they will be ready for the new information and request that information at a time that takes into account the delay. This would result in shorter keypress latencies with longer delays, measured from the onset of the information needed complete a step. Information requests might be initiated on a rhythmic basis, or on the basis of internal or external events that serve as process completion markers. If, on the other hand, participants must wait until a

step is completed to instantiate a goal for the following step, keypress latencies will not vary as a function of delay. This might be the case if, for example, problem-solving steps are realized by production rules with inaccessible internal structures.

In all three experiments, we found evidence of temporal tuning: With practice, subjects in conditions with longer delays learned to request information earlier than did those in conditions with shorter delays. When operators for all steps were continuously visible (Experiment 1), temporal tuning was more precise than when the operator for each step was displayed only on request (Experiments 2 and 3). For the arithmetic task, performance was also slower and less accurate when operators appeared step by step. This difference suggests constraints on the ability to anticipate and control the timing of mental activity. One possible constraint is that a goal based on the operator to be applied must be instantiated to initiate a procedure that provides a basis for anticipatory timing.

We consider alternative accounts of how temporal tuning might be accomplished. It appears that typical production-system models of cognitive skill would have to be extended to accommodate the phenomenon of temporal tuning. We consider the implications of this phenomenon for the role of on-line instantiation of goals in theories of cognitive skill.

# Hemispheric Effects in Fusiform Gyrus Across Face Encoding Tasks

Daniel J. Casasanto (dcasasan@mail.med.upenn.edu)

John A. Detre (detre@mail.med.upenn.edu)

Department of Neurology, University of Pennsylvania Medical Center  
3400 Spruce Street, Philadelphia, PA 19104 USA

## Introduction

Functional Magnetic Resonance Imaging (fMRI) was used to examine neuronal activation during two explicit face memory tasks. Numerous neuroimaging studies have shown bilateral activation of posterior temporal-occipital structures during processing of visually presented stimuli; preferential left-hemisphere activation has been associated with object processing, and preferential right-hemisphere activation has been associated with face processing (Sergent, 1995). Lesion studies suggest a special role for the right fusiform gyrus in the encoding of structural physiognomic information, an early stage of face processing (Sergent, 1993). It was hypothesized that intentional encoding of unfamiliar faces would be associated with preferential activation of right-hemisphere mesial temporal lobe structures, including the fusiform gyrus.

## Methods

### Task Design

For each of two face memory encoding tasks, healthy, right-handed volunteers viewed blocks of unfamiliar face photographs, alternating with blocks of a repeatedly presented pixelated control image (six 40s task/control blocks, 10 stimuli per block, 3.5s presentation, 0.5s ISI). Face stimuli were constructed from University of Pennsylvania ID card photographs. For the first task, full-head photographs were shown, including hair, neck, and upper shoulders. In some cases, clothing and jewelry were visible. For the second task, the same set of face photographs was used, but each photograph was cropped so as to include the brow, eyes, nose, and mouth, but exclude ears, hair, and any extraneous items. Two separate groups of six subjects were consecutively recruited for each of the two tasks. Subjects were instructed to remember the faces for a post-scan recognition test, and to attend the control images but not to memorize them. Scanning occurred during the encoding tasks but not during recognition testing.

## Image Acquisition and Processing

BOLD functional imaging data were collected at 1.5 Tesla in 20 contiguous 5mm axial slices, using a GE Signa EchoSpeed MRI scanner. Data were corrected for motion and static susceptibility-induced artifacts, and transformed into three-dimensional space. Using SPM 97 software, a statistical parametric map was constructed for each subject. Group activation maps were then constructed for each task using the SPMt Random Effects model. Activation exceeding a mapwise statistical threshold ( $\alpha=.05$ ) was quantified within the right and left fusiform gyri, and was compared using a hemispheric asymmetry ratio ( $AR=R-L/R+L$ ).

## Results

Suprathreshold activation was found bilaterally during both encoding tasks. Activation associated with encoding of full-head stimuli was slightly greater left than right ( $AR=-0.20$ ;  $Z=.91$ , *ns*). (See figure 1a.) Activation associated with encoding of cropped face stimuli was significantly greater right than left ( $AR=0.31$ ;  $Z=-2.45$ ,  $p<.05$ ). (See figure 1b.)

Figure 1a.

Figure 1b.

## Discussion

Cropped face encoding elicited the hypothesized preferential right-sided activation in the fusiform gyrus, while full-head encoding did not. One possible explanation for these findings is that the former task constrained subjects' encoding strategies to the visuospatial domain, while the latter task allowed verbal encoding of nameable objects, as well.

## Introduction

In his work on the perception of biological motion, Johansson found that people can readily detect a human figure in point-light displays — displays where the motion of human walkers is represented by lights corresponding to major human joints (Johansson, 1973). Following up on his work, researchers have examined a number of effects related to the perception of biological motion. Observers have been shown to accurately detect gender and identify specific types of motion, such as dancing. It appears that people have a special ability to detect upright human figures in these, and similar, displays. When such figures are inverted accuracy of figure identification and detection sharply declines (Bertenthal and Pinto, 1994). Inversion effects such as those found in humans have been found by Pinto and Shiffrar (1999) in some non-human animal displays (horses and dogs), but not others (birds). It has been hypothesized that the ability to detect upright humans and the inability to detect some animals and inverted humans can be linked to the human motor system. Observers walk, and the information provided by their own walking may help organize the complex motion patterns that are present in point-light displays. Another possibility is that experience provides an organizational framework for point-light displays. If this were so, previous findings that observers did not accurately identify non-human animals and showed no inversion effect might both be traced to a lack of pertinent experience. Most of the subjects who participated in these studies had had extensive experience observing and interacting with moving people; few had a comparable history of interaction with non-human animals. The current study examines the potential role of experience in the identification and detection of animal figures in masked point-light displays.

## Methods

To test the effect of experience on the perception of point-light animals, the performance of professional seal trainers was compared with that of professional dog trainers and naive subjects on detection of point-light seals, dogs and humans. Subjects included professional seal trainers from the Camden Aquarium in New Jersey, professional dog trainers from the Philadelphia area, and Temple University undergraduates. On average, seal trainers had been employed by the aquarium or a similar agency for 3 years and dog trainers had spent 4 years training dogs at the time of this study. Dog trainers had no professional experience with seals; 5 of the 7 seal trainers had dogs as pets, and one also worked as a professional dog trainer.

Displays were generated from a video segment of a seal, dog or human walking. Seals, dogs, and humans were marked with spots at homologous joints and then videotaped as they

moved from one place to another on land. A 2-second point-light display was generated for each animal. Subjects were presented with a signal-detection task, in which they were to determine the presence and absence of point-light humans, seals and dogs when presented within a set of masking points. Each species was presented upright and upside-down. Two levels of masking were used. Signal-present displays had either one masking point for each point on the animal or two masking points for each point on the animal. Signal-absent displays were generated by combining 2 or 3 sets of masking points so that they had the same number of elements as the corresponding signal-present display. Masking points were generated by randomly perturbing the spatial location and phase of each element in the display. Subjects were shown a target display where the stimulus was shown repeatedly over a period of 20 seconds without any masking elements. They were then asked to decide whether that target was present in each of the following 40 trials. Each subject completed one block of trials for each of the 12 conditions.

## Results and Discussion

All groups detected humans more accurately than seals or dogs. There was no overall effect of expertise, seal trainers were no better than the other subjects at detecting seals, and vice versa. All subjects showed an inversion effect for humans, but there was no inversion effect for familiar animals. If anything, the opposite of the anticipated effect was found—a small inversion effect was present for the less familiar animal (e.g., seal trainers were better at detecting right-side-up dogs than up-side-down dogs). These findings suggest that experience does not play a role in the grouping of complex motion in point-light displays. These results support an account of perception of point light displays that is based on some unique, perhaps structural, aspect of humans. They may reflect the use of a motor code to represent motion. Such a code, which might normally allow us to copy the movements of others, might also unify the elements of a point-light display.

# Familiarity and Categorical Inference

David Collister ([dc@psych.stanford.edu](mailto:dc@psych.stanford.edu))

Department of Psychology, Bldg. 420, Jordan Hall, Stanford University,  
Stanford, CA 94305-2130

Stanford, CA 94305-2130

Many if not most categories have internal structure in that more “central” category members evoke optimal responses across a number of measures, including “goodness-of-example” ratings, priming, category verification times, production frequencies, and rates of learning. A number of studies (Rips, 1975; Osherson, Smith, Wilkie, López, & Shafir, 1990; Sloman, 1993) have presented evidence that people rely on internal structure when making inferences about members of a category. Atypical category members are judged more likely to have the properties of typical members, rather than vice versa. Similar members are judged more likely to share a property than are dissimilar ones.

Based on this evidence, models of categorical inference have been proposed that assume 1) category structure is due the number of properties shared by members, and 2) categorical inference operates across these properties (e.g., Osherson, et al., 1990; Sloman, 1993). However, not all measures of category structure appear to be about shared properties. For example, verification times and production frequencies are more closely related to the availability and familiarity of members rather than what properties they have in common. Further, measures based on these different types of category structure are not perfectly correlated. Some members are more typical than they are familiar. Other have the reverse relationship. Thus, familiarity may be another source of category structure for inference to operate over - one based more on the frequency of occurrence rather than the number of shared properties.

Four experiments were conducted that examined the role of familiarity in categorical inference. In all experiments, participants were shown one-premise syllogisms about various category items, and asked to evaluate the likelihood that the syllogisms were true. Items were selected from a number of natural and artifact categories such that some items varied in familiarity within different levels of typicality, and others had the reverse relation. In addition, syllogisms were about “blank” properties to minimize participants’ reliance on background knowledge and maximize their reliance on category structure (see Osherson, et al., 1990). In experiments 1 & 2, an asymmetric effect of familiarity was found that was opposite the usual effect of typicality: Participants were less likely to make inferences from familiar rather than unfamiliar items (experiment 1), and more likely to make inferences to familiar rather than unfamiliar items (experiment 2). In a third experiment, the

effect of familiarity was diminished when participants were asked to explain why they thought some syllogisms were better than others. Further, almost every reason given for preferring one syllogism over another was one based on some similarity between items, even when the similarity was acknowledged to be negligible. In the final experiment, the availability of items was increased through repeated exposure. Effects paralleled that of familiarity: Participants preferences for syllogisms increased and decreased with the availability of the conclusion and premise items respectively. The pattern of results across the experiments suggest that categorical inference may be affected differently by analytic versus nonanalytic task demands (e.g., Whittlesea & Price, 1999). When allowed to evaluate syllogisms without analytic demands (i.e., without having to give explicit justifications) people may be influenced (at least partly) by the availability of the items. For example, the fluency of processing that accompanies both more available and more familiar items may be a general phenomenon that accompanies a number of different cognitive processes. In this case, participants may misattribute the feelings of fluency as arising from some other process relevant to the problem at hand, e.g., an estimate of the prior likelihood that the items in question share a property, etc. However, when asked to justify their inferences people have to at least report if not rely on strategies that are more easily identified. In this case, people may discount ‘free-floating’ feelings of fluency and instead look for describable properties and relations between items that they can use to justify a response.

# How Words Get Special

**Eliana Colunga** (ecolunga@cs.indiana.edu)  
Department of Computer Science; Lindley Hall 215  
Bloomington, IN 47408 USA

**Linda B. Smith** (smith4@indiana.edu)  
Department of Psychology; 1101 East Tenth Street  
Bloomington, IN 47405 USA

Words seem to have a special status among perceptual signals. Having a label for an object changes the way it is categorized for both adults and children. For example, when asked to generalize an object name to new instances, children and adults generalize by shape. However, when asked to find an object that “goes with” another, they choose by overall similarity. A label also makes children’s choices shift from thematic to taxonomic and from surface to more conceptual similarities.

Recent studies by Woodward and Hoyne (1999) and Namy and Waxman (1998) suggest that the power of words is not there at the beginning of development but rather that it emerges. At 13 months of age, babies seem willing to pair objects with any kind of signal, such as gestures and non-linguistic sounds. However, by 20 months of age children are more constrained in what they will take as a label, only taking words as labels for objects. This paper is concerned with how this special status of words develops. We propose that words get their special status by virtue of being systematically used for labeling categories. We present a connectionist model of this process and test a prediction that derives from the model.

## The Model

We use a simple settling network to model an abstract version of Woodward and Hoyne’s results. The network has an Auditory Signal Layer and a Visual Signal Layer connected through a Hidden Layer.

The training set consists of 20 “words” and their corresponding “objects”. The words are presented on the Auditory Signal Layer and the objects on the Visual Signal Layer. We assume words are drawn from a constrained space of the possible values of the auditory dimension. The training set is constructed by randomly generating “words” and their corresponding “objects”; the pairings of words to objects are, thus, arbitrary. At the start of learning, words (that is, input from the constrained portion of the auditory space) have no special status over other inputs that may be paired with objects. During training, the word and its corresponding object (plus noise) are presented together and weights are updated using Contrastive Hebbian Learning. So, during training individual objects are systematically paired with words and unsystematically paired with other auditory or visual inputs.

After the network has reached 90% accuracy in the training set, the network is trained on novel word—object pairs and novel non-word—object pairs. Like the older children in

Woodward & Hoyne (1999), the network shows an advantage when learning novel word-object pairs, that is when pairing objects to patterns in the Auditory Signal layer which are within the constrained space of words.

In this model, all that matters for achieving “special status” is the systematic pairing of objects with points in a constrained region of auditory space. Thus, any signal that correlates systematically with any feature becomes subsequently easily associated with it. Such systematic correlations do exist in the input to children, beyond words as labels for objects. For example, animals make sounds, so animals (animate features) should become easily associated with (animal-like) sounds. In the following experiment we test this prediction.

## The Experiment

This study follows Woodward and Hoyne’s procedure, except that the objects used are all unusual animal toys. Thirty-six 13 month-olds and thirty-six 20 month-olds were shown an animal and the animal was labeled for them. In the Word condition the object was labeled with a novel word (i.e. “Look! Dax See? Dax”). In the Animal Sound condition, the object was labeled with a non-linguistic vocal sound (i.e. “Look! Yeep yeep yeep See? Yeep yeep”). In the Arbitrary Sound condition a non-linguistic, non-vocal sound (i.e. a clap) was used instead. Between training trials, the babies were shown and allowed to play with toy animals that later served as distracters during the test phase.

During the test phase, children were presented with the target object and a distracter on a tray. The child was then asked, “Can you get the <label>?”. The baby’s choice was coded as the object that he or she removed from the tray.

The results show that while 13 month-olds in all three labeling conditions learn the label-animal correspondences, 20 month-olds only learn the associations in the Word and Animal Sound conditions. This result suggests that it is the systematicity of prior learned pairings that determine which associations will be formed.

This study continues previous work investigating the neural basis for grammatical and short-term memory components of sentence comprehension. We hypothesized that greater demands placed upon a third component, information processing speed in the form of a faster stimulus presentation rate, is shouldered by the caudate nucleus. To test this hypothesis, neural activity was measured with fMRI in 15 healthy, right-handed English-speakers as they determined the agent of the action in sentences with subject-relative (SR) or object-relative (OR) center-embedded clauses that included "short" (three-word) and "long" (seven-word) spans between the antecedent noun phrase (NP) and the "gap" where the NP is interpreted. These 13-word sentences were presented visually in a word-by-word fashion at 500 msec/word and 750 msec/word, the 500-msec rate requiring rapid information processing but the 750-msec rate requiring greater short-term memory.

Subjects were imaged on a 1.5T GE Echospeed scanner, and gradient echo echoplanar images were obtained to detect alterations in blood oxygenation (5mm slice thickness, effective TE 50msec, 64 x 40 matrix, voxel size of 3.75 x 3.75 x 5mm). The images were registered, aligned to Talairach space, smoothed with 8mm and 2.8sec Gaussian

kernels, and analyzed with SPM96 using appropriate protection for multiple comparisons.

Wernicke's area supported sentence comprehension of the four main sentence types (SR short, SR long, OR short, OR long), duplicating results from an earlier 7-subject study. In this study, left middle frontal cortex and left caudate were additionally recruited during OR sentences. Broca's area was additionally recruited during OR-long sentences, again confirming earlier results.

When words were presented at a rapid rate and short-term memory demand was minimized in the short antecedent-gap sentences, Wernicke's area and caudate were recruited. This was true for both SR and OR sentences. Long antecedent-gap sentences presented slowly to maximize short-term memory load revealed Wernicke's area but no caudate activity. This too was true for both SR and OR sentences. These observations support the hypothesis that the caudate contributes to sentence processing in the form of negotiating rapid information processing, not short-term memory demand, during sentence comprehension.

# Experimentally Uncovering Hidden Strata in English Phonology

Lisa Davidson (davidson@cogsci.jhu.edu)

Department of Cognitive Science, Johns Hopkins University  
3400 N. Charles St, Baltimore, MD 21218

## Introduction

The final state of the phonological grammar of a language *L* permits those structures that are legal in *L* and disallows those which are not. With respect to phonotactics, a possible assumption is that all consonant clusters prohibited by the phonology of *L* should be “equally illegal” for a speaker of *L*. However, several studies of the second language (L2) acquisition of consonant clusters have shown that not all clusters illegal in a speaker’s native language are equally difficult for learners acquiring a language with a different cluster inventory than their own (i.e. Broselow & Finer, 1991; Eckman & Iverson, 1993). Assuming that beginning L2 learners or naive speakers faced with foreign words use their native language grammars to produce these words, the graded performance on different consonant clusters sheds light on the nature of the final state of the native grammar. The present study uses an Optimality Theoretic (OT) approach (Prince & Smolensky, 1993) to examine the final state of a native speaker’s grammar and to account for this graded performance on clusters. New markedness constraints presented here that pertain to several different types of clusters are not only useful for characterizing speakers’ performance, but also for explaining consonant cluster typology more generally.

## Experiments 1 and 2

**Methods.** Previous research has explored minimal sonority distance (MSD) as a major factor affecting the differential acquisition of consonant clusters (Broselow and Finer, 1991; Eckman and Iverson, 1993; Hancin-Bhatt and Bhatt, 1998). Because English has an MSD of 1, it can be hypothesized that English speakers will have difficulty with clusters with an MSD of 0. Instead of using L2 learners, the present experiment examines the productions of native English speakers on Polish initial consonant clusters that have a sonority distance of 0 (SD 0) (/kt/,/kp/,/pt/,/č k/,/vz/), non-English clusters with an SD of 1 or more (SD 1) (/dv/,/vn/,/tʃ/,/zr/,/zm/) and English clusters with an SD of 1 or more (SD 1E) (/ʃr/,/ʃl/,/sm/,/sn/,/fr/). In experiment 1, subjects heard a pseudo-Polish word with one of the previous 15 clusters produced by a native speaker of Polish and then were told to read and memorize an English sentence containing a written version of the foreign word. The sentence then disappeared and the subjects repeated the sentence aloud. The subjects were explicitly instructed to pronounce the foreign words as they would if they were English words.

**Results.** A spectrogram of each target was examined to determine the response. An ANOVA showed that while subjects were significantly better on the English possible clusters than impossible clusters ( $p < .0001$ ), the distinction

between non-English clusters was not significant (SD 0: 33% correct, SD 1: 42% correct,  $p < .30$ ). It was concluded that SD cannot be the most important factor in determining the difficulty of clusters. A breakdown of subjects’ performance on individual clusters instead suggested the following groupings (from worst to best performance): A: /vn/,/vz/,/dv/ > B: /kt/,/kp/,/pt/,/č k/,/tʃ/ > C: /zm/,/zr/ > D: /ʃr/,/ʃl/,/sm/,/sn/,/fr/. Post-hoc comparisons indicated that each group was significantly different from every other.

Using a modification of the original procedure intended to minimize memory demands, experiment 2 successfully replicated experiment 1 (with the difference between groups B and C marginally significant,  $p < .12$ ).

## Discussion

An English phonological grammar that makes distinctions between different types of illegal clusters can be captured naturally within OT. In order to achieve graded performance, different markedness constraints must target each of the groups (A-D) of illegal clusters above. These rankings produce hidden strata that distinguish between increasing “foreignness” in nonnative words, much like the strata that correspond to decreasing nativization in loanwords (Itô & Mester, 1999). Native speakers are able to exploit the hidden rankings among these constraints by promoting faithfulness constraints to different points in the hierarchy when producing illegal clusters. Assuming that this movement is performed anew for every target, a speaker can exhibit performance that is not simply 0% or 100% on any given set of clusters. However, the fixed ranking of markedness constraints predicts that if a speaker can produce a more marked group of clusters (such as B) her performance on the less marked group (such as C) must be at least as good as or better. The relevant markedness constraints demonstrate that a universal, cross-linguistic account of consonant clusters must integrate sonority-like constraints with co-occurrence restrictions that employ non-sonority aspects such as place and cluster position.

## Introduction and Rationale

There is no question that on-going seizure activity in children has a debilitating effect on all aspects of cognitive development, including language (Dulac et al., 1996; OLeary et al., 1983; Rossi et al., 1996). Comparing the effect of left- versus right-temporal lobe origin seizures, Cohen (1992) reported the expected correlation between side and auditory/verbal vs visual/spatial memory in children with complex partial epilepsy. Furthermore, specific aspects of linguistic performance were shown to be differentially affected in children with simple-partial left hemisphere epilepsy (Cohen & Le Normand, 1998). Linguistic comprehension tested in this study gradually improved to reach normal performance levels while production remained quite poor in comparison with controls. A general conclusion drawn from these and other studies is that cognitive development in children with epilepsy is severely compromised in comparison to neurologically intact children.

It is thus surprising to find that the effect of seizure control in post-surgical patients and its relevance to improved cognitive and linguistic functioning remains an area of great controversy. A few studies report that seizure-free patients perform no better cognitively than their counterparts who continue to have seizures after surgery (Grande et al., 1997; Seidel et al., 1997). However, post-surgical seizure control and linguistic outcome have not been specifically explored to our knowledge, though some reports indicate that this relation is far from linear (Vargha-Khadem & Mishkin, 1997). It seems that seizure control by itself does not guarantee improved linguistic functioning in hemispherectomy patients. However, patients who become seizure-free after surgery performed early in life are asserted to demonstrate a better linguistic prognosis.

This is a preliminary report of a pilot study examining the validity of the latter claim and adding to the quantitative investigation of the effects of seizure control on language outcome by evaluating spoken language outcome as a function of seizure control,  
age of seizure onset, and  
seizure duration

in a large population of pediatric hemispherectomies.

## Methods

Subjects consisted of 42 patients who underwent hemispherectomy for intractable seizures at UCLA Medical Center. Age at onset of seizures: 0;0 – 11;0 years, age at surgery: 0;3 – 17;3 years, seizure duration: 0;3 – 14;1 years, post-surgical evaluation: no less than 5 years. Postoperative spoken language outcome was rated on the basis of free language samples from 0 – no language to 6 – fluent mature speaker.

## Results and Discussion

Based on the analysis of the entire population the following results were obtained: 1) age at seizure onset positively correlated with language outcome ( $p > 0.013$ ); 2) postsurgical seizure control positively or negatively correlated with language outcome in a statistically significant way ( $p > 0.0082$ ). Seizure duration did not reach statistical significance.

Although it is clear from this preliminary analysis that clinical variables related to seizure activity are relevant in predicting post-surgical cognitive outcome in hemispherectomy patients our major concern and intuition was that for many children in our sample the respective prediction would not prove accurate. Indeed, we have found that some children go on to develop language despite on-going seizures while other patients *with* seizure control remain without any language. We thus hypothesized that 1) post-surgical seizure control is just one measure of the integrity of the remaining hemisphere and cannot be approached without accounting for specific etiologies. As a result of this prediction variables of language outcome and seizure control are currently analyzed separately for the three major etiologies (cortical dysplasia, Rasmussen's encephalitis and infarct). 2) Different language outcomes in the patients without seizure control can be explained by differentiating between those seizures that result from a structural lesion in the remaining, presumably "healthy" hemisphere and seizures that result from functional damage sustained as a result of pre-surgical seizures/abnormal functioning from the removed hemisphere. To date our hypotheses have been confirmed.

# Compositional Functions in Nominal Combination

Zachary Estes (zcestes@princeton.edu)  
 Princeton University  
 Department of Psychology; Green Hall  
 Princeton, NJ 08544-1010 USA

Compositional functions are the cognitive processes by which two independent units of meaning are understood as a single compound meaning. For instance, some nominal combinations are interpreted attributively (e.g., ‘sponge memory’ as “a good, *absorptive* memory”), while others are interpreted relationally (e.g., ‘rodeo magazine’ as “a magazine *about* rodeos”). One question of recent interest is whether attributive combination is cognitively distinct from relational combination, or whether attribution is simply a *resembles* relation (e.g., ‘sponge memory’ as “a memory that *resembles* a sponge in some way”). If the two combination-types respond differently to the same manipulation, then one can infer that they are in fact distinct processes.

Attributive and relational combinations were preceded by prime combinations that either did or did not share the same attribution/relation in a sense-nonsense judgment task. In Experiment 1, the prime also shared either the modifier or the head concept with the target. In Experiment 2 there was no lexical overlap between prime and target. Experiment 3 tested whether priming of attributive combination was purely associative. All experiments also included an uninformative baseline prime. See Table 1.

Table 1: Sample stimuli, Experiments 1, 2 and 3.

Prime-type		
Experiment 1		
M-Consistent:	sponge towel	rodeo documentary
M-Inconsistent:	sponge nurse	rodeo clown
H-Consistent:	warehouse memory	motorcycle magazine
H-Inconsistent:	childhood memory	library magazine
Experiment 2		
Consistent:	warehouse mind	motorcycle documentary
M-Control:	warehouse guard	motorcycle gang
H-Control:	gutter mind	epic documentary
Experiment 3		
Consistent:	warehouse brain	
Reversed:	brain warehouse	
Inconsistent:	seesaw relationship	
Target:	sponge memory (attributive)	rodeo magazine (relational)

When the prime combination used the same attribution/relation and one of the same constituents as the target combination, then comprehension of that target was facilitated (see Figure 1). When there was no lexical overlap between prime and target, only attributive combination was

facilitated (see Figure 2). However, this facilitation for attributive combination was due to associative priming and did not generalize to other attributions (see Figure 3). Thus, although attributive combination may be more susceptible to associative priming than relational combination, the two compositional functions behaved similarly.

Figure 1: Priming of response times, Experiment 1.

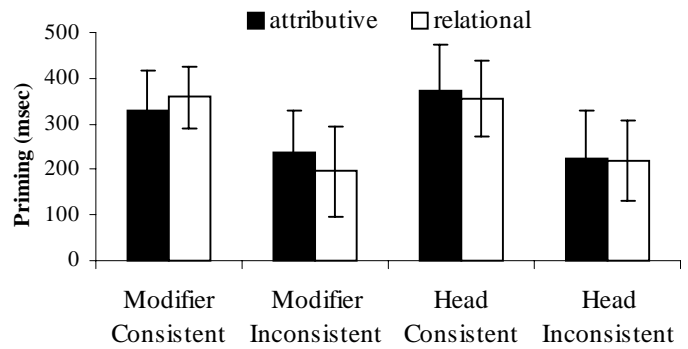

Figure 2: Priming of response times, Experiment 2.

Figure 3: Priming of response times, Experiment 3.

Any theory of face recognition must specify what is encoded in order for a face to be recognized at a later time. Theories of face recognition tend to highlight the importance of either individual feature encoding or holistic processing (see Valentine, 1988, for review). However, very little information is available about where exactly people look when processing a face. The current study examined the nature of eye movements in the learning and recognition of human faces. The goals of the study were twofold: (a) to determine where people look when learning and recognizing faces, and (b) to determine if fixation patterns change as a function of face inversion.

Sixteen participants studied 20 color photographs of faces for 10 seconds each in preparation for a recognition memory test. In the test phase all 20 previously viewed faces (familiar) and 20 novel faces (unfamiliar) were presented in pseudo-random order until the participant responded (mean response time = 2397 ms). Half of the familiar faces and half of the novel faces were presented in the upright orientation. The remaining faces were presented in the inverted orientation. Eye movements were recorded during both the study and test phases using a dual-Purkinje image eyetracker.

Mean percent correct was lower for inverted (66%) than for upright faces (79%),  $p < .05$ , suggesting that the participants were engaged in a representative face processing task.

During the study phase, 56% of total viewing time was spent fixating on the eyes, 18% on the nose, 12% on the mouth, and the remaining 13% on the rest of the face (ears, chin, cheeks, and forehead). Thus, fixating on the eyes is an important part of the face encoding process. Because the amount of total viewing time differed from the study to the test phase, viewing time on specific regions was compared as proportions of total viewing time. Overall, as Figure 1 shows, the proportion of total fixation time spent on facial features for the study and the test sessions was very similar. However, there were reliable differences in the proportion of total viewing time for the mouth and the ear features,  $p < .05$ . These findings suggest that similar features are chosen for analysis during both face learning and recognition. Figure 1 also shows that the familiarity and inversion manipulations produced very little change in the proportion

of time devoted to these selected features with only the mouth showing a reliable difference,  $p < .05$ .

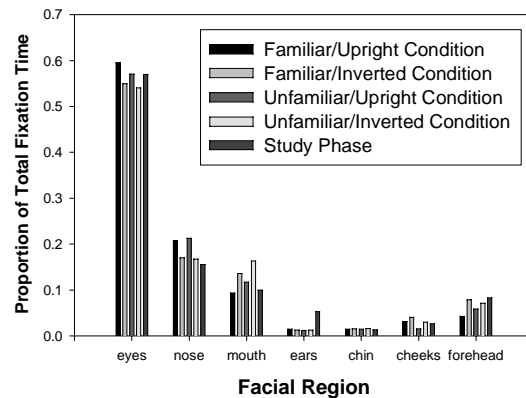

Figure 1: Proportion of total time in facial region for study condition and four test conditions.

If holistic processing is more likely with upright faces than inverted faces, we might expect less sampling of individual facial features in the former condition compared to the latter. Instead, the proportion of fixations on which the eyes moved from one facial region to a new region was not reliably different as a function of orientation (.84 upright, .81 inverted,  $F < 1$ ). Therefore, the decrement in recognition performance due to inversion does not appear to be a consequence of the differential sampling of facial features.

Overall, the results indicate: (a) that similar facial features are selected for analysis during face learning and recognition, and (b) that there is very little difference between the fixation patterns for upright and inverted faces.

## Abstract

There have been several investigations into the acquisition of passive constructions, most based on empirical data from English children. These have thrown up a variety of theories regarding the nature of the strategies underlying passive acquisition. However, is it reasonable to assume that in different languages children use the same strategies to learn the passives? Will passives in all languages demand the same cognitive skills from the language learner? Or, in each language will children show a different pattern of development?

Slobin (1981) states that in each type of language, children initially isolate and generalise basic sentence forms. According to Slobin, prototypical events and canonical sentence forms constitute a nucleus for the growth of language. For the purpose of the research reported here, it is important to specify the meaning of *basic sentence form*, *prototypical event* and *canonical sentence*. The former combines structural and typological characteristics, and will show some variation depending on the number of constituents requested by the verb as well as the frequency of a given structure in a language. The second is defined in conceptual terms, following Hopper & Thompson's (1980) Transitivity Hypothesis. A more prototypical transitive event will present two or more participants, an action, an actor high in potency, and an affected non-actor. Lastly, a canonical passive sentence resembles Givón's (1990) 'promotional passive' or Maratsos *et al.*'s (1985) 'typical passive', embodying three important features. First, a non-agent will be the pragmatic topic of the sentence, placed in the syntactic subject position. Second, the semantic agent will optionally appear in a special oblique case. Finally, an actional verb will be coded in a more stative form (be/get + past participle). We hypothesised that order of acquisition of sentences structures will follow Slobin's (1981) prediction: first children will acquire the more prototypical and basic sentence forms and only later will children be able to generalise to less prototypical sentence forms.

In order to investigate this hypothesis, two studies were designed, testing comprehension in four different types of active and passive sentences: more prototypical transitive scenes (irreversible, reversible) and less prototypical transitive scenes (dative and locative). Subjects from Study 1 are all monolingual English speakers residing in UK whereas subjects from Study 2 are all monolingual Portuguese speakers living in the south of Brazil. In both studies participants were children (aged 3 to 10) and adults. The results show a prototypicality effect on the acquisition of passives in both languages. More prototypical passive sentences as well as more prototypical actives were understood at younger ages than less prototypical sentences. This cross-linguistic similarity might indicate that the process of pattern formation is an important cognitive strategy for the language learner.

# Why Are Some Problems Easy? New Insights into the Tower of Hanoi

Glenn Gunzelmann (glenn@andrew.cmu.edu)  
Department of Psychology, Carnegie Mellon University  
Pittsburgh, PA 15213

Stephen Blessing (blessing@carnegielearning.com)  
Carnegie Learning, 372 N. Craig St., Suite 101  
Pittsburgh, PA 15213

## Introduction

Researchers have found large differences in difficulty and varying amounts of transfer among isomorphs of the Tower of Hanoi (Kotovsky, Hayes, & Simon, 1985; Hayes & Simon, 1977). Because the tasks have the same formal structure, these differences must result from the surface representations. To explain these findings, Kotovsky, et. al. pointed toward the ability to relate the rules to real-world knowledge and representation influence such as the externalization of rules (rules embedded in the external problem representation; also see Zhang, 1997).

Despite this research, many questions remain about the processes underlying problem solving and transfer of learning. This experiment uses standardized presentations of the isomorphs and presents more problems per participant than in past experiments. These manipulations should enhance transfer and help clarify findings that involve differential difficulty.

## Method

Participants were presented with 12 problems for each of three isomorphs of the Tower of Hanoi (the Standard Tower of Hanoi, Monster Move, and Paint Stripping; order of isomorphs was varied across participants) and two filler tasks. For each task, participants were presented with a description, a set of rules, and an explanation of the interface before beginning. They were instructed to solve each problem by reaching the goal presented on the screen. After solving all of the problems, participants were asked questions to determine how noticeable the relationships among the isomorphs were.

## Results and Discussion

The verbal reports were used to help determine what information may have transferred from the source isomorph to the target. While some participants claimed to notice a similarity, only 2 (of 37) were able to accurately describe it. Despite this lack of awareness, transfer of learning was clearly shown. Time to solve decreased across isomorph position,  $p < .01$  (Figure 1). Also, any of the isomorphs was sufficient to produce transfer. In addition, the degree of transfer was much greater than has been found previously, owing to the standardized interface as well as increased practice. Performance on the Tower of Hanoi was not facilitated by previous exposure to another isomorph (likely due to a floor effect; see Figure 1). These findings, combined with the lack of awareness about the similarities, suggest that more general procedural

knowledge (execution of general strategies) is largely responsible for the transfer. They also suggest that the Tower of Hanoi was relatively easy for participants to solve.

The comparison of isomorphs showed that the Monster Move isomorph was most difficult, followed by the Paint Stripping isomorph, with the standard Tower of Hanoi being the easiest,  $p < .001$ . Representational influences seem to drive this effect, with the rules for the Tower of Hanoi being largely inferable from the presentation. In contrast, all of the Monster Move rules need to be learned explicitly, while at least some of the Paint Stripping rules are not intuitive based solely on the presentation. These results suggest that the incorporation of problem constraints (rules) into the problem representation can reduce problem difficulty by reducing cognitive load. These results can be generalized beyond the simple problems used here, and suggest simple ways of achieving improved performance in virtually any task domain.

Figure 1. Average time (sec.) to solve problems for each of the isomorphs for each isomorph position.

# Stages of Phonological Processing in Spoken Production

Matthew Goldrick (goldrick@jhu.edu)  
Brenda Rapp (brenda@mail.cog.jhu.edu)  
Paul Smolensky (paul@mail.cog.jhu.edu)

Department of Cognitive Science, Johns Hopkins University, Baltimore MD 21218 USA

Processing theories of spoken word production have generally drawn a distinction between two general stages of phonological processing. The first stage (“lexical processing”) involves retrieval of stored phonological information specific to a particular lexical item. The second stage (“post-lexical processing”) transforms this information into a form which can be used to access subsequent processes for speech execution.

Investigations into impairments of these stages of processing (e.g. Kohn & Smith, 1994) have often proceeded by making representational and processing assumptions about each stage and using these assumptions to predict patterns of impaired performance following damage to each stage. This approach has not been unproblematic: there is widespread disagreement as to the nature of processing at each stage, preventing consistent interpretation of empirical results.

Here we report on results obtained using a different approach. We propose that picture naming tasks require the use of lexical phonological processing, while repetition tasks may bypass this stage by making use of non-lexical acoustic-to-phonological conversion procedures. This proposal predicts that damage to lexical processing will affect picture naming, as the task must access the lexical process, but it will not affect repetition, as this task can bypass the impaired process. In contrast, damage to post-lexical processing will impair both tasks equally, as both tasks must make use of this process. This method will allow us to more closely examine the characteristics of lexical and post-lexical phonological processing.

## Determination of Deficit Locus

BON is a 62 year old right handed woman who suffered a left hemisphere stroke affecting the superior posterior frontal and lateral parietal regions. CSS is a 62 year old right handed man who suffered a stroke affecting the parietal regions of the left hemisphere and the right basal ganglia. Their comprehension and articulation were normal.

Each subject was administered a common set of stimulus items in repetition and naming. Consistent with a post-lexical deficit, BON exhibited impaired performance in both naming (79% accuracy) and repetition (84%). The difference in performance was not significant. Consistent with a deficit to lexical phonological processing, CSS exhibited close to normal performance in repetition (96% accuracy), while being impaired in picture naming (87%). The accuracy difference between these tasks is significant.

All subsequent analyses examined performance on a larger set of items: picture naming performance for CSS (n=1680); and performance on all spoken output tasks for BON (n=851).

## Phonological Analyses

BON was significantly worse on low frequency (9.8% error) versus high frequency phonemes (5.6%); on dorsal segments (20.7%) versus coronal segments (8.5%); and on coda segments (8.7%) versus onset segments (2.5%). (The coda versus onset effect could not be attributed to segment frequency or place of articulation effects.) CSS exhibited none of these effects. This contrasting pattern of performance supports the approach and suggests that the post-lexical process is especially sensitive to the characteristics of phonemes. Subsequent analyses of her performance suggest the post-lexical process respects grammatical constraints and language-particular frequency.

## Lexical Analyses

Compared to BON, significantly fewer of CSS’s errors result in nonwords (57% of his errors are nonwords, compared to 70% for BON). This suggests the lexical process (unlike the post-lexical process) is biased to produce lexical items. Analysis of CSS’s whole word substitution errors suggests a definition of phonological neighborhood which, unlike other measures of density (e.g. Luce & Pisoni, 1998), does not require that neighbors share the target’s phonemes in the same position. Analyses including this density measure suggest effects of frequency, length and neighborhood density on his performance.

## Conclusion

Using task differences to determine the loci of phonological deficits is a fruitful approach. The results suggest that lexical processing involves lexically-guided retrieval of stored segmental information; this information is then used by the post-lexical process to construct a fully specified phonological representation.

University at Buffalo  
Buffalo, NY 14260 USA

How specific are infants' representations of words? Do words that sound similar to each other present any special difficulties, or benefits, in early lexical acquisition? That is, experience in encoding certain kinds of phonotactic sequences and metrical patterns could facilitate the acquisition of new word-to-world mappings (Jusczyk, 1997). Alternatively, competition from existing lexical items that share similar phonotactic and phonetic properties could also inhibit children's ability to encode a new item (see Luce & Pisoni, 1998; Marslen-Wilson, 1989; McClelland & Elman 1986; Norris, 1994). Thus, for example, children who know the word, "hat," could conceivably learn the word, "had," more quickly than a phonetically unrelated word because their experience with the "ha-" sound structure makes forming an acoustic package easier. On the other hand, competition from the "hat" representation, could make "had" very difficult to learn and inherently confusable with "hat."

Two studies are reported that examine infants' abilities both to detect the similarity among such "lexical neighbors," words that differ by a single phoneme, and to learn a referent for a novel neighbor after an exposure to a high number of these similar sounding words. In all studies, the lexical neighbors were constructed of CVC non-words that differed in the initial consonant, the vowel, or the final consonant of a prototype. All lists were controlled for word phonotactics, frequency, and their relation to English lexical neighborhoods.

In study 1, 15-month-old infants exhibited a novelty preference for a neighborhood prototype, after being familiarized in the head turn preference procedure with twelve lists of twelve neighbors. The mean looking time in seconds, with the standard error in parentheses, to the novel and prototypical words was 7.95 (0.52) and 6.70 (0.68), respectively. This suggests that, even by 15 months, infants are capable of detecting the neighborhood similarity among words.

In study 2, 17-month-olds were tested on their ability to learn the referent of two novel prototypes after being exposed to their respective lexical neighbors. In one condition, the high-density condition, six lists of twelve neighbors were

used. The low-density condition utilized six lists of three neighbors plus nine filler items. Results obtained with the intermodal preferential looking procedure indicated that word learning was significantly better in the low density condition, both in overall looking times and in infant reaction times to the targeted word. The mean difference in looking times between the target and non-target in the high- and low-density conditions was  $-0.14$  (0.14), and  $0.59$  (0.21) seconds, respectively.

Taken together, these results fit well with current models of spoken language recognition, many of which suggest a competitive effect for words arising from dense lexical neighborhoods. However, preliminary results from a control study seem to indicate that some exposure to a neighborhood may be better than no exposure at all. Thus, 17-month-old infants that were tested on their word learning ability after being exposed to twelve lists of only filler items performed worse than those from the low-density condition reported above did. This suggests that some exposure to lexical neighborhoods might facilitate and strengthen infants' ability to form a representation of the new word, while too much exposure might fatigue the system and/or introduce strong competitive effects.

# Modelling Language Acquisition at Multiple Temporal Scales

Steve R. Howell (showell@hypatia.psychology.mcmaster.ca)

Department of Psychology, McMaster University, 1280 Main Street West, Hamilton, Ontario, Canada

Suzanna Becker (becker@mcmaster.ca)

Department of Psychology, McMaster University, 1280 Main Street West, Hamilton, Ontario, Canada

The problem of incorporating time in a neural network is an important one. Networks with feedback, such as Simple Recurrent Networks (SRNs) (Elman, 1990) have been argued to represent time more realistically through its effects on the processing of input, compared to standard feedforward networks. In effect, SRNs' context units act as a memory, which incorporates a "smeared-out" representation of the network's internal states over time.

A problem does exist with this representation, however, especially for complex domains like that of language. The nature of argument agreement, embeddings and similar phenomena means that the SRN must be able to represent important past states (such as head noun for verb agreement) in spite of the declining effects of past context. While most word inputs will be related most strongly to words co-occurring close by in the input stream, verb agreement, for example, is largely determined by its corresponding noun, even in long, multiply-embedded sentences. SRN models should therefore be able to preserve representations of vital early structure for later use, in spite of the generally appropriate decline of short-term context. This issue has been addressed in an architectural fashion by others (Weckerly and Elman, 1992), but can perhaps be addressed more generally by allowing for more than one duration of context in an SRN's operation.

It is possible to apply the concept of hysteresis to the SRN's context units. That is, the update from the hidden units to the context units may be other than the usual 1-to-1 copying; the context units may also incorporate self-recurrent connections of varying strengths. In particular, we have been experimenting with SRNs using the hysteresis function suggested by Wermter, Arevian, and Panchev (1999) on the self-recurrent connections:

$$\text{Context}_i(t+1) = (1-\text{Hy}) * \text{Hidden}_i(t) + \text{Hy} * \text{Context}_i(t)$$

We have conducted initial experiments using a test corpus derived from the original simplified test corpus used by Elman (1990). Our version differs from the original in that it includes not only consonant to vowel relations, but also word-to-word relations. That is, some of the consonant-vowel combinations (words) can only occur immediately following others.

Thus in addition to the network needing to learn, for example, that u's only come after G's or U's (Guuu), it must also learn that Guuu only comes after Da. It is in this capacity that the hysteresis parameter should most come into play, for it specifies, in effect, the duration of retention

of the states of the context units. For short term letter to letter relations, small to zero hysteresis values should be adequate, as demonstrated originally by Elman's success. In that experiment, the network error declined consistently within a word, but jumped at word boundaries, representing the fact that word distribution was random in that corpus. In our experiments, manipulating the hysteresis parameters was expected to bias the network in favour of either short or long term relationships. Also, simulated annealing of the learning rate, another technique not typically used with SRNs, is used in both control and experimental networks. In pilot work this feature smoothed oscillations in the gradient descent of error.

The initial results of a number of simulation runs from different random initial conditions indicate that small hysteresis values (of other than 0) are indeed an advantage in learning this prediction task, with error per epoch declining noticeably, though not exceptionally, faster with  $0.2 > \text{Hys} > 0.1$ . Presumably this modest net gain is actually composed of both a larger gain for word-to-word relationships and a small decline for letter-to-letter prediction. Explorations of the exact nature of this advantage are underway, as is investigation of the best range of hysteresis parameters for various language tasks.

With the ability to change the hysteresis of context layers, it becomes useful to incorporate multiple hidden layers into an SRN (Wermter, 1999), with layers having a different 'span' of context via different hysteresis settings. We also describe a model with multiple hidden layers that is being applied to more complex language corpora, and is designed to be able to learn at multiple time scales simultaneously, by capturing longer-range temporal structure in progressively higher layers.

## Abstract

This experiment investigated how people use perceptual (i.e., axes of symmetry) and experience-dependent information (i.e., remembered possible target locations) to maintain location information in memory over short-term delays. Participants pointed to target locations on a tabletop following variable delays. Analyses of directional error indicated that location memory is repelled from axes of symmetry and attracted toward remembered possible target locations.

## Introduction

Previous experimental findings suggest that two factors produce systematic biases in location memory. First, remembered locations are repelled from axes of symmetry (McNamara, Hardy, & Hirtle, 1989), suggesting that people use symmetry axes to organize space into categories. Second, remembered locations are attracted toward an average or prototypical location within each category (e.g., Huttenlocher, Hedges, & Duncan, 1991; Huttenlocher, Newcombe, & Sandberg, 1994), suggesting that people use a longer-term memory of the *possible* target locations to facilitate memory. Generally, these two factors have been studied using tasks that require participants to remember many locations within task spaces with several symmetry axes. Thus, the factors that underlie memory biases often are confounded, making it difficult to determine whether biases are caused by two competing processes or one process.

Recently, Spencer and Hund (2000) used a simplified task to investigate how location memory biases change over short-term delays. Participants pointed to three remembered locations within a large, homogeneous task space following variable delays. Results indicated that responses were repelled from a midline axis of symmetry. Furthermore, these repulsion effects increased in magnitude over delay.

Here we extend these results to examine whether both factors—repulsion from symmetry axes and attraction toward remembered possible locations—influence how people maintain location information in memory. More specifically, we separated the possible target locations from the midline symmetry axis to determine whether location memory biases result from one or two memory processes.

## Method

Sixty right-handed adults participated. On each trial, 1 of 3 possible target locations appeared on a large tabletop. Following a variable delay, participants pointed to the remembered location. They received accuracy and timing feedback after each trial.

Targets were presented in different layouts relative to the midline axis of the task space (e.g.,  $-60^\circ$ ,  $-40^\circ$ ,  $-20^\circ$  v.  $20^\circ$ ,  $40^\circ$ ,  $60^\circ$ ) such that the mean of the possible target locations was not at midline. In addition, three bias conditions (no bias, bias left, bias right) were included to examine experience-dependent memory effects. Trials were divided evenly among the 3 possible targets in the no bias condition. In the bias conditions, 2/3 of all trials were to a biased target (left or right) and 1/3 of the trials were equally divided between the two remaining targets.

## Results

As reported in Spencer and Hund (2000), directional responses to all targets were biased away from midline. These repulsion effects increased systematically over delays. In addition to midline repulsion effects, participants' responses were biased away from the  $45^\circ$  diagonal symmetry axes when the targets were centered near these axes. Finally, biasing either the left or right target shifted participants' responses leftward or rightward, suggesting that they used a longer-term memory of possible target locations to remember the target location on each trial.

## Discussion

Data demonstrate that location memory biases result from two memory processes. Over short-term delays, memory is repelled from perceived axes of symmetry and attracted toward remembered possible target locations. In addition, data indicate that adults can select particular reference axes to facilitate memory. Future studies are needed to clarify the factors the influence reference axis selection and how experience-dependent effects are built-up over learning.

Certain word attributes have been demonstrated to be important determinants of speed of processing in lexical tasks (such as picture naming, recognition tasks). Traditional accounts of lexical tasks using words and pictures have held that the most important among these word attributes is word frequency. However, there are a number of studies that indicate that, in some lexical tasks, apparent frequency effects may be wholly or partly accounted for by word age-of-acquisition (AoA), or word-learning age (Carroll & White, 1973a; Morrison et al., 1995).

In the literature, the methods used to obtain AoA data can be broadly grouped into two. The first method is objective and relies on the data collected directly from vocabulary tests and parental reports of children's abilities (Walley & Metsala, 1992). The second method is subjective and involves researchers obtaining age-of-acquisition ratings from adults. This second method allows for easier data collection and has been used in several studies (Carroll & White, 1973a, 1973b; Morrison et al., 1997; Snodgrass et al., 1996). Such studies have suggested that adult ratings of word acquisition age are a reliable tool to measure real word learning age and are also a better predictor (as compared to frequency and familiarity ratings) of subjects' performance on certain lexical tasks such as picture naming and recognition. Until recently, most studies have collected these adult AoA ratings using off-line techniques and using a relatively small number of stimuli (words and/or pictures).

The present study is an on-line experiment where we examined the AoA phenomenon in 50 normal, monolingual adults using a larger set of stimuli (520 words and/or pictures). The basic task, adapted from Carroll and White (1973b), involves subjects rating each item presented on a computer screen, on a 9-point age scale (2, 3, 4, 5, 6, 7-8, 9-10, 11-12, 13+ years) marked on the keyboard. The subjects' rating

responses and time taken to make these decisions are recorded. Results are discussed with reference to previous AoA studies and developmental norms. These results confirm that AoA ratings are good predictors of real word-learning age, and may be better predictors of naming latencies when compared to existing frequency norms and familiarity ratings. These results also raise some interesting theoretical issues regarding what these AoA adult rating measures tap into and its relevance to lexical access. Researchers have not been able to truly understand why the adult ratings are an important variable. However, many have tried to explain the relative advantage of AoA ratings over other word attributes such as frequency and familiarity.

Fluent speech contains no reliable pauses between words. By 7.5 months infants can segment words from fluent speech. At this age infants rely most heavily on prosodic cues such as word initial stress and distributional cues such as the transitional probabilities between syllables (Saffran et al, 1996). During the second year of life, infants' word recognition abilities undergo considerable improvement. Finally, by the age of 24 months, infants appear to be approaching adult-like word recognition skills (see Jusczyk, 1999 for review).

Many adult word recognition models emphasize the importance of existing items in the lexicon for recovering words from fluent speech (see Brent, 1999 for review). A question that arises about these segmentation abilities has to do with how infants integrate information from different types of word boundary cues. For instance, Norris et al (1997) suggested that a Possible-Word Constraint (PWC) could ease word recognition by limiting the number of lexical candidates activated by a given input. This constraint requires that, whenever possible, the input should be parsed into a string of feasible words. Any segmentation resulting in impossible words (i.e. a single consonant) is impossible. Norris et al (1997) used a word spotting task to demonstrate that adults find words such as "apple" more easily in a possible condition (ie vuffapple) rather than in an impossible condition (fapple).

In the present study, we investigated whether or not 12-month-olds could use the PWC to aid them in word recognition. In Expt. 1, we exposed 32 infants to lists of 2 words: rush and lop or rack and win. After 30 seconds of familiarization to both words, the head-turn preference procedure was used to determine whether these words were easier to recognize in a possible as opposed to impossible condition. During the test phase, infants were presented with test lists containing the target words embedded within possible (i.e. nprush) or impossible (i.e. prush) conditions. Infants tested with targets in possible conditions listened significantly longer to the lists containing the targets words ( $p < .01$ ), whereas infants tested with lists containing targets in impossible conditions did not. This result suggests that

12-month-olds, like adults, may use existing knowledge about possible words to constrain their hypotheses concerning words in the input. Infants familiarized with the word "rush" did not recognize the word "rush" when it was buried within a container like "prush." This result fits with the PWC because positing that "rush" is contained within "prush" would leave a residue which cannot form a word on its own: the consonant "p."

Experiment 2 tests whether infants use PWC when processing fluent speech. Infants are familiarized with pairs of words (rest and low or rise and lay). However, in the test phase they hear passages rather than word lists. Half of the infants in each of these two conditions are being tested with passages containing the target words in a possible condition (i.e. "delay"), while the other half are being tested on passages containing the words in impossible conditions (i.e. "play"). Preliminary results suggest that infants will recognize the words when they are presented in a "possible" condition.

In addition to Expt. 2, we have been carrying out 2 additional studies similar to Expts. 1 and 2. However we have moved the target to the beginning of the filler rather than the end. For example, the target word dull has been buried in a possible container such as "dullkef" or an impossible container such as "dullk." In combination, these 4 studies provide some interesting evidence concerning the role of context on infants' ability to find words in fluent speech.

# Familiarity for Nouns and Verbs: Not the Same as, and Better than, Frequency

Natalie Kacinik (kacinn01@student.ucr.edu)  
Connie Shears (shearc01@student.ucr.edu)  
Christine Chiarello (christine.chiarello@ucr.edu)

University of California, Riverside

Riverside, CA 92521, U.S.A

Much of the study of language processing has centered on the single word recognition paradigm. Many cognitive theories regarding semantic memory have emerged from this research, and several lexical dimensions (i.e., imageability, frequency) have been found to influence the processing and recognition of nouns (Balota, Ferraro, and Connor, 1991). Indeed, efforts are typically made to balance word stimuli on factors such as length and frequency. However, the importance of different orthographic and semantic dimensions in determining the speed and accuracy with which words are responded to has not been extensively investigated. Moreover, most of this research has either not considered different word types (nouns vs. verbs), or has focused on concrete, imageable nouns, largely because of the lack of word norming corpora available for other word types.

Recently, new measures have been developed (Chiarello, Shears, & Lund, 1999) computing typicality of grammatical class (noun vs verb) and examining grammatical class differences in imageability and frequency, using established corpora such as Francis and Kucera (FK, 1982), as well as using the more contemporary Usenet corpus. While these semantic dimensions and word class comparisons have provided valuable tools for word recognition researchers, most studies have failed to consider word familiarity as an important determinant of speed and accuracy of responding (but see Gernsbacher, 1984, and Balota, Cortese, & Pilotti, 1999).

We report a series of regression analyses using data obtained from 2 lexical decision experiments and other corpora. We investigated the influence of variables identified in Chiarello et al. (1999) [i.e., imageability, length, noun-verb distributional distance (NVDD), FK and Usenet frequency, and recently collected familiarity ratings] on the speed and accuracy of lexical decision responses to nouns and verbs. Familiarity, measured on a 7 pt. scale, was defined as 'common in everyday experience'.

Overall, familiarity was found to be highly correlated with RT ( $r = -.70$ ,  $p < .001$ ), thereby accounting for nearly half of the variance. Although significantly correlated with imageability, NVDD, FK and Usenet frequency ( $r = .22$ ,  $.23$ ,  $.39$ , and  $.40$ , all  $ps < .005$ ), regression analyses indicated that much of the RT variance accounted for by familiarity was unique. The importance of these variables in predicting RT also varied by word class (nouns vs verbs). Specifically, familiarity, then frequency, and then imageability were found to be the most important predictors

of noun RT, whereas familiarity, then imageability, then frequency, and finally NVDD were found to be the most important predictors of verb RT.

In conclusion, our results support and extend Gernsbacher's (1984) earlier demonstration of familiarity as a powerful contributor to word recognition, possibly because it is a contemporary metric of actual encounters, related to the variety of contexts a word has been experienced in, and the ease with which individuals can recall those contexts (Audet & Burgess, 1999). Our findings indicate the need for researchers to consider the importance of processing differences based on *the familiarity of stimuli to the subject population* (i.e., controlling only for frequency and imageability may not be enough). Finally, we also demonstrate the need for researchers to carefully consider the issue of word class, as different dimensions appear to be more or less important for the processing of nouns and verbs.

# Random Indexing of Text Samples for Latent Semantic Analysis

Pentti Kanerva Jan Kristoferson Anders Holst

kanerva@sics.se, janke@sics.se, aho@sics.se

RWCP Theoretical Foundation SICS Laboratory

Swedish Institute of Computer Science, Box 1263, SE-16429 Kista, Sweden

Latent Semantic Analysis is a method of computing high-dimensional semantic vectors, or context vectors, for words from their co-occurrence statistics. An experiment by Landauer & Dumais (1997) covers a vocabulary of 60,000 words (unique letter strings delimited by word-space characters) in 30,000 contexts (text samples or “documents” of about 150 words each). The data are first collected into a  $60,000 \times 30,000$  words-by-contexts co-occurrence matrix, with each row representing a word and each column representing a text sample so that each entry gives the frequency of a given word in a given text sample. The frequencies are normalized, and the normalized matrix is transformed with Singular-Value Decomposition (SVD) reducing its original 30,000 document dimensions into a much smaller number of latent dimensions, 300 proving to be optimal. Thus words are represented by 300-dimensional semantic vectors.

The point in all of this is that the vectors capture meaning. Landauer and Dumais demonstrate it with a synonym test called TOEFL (for “Test Of English as a Foreign Language”). For each test word, four alternatives are given, and the “contestant” is asked to find the one that’s the most synonymous. Choosing at random would yield 25% correct. However, when the semantic vector for the test word is compared to the semantic vectors for the four alternatives, it correlates most highly with the correct alternative in 64% of the cases. However, when the same test is based on the 30,000-dimensional vectors before SVD, the result is not nearly as good: only 36% correct. The authors conclude that the reorganization of information by SVD somehow corresponds to human psychology.

We have studied high-dimensional random distributed representations, as models of brainlike representation of information (Kanerva, 1994; Kanerva & Sjödin, 1999). In this poster we report on the use of such a representation to reduce the dimensionality of the original words-by-contexts matrix. The method can be explained by looking at the  $60,000 \times 30,000$  matrix of frequencies above. Assume that each text sample is represented by a 30,000-bit vector with a single 1 marking the place of the sample in a list of all samples, and call it the sample’s *index vector* (i.e., the  $n$ th bit of the index vector for the  $n$ th text sample is 1—the representation is unitary or local). Then the words-by-contexts matrix of frequencies can be gotten by the following procedure: every time that the word  $w$  occurs in the  $n$ th text sample, the  $n$ th index vector is added to the row for the word  $w$ .

We use the same procedure for accumulating a words-by-contexts matrix, except that the index vectors are not unitary. A text-sample’s index vector is “small” by comparison—we have used 1,800-dimensional index

vectors—and it has several randomly placed  $-1$ s and  $1$ s, with the rest 0s (e.g., four each of  $-1$  and  $1$ , or eight non-0s in 1,800, instead of one non-0 in 30,000 as above). Thus, we would accumulate the same data into a  $60,000 \times 1,800$  words-by-contexts matrix instead of  $60,000 \times 30,000$ .

Our method has been verified with different data, a ten-million-word “TASA” corpus consisting of a 79,000-word vocabulary (when words are truncated after the 8th character) in 37,600 text samples. The data were accumulated into a  $79,000 \times 1,800$  words-by-contexts matrix, which was normalized by thresholding into a matrix of  $-1$ s, 0s, and  $1$ s. The unnormalized 1,800-dimensional context vectors gave 35–44% correct in the TOEFL test and the normalized ones gave 48–51% correct, which correspond to Landauer & Dumais’ 36% for their normalized 30,000-dimensional vectors before SVD, for a different corpus (see above). Our words-by-contexts matrix can be transformed further, for example with SVD as in LSA, except that the matrix is much smaller.

Mathematically, the 30,000- or 37,600-dimensional index vectors are orthogonal, whereas the 1,800-dimensional ones are only nearly orthogonal. They seem to work just as well, in addition to which they are more “brainlike” and less affected by the number of text samples (1,800-dimensional index vectors can cover a wide-ranging number of text samples). We have used such vectors also to index words in narrow context windows, getting 62–70% correct, and conclude that random indexing deserves to be studied and understood more fully.

**Acknowledgments.** This research is supported by Japan’s Ministry of International Trade and Industry (MITI) under the Real World Computing Partnership (RWCP) program. The TASA corpus and 80 TOEFL test items were made available to us by courtesy of Professor Thomas Landauer, University of Colorado.

# Auditory and Visual Continuity Perception: A Unifying Theory

Leah M. Knightly (leah@psych.ucla.edu)  
UCLA Department of Psychology; Box 951563  
Los Angeles, CA 90095-1563 USA

## Introduction

Researchers in the field of auditory and visual perception have been intrigued by our ability to unify partially occluded objects (Shipley & Kellman, 1992; Kellman & Shipley, 1991) and partially masked sounds (Dannenbring, 1976; Ciocca & Bregman, 1987). In vision, an object may be partially occluded by another object yet we may perceive the object as continuing behind the occluder. In audition, sounds may be partially masked by another sound, yet we may hear the sound as continuing through the mask. Though these phenomena are considered to be analogous (Bregman, 1990), separate theories exist to predict the conditions under which continuity perception occurs in vision (Relatability Theory - Kellman & Shipley, 1991) and audition (Frequency Proximity and Trajectory principle - Ciocca & Bregman, 1987). The purpose of this paper is to propose that the conditions under which continuity perception occurs for edges and tones may be predicted by one theory. This theory, introduced here and inspired by Relatability Theory, is called "Continuity Theory Audio-Visual (AV)."

## Continuity Theory (AV)

Continuity Theory (AV) predicts that a partially occluded stimulus will be perceived as continuing behind an obstruction if the linear extensions of the stimulus on either side of the obstruction meet within the bounds of the obstruction. For the visual domain, this means that an edge partially covered by an occluder will be perceived as continuing behind the occluder if the linear extensions of the edges meet within the area occupied by the occluder. For the auditory domain, this means that a tone partially masked by a noise burst will be perceived as continuing through the noise burst if the linear extensions of the pre and post-noise frequencies meet within the duration of the mask.

Evidence that Continuity Theory (AV) can predict the conditions under which edges and tones are perceived as continuous is provided through a critical analysis of the results obtained in two studies – Shipley & Kellman (1992) on unit formation in vision and Ciocca & Bregman (1987) on perception of tones through noise. In Shipley & Kellman (1992) participants perceived partially occluded figures as unified if the linear extensions of their edges met within the bounds of relatability (see Kellman & Shipley, 1991 for details). In Ciocca & Bregman (1987) listeners perceived sounds as continuing through a burst of noise depending on

the frequency and trajectory (i.e. linear extension) of the pre and post-noise tones. Close examination of the results from these two studies reveals that one theory is sufficient to describe the conditions under which continuity perception occurred. This theory is Continuity Theory (AV). The advantage of the theory is it can account for the results obtained in vision and audition. In addition, the theory includes size/duration of the occluder/mask as a factor in unit formation, a variable not incorporated in other theories of continuity (Kellman & Shipley, 1992; Ciocca & Bregman, 1987) yet considered to be important in continuity perception (Vicario, 1982).

## Future Directions

In summary, Continuity Theory (AV) provides a simple and general cross-modal rule that predicts continuity perception for those conditions tested in Shipley & Kellman (1992) and Ciocca & Bregman (1987). Future work should involve testing Continuity Theory (AV) for those conditions not examined in Shipley & Kellman (1992) (i.e. when linear extensions meet at an angle  $< 90^\circ$ ) and in Ciocca and Bregman (1987) (i.e. when linear extensions meet at an angle  $> 90^\circ$ ).

# The Role of Working Memory in Homograph Recognition

Yuki Kobayashi (yukikoba@srt.l.u-tokyo.ac.jp)

Department of Psychology, University of Tokyo; 7-3-1 Hongo Bunkyo-ku  
Tokyo, 1130033 Japan

Recognition of homographs is usually assumed to consist of two process stages: automatic access to mental lexicon and inhibition of meanings irrelevant to context (Miyake et al., 1994). Working memory is related to the inhibition: Kobayashi and Takano (1999) showed that readers with larger working memory capacity can inhibit irrelevant meanings faster than those with smaller capacity. The homographs used in the study had only two major meanings. The number of meanings can effect to recognition of homographs. I predicted that readers with larger working memory capacity cannot inhibit when the number of meanings increases more than two meanings.

## Method

### Subjects

The subjects were 29 undergraduates from the University of Tokyo. All were native speakers of Japanese.

### Materials

**Lexical Decision Task** Fifteen homographs were selected as first primes. Five homographs each had four major meanings, and ten each had two major meanings. They were all written in *kana* (i.e., Japanese phonogram). Targets were these homographs written in *kanji* (i.e., Chinese ideogram). Second prime was a pair of *kanji* related to the target in meanings (consistent condition), an asterisk (neutral condition), and a pair of *kanji* related to another target in meanings (inconsistent condition).

**Japanese Reading Span Test** We used Osaka and Osaka's (1994) Japanese version of the test.

### Design

The independent variables were consistency (consistent vs. neutral vs. inconsistent) and number of irrelevant meanings (three vs. one). I examined reading span scores as a pseudo-independent variable, too. The dependent measure was RT for targets.

### Procedure

**Japanese reading span test** Osaka and Osaka's (1994) test was administered.

**Lexical Decision Task** After a fixation point was presented for 1s, first prime, second prime and target were presented successively. The SOA of primes was 500ms. Subjects were requested to judge whether the target was word or non-word as accurately and quickly as possible.

## Results and Discussion

Subjects with reading spans of 3.0 or greater were considered to be high-span readers; those with spans of 2.5 or less, to be low-span readers.

The main results are presented in Figure 1. High span readers took longer time in inconsistent condition than in neutral condition, whereas low span readers showed no significant difference between neutral condition and inconsistent condition (Figure 1). The number of meanings had no significant interaction with consistency and reading span. High-span readers could inhibit irrelevant meanings though meanings increased, whereas low-span readers couldn't even inhibit one irrelevant meaning. We conclude that the number of meanings didn't effect to inhibition in working memory.

Figure 1: Reaction time of low span readers and high span readers.

# Attentional Perseveration after the Inverse Base–Rate Effect

John K. Kruschke, Mark K. Johansen, and Nathaniel J. Blair

kruschke@indiana.edu, mjohanse@indiana.edu, nblair@indiana.edu

Department of Psychology; Indiana University

Bloomington, IN USA 47405-7007

We report new results that demonstrate that selective attention to features is learned in the inverse base-rate effect. The inverse base-rate effect (Medin & Edelson, 1988) is found after participants have learned categories with different base rates (frequencies of occurrence). When tested with conflicting cues, participants tended to non-normatively respond with the low frequency category, suggesting that they were ignoring base-rate information.

The top of Table 1 (Training 1) shows the category structure for producing the inverse base-rate effect in disease diagnosis. The common diseases (C1 and C2) occur three times more frequently than the rare diseases (R1 and R2). One symptom (I1 or I2) is shared by two diseases and is an imperfect predictor. The other symptoms are perfect predictors, that is, they are associated with one and only one disease. In the testing phase (in the middle of Table 1) when shown I1 alone, participants tended to respond with C1. But, when tested with PC1&PR1 simultaneously participants tended to respond R1. The normative response, however, would have been to use the 3:1 base–rate information and respond C1.

Kruschke (1996) hypothesized that the inverse base-rate effect occurs because participants rapidly shift attention to reduce error while learning. Specifically he argued that participants tend to learn C1 before R1 because it occurs more frequently, and encode C1 in terms of both I1 and PC1. When subsequently learning R1, participants shift attention away from I1 and toward PR1 to avoid incorrectly responding with C1 and to protect what they have already learned about C1. Hence R1 tends to be encoded primarily in terms of PR1. Kruschke (1996) formalized this hypothesis in a connectionist model called ADIT which provides an extremely accurate account of the inverse base-rate effect data.

If the attentional account of the inverse base-rate effect is correct, it suggests that attention to the symptoms should *perseverate* into a subsequent learning task. To test this hypothesis, we added two different conditions after the test phase (the bottom of Table 1). The first condition (Training 2: “EASY”) was designed to be easy to learn because PR is relevant for correct diagnosis, just as in previous training. This should have been easy because subjects should have already learned to shift attention away from I1 and toward PR1 (or away from I2 and toward PR2).

The second condition (Training 2: “HARD”) was designed to be hard to learn because PR is irrelevant, unlike previous training. This should have been hard because while subjects should have previously learned to attend to PR1 (and

Table 1: Design of the experiment

Training 1:	I1&PC1 → C1 (3×)	I2&PC2 → C2 (3×)
	I1&PR1 → R1 (1×)	I2&PR2 → R2 (1×)
Testing:	I1? (→ C1)	PC1&PR1? (→ R1)
	I2? (→ C2)	PC2&PR2? (→ R2)
Training 2:	EASY: <b>PR</b> is relevant	HARD: <b>I</b> is relevant
	I1&PR1 → R1	I1&PR1 → R1
	I2&PR1 → R1	I2&PR1 → R2
	I1&PR2 → R2	I1&PR2 → R1
	I2&PR2 → R2	I2&PR2 → R2

PR2) and ignore I1 (and I2), I1 and I2 now were essential to learning the new diagnoses.

Participants learned the “EASY” condition in phase II significantly faster than they learned the “HARD” condition. These results, along with others involving I and PC, support our hypothesis that learned attention to features perseverates into later learning. These results cannot be explained by an eliminative inference account, such as that presented by Juslin, Wennerholm, & Winman (1999).

Rapid attention shifts have also been implication in probabilistic learning tasks (Kruschke & Johansen, 1999). Perseveration of learned attention has also recently been implicated in the classic learning phenomenon of blocking (Kruschke & Blair, 2000).

Do readers make predictive inferences about what protagonists in a story are talking about? Lea, Mason, Albrecht, Birch, and Myers (1998) showed that when two protagonists part and then reunite, information associated with the protagonists is reactivated by their reunion via a low-level memory process (resonance). We used Lea et al.'s passages to test whether this reactivated information is then used to make predictive inferences about what the protagonists talk about after their reunion. In an example passage, Gloria tells her roommate Jane that she is going out and that they will meet later. In the intervening interval, Gloria has dinner with her cousin, while Jane makes dinner at home. Later in the passage, Gloria returns home (reunion), and they "chat for a while." Previous work has shown that the cousin is significantly more active after the reunion sentence than before it (the "reunion effect") — we wondered whether readers then use that activated information to infer what Gloria and Jane are chatting about.

In Experiment 1 we measured activation of COUSIN after two types of discussion sentences and compared them to a no-discussion control. A sentence like "They chatted for a while." was used in the Discussion condition (D); a sentence like "Just wait until you hear this." appeared in the Urgent-Discussion (UD) condition; and the No-Discussion (ND) control passage described a situation in which the protagonists reunited but no discussion was possible (e.g., because one of them was asleep). In all three conditions the target character (e.g., COUSIN) should be reactivated after the reunion, but if readers infer that the cousin is part of the discussion then its reactivation should be potentiated by the discussion sentences. We found that both discussion sentences lead to significantly faster recognition times than the control. The UD passages produced faster response times than the D passages, but the difference was not significant. Thus it appears that readers were making predictive inferences about the topic of the protagonists' discussion.

An alternative explanation for the results of Experiment 1 is that the activation difference reflects a difference in the reunion sentences, not a difference in the discussion sentences. All three versions contained reunion sentences in which both protagonists were mentioned, however, the no-discussion control passages required different reunion sentences in order to create a convincing no-discussion-possible situation. Resonance theory (e.g. Myers &

O'Brien, 1998) would not predict a difference between the two reunion types, but the possibility remains that a "linguistic" reunion like "Jane was asleep when Gloria returned home" does not reactive COUSIN to the same degree that a "physical" reunion such as "Jane was still awake when Gloria returned home" does. So in Experiment 2 we probed immediately after both types of reunion and used a before-reunion probe position control. If reunion-type makes a difference, then we should find a differential before-after reunion effect. However, we found that the target character was reactivated equally after both linguistic and physical reunions, thereby supporting the conclusion that Experiment 1's results are due to the discussion sentence manipulation and not to a difference between the reunions.

Experiment 3 was a paper-and-pencil experiment in which subjects were presented with printed versions of the passages that ended with the discussion sentence, and they were instructed to write a sentence or two about what they thought would be a likely continuation of the story. We conducted this off-line experiment to obtain converging evidence that readers were in fact making an inference that the target character was being discussed. As predicted, subjects were significantly more likely to mention the target character after the discussion sentences compared to the no-discussion control. Interestingly, the UD condition lead to significantly more mentions than the D condition, a difference that was only a trend in Experiment 1.

Together, the three experiments demonstrate how low-level, memory-based text processing can work in concert with more expectation-driven processing. In our passages, reintroducing a protagonist reactivated that target character with whom she was associated and, once reminded, the reader exploited the availability of that information to make a forward inference about the likely topic of the protagonists' conversation. Future work will explore further the collaboration between bottom-up processes like resonance, and more top-down reading processes such as predictive inference.

# A Model of Prefrontal-Hippocampal Interactions in Strategic Recall

Jean C. Lim, [lim@curie.psychology.mcmaster.ca](mailto:lim@curie.psychology.mcmaster.ca)

Suzanna Becker, [becker@mcmaster.ca](mailto:becker@mcmaster.ca)

Department of Psychology, McMaster University, 1280 Main St. West, Hamilton, ON, Canada.

May 24, 2000

Retrieval of episodic memories may be aided by the prefrontal cortex either by its providing contextual, temporal source cues or by serving an executive role - strategically organizing information into chunks, categorizing, and separating lists (Stuss, 1986). The hippocampal region is also believed to play a role in encoding episodic memories (Zola-Morgan et. al., 1990). Modelling human performance on free recall tasks that involve strategic organization of items is difficult because temporal memory of events, delayed rewards and learning in the absence of external reinforcement are required. For example, in the California Verbal Learning Test (CVLT) the task is to study a list of 16 words (four words each from four different semantic categories) and recall the list over five repeated trials (Delis et. al., 1987). Young healthy subjects typically use a semantic clustering strategy to recall the list. Elderly and frontal lobe damaged patients fail to subjectively organize such words and show poorer recall performance (Hultsch, 1975).

To simulate the hippocampal component of our model, we used a Hopfield network (Hopfield, 1982), because of its rapid learning, pattern association, recall and recognition capabilities. For our prefrontal module, we used a recurrent network trained with a reinforcement learning rule similar to that proposed by Barto and Sutton (1986) which can detect correlations between traces of past inputs and changes in outputs. For our list-learning task, a positive reward signal was used to strengthen relevant prefrontal weights during study. During retrieval, recall of non-studied items resulted in an internally generated negative signal.

The hippocampal module consisted of 400 recurrent, symmetrically connected units with no self-feedback connections. Bidirectional and symmetrical weights connected each unit of the Hopfield network to two layers: (1) the prefrontal cortex - a layer of 10 units; and (2) an input/output layer of 52 units - localist representations of the vocabulary words.

Weights to each localist word unit were pre-trained with a Hebbian update rule. This established the network's pre-experimental vocabulary of 52 word patterns. Sixteen of these words, drawn from four different semantic categories (four words from each), were the study list words. Of the remaining 36 words, 20 were semantically similar to the study list, eight were drawn from two new semantic categories, and eight were sparse random vectors. The representation of a word consisted of a distributed vector of 400 semantic features, with semantically related words having more highly correlated feature vectors. The simulation consisted of 5 study and recall trials. During study, the network was trained on the 16 list word patterns. During retrieval, the prefrontal acti-

vations served as cues to recall the list words. Learning in both phases took place in the connections between the prefrontal and hippocampal modules. A recalled word could be "correct", a perseveration (repetition) or an intrusion (non-list word). Clustering performance was determined by comparing the observed semantic clustering score to the expected clustering score.

We modelled a frontal lesioned network by freezing its prefrontal weights at zero. Calculated ratios of observed to expected cluster scores showed that the lesioned network did not cluster above chance whereas the normal network did. The lesioned model also produced, in order of frequency, more perseverative errors, similar intrusions and random intrusion errors than the normal model. Simulation results suggest that an elderly or frontal-lobe damaged subject, modelled by a hippocampal system operating independently of the prefrontal layer, is capable of pattern recognition and recall when given external guidance and cues. To perform more complex tasks such as free recall and provide context-rich source cues, an additional layer, represented in our model as the prefrontal cortex, is needed. With temporally predictive reinforcement learning, the prefrontal module was able to detect semantic clustering of word patterns, and use this to generate retrieval cues to recall the list items optimally.

# An Adaptive Model of Simple Communication

Michael Matessa & John R. Anderson (matessa@cmu.edu)

Department of Psychology; Carnegie Mellon University  
Pittsburgh, PA 15213 USA

When people communicate they try to establish mutual knowledge. Garrod and Anderson (1987) proposed that a way to minimize effort during this process would be to follow a “output/input coordination” principle, where output to a partner is formulated according to the same principles of interpretation as those needed to interpret input from a partner. A computational model of establishing mutual knowledge efficiently can be given in the ACT-R architecture (Anderson & Lebiere, 1998) where goals that are completed successfully can be retrieved and used later. Applied to communication, goals of presenting and accepting information include semantic and syntactic representations of that information, and these goals can later be retrieved to provide templates for the creation of new utterances. Results from an ACT-R model communicating with human subjects show similar performance to that of human subjects communicating together.

The ACT-R model incorporates current theories of collaborative communication which fit naturally into the architecture. These theories include the creation of common ground by way of successful goals of presentation and acceptance (Clark & Schaefer, 1989), the use of dialogue acts to represent actions performed by speech (Core & Allen, 1997), the use of communicative obligations to motivate conversation (Traum & Allen, 1994), and the use of input from a partner to formulate output to that partner (Garrod & Anderson, 1987).

Subjects in a communication task were found to use fewer words to solve problems over time. An ACT-R model

interacting with subjects also used fewer words over time because previous utterances from its human partner were used as templates to create new utterances.

This behavior can be shown to be partner-dependent by showing the difference in message length within pairs is less than the difference between pairs. This was true for both the ACT-R model interacting with subjects and subjects interacting with other subjects.

Work in progress includes the creation of a model that purposely formulates output that is different than the input from a partner's speech to test the effect of non-accommodation on communicative efficiency.

# Morphological Influences on Phonetic Categorization

Kerstin Mauth (kerstin.mauth@mpi.nl)  
Max-Planck-Institute for Psycholinguistics, Wundtlaan 1  
6525 XD Nijmegen, Netherlands

Listeners' phonetic decisions about ambiguous sounds are influenced by lexical information as well as syntactic and semantic information from sentences. A series of experiments was constructed to test whether preceding sentential context can modulate the perception of inflectional morphemes. The morpheme under investigation was the verbal 3rd person singular marker -t in Dutch. Listeners were presented with two different types of sentences: (A) *Vraag jij of Jan morgen gaat?* 'Are you asking whether Jan leaves tomorrow?' (B) *Zie jij nog wel eens een plaat?* 'Do you see a record now and then?' The final words were chosen so that they were semantically not highly predictable from the context. But they were syntactically predictable: the first sentence had to end with a verb while the second had to end with a noun. The final consonant in each sentence was a stop that varied along a place of articulation continuum from [t] to [k]. The [k]-endpoints always formed nonwords. Sentences like (A) and (B) were compared with matched control sentences ending with [t]- and [k]-final nonwords (e.g., *snaat / snaak*).

Listeners were required to categorize the final consonants, which were clear instances of [t] and [k] at the respective endpoints and ambiguous between the two in six intermediate steps. The main question was whether the shift in the categorization function towards the [t] would be any different for the verbal context (A) as compared to the nominal context (B). Would people benefit from the fact that the phoneme [t] is more or less predictable on the basis of the verbal context because of its morphological status? If yes, this might indicate the operation of a morphological decomposition process.

As shown in Figure 1 the bias towards [t] was indeed greater in the verbal context than in the nominal context. Separate analyses within RT ranges (fast, medium and slow) also showed different patterns over time for verbal and nominal contexts. While the shift in the identification

function towards [t] in the verbal context was largest in the fastest reactions it was not reliable in this RT range in the nominal context. In the medium RT range the shift weakened in the verbal condition but built up in the nominal condition. No significant shifts were observed in the slowest responses.

But how far can this result be attributed to the listeners' processing of the context? Would a similar difference between the functions for verbs and nouns show up when these words are presented in isolation? The results (as shown in Figure 2) of a follow-up experiment where the final words and nonwords of the previous experiment were presented in isolation showed that this was not the case.

In an overall analysis listeners did not give significantly more [t]-responses in word contexts than in nonword contexts. This result with high quality materials is congruent with previous findings by McQueen (1991) who found a significant lexicality effect for word final phonemes only when the material was degraded. In the fast RT range of the present data, however, there was a lexicality effect, which was larger for nouns than for verbs.

These results suggest that people do benefit from the morphological status of the last phoneme in a word when not only the word but also its inflection is predictable from the context. As the largest shift in the identification function in the verbal context appears in the fastest RTs this morphological decomposition process is a very rapid one. Without preceding context, however, an inflectional morpheme is not treated differently from phonemes that are part of the word's stem.

# Unique Entropy As A Model Of Linguistic Classification

Toben H. Mintz (tmintz@usc.edu)

Department of Psychology, SGM 501; University of Southern California  
Los Angeles, CA 90064-1061 USA

Several researchers have proposed that young children could make use of statistically weighted distributional information as a significant source of information about the categories of words in their language (Cartwright & Brent, 1997; Mintz, Newport, & Bever, 1999; Redington, Chater, & Finch, 1998). Most of these analyses result in a hierarchical cluster analysis (HCA) which clusters words together based on their distributional similarity. HCAs do not produce categories, but rather graded clusters based on similarity. A similarity threshold must be chosen such that words in clusters which exceed the similarity threshold are said to belong to the same category. Finding a deterministic method for selecting the categorization threshold which results in optimal linguistic categorization, and which does not rely on *a priori* knowledge of the correct linguistic categories, has been problematic. In this poster, I propose a deterministic solution for choosing categorization thresholds in HCAs. I present the notion Unique Entropy which, when applied to linguistic corpora, yields an optimal categorization of words into grammatical categories.

One can characterize the notion "best categorization point" for a HCA on formal, information-theoretic grounds. Specifically, the similarity threshold which yields the highest Entropy (Equation 1,  $l$ =number of groups), will provide the categorization level which maximizes the intrinsic information carried by the resulting category structure. "Best categorization" in this sense means "best" in terms of the amount of information inherent in the resulting category structure, independent of whether it best approximates the linguistic categories being sought. It is an empirical question, whether the best information theoretic classification results in the best linguistic classification. I now demonstrate that it does, at least for the four corpora analyzed in Mintz et al. (1999).

$$(1) E_l = -\sum_1^l \log(p(i))p(i), \quad p(i) = \frac{\text{number of elements in cluster } i}{l}$$

$$(2) UE_l = E_l - ((-\log(\frac{m-(n-1)}{m}))(\frac{m-(n-1)}{m})) + (n-1)(-\log(\frac{1}{m})(\frac{1}{m}))$$

The Entropy, or Information, in a set of categories is affected in two ways by the structure of the set. 1) For a set of a given number of categories, information contained in the category structure (Entropy) will be higher when categories contain the same number of items than when items are unevenly distributed among categories. 2) All else being equal, having more categories results in greater Entropy. In selecting an optimal categorization point based on maximum Entropy, one only wants to consider sources of Entropy that are due to the specific characteristics of the HCA in question and not which are due to merely having a certain number of

categories. Therefore, to determine the unique information provided by a HCA of  $m$  items at a given categorization threshold,  $l$ , which yields  $n$  categories, one must subtract out the base information that would come merely from having  $n$  categories. The result of this subtraction I call Unique Entropy (UE, Equation 2).

Figure 1a plots Unique Entropy by number of categories for the distributional analyses of four corpora presented in Mintz et al. (1999). Mintz et al. reported that the best linguistic categorization in their HCAs was obtained when members were divided into about 30 groups. This is shown by the vertical bar in Figure 1a, and corresponds to the regions with the highest Unique Entropy points for each corpus. Thus, it appears that the best linguistic classification for these corpora is achieved by selecting the classification level with the highest Unique Entropy.

Figure 1b shows that the specific character of the UE curves produced by the distributional analyses of child directed speech is not a necessary consequence of performing such an analysis on any corpus. The lowest line plots the average UE of 10 pseudo-corpora generated by randomly ordering the words in one of the four Mintz et al. corpora. This UE curve shows that any information inherent in the random pseudo-corpora HCAs is due simply to having a given number of categories. The top curve in Figure 1b shows the upper bound for UE when classifying 200 items into  $n$  categories. The four corpus based curves are repeated in Figure 1b. The structure of the actual corpus based HCAs are nearly maximally informative by this measure.

Further research will explore the implications of this finding for psycholinguistics, as well as investigate how it extends to other areas of human categorization. Perhaps humans have evolved categories which are structurally the most informative.

## Introduction

Research on semantic memory has often tacitly treated semantic relations as simple conduits for spreading activation between associated object concepts, rather than as integral components of semantic organization (e.g., Quillian, 1968). Yet conceptual relations, and the role bindings they impose on the objects they relate, are central to such cognitive tasks as discourse comprehension, inference, problem solving, and analogical reasoning (see Holyoak & Thagard, 1995, for review). The present study addresses the question of whether semantic relations and their bindings can influence access to semantic memory.

## Method

The experiment we report investigated whether, and under what conditions, presenting a prime pair of words linked by one of 10 common semantic relations would facilitate processing of a target pair of words linked by the same relation. For instance, the prime pair bird/nest is bound by the semantic relation “lives in”. If bird/nest is presented as a prime pair then naming bear/cave should be faster relative to a target pair bound by a different relation, (e.g., razor/shave—“used to”). Primes and targets were presented as shown in Figure 1. In Experiment 1a participants were instructed to read each word silently as it appeared and then to say out loud the word printed in all capital letters. Naming latencies were measured from the time the second word in the target pair appeared. In Experiment 1b, participants were also instructed to “note and use” the semantic relations.

## Results and Discussion

No effect was observed when participants merely read the prime pair ( $F(1,27) < 1$ ); however, under instructions to note and use the semantic relations, participants were significantly faster at naming target pairs after same relation primes ( $M = 833$  ms) than after different relation primes ( $M = 847$  ms),  $F(1, 27) = 4.45$ ,  $p < .05$  and  $F(1, 119) = 5.50$ ,  $p < .05$  in the item analysis.

Although the full set of conditions under which analogical priming may occur remains unclear, we have shown the importance of instructions when facilitation is achieved by a single same relation pair of words. McKoon and Ratcliff (1995) have demonstrated a similar effect through the context of target words; however, it is yet unclear whether the version of the effect obtained in their study may be the re-

Figure 1: Analogical priming naming task

sult of an implicit strategic set similar to that imposed by our instructions. Although many questions about the nature of analogical priming remain unanswered, the phenomenon may prove central in providing theoretical linkage between basic mechanisms for accessing semantic memory and mechanisms for comprehension and reasoning.

## Acknowledgments

This research was supported by NSF Grant SBR-9729023. We thank Sondra Bland for creating a pilot version of the naming task, Krystal Long for excellent technical assistance, and Bao Truong, Ofilio Vigil, and Tannaz Sassoni for running participants.

# Finding Common Ground in Children's Referential Communication

Aparna Nadig (Aparna\_Nadig@brown.edu)

Department of Cognitive and Linguistic Sciences; Brown University Box 1978  
Providence, R.I. 02906

Julie Sedivy (Julie\_Sedivy@brown.edu)

Department of Cognitive and Linguistic Sciences; Brown University Box 1978  
Providence, R.I. 02912

For referential communication to be effective, it must be made with respect to the discourse context shared by the interlocutors--their **common ground**. It appears that young children may have particular difficulty incorporating common ground information in their production and processing, as they often fail to adapt their speech to a listener's perspective. For example, they often make ambiguous references and frequently fail to establish the antecedents of pronouns and definite noun phrases in their speech (Warden, 1976; Warren & Tate, 1992). This apparent communicative egocentrism could stem from an inability to ascertain or employ what information is shared in common ground.

Results from language processing studies suggest that even adults show evidence of difficulty with integrating common ground information. Keysar and colleagues compared two conditions which tested whether adults completely exclude information *not* shared in common ground from initial consideration. The authors found that privileged information is not completely excluded from initial consideration, and propose a two-stage model in which common ground information is used late in processing (Keysar, Barr, Balin & Paek, 1998). The present study investigated to what extent and when preschool children *do* rely on common ground information in their production and comprehension.

5 to 6 year-old children's ability to identify a unique referent with respect to common ground was tested 1) in an elicited production task, and 2) by the analysis of their eye movements, obtained from a head-mounted eye-tracking system, as they interpreted instructions in a comprehension task.

In both tasks, children viewed a vertical display containing four objects, one of which was hidden from an experimental confederate's view. Three conditions were compared: in the Contrast condition the target object and a competitor object that differed from the target with regard to a scalar feature (e.g. a big cup and a small cup, respectively) were visible to both participants; in the Contrast-Obscured condition the competitor object was available in the child's privileged view but obscured from the confederate's view; and in the No Contrast condition the competitor object was replaced by an unrelated object.

In the elicited production task children had to instruct their adult partners to pick up the target object. Children used modification in their description of the target object significantly more frequently in the Contrast condition, when both the target and competitor object were visible to both participants (requiring additional modification to distinguish between them), than in either of the other two

conditions, indicating the use of common ground in their production.

The on-line comprehension task using eye movement monitoring showed particularly striking use of common ground information. Children were instructed to pick up the target object and their eye movements were monitored as they interpreted this instruction. The description of the target object was always in the form of the head noun (e.g. the cup), regardless of condition. The eye movement data from the Contrast-Obscured condition showed no evidence of interference of the competitor object when it was hidden from the confederate's view, even from the very earliest moments of processing a target description. The time children took to identify the target object was not significantly different in the Contrast-Obscured and No Contrast(baseline) conditions. However, when the competitor object was in common ground, massive interference effects were found. Although the competitor object was visible to children in both conditions, it only impacted their processing of the instruction when it was part of the common ground information they shared with their interlocutor.

These results suggest that, in a sufficiently simple task, common ground information can be used in the earliest moments of processing, even by young children. This finding corroborates research done with adult subjects by Hanna et al. (1998) and Arnold et al. (1999), which found common ground information to be used as a partial constraint on initial interpretation.

# If robots make choices, are they alive?: Children's judgements of the animacy of intelligent artifacts

Milena K. Nigam (mkoziol@andrew.cmu.edu)

David Klahr (klahr@cmu.edu)

Department of Psychology; Carnegie Mellon University  
Pittsburgh, PA 15213 USA

## Introduction

Much of the research on children's developing concepts about the natural world has focused on how they distinguish between living and non-living entities (Carey, 1985). In addition to the well-established cue of autonomous movement, Richards and Siegler (1986) found that six- and seven-year-olds also include mental states as attributes of living things. However, there are different types of mental states (e.g., thoughts and emotions), and in today's technological environment, where even preschoolers have experience with "intelligent" artifacts such as computers and robots, children's understanding of the complex relationship between mental states and animacy judgments remains to be explored (Turkle, 1984).

We considered three types of mental states: (a) cognition (thinking), (b) emotion (having feelings) and (c) volition (having desires/goals). We expected that children's attributions of volition and emotion would be associated with animacy judgments, whereas attributed cognition, on its own, would *not* be associated with positive animacy judgments of computers and robots. (Note that we are making no claims about the causal direction of any such associations. This issue will be explored in future research.)

## Method

We tested children in three age groups spanning the period in which adult-like judgments of animacy emerge (Carey, 1985): 14 preschoolers and kindergartners, 14 second graders, and 11 fourth graders. Children were shown color photographs of three classes of entities: (a) natural kinds (person, monkey), (b) intelligent artifacts (robot, computer), and (c) simple artifacts (doll, TV, hammer). For each entity, children were asked whether it was silly or OK to say a particular statement about that entity. (E.g., "Is it silly or OK to say: 'A robot can think.?'") (Cf. Keil, 1979.) Children were asked to make judgments concerning (a) the entity's animacy status (alive or not alive) and (b) its mental state capabilities. The presentation of mental states and animacy status was counterbalanced across entities.

## Results and Discussion

Robot was the only entity where we found a substantial variation in animacy responses. We dropped fourth graders from this analysis because they all said that a robot was not alive. The distribution of mental state attributions related to robot animacy judgments is presented in Table 1.

Table 1

Covariation Matrix for Animacy and Mental State Attributions

	<u>Cognition</u>		<u>Emotion</u>		<u>Volition</u>	
	Yes	No	Yes	No	Yes	No
<b>Alive</b>	.26	.04	.30	0	.26	.04
<b>Not Alive</b>	.18	.53	.28	.42	.11	.60

To test which mental state attributes were most predictive of positive animacy judgments, we ran a stepwise logistic regression. It revealed that volition was the strongest predictor variable (odds ratio 1.8 [95% CI 1.2 to 2.9]  $p = .004$ ) for robot animacy judgments. (This analysis yields the odds of saying that robot is alive given a judgment that it is volitional.) Note that nearly 30% of responses attributed emotion to a nonliving robot, and nearly 20% of responses attributed cognition to a nonliving robot. However, only 10% of responses attributed volition to a nonliving robot. Thus, this study reveals the emergence of children's early understanding of the nature of complex intelligent artifacts and its relation to the concept of animacy.

# Effects of Visualization on Familiar Motion Problems

Matia Okubo

matia@srt.L.u-tokyo.ac.jp

Department of Psychology

University of Tokyo

7-3-1 Hongo, Bunkyo-ku, Tokyo 113-0033, Japan

## Introduction

Kaiser, Jonides, and Alexander (1986) claimed that people can reason more appropriately about the curvilinear motion problems when they are related to familiar experiences than when they are not. It is, thus, predicted that visualizing the familiar experience of the motion will lead to the correct response for the curvilinear motion problem. However, Hubbard (1996) hypothesized that the visualization strategy for the curvilinear motion problem leads to the incorrect curvilinear impetus response.

To differentiate these two opposite theoretical predictions, the effects of visualization have to be subjected to empirical test. The problem used by Kaiser et al. (1986) was modified and three instruction groups were prepared: The water group predicted a path of water spouting from a spiral tube. Besides the path prediction, the hose-analogy group was reminded of the experience of using a garden hose, and the visualization group visualized the scene in which water spouted from a garden hose.

## Method

### Participants

Eighty-four female college students without college-level physics education were randomly and evenly assigned to one of three instruction groups (i.e. water, hose-analogy, and visualization groups).

### Materials and Procedure

Each participant received a booklet, where a schematic diagram of a spiral tube and one of the three instructions were printed to describe the problem. Nine alternative paths were also printed. Among those paths, one was the correct straight path. Four were curvilinear impetus paths that curved inwardly, and the other four were centrifugal force paths that curved outwardly. Participants selected the path that matched their prediction.

## Results and Discussion

Performance significantly differed across the three groups ( $\chi^2 L(4) = 17.31, p = .002$ ). Percentage of curvilinear impetus responses in the visualization group was smaller than those in the other two groups. This finding clearly disagrees with Hubbard's hypothesis (Hubbard, 1996). The visualization and water groups responded more correctly than the hose-analogy group. Although there was little difference between the visualization and water group, the results might agree

with the prediction by Kaiser et al. (1986). Because percentage of correct responses in the visualization group was larger than those in the hose-analogy group, and it might be higher than those in previous studies which reported that 37 - 46 % of participants without formal physics training predicted the correct path for the abstract curvilinear motion problems (e.g., Kaiser et al., 1986; McCloskey & Kohl, 1983). The difference between the visualization and hose-analogy groups suggests that not recalling but visualizing the familiar experience is responsible for the effects of visualization.

In conclusion, we can say that visualizing the familiar experience leads to the correct response rather than the incorrect curvilinear impetus response for the curvilinear motion problems.

Table 1: Percentage of Participants Choosing Correct, Curvilinear Impetus, and Centrifugal Force Responses.

Instruction	Response		
	Correct	Curvilinear impetus	Centrifugal force
Water	64	18	18
Hose-analogy	36	50	14
Visualization	68	11	21

Note. There were 28 participants in each group.

# The Problem of Relevance in Blended Mental Spaces

David Paxman

([david\\_paxman@byu.edu](mailto:david_paxman@byu.edu))

English Department, Brigham Young University

3136 JKHB BYU, Provo, UT 84602 USA

Herbert Simon's 1994 essay "Literary Criticism: A Cognitive Approach" proposed that cognitive science could ground a more unified, less volatile method of literary study. Interpretation is to be seen as a process by which meanings are evoked in readers' minds when readers select actual meanings from among potential meanings, induce contexts, invoke archetypes, and utilize local knowledge derived from the text. Many respondents alleged that Simons merely showed how problematic was the question he thought he was answering: how do we determine relevance from among myriad potential mental representations, associations, and infinite relations among them?

I don't have an answer to this problem, but I have, by way of speculation, a suggestion that may comprise part of the solution. The brain may have a discrete number of default modes in which it processes and stores a given concept. Just as visual images are processed and stored by different parts of the brain specializing in size, color, shape, motion, and proximity, so less physical concepts may be processed and stored in a series of modes. I use the common-sense term *aspects* to name these modes.

A minimum number of aspects available for any concept would include:

- Image: the concept as icon, prototype image, or gestalt
- Agent: the concept as organism capable of action
- Structure: the concept as a form with relationships among parts
- Hierarchy: the concept's place in subordinate and superordinate classes
- Use or purpose: the ends to which the concept is applied
- Phase or stage: the concept as a specifiable part of a process
- Action: the concept as an action
- State or condition: the concept as a state of being
- Cause or effect: the concept as a result or cause of some thing or state

The concept "war," for example, can be apprehended as an image or images, as an agent, a structure with parts (conflict with combatants, etc.), a hierarchy (more specific than "conflict" but less so than "WWII"), a purpose, a phase or stage, an action, a state of being, or the cause or effect of other states. Because all aspects are potentially available when any concept occurs, any one aspect may be used as metaphor or metonymy for any other.

Something like these default aspects must exist to

explain how readily we create blends such as "boat house" and "house boat" and know which aspects of the concepts *boat* and *house* to blend in each case. Turner and Fauconnier have shown that "house boat" blends conceptual counterparts (things common to both concepts) such as place of residence, sleeping spaces, and kitchens; while "boat house" blends the same two domains by recruiting boat as an occupant of "house," which here is seen in its aspects of gestalt and purpose—a building meant to house and shelter people. To accomplish this feat, the mind must have algorithms for purpose and likely outcomes as it recruits potential elements from each domain for specific purposes.

Literary examples will be offered to show that a complex blended space can be explained as a series of concepts appearing in their relevant aspects.

# Interpreting Eye-Movement Protocols

**Dario D. Salvucci** (dario@cbr.com)  
Cambridge Basic Research; Four Cambridge Center  
Cambridge, MA 02142

**John R. Anderson** (ja+@cmu.edu)  
Department of Psychology; Carnegie Mellon University  
Pittsburgh, PA 15213

Eye movements reveal a great deal about our thoughts and intentions. Exploiting this benefit, researchers have utilized eye movements increasingly as a tool for understanding human behavior at a fine-grained level. However, the popularity of eye-movement data has been tempered by the difficulty of analyzing these data, which typically contain a great deal of individual variability and equipment noise. Researchers must often choose between analyzing a small number of protocols by hand or analyzing a larger number of protocols with very coarse, aggregate measures.

We have developed a class of methods that automate the analysis of eye-movement protocols (Salvucci & Anderson, 1998; Salvucci, 1999). The methods analyze, or interpret, these protocols by means of *tracing* — mapping the observed sequence of eye movements to the sequential predictions of a cognitive model. The tracing process begins by running the cognitive model and generating sequence(s) of predicted thoughts and actions. The tracing process then determines the correspondence between an observed protocol and the predicted sequence that best matches the protocol.

Our tracing methodology includes three methods of varying complexity and accuracy. The simplest method, *target tracing*, performs tracing using a sequence-matching algorithm popularized for user protocol studies (Card, Moran, & Newell, 1983). The two more sophisticated methods, *fixation* and *point tracing*, utilize hidden Markov models, powerful statistical tools that have been applied with great success in speech and handwriting recognition (see Rabiner, 1989). All three methods provide fast and accurate interpretations and are robust in the presence of noise and variability. The tracing methods have been implemented into a working system, EyeTracer, that provides an interactive environment for manipulating, replaying, viewing, and analyzing protocols.<sup>1</sup>

We have rigorously tested the tracing methods in three illustrative domains: equation solving, reading, and “eye typing”. In the equation-solving domain, we collected protocols from students solving equations of a particular form and compared the interpretations of the tracing methods to those of expert human coders. Results showed that the tracing methods interpreted the protocols as accurately as the human experts in significantly less time (at least an order of magnitude difference). We also applied the tracing methods with a “trace-based methodology” (Ritter & Larkin, 1994) to develop a cognitive model of student behavior in the task. The tracing methods facilitated both exploratory and

confirmatory analysis of the protocols and resulted in a successful model of student behavior.

In the reading domain, we evaluated the ability of the tracing methods to compare cognitive models with respect to their sequential predictions. For this purpose, we used two competing models of eye-movement control in reading, E-Z Reader 3 and E-Z Reader 5 (Reichle et al., 1998); these models produced similar predictions of non-sequential measures, but E-Z Reader 5 produced qualitatively better predictions of sequential measures. By tracing a reading data set using these models, the tracing methods provided quantitative evidence that E-Z Reader 5 was indeed the better model. The tracing methods also significantly cleaned up the data and facilitated analysis of aggregate duration and fixation probability measures.

In the “eye-typing” domain, computer users typed words by looking at letters on an on-screen keyboard. Unlike earlier eye-typing interfaces, our interface had no restrictions on how long users needed to fixate letters; this feature facilitated fast input but complicated interpretation of user eye movements. Provided with a model of user input, the tracing methods greatly facilitated data analysis and resulted in faster, more accurate user input than was possible using earlier analysis methods.

# Learning to Learn by Modular Neural Networks

**Akio Sashima** (sashima@etl.go.jp)

Electrotechnical Laboratory  
1-1-4 Umezono, Tsukuba, Ibaraki, 305-8568, JAPAN

**Kazuo Hiraki** (hiraki@idea.c.u-tokyo.ac.jp)

Department of Systems Science, The University of Tokyo  
3-8-1 Komaba, Meguroku, Tokyo, 153-8902, JAPAN

## Introduction

Encountering a stream of learning tasks, humans learn not only knowledge of current task but also biases of learning future tasks. Thrun (1998) insists that modeling this human ability is one of the promising new approaches in the area of machine learning research and call this approach “Learning to Learn”(LTL).

Although some LTL algorithms have been proposed by machine learning researchers, little is known about the relation between LTL and representation of mind.

In this paper, we discuss LTL in the context of modular representation of cognitive system. We hypothesize that modules of a cognitive system are building blocks for learning new tasks (Hiraki, 1998). If each module learns a reusable basic function at the initial task, mixture of modules can learn various complex functions at future tasks. That is, generality and reusability of each module enables the ability of LTL. We implement this hypothesis using modular neural networks and examine it with a function approximation task.

## Function Approximation Task

**Functions** The networks are trained to approximate the following functions:

### Function A

$$f(x, y) = \begin{cases} \cos(x) & \text{for } y = 1.0 \\ -\cos(x) & \text{for } y = -1.0 \end{cases}$$

### Function B

$$f(x, y) = \begin{cases} |\cos(x)| & \text{for } y = 1.0 \\ -|\cos(x)| & \text{for } y = -1.0 \end{cases}$$

Where  $|x|$  represents function that computes absolute value.

**Training procedure** The training procedure is divided into two consecutive stages to examine the effects of learning function A at initial stage. We compare the approximations to function B in the following two tasks:

- **AB task** The networks learn function A first, and then learn function B.
- **BB task** The networks learn function B twice.

Training times of each stage at two tasks are the same.

**Modular Network Architecture** We implement our model using multiple forward models that are part of the architecture recently proposed by Wolpert & Kawato (1998). The networks have 2 expert modules and 1 gating module.

## Result and Discussion

By all trials (20 times), the networks at AB task can correctly approximate function B, but the networks at BB task cannot approximate it. As an analysis of output of each module, we find that the training procedure makes difference in module formation of function B.

For the BB task, one expert module captures  $|\cos(x)|$ , another captures  $-|\cos(x)|$  and the gating module switches between the output of these two modules based on  $y$ . A single module network cannot correctly approximate the absolute value function, so the networks fail to approximate function B. Alternatively, for the AB task, one expert module captures  $\cos(x)$ , another captures  $-\cos(x)$  and the gating module switches between these modules based on  $x$  and  $y$ . These expert modules were already formed during the initial stage to approximate function A. So the networks have only to learn a mixture of these modules to approximate function B.

This result shows that learning a stream of tasks with modular representation is strongly affected by task order. We consider that modular representation is one of the key factors for LTL.

We believe our model of LTL can help us to understand relation between developmental process and module formation. Karmiloff-Smith (1992) argues that humans show the developmental stages that correspond to module reformation. Humans may need each developmental stage to learn simple skills that enable more complex one for later stages. We will test for these effects in developmental tasks, such as learning arm control and eye movement.

# Modeling Embodied Cognition in a Complex Real-Time Task

Michael J. Schoelles (mschoell@gmu.edu)

Wayne D. Gray (gray@gmu.edu)

Human Factors & Applied Cognition  
George Mason University  
Fairfax, VA 22030 USA

The interaction between perception and cognition is an important component of human performance in complex dynamic tasks. In time critical situations we propose that subjects develop microstrategies (Gray, Schoelles, & Fu, 1999) that manipulate these interactions to improve performance. In this paper, we report on our effort to model these interactions. The model in its current state performs a complex dynamic decision making task in a scaled world simulation of a radar operator (Argus Prime). The ultimate goal of the model is to predict changes in performance as the cognitive and perceptual workload of the task changes.

The task in the Argus Prime experimental environment requires a mix of perceptual and cognitive actions. The task involves four subtasks. For target selection, the user attends to icons on the screen (perception), decides to process an icon (cognition), and selects it (motor). In information retrieval the user reads the raw data values for this object (perception). Score calculation entails mapping raw data to target score (cognition), mapping score to threat value (cognition), selecting a threat value (perception and motor), and entering the decision (motor). Finally, feedback processing consists of perceiving feedback (perception) and processing the feedback (cognition). As this brief task analysis illustrates, each subtask combines cognitive, perceptual, and motor operators. Less apparent from this overview is when the actions can proceed in parallel and when they constrain each other.

The cognitive architecture on which the model is built is ACT-R/PM. The ACT-R/PM architecture combines ACT-R's theory of cognition (Anderson & Lebière, 1998) with modal theories of visual attention (Anderson, Matessa, & Lebière, 1997) and motor movement (Kieras & Meyer, 1997). ACT-R/PM explicitly specifies timing information for all three processes as well as parallelism between them. The software architecture facilitates extensions beyond the modal theory of visual attention and motor movements. Our current efforts are taking advantage of this architectural feature to match the modeling effort with the issues raised by the analytic and empirical research in the Argus effort. In particular, we are working on three extensions, one for eye movements, tracking objects, and perceptual support for working memory.

*Eye Movements.* For the analysis of the eye tracking data shows we have incorporated Eye Movements and Movements of Attention extension (EMMA) (Salvucci, 2000) into the model. EMMA provides multiple eye movements per attention shift and provides encoding time for objects based on frequency of attending to the same object and the object's distance or eccentricity from the current point-of-gaze

*Tracking Objects.* We are currently incorporating into the target selection task a theory of multiple object tracking. Sears and Pylyshyn (in press) have applied the FINST model to multiple object tracking. This theory hypothesizes a stimulus driven mechanism that individuates objects in the environment by pointing to them; that is, assigning an index. The indexing precedes object identification and the index remains bound to the object even if characteristics of the object change. In particular, if the location of the object changes continuously then the index can still be used to point to the object. Attention can be directed to the *object* with the index as its argument. The dynamic environment of Argus Prime seems well suited to modeling this theory as a possible mechanism used by subjects in the target selection phase.

*Perceptual Support for Working Memory.* ACT-R/PM provides for both external and internal sources of activation for memory retrieval. Currently the amount of external source activation is a free parameter. Our current efforts are involved with quantifying *how* the level of external source activation varies with task conditions and what microstrategies subjects develop to optimize retrievals by controlling the mix of internal and external source activation.

The rational analysis of memory (Anderson, 1990) proposes that human memory has evolved to cope optimally with the informational demands that the environment places on people. We have shown that human memory performance reflects patterns with which environmental stimuli (e.g., words) occur and reoccur (Anderson, & Schooler, 1991; Schooler & Anderson, 1997). Because the human cognitive system did not evolve in our modern environment, Shettleworth (1998) has questioned the validity of our previous analyses: "to consider Anderson and Schooler's results relevant to pressures that have caused memory to evolve, one has to assume that headlines in late 20<sup>th</sup>-century newspapers reflect a general and enduring property of events in the world."

It is, of course, impossible to study the informational demands that the environment placed on early hominids. About the best we can do is study the informational demands placed on animals whose current ecological niches share something in common with the ecological niches in which hominids evolved. The question, then, is which animals fill the appropriate ecological niches. Dart (1926) argued that time spent on the savanna was critical in the development of intelligence. More recently Milton (1981) has pointed out that hominids evolved first in tropical forests, where "the extreme diversity of plant foods in tropical forests and the manner in which they are distributed in space and time have been a major selective force in the development of advanced cerebral complexity in higher primates." She argues that "to understand the origins of mental complexity, one must look not only at life in the savannas but also life in tropical forests." Thus, studying how primates move through forests and savannas represent good starting points for understanding the informational demands that shaped early hominid evolution.

We have analyzed existing data on the ranging patterns of howler monkeys through forests, and baboons through savanna. Serio-Silva, using the focal animal method, recorded the identification numbers of the trees the howlers were visiting. Rhine's group used the focal animal method as well. They recorded the positions of the baboons in terms of quadrats measuring 720 m<sup>2</sup>. It appears that the visitation patterns of howlers and baboons match up with the statistics of the modern environments. Our analyses show that there are statistical properties shared among domains as diverse as

word usage in the New York Times and the ranging patterns of howler monkeys in trees. These analyses suggest that there are "general and enduring" properties shared between modern and early hominid environments.

Beyond demonstrating the feasibility of performing environmental analyses of primates in natural environments, these analyses have implications for the kinds of memory mechanisms to explore. By exploiting enduring statistical properties of the environment, the memory system could rely on mechanisms that need only infer the *parameters* of known functions. This is a far simpler task than trying to infer what these functions might be. This supports a general-purpose memory system that just estimates parameters for various memory traces.

Some have argued that such general-purpose mechanisms are unlikely to evolve. "General-purpose mechanisms can't solve most adaptive problems at all, and in those cases where one could, a specialized mechanism is likely to solve it more efficiently." Cosmides & Tooby (1994). Implicit in their argument is the assumption that diverse domains do not share fundamental features in common. To the extent that a variety of domains do share statistical properties a general-purpose memory system would be efficient and evolvable.

# **Knowledge Construction Links: Cues and Trajectories as Prior Experience and Knowledge**

**Kathy L. Schuh** ([kathy-schuh@uiowa.edu](mailto:kathy-schuh@uiowa.edu))  
Instructional Design and Technology, 361 Lindquist Center  
Iowa City, IA 52242 USA

## **Background and Purpose**

The constructivist perspective asserts that new knowledge is based on individuals' prior experience and knowledge, and is, therefore, idiosyncratic. Although constructivist instructional strategies (e.g., problem based learning, cognitive apprenticeship, and anchored instruction) have shown promise in classrooms, little research is available on why these methods are helpful at a cognitive level (i.e., how and why learners construct their unique knowledge). This study begins to address this foundational omission using an emergent research methodology to identify the use of trajectories and cues in knowledge construction.

## **Methodology**

This instrumental collective case study reports incidents of learners' use of prior knowledge and experience into their new learning opportunities as a component of describing knowledge from a constructivist perspective. Participants were students in three sixth-grade classrooms (N=74) that differed in learner-centeredness, a characteristic of constructivist classrooms. Learner-centeredness was determined by students' perceptions as measured through the Learner-Centered Battery. Data were gathered through observation, interviews, and a writing activity during subject units that spanned two to seven weeks. Knowledge was operationalized as links (verbally or in writing) through which learners included information that was often tangential to the current topic (i.e., prior experiences and knowledge). Interview participants were selected based on these comments or through random selection. In the open-ended independent writing activity, students were asked to begin their writing with the subject matter topic but also told that they could follow tangential connections.

Given the instrumental nature of the study, the knowledge construction links were first identified. Further analysis proceeded as in qualitative studies, seeking emergent trends in the data, i.e., characteristics of the knowledge construction links as well as the environment in which they were embedded.

## **Findings and Interpretation**

Emerging in the data were cues, those stimuli that prompted learners' to link new information with their prior experience and knowledge. Cues were singular or multiple and often led to tangential comments or questions. For example, a student described the role of vitamin C (the focus of her independent science inquiry project) in a discussion of the Middle Ages and "citrus fruit" (the cue). Once a learner encounters a cue, a trajectory may follow. Trajectories were described by the features of the prior knowledge. Given the richness of an individual's reconstructions, trajectories often contained multiple types, in particular, the type of experience and the characters who were involved.

Ten cue types (sounds like, looks like, feels like, is a, same word but different concept, same concept but different context, same concept and same context but different content, same concept and same context with same content, different concept within same context, series, and complex relationships) and ten trajectory types (acting, general acting, future, and operative experiences, family, friends, school, society, media, and affect/emotion) were identified in this data set.

These constructs captured a view of knowledge that focused on the uniqueness of knowledge: the potential and necessity of considering knowledge within learning situations as unbounded and freely crossing domains and contexts, and dynamic by necessity given each learners' prior experience and knowledge. Further, these constructs, although occurring in all three classrooms, were fostered in the most learner-centered classroom, thus providing exploratory explanations of this fundamental learning process for constructivist instructional strategies (i.e., why these strategies foster learning).

These constructs within the construction process as it occurred in these classrooms provide a variety of opportunities for describing knowledge and knowing. In this poster session I seek opportunities for collaboration with other cognitive scientists to begin to explore how these constructs can be modeled.

# A Delay-dependent Switch in the Information Children Use to Remember Locations

Anne R. Schutte (Anne-Schutte@uiowa.edu)  
Department of Psychology, E11 Seashore Hall  
Iowa City, IA 52246

John P. Spencer (John-Spencer@uiowa.edu)  
Department of Psychology, E11 Seashore Hall  
Iowa City, IA 52246

## Abstract

Several types of information can be used to remember the location of an object over short-term delays. The current study looked at how young children integrate three specific types of information over delays—metric information (i.e., direction and distance), reference locations (i.e., landmarks), and longer-term memories of where objects have been found in the past. Three-year-olds pointed to remembered targets in a large, homogeneous task space. The layout of the targets and how often each target appeared was varied across conditions. Three-year-olds' responses were biased toward the center of the task space and toward an average remembered location, and these biases increased as delays increased. In addition, the bias toward the average remembered location was stronger when the memory of a single location was differentially strengthened.

## Introduction

There are many ways to remember the location of hidden objects. For example, the location of a set of car keys might be remembered as being “on the desk”, in the upper left corner of the desk, or, more specifically, a few inches from the left edge. Evidence suggests that young children use three specific types of information: metric information (i.e., direction and distance), reference locations (i.e., landmarks), and longer-term memories of where objects have been found in the past (Huttenlocher, Newcombe, & Sandberg, 1994; Smith, Thelen, Titzer, & McLin, 1999). Here, we investigated how young children integrate these three types of information in memory during delays.

## Method

Thirty-six to 40-month-olds were asked to remember the location of small, spaceship-shaped lights on a large table with no salient landmarks in the task space. On each trial, a marker was moved to a start location. Then a spaceship appeared for 2s and disappeared. This was followed by a delay of 0, 5, or 10s, after which participants heard a go signal instructing them to move the marker to the

**Figure 1.** Examples of the target layouts on the table top. The child stood within the black arc.

remembered spaceship location. In each condition, targets were separated by 20°, but the number and layout of the targets was varied across conditions. In the Center 0° condition, three targets were used. These targets were positioned symmetrically with respect to the midline of the table (see Figure 1). In the Center 40° conditions, three targets on the same half (right or left) of the table were used, with the center target at 40° or -40° (see Figure 1). In the Bias 60° conditions, the participants moved to two possible targets located at 40° and 60° (or -40°, -60°). Participants moved to the 60° (-60°) target twice as often as the 40° (-40°) target to differentially strengthen this location in memory.

## Results

As the delay increased in the Center 0° condition, participants made larger directional errors toward the midline of the table when moving to the left and right targets. In the Center 40° conditions, three-year-olds' responses to the 60° and -60° targets were biased inward, toward the midline of the table, but responses to the ±20° and ±40° targets were not significantly biased. Data from the BIAS conditions clarified why these responses were not biased towards midline. In the BIAS conditions, responses to the non-biased (±40°) targets were pulled toward the biased (±60°) targets over delays. Thus, memory responses are pulled towards two types of information—the midline of the table and a longer-term memory of an average remembered target location.

## Discussion

Results from the present study demonstrate that there are systematic delay-dependant biases in how young children maintain location information in memory. As delays increase, children's memory responses are biased towards reference axes—the midline of the table—and towards a longer-term memory of previously moved-to locations. Three-year-olds' resultant memory errors depend critically on the delay duration and the relative strength of each type of information.

## 19-Month-Olds' Sensitivity to Negation/Tense Dependencies

Melanie Soderstrom (melsod@jhu.edu)

Johns Hopkins University/Department of Psychology  
3400 N. Charles St. Baltimore MD 21218

Kenneth Wexler (wexler@psyche.mit.edu)

Massachusetts Institute of Technology/Department of Brain and Cognitive Sciences  
77 Massachusetts Ave. Cambridge MA 02139

Recent comprehension studies have shown that infants have early knowledge of adult syntactic relationships long before they are capable of demonstrating this knowledge in productive speech (e.g. Santelmann & Jusczyk, 1998). The current study addresses the relationship in infant grammar between negation and tense in two related contexts - the difference between adverbs and negation in their effect on the placement of tense marking, and the connection between negation and the presence or absence of tense marking.

In English, tense markings are found before a negation, but after an adverb. For instance, compare the following sentences:

- 1) Mary never goes to the store.
- 2) \*Mary not goes to the store.
- 3) \*Mary does never go to the store.
- 4) Mary does not go to the store.

Harris and Wexler (1996) showed that the productions of children are consistent with this adult pattern as early as 1.5 years old. In Experiment 1, the Headturn Preference Procedure (HPP) was used to determine whether the preference patterns 19-month olds follow this same pattern. Infants were tested on two sets of passages that were produced using synthesized speech (Dectalk). Both sets contained sentences with verbs in 3rd person singular, present tense. In the grammatical set, the verb was preceded with "never" (see sentence 1). In the ungrammatical set, the verb was preceded with "not" (see sentence 2). Passages were played in random succession to either side of a testing booth, with playing time for each trial contingent on the infant's interest as measured by orientation of gaze to a paired light stimulus. The dependent measure was total orientation time to the paired side light. Mean scores across trials were calculated for the grammatical passages and ungrammatical passages for each infant.

Twenty-two out of 28 infants oriented longer to the grammatical passages than the ungrammatical passages. The overall mean scores were 8.5 s for the grammatical passages, and 6.8 s for the ungrammatical passages, with  $p = .028$ . Overall, these data support the notion that 19-month-olds are sensitive to the differences between negation and negative adverbs.

One striking feature of children's early production is the optional use of infinitival (not tense-marked) forms of verbs

in contexts where a tensed verb is used by adults, often referred to as the Optional Infinitive (OI) stage. So far the evidence for this phenomenon in normal acquisition is only productive in nature (but see Rice et al. (1999) for comprehension evidence of OI in children with SLI and for normal older children). Experiment 2 compared 19-month olds' preference for passages containing sentences like that in (2) with similar sentences lacking the tense marking:

- 2) \*Mary not goes to the store.
- 5) ?Mary not go to the store.

Both of these sentences are ungrammatical for adults. However, Wexler's (1994) analysis of OI productions predicts that only sentence 2 is ungrammatical for children in the OI stage, while sentence 5 is treated as grammatical.

Surprisingly, 20 out of 28 infants oriented longer to the tense-marked passages (2) than the unmarked passages (5). The overall mean scores were 7.8 s for the tense-marked passages, and 9.5 s for the unmarked passages, with  $p = .027$ . This finding is not predicted by current production-based theories of acquisition.

One explanation for the unexpected finding is that infants are not attending to the "not" in this context, although they did detect the not/never distinction in Experiment 1. We are currently exploring this possibility using nonsense words before the main verb.

## Scaling and Testing for Non-Euclidean Spaces

Jesse Spencer-Smith (jbspence@indiana.edu)

Department of Psychology; Indiana University; 1101 E. 10th St.  
Bloomington, IN 47405-7007 USA

Most current models or theories that posit the existence of geometric or spatial representations (*e.g.*, Valentine, 1991), or that rely on representations generated by multidimensional scaling such as the Generalized Context Model (Nosofsky, 1984), assume that the spaces in which the representations are embedded are Euclidean, or are endowed with a Minkowski power metric. Although the need for investigation of more general spaces was noted as early as 1964 (Shepard, 1964), and has been argued more recently (Townsend and Thomas, 1993), non-Euclidean spaces have been largely overlooked. A natural generalization of Euclidean space are the Riemannian spaces. The sphere (with distances measured on the surface) is an example of a Riemannian space. In the current investigation, qualitative and quantitative tests to uncover properties of perceptual spaces are developed and tested.

Locally, Riemannian spaces are well-approximated by Euclidean spaces. Accordingly, for sufficiently-restricted stimulus sets, non-Euclidean properties of the spaces (such as curvature) may not become evident. If points on a sphere are sufficiently close, the distances between those points can be approximated by assuming the points lie on a plane. While cities in the continental U.S. can be approximated as lying on a plane, regular discrepancies are apparent. Approximating cities in the western hemisphere as lying in a plane results in far greater errors, while an approximation of the cities around the globe in a similar manner would misrepresents fundamental properties of the space. Between antipodal points on a sphere, for example, there exist not one shortest path, but infinitely many.

A metric multidimensional scaling tool which assumes constant-curvature Riemannian spaces (such as the sphere, pseudosphere, or plane) based on work by Lindman and Caelli (1972; see also Indow, 1982) is implemented in Matlab and is applied to new and existing data. Qualitative tests for curvature are developed and demonstrated, and applied to new and existing data.

### Critiques of Geometrical Models

Some of the most insightful and widely-cited critiques of geometric models of similarity (*e.g.* Gati and Tversky, 1982; Beals, Krantz and Tversky, 1968) address spaces which are endowed with Minkowski power metrics, and do not apply to spaces endowed with Riemannian metrics. The specific tests which fail with certain Riemannian spaces are detailed.

### Acknowledgments

James T. Townsend, Rudy Professor of Psychology, Indiana University provided invaluable advice during the development of this work. The work has also benefited greatly from conversations with Bruce Solomon of the Department of Mathematics, Indiana University.

# Variation in Children's Word Production: Can 'Competence' Models deal with young Children's Truncation Patterns?

Helena Taelman  
(taelman@uia.ac.be)

Steven Gillis  
(gillis@uia.ac.be)

University of Antwerp - CNTS, Universiteitsplein 1,  
2610 Wilrijk, Belgium

Young children (often) truncate words: they omit whole syllables from multisyllabic words, as exemplified in (1):

(1) elephant /olifAnt/ [olwant] (Maarten, 1;10.19)

The truncation patterns have been extensively studied: most existing models account for truncations in terms of children's linguistic (i.e. prosodic) competence (i.a. Fikkert, 1994; Demuth, 1995; Gerken, 1996; Pater, 1997; Bernhardt & Stemberger, 1998). These models make two crucial predictions:

1. Truncation patterns are explained as a way to accommodate words into prosodic templates, which are determined by children's (limited) knowledge of the prosodic regularities of the language. The initial rhythmic template is defined as a trochaic foot. Hence, early truncations are considered to be adaptations of words to the trochaic template (Gerken, 1996).

2. Development is conceptualized as a stage-wise progression, which is determined by an elaboration of children's knowledge of the prosodic rules of the language (Fikkert, 1994).

Although metrical competence models have received empirical support (i.a. Fikkert, 1994), a comprehensive test with a large corpus of child language data is currently lacking so that the breadth and the accuracy of the metrical competence accounts of children's truncations still need to be determined.

We present a naturalistic, longitudinal, observational case study of a Dutch speaking boy (age 1;8.29 – 1;11.15). The corpus (available through CHILDES) consists of 19,960 tokens. On the basis of a fine-grained quantitative and qualitative analysis of this corpus, we will challenge the two predictions outlined above:

1. A significant portion of the child's word productions *cannot* be explained as accommodations to a (trochaic) rhythmic template. The relevant data consist of (a) truncations which result in iambic production forms, and (b) truncations of trochaic words.

We identified a number of non-prosodic factors which determine truncations, viz. segmental factors (deemed irrelevant in existing models) and 'performance' factors such as imitation (an interactional influence) and utterance length (a processing factor).

2. A stage-wise progression model is untenable because of (a) inter-word variability (contrary to the predictions, words

with the same prosodic pattern do not evolve concurrently: different truncation patterns are found at the same time) and (b) intra-word variability (contrary to the predictions, words show within-word inconsistencies: correct and various truncated variants of the same word coexist).

We identified a number of non-prosodic factors which determine the observed patterns: i.a. word age, frequency in the input, frequency in the child's own production, and truncation rate.

We conclude that current 'competence' models are unable to deal with the variations in children's actual production data and that an alternative model is called for in which the non-prosodic 'performance' factors identified in this study can be accommodated.

# Is Musical Ability Related to the Prosody Learning of Second Language?

Akihiro Tanaka (tanaka@srt.L.u-tokyo.ac.jp)

Yohtaro Takano (takano@L.u-tokyo.ac.jp)

Department of Psychology, University of Tokyo

7-3-1 Hongo, Bunkyo-ku, Tokyo, 113-0033 Japan

Some recent studies have reported that phonological ability for second language (L2) is correlated with phonological loop capacity (e.g. Baddeley, Gathercole, & Papagno, 1998). In addition, Slevc & Miyake (Manuscript in preparation) reported that adult learners' L2 phonological ability is correlated with their musical ability.

However, the previous studies have dealt only with phonology. The purpose of this study is to examine the prosodic aspect, especially the intonation, and its relations to musical and verbal memory abilities in L2 learning. We use Chinese language as L2 because it has an intonational property known as "four tones".

## Method

### Participants

The participants were 35 high school and undergraduate students in Japan. None of them had ever learned Chinese.

### Materials and Procedures

The experiment consisted of three parts: musical ability test, verbal memory ability tests, and Chinese learning session.

**Musical Ability Test** The frequency difference limen for pure tone was recorded. Though this pitch discrimination ability is only a part of musical ability, we refer to this measure as musical ability for convenience.

**Verbal Memory Ability Tests** Two tests were used to measure verbal memory ability. Reading span (RS) was measured by the Japanese version of the reading span task; and letter span (LS) was measured by the letter span task.

**Chinese Learning Session** Session consisted of five blocks. Each block had a learning phase and a test phase. In the learning phases, the speech sound of the Chinese words and the Japanese equivalents were presented. In the test phases,

a target and a distractor were auditorially presented after a Japanese word was presented. Participants' task was to choose a correct word in 2-alternative forced-choice form. The distractor was one of the following words: phonologically-changed words, words differing in intonation, or other words presented in learning phases. The scores for the trials with these distractor words were recorded as phonological, prosodic, and associative scores, respectively.

## Results and Discussion

Table 1 shows the correlations between the memory ability measures and the mean scores of the five test phases (from 1<sup>st</sup> through 5<sup>th</sup> blocks) in the Chinese learning session. The prosodic score significantly correlated only with RS, while the associative and the phonological scores correlated with both LS and RS. Performance in the RS task is considered to be closely related to efficiency of the central construct of working memory. Therefore, these results imply that prosody learning is free from phonological loop capacity and is related to the central construct.

Table 2 shows the improvements (correct rate of 5<sup>th</sup> block – that of 1<sup>st</sup> block) of each scores for high and low musical ability groups. There was a significant difference only in the improvements of the prosodic scores between high and low groups ( $F(1,33)=7.39, p<.05$ ). This result can be interpreted that the learners with high musical ability are able to analyze the intonational feature with higher accuracy.

In sum, the results imply that when we learn the auditory features of L2, the prosodic features are learned through musical ability, while the phonological features are learned through verbal memory ability.

Center for Cognitive Brain Imaging

5000 Forbes Ave Pittsburgh-PA 15213 USA

Main idea identification is at the very heart of human thinking, being a skill required in everyday situations such as reading a message, interpreting an interlocutor's utterance, listening to the news and attending a lecture. It is part of the human nature to try to integrate incoming information and build a macrostructure containing the main points of the input, so that this information can be more easily stored in memory and retrieved when needed. Despite its importance in human interaction, the process of main idea identification is yet little understood.

Cognitive brain imaging has provided researchers new possibilities for trying to unravel what happens in the human brain during the performance of various complex tasks. This study uses fMRI to investigate the amount of brain activation in a set of cortical areas in the task of main idea identification. Readers were assigned to two types of reading situations, the difficulty of processing being manipulated as follows: in an easier condition, the passages contained the main idea in an introductory topic sentence, followed by two sentences whose content was difficult to interpret in the absence of the topic setting introductory sentence. In a more difficult condition, the

two such sentences occurred at the beginning of the passage, and the topic sentence occurred last. The greater cognitive complexity in processing the two abstract sentences prior to knowing the topic was expected to translate into an increase in brain activation in the right hemisphere for the hard condition.

Results indicate that the complex task of main idea identification is associated with increased neural activity in a range of brain regions of both hemispheres, including the temporal lobe, the extrastriate cortex, the parietal lobule and the inferior frontal gyrus, regardless of the position of the main idea in the paragraph. Furthermore, particularly prominent activity is found in the temporal regions of both cerebral hemispheres when compared to the other areas.

# Schema Acquisition and Solution Strategy in Statistics Problem Solving

David Trumpower (dtrumpow@unm.edu)  
Department of Psychology; University of New Mexico  
Albuquerque, NM 87131 USA

## Introduction

Research on multistep problem solving in knowledge-rich domains, such as physics and mathematics, has revealed several differences between experts and novices. Experts tend to classify problems according to abstract principles useful for their solution (Chi, Feltovich, & Glaser, 1981) and solve problems using a forward-working strategy (Simon & Simon, 1978), whereas novices tend to classify problems based on surface features and solve problems using a backwards-chained strategy. To explain these findings it is generally posited that experts possess domain-specific knowledge in the form of schemas. However, schemas are theoretical constructs inferred from the phenomena they are used to explain. It is proposed here that empirically derived knowledge representations using the Pathfinder scaling algorithm can provide a more direct observation of schema acquisition associated with the attainment of expertise. Pathfinder operates on proximity data to provide a network representation with the most efficient connections between concepts, and has been used as a valid assessment of classroom learning (Schvaneveldt, 1990).

## Methods

Twenty-eight students enrolled at UNM served as participants. They were asked to think aloud as they solved 17 statistics word problems (13 training, 4 test problems). All could be solved using the following equations:  $df_B = a - 1$ ,  $MS_B = SS_B / df_B$ ,  $F = MS_B / MS_W$ . Participants' solutions and verbal protocols were recorded. After solving all problems, participants rated the relatedness of all pairwise combinations of the six concepts contained in the equations above.

## Results and Discussion

Problem solutions were analyzed to determine the strategy used on each of the test problems, and relatedness ratings were submitted to Pathfinder to derive visual representations of participant's acquired knowledge structures.

In all of the problems, participants were given two of the following values and asked to solve for the other:  $a$ ,  $MS_B$ ,  $SS_B$ . Thus, all problems could be solved by first calculating  $df_B$  and then calculating the goal value. A schema useful for solving these problems, then, would involve the relationships between  $df_B$  and each of  $a$ ,  $MS_B$ , and  $SS_B$ . This "df schema" can be seen in the knowledge structures as links between those concepts (see Figure 1). Participant's knowledge structures were analyzed for the presence of this schema.

Figure 1: Sample knowledge representation

If schemas defined in this manner are associated with expert-like problem solution, then participants that possess the df schema should be more likely to solve problems in a forward manner. A solution was considered forward if the subgoal ( $df_B$ ) was calculated before consideration of an equation containing the goal; otherwise it was considered backward. Overall, ten participants solved all of the test problems using a forward strategy. Seven of these ten possessed the schema. Of seven participants, on the other hand, who solved one or fewer test problems using a forward strategy, only one possessed the schema. This discrepancy is found to be significant by a Fisher's exact test,  $p = .05$ .

In the final test problem, participants were given values for  $MS_W$ ,  $F$  in addition to  $a$ ,  $SS_B$  and asked to find  $MS_B$  (Note that participants were not trained on this type problem). Thus, they could use the forward solution described above, or they could work backwards using the equation  $F = MS_B / MS_W$  to solve for the goal in one step. It was hypothesized that participants possessing the df schema would use the former strategy while those that did not would use the latter. Nine of 13 participants possessing the df schema did solve the final problem using the forward strategy, while only three of 15 participants that did not possess the schema did so. This discrepancy is also significant,  $p = .02$ .

These results show that Pathfinder derived representations can reveal the acquisition of schemas that guide expert-like solution of statistics problems. In the absence of these schemas, problem solvers tend to rely on backwards-chained strategies, as predicted.

# Management of Multiple Goals on the basis of Situational Urgency

**Takafumi Tsuchiya (tsuchiya@scs.chukyo-u.ac.jp)**

School of Computer and Cognitive Sciences, Chukyo University,  
101 Tokodate Kaizu Toyota 470-0393 Japan

The functional studies have considered human beings with multiple goals as efficient problem solving systems. While this approach revealed the situated nature of cognitive architecture, it still leaves out some important issues concerning the everyday problem solving. One such issue is that of time, and another is that of the subjective values assigned to achieving each goal. In order to deal with the multiple goals, a person ought to be efficient in setting, concentrating, suspending, discarding, and achieving some of possible goals in accordance with the person's cognitive appraisal of the urgency with which each goal presents itself.

The urgency of a goal is an important situational cognition made by a problem solving agent with a limited temporal resource. When it manages multiple goals and may achieve some of possible goals, it should appraise the subjective value of each goal to be gained. Then it would make an effort to succeed in the achievement of the important goal, and allocate its own time over activities to do so. The urgency of each goal at a given time is defined by the following three parameter values: the subjective value to be lost if the goal is not achieved, the subjective probability of achieving the goal, and the available time for doing accomplishing the goal-achievement action.

The purpose of this research is to design an autonomous agent that is required to set and achieve multiple goals with various degrees of urgency in a simple world of a video game type. For the functional study of emotional architecture, Simon (1967) discussed an interruption mechanism of ongoing processes on a serially fashioned cognitive architecture. Frijda (1986) pointed out that there were a set of mechanisms ensuring personally valuable goal satisfaction. Sloman (2000) proposed their 'three layer' model and discussed the interaction of layers. This research employs a serially fashioned architecture for coping with situations in the simplified world, and intends to specify various functions for the management of multiple goals.

The agent embedded in the world is designed to have three phases in its course of problem solving. The first phase is planning to make a better plan searched as a solution path of operators in the problem space for achieving each single goal. The second phase is goal scheduling in the face of multiple goals, whose function is to schedule how to achieve the given set of goals in what order. Note that, while the target goal is being achieved, the urgency values of other goals in queue will increase due to the decrement in the available time for their achievements. The scheduling rule by a heuristics called urgency comparison is proposed. What it is aimed to do is to reduce the sum of urgency values of all the goals. The third phase, that of action mode selection, does the switching of its action mode between the execution

mode and the deliberation mode to be done in accordance with the urgency presented by the current goal. If this urgency value is very high, the agent should allocate its time for rush execution of some operators in a plan, despite of its limited plausibility. On the other hand, if the urgency is relatively low, the agent may be able to engage in a more deliberate appraisal of the global situation.

## Poster Summary

The design of our simple world will be introduced, first. A task given for the agent is to rescue as many falling objects as possible, which appear randomly in the world. Symbolic descriptions of states constituting the problem space and a plan that the agent would generate, based on the expected utility taking into account the success probability of operation, will be given (Feldman & Sproull, 1977). After the formulation of the urgency value for a goal (Toda, 1995), the two phases in the agent's problem solving, the goal scheduling and the action mode selection, will be discussed. The goal scheduling produces a quasi-optimal goal queue in a dynamic fashion in accordance with the urgency of the current goal (Minton et al. 1992; Zilberstein 1996). The action mode selection allocates limited time for actual execution and deliberate planning. High urgency value of the current goal may make the agent stay in the execution mode for a period of the available time. The final section will describe the current level of implementation and future directions of our research.

## Transformations and Symmetry Optimization in Visual Perception

Visual perception readily lends itself to conceptualization as an optimization process. A primary difference between perceptual theories concerns the nature of the optimized quantity. Most theories suggest that this is either economy of coding or some form of likelihood (Palmer, 1999).

A smaller number of theorists have sought to explain perception in terms of maximizing symmetry (e.g., Leyton, 1992). On our version of this view, the perceptual system subjects image elements to multiple transformations and represents structure by the parameters of those transformations that maximize correspondence with the current sensory input (Vickers, Navarro, and Lee, in press). This paper examines two applications of this approach.

## Perception of Projections of the Platonic Solids

In an early experiment, Hochberg and Brooks (1960) showed that the tendency to see outline figures as two- or three-dimensional was a function of the number of angles and line segments required to specify them in two or three dimensions. According to a transformational approach, whichever perception is associated with more symmetry-preserving transformations will occur more readily than one associated with fewer such transformations.

To test this prediction with stimuli that are representative of major classes of geometrical objects, we asked 50 observers to rate printed examples of 16 and 18 orthographic projections, respectively, of the first two of the regular polyhedra (the Platonic solids): the cube and the tetrahedron. The projections were generated in Mathematica by systematically rotating the figures around the two axes orthogonal to the line of sight

The means and standard deviations in observers' preferences for a two- or a three-dimensional interpretation covaried in a continuous manner that was (weakly) predicted by both the discontinuous differences in the symmetries of the two- and three-dimensional figures and by a count of the number of distinguishable elements. Further analyses suggested that the data may be better accounted for in terms of subjectively perceived symmetry, either as rated by observers or as estimated by the symmetry maximizing program developed by Vickers, Navarro, and Lee (in press).

## Memory and the Perception of Process History

Leyton (1992) has argued that visual perception consists of recovering the process-history undergone by an object. According to Leyton, this recovery proceeds by progressively removing asymmetries or "distinguishabilities", so as to infer an original object that is maximally symmetric. A similar evolution towards regularity is claimed for the successive reproductions of random arrays (Giraud & Pailhous, 1999). However, there has been no quantitative investigation of either of these tendencies towards symmetry.

An experiment, modeled on Bartlett's (1932) method of serial reproduction, was carried out, in which 44 observers, tested in five groups of 4 to 13, were asked to reproduce briefly presented, irregular heptagons, drawn randomly from an original pool of 168 figures. Observers were then presented with each other's (randomly allocated) reproductions and asked to reproduce them. This process was repeated until each observer had made 20 reproductions. In agreement with Leyton's hypothesis, analysis of the 57 (or more) figures that were reproduced at least 10 times showed that observers had a progressive tendency to reproduce figures with a smaller perimeter and with more nearly equidistant vertices, as measured by a reduction by a quarter and a third, respectively, in the mean and the standard deviation (normalized for perimeter size) of the lengths of the edges.

# Use of Agent and Object-Oriented Information in Language Acquisition

Laura Wagner (wagner@psych.umass.edu)

Department of Psychology, University of Massachusetts, Amherst, MA 01003 - 7710

The purpose of this study is to investigate children's bias to focus on agency information when they map meanings onto linguistic forms. Fisher et al. (1992) have shown that children have an agency bias in construing a verb's meaning so that the most agentive participant will be the verb's syntactic subject. This bias makes verbs like "give" (the giver is the most agentive actor) very easy to learn but means that learning verbs like "take" (the giver is still most agentive) require exposure to particular argument structure cues. This study asks if the agency bias extends beyond verb learning, to the grammatical encoding of events more generally.

The domain of this investigation is the English progressive construction (be + V-ing). This construction conveys information related both to the agents and to the objects of events (cf. Smith 1991). As the imperfective grammatical aspect marker, it removes completion entailments from an event, and when relevant, from the object of the event. Thus (1) indicates that (at least potentially) the event of flower-drawing is incomplete, as moreover, is the flower. In this guise, the progressive contrasts with perfective forms (2) which entail the completion of the event and when relevant, the object of the event.

- (1) The girl was drawing a flower
- (2) The girl drew a flower

In addition to this object-oriented function, the progressive also codes for the dynamicity and engagement of the agent of the event. Thus, the difference between (3) and (4) is not one of object completion (there is no object to speak of) but rather of highlighted properties of the agent.

- (3) Jenny was sitting in the chair
- (4) Jenny sat in the chair

Previous work in children's acquisition of the grammatical aspect (e.g. Weist 1991) has claimed that children understand the grammatical aspect (i.e. object-oriented) entailments of the progressive by as young as age 2;6. Children in these studies were able to consistently match a progressive sentence (1) to a picture of an incomplete event (a girl in the midst of drawing a flower) and a perfective sentence (2) to a picture of a complete event (a girl next to a completed flower). However, these studies failed to differentiate between object and agent oriented information: in all cases, the incomplete event was signaled both by the presence of an incomplete object (a half-drawn flower) and by an engaged agent (the girl working on the flower), while the complete event was signaled by both the presence of a complete object (a fully drawn flower) and an un-engaged agent (the girl proudly considering her picture). These studies cannot, therefore, tell us whether children were using object or agent oriented information (or both) to solve this task.

Additional work on grammatical aspect that limited itself to using object-oriented cues (e.g., just the half-drawn and fully drawn flowers) found very different results, including a substantial age delay in comprehension (Wagner 1998).

This result suggests that children's success in the previous tasks may depend on the accessibility of agency information.

The current experiment explicitly manipulates the information available about the agent and object, thus allowing us to see developmentally the relative importance of each source of information. It uses the same forced choice sentence-to-picture matching task used previously, in which children are presented with two depictions of the same event and asked to match these pictures to descriptions containing either the progressive or non-progressive form of a predicate. This experiment uses four kinds of picture pairs: type (1) contains only object information (parallel to the work of Wagner 1998), type (2) contains only subject information (atelic/non-completive events are used so that the status of the event's object remains constant in both depictions), type (3) contains both object and subject information consistent with each other (parallel to Weist 1991), and type (4) contains both object and subject information but at odds with each other, so that the completed object is combined with the dynamic agent and the incomplete object with the less-engaged agent.

Adults, who presumably are able to use both agent and object oriented information, should succeed with picture types (1), (2), and (3), but should provide inconsistent responses when the two types of information are at odds with each other. A child reliant on agency information, on the other hand, would succeed with types (2) and (3), fail with type (1), and behave consistently with type (4), since this child will be insensitive to the competing cues.

Preliminary results (so far, N = 20 across three groups: adults, 5-year-olds and 3-year-olds), show that all groups are able to use both object and agent-oriented information to some degree, but the 3-year-old group is much more dependent on agent-oriented information compared to the other two groups. These results therefore suggest a larger role for the agency bias in acquisition; wherever language encodes event-related information, agency information appears to play a disproportionately large role in young children's mapping process.

# Domains, Knowledge, and Constraints on Classification

**William D. Wattenmaker (wwattenmaker@njcu.edu)**

Department of Psychology; New Jersey City University  
2039 Kennedy Boulevard; Jersey City, NJ 07305

**Kathleen A. Filak (kfilak@njcu.edu)**

Department of Psychology; New Jersey City University  
2039 Kennedy Boulevard; Jersey City, NJ 07305

**Josephine A. Mendoza (jmendoz2@njcu.edu)**

Department of Psychology; New Jersey City University  
2039 Kennedy Boulevard; Jersey City, NJ 07305

This research examined the domain-generalizability of learning and processing characteristics. Wattenmaker (1995) investigated the importance of linear separability as a constraint on categorization in object and social domains. Linear separability is a principle that has been investigated as a constraint on information integration in a number of different domains including connectionist modeling and categorization (e.g., Waldmann, Holyoak, & Fratianne, 1995). In relation to categorization, linearly separable categories are categories that can be partitioned on the basis of a weighted, additive combination of component information. Several different concepts from object and social domains were used in the Wattenmaker (1995) experiments, and in all cases linearly separable structures were easier to learn when they were represented by social descriptions (e.g., trait or behavioral features) than when they were represented by object descriptions (e.g., features of animals or human artifacts).

These results were interpreted as indicating that there are fundamental differences in the structure of domains and these differences lead to different types of background knowledge being associated with different domains. If the structure of knowledge varies with domain, then it will be difficult to formulate domain general constraints in terms of abstract structural properties such as linear separability.

In the present research, a number of implications of this knowledge-based approach to domain differences were investigated in five experiments, and the results provided several important extensions of previous research. The structural property of interest in the present experiments was Family Resemblance (FR), which is a property that is closely related to linear separability and that has been investigated extensively in categorization research. Compatibility with FR principles was examined by asking participants to divide descriptions into groups (e.g., see Medin, Wattenmaker, & Hampson, 1987).

One goal of the present research was to examine domain generalizability with a broader range of domains than was used in the Wattenmaker (1995) experiments. Thus, in addition to object and social domains, we included medical categories. In two experiments that used several different medical and social categories, many more FR categories were formed in the social domain than the medical domain. This result extends prior findings to a new domain and strengthens the

conclusion that the naturalness of structural properties will vary with domain

The results also revealed clear intra-domain differences. Previous research directly contrasted concepts from one domain with concepts from another domain. However, the knowledge view predicts that if types of concepts within a domain are associated with different knowledge, then differences should be observed within that domain. Indeed, we found clear differences within the social domain as FR structures were more compatible with social trait categories than with occupation or social event categories.

The results also supported the generality of the previous findings in that in all of the experiments FR constructions occurred much more frequently in the social than the object domain. Indeed more FR constructions occurred in the social domain even when social categories were contrasted with abstract categories such as “beautiful” and “freedom.”

In summary, the results support the finding that the structure of knowledge varies with domain and these differences in knowledge will make some strategies and processes more natural in some domains than others. This will make it difficult to specify domain general constraints in terms of abstract structural properties such as linear separability or family resemblance. Future research that directly compares different domains will allow us to converge on those aspects of structure and process that are domain-general.

# Knowledge Effects, Conceptual Structure, and Incidental Learning

**William D. Wattenmaker (wwattenmaker@njcu.edu)**

Department of Psychology; New Jersey City University  
2039 Kennedy Boulevard; Jersey City, NJ 07305

**Josephine A. Mendoza (jmendoza2@njcu.edu)**

Department of Psychology; New Jersey City University

**Vanessa K. Nieves (vnieves@njcu.edu)**

Department of Psychology; New Jersey City University

A major theme in recent research on concepts has been the influence that theories have on conceptual structure (e.g., Keil, 1989; Murphy & Medin, 1985; Wattenmaker, 1999). The terms theories and knowledge structures refer to informal theories, mental models, and general world knowledge. A second recent theme in research on concepts has been a focus on the types of concepts that are formed as a result of different encoding tasks, especially incidental and intentional tasks (e.g., Anderson & Fincham, 1996). Research on these two issues has proceeded independently, however.

Consistent with the independence of research on knowledge and research on encoding tasks, the influence of background knowledge has only been investigated with intentional tasks. Intentional tasks represent only a small subset of possible encoding tasks, however. Indeed learners in intentional tasks tend to be highly strategic problem solvers. In natural learning conditions, however, people often develop concepts when they are not in a highly analytic problem solving mode. Thus research on knowledge effects has told us very little about how prior knowledge influences concept formation in a broad range of important encoding tasks.

The present research was designed to examine knowledge effects in incidental tasks. With incidental learning, participants perform an encoding task that is unrelated to categorization. Thus although prior knowledge has been found to have a powerful influence with intentional encoding, knowledge effects might not be as great with incidental encoding. Indeed, in the process of generating hypotheses, participants in intentional conditions often actively search for relevant information. This might lead to more pronounced knowledge effects with intentional encoding.

An alternative possibility is that the activation and application of relevant knowledge will occur automatically. If this occurs, then similar types of knowledge might be applied regardless of the encoding task.

In an initial investigation of this topic, Wattenmaker (1999) examined the ability of participants to detect conceptually related feature co-occurrences. The results of these experiments revealed that background knowledge was as beneficial in incidental as intentional conditions. The present research was designed to determine if the Wattenmaker (1999) results would generalize to situations in which the application of background knowledge required more complex processes. To accomplish this, we presented participants with descriptions that could be perfectly partitioned

into two categories if an underlying theme that was consistent with prior knowledge was activated.

The results of a control condition indicated that participants rarely formed the knowledge-based categories if they had minimal exposure to the exemplars. This control condition was compared to intentional and incidental conditions. In the intentional condition, participants were told to try to discover groups that the descriptions could be divided into. In the incidental condition, the presence of groups was not even mentioned. Instead, participants were given an unrelated task. After the encoding task, participants in both conditions were given the task that was used in the control condition: all the descriptions were presented and participants were asked to divide them into two groups.

The knowledge-based categories were formed more often in the incidental than the control condition and equally often in the incidental and intentional conditions. These results occurred even though the formation of the knowledge-based categories required that prior knowledge guide the interpretation and integration of features from several dimensions.

Even though applying prior knowledge required elaborate inferential processes, background knowledge had the same degree of influence in incidental and intentional conditions. Thus these experiments provide an important extension of the finding that many types of knowledge effects will be strategy-independent (Wattenmaker, 1999). The results underscore the pervasiveness and power of the influence of background knowledge on concept formation.

# Using Cognitive Models in the Design and Evaluation of Team Structure

Monica Z. Weiland (monica\_weiland@chiinc.com)

James L. Eilbert, PhD (jim\_eilbert@chiinc.com)

CHI Systems, Inc.

716 N. Bethlehem Pike, Suite 300

Lower Gwynedd, PA 19002-2650

The Navy is moving rapidly toward deployed systems that increase use of automation while dramatically reducing manning, as in the Surface Combatant of the 21st century (SC-21) ship. With more automation and fewer people, these future systems will place more emphasis on human cognitive performance. These changes will require new organizational designs that are optimized for the cognitive role of humans and their automated counterparts. Thus, new and more general methodologies for designing organizations and optimizing the allocation of functions to individual team members must be developed.

Organizational computational models deal with the organizational structure and its effects on decision processes and information flows within the structure. They characterize organizational decisions as the aggregate of individual agents characterized by demographic and psychological parameters (Carley & Behrens, 1999). Modeling at this level, while useful for high level analysis of organizational behavior, masks the processes that occur at the individual level. To study the relation between these high level processes and individual behavior, we have been extending the COGNET theory and computational model of individual cognition (Zachary, 1992) using concepts from team training research (Smith-Jentsch, Zeisig, Acton & McPherson, 1998). This new model of organizational cognition is termed ORGNET.

To use ORGNET for designing and evaluating new designs or redesigns, we developed the Process for Redesign of Organizations (PRO) methodology and associated toolset. PRO is a flexible environment for discovering the structure of organizations/teams already in place or for building new structures. The starting point of PRO is to build an aggregate ORGNET simulation model of the overall team as a set of interacting tasks and knowledge that can perform an overall job or mission. In addition to demonstrating the basic competence of the tasks to do the team's job, the team model provides a set of measures that are used to characterize the team's basic tasks and their interactions. The measures include complexity and workload of individual tasks, as well as the information flows and workflows that emerge from model runs against representative scenarios. The user can visualize and analyze these measures to discover the basic structure and relationships of the tasks to each other.

These measures are tied to a set of design principles, such as minimizing the overall levels of communication, or

leveling workload. These design principles give the user guidance on how the measures should be used (i.e. minimized or maximized) to optimize the team structure.

The next step in PRO is to build candidate function allocations (i.e. cluster tasks into roles) based on design principles selected by the user. The user may do this manually through a graphical interface or through optimization algorithms. These algorithms find team structures that conform to the set of principles and other constraints on the organizational design defined by the user.

After an initial team structure is found, an iterative process is carried out. Tasks associated with separating the team into distinct members, i.e. communication to maintain situation awareness, task management, and backup, are added to the model and the measures are recalculated.

The user of the ORGNET software can iteratively refine the team structure either by changing the set of principles used in clustering the tasks, or by manually moving tasks between roles and seeing the results of those changes on the conformance of the design to the selected principles. We are in the process of testing various assumptions, including the efficacy of using measures from the monolithic model to predict team performance, and the use of low-fidelity aggregate models in finding an initial team structure.

# Scene Context and Change Blindness: Memory Mediates Change Detection

Carrick C. Williams (carrick@eyelab.msu.edu)

Andrew Hollingworth (andrew@eyelab.msu.edu)

John M. Henderson (john@eyelab.msu.edu)

Department of Psychology and Cognitive Science Program  
Michigan State University, East Lansing, MI 48824

Viewers often fail to detect changes to natural scenes when the change occurs during a visual disruption such as a saccadic eye movement. This *change blindness* phenomenon has led some researchers to claim that visual representation is limited to the currently attended object (e.g., Rensink, O'Regan & Clark, 1997). This *attention hypothesis* holds that once visual attention is withdrawn from an object, no visual object representation remains to support change detection. An alternative view, the *memory hypothesis*, holds that despite the change blindness phenomenon, a relatively detailed representation is retained in memory from previously attended objects (Hollingworth & Henderson, 1999).

To test these competing hypotheses, we examined participants' ability to detect changes to the visual form of a target object. Changes were made during a saccade that took the eyes away from the target object after it had been fixated the first time (Henderson & Hollingworth, 1999). Because attention precedes the eyes to the next fixation position, the target object was not within the current focus of attention when it changed. Thus, the attention hypothesis predicts that these changes should not be detected, whereas the memory hypothesis holds that visual memory can be detailed enough to support token-change detection.

In addition, we manipulated the semantic relationship between the target object and the scene in which it appeared. Research on long-term scene memory has demonstrated that semantically inconsistent (i.e., improbable) objects are retained more accurately in memory than consistent objects (Friedman, 1979). Thus, the memory hypothesis predicts not only above-floor change detection rates, but also a detection advantage for semantically inconsistent objects.

## Method

Twelve volunteers' eye movements were monitored as they viewed 24 black-on-white line drawings of realistic scenes. In each scene a semantically consistent target object (e.g., mixer in kitchen) was chosen, and targets were swapped across scenes to create stimuli for the semantically inconsistent condition (e.g., mixer in farmyard). When a change occurred, the target was replaced with a different example of that type of object (e.g., the mixer replaced by a visually different mixer). A control condition was included in which no change occurred. Participants were instructed to view each scene to prepare for a memory test and to press a button if a change occurred.

## Results

We examined the percentage of trials on which the participant detected a change in a scene. There was a

reliable difference between the consistent (18.1%) and inconsistent conditions (35.2%),  $F(1,11) = 5.28, p < .05$ . This difference was likely due, at least in part, to the fact that gaze duration prior to the change was longer for inconsistent (628 ms) versus consistent targets (489 ms),  $F(1,11) = 7.46, p < .02$ . In addition, a significant percentage of detections (41%) was delayed more than 1500 ms after the change. Of these late detections, 94% occurred upon refixation of the target. Finally, for trials on which a change was not detected, mean gaze duration when the eyes returned to the changed object (749 ms) was longer compared to the equivalent entry in the control condition (499 ms),  $F(1,11) = 6.29, p < .05$ .

These data demonstrate that participants can detect changes to the visual form of an object that is not within the current focus of attention at the time of change. Thus, these data are consistent with the memory hypothesis but not with the attention hypothesis. The modulation of detection performance by semantic consistency provides converging evidence that inconsistent objects are preferentially retained in memory. In addition, the fact that many detections were delayed more than 1500 ms and that these detections tended to occur upon refixation suggests that visual information was often retained for a relatively long period of time and consulted only when focal attention was directed back to the changed region (Henderson & Hollingworth, 1999). Finally, the large implicit effect of change on gaze duration indicates that the explicit detection measure underestimated the extent to which visual information was retained in memory.

# Sequential Probability as a Segmentation Cue for Cantonese

Michael C.W. YIP

Department of Psychology

Chinese University of Hong Kong, Shatin, Hong Kong

[mcwvip@psy.cuhk.edu.hk](mailto:mcwvip@psy.cuhk.edu.hk)

## Introduction

Listeners appear to use sequential probability in the segmentation of Cantonese continuous speech. Because there are some sounds appear more frequently at the beginning or ending of Cantonese syllables than the others, and these kinds of probabilistic information within syllables may cue the locations of possible syllable boundaries in continuous speech signal. Three syllable-spotting experiments were conducted to examine the role of sequential probability in recognition of Cantonese syllables in the continuous speech.

## Experiment

In the syllable-spotting experiment, listeners were presented with a nonsense syllables strings [si:l~~l~~Qj4] which involved a high SP onset consonant or [si:lkwQj4] which involved a low SP consonant onset; and then listeners were instructed to spot any real Cantonese syllables [si:l], literally means lion, embedded on the basis of the acoustic alternations and the phonological information provided by the sound strings by pressing a response key and then named aloud the spotted target syllable.

## Results and Discussion

Response latencies for each target syllables shown that listeners are actually sensitive to the sequential probability on a syllable's onset during online speech segmentation. But these effect was absent on the syllable's final portion (neither the whole rime or only the final consonant). These results implied that the likelihood of a syllable's onset seems to be more important than the likelihood of a syllable's offset, that is in line with other psycholinguistics studies whose also emphasizing the importance of a syllable's onset in the fast recognition of words in continuous speech (Connine, Blasko & Titone, 1993; Grosjean, 1980; Li & Yip, 1998; Yip, in press). In addition, the absence of probabilistic effects on syllable-final may be due to the fuzzy phonotactic structure of Cantonese syllables (Yip, 2000).

Finally, together with other related research findings from other languages (Gaygen, 1999; van der Lugt, 1999), it is argued that sequential probability is an useful source of information in the segmentation of spoken language.

# The Effect of Languages on Children’s Use of Action Information

Hanako Yoshida (hayoshid@indiana.edu)

Linda B. Smith (smith4@indiana.edu)

Department of Psychology; 1101 E. Tenth Street  
Bloomington, IN 47405-7007 USA

## Introduction

Noun meanings, and particularly the meanings of object names, do not differ much across languages. The verbs of different languages, however, differ dramatically in the meanings they lexicalize. The developmental implications of these have generated considerable controversy. In this paper, we do not speak directly to this controversy, which has been narrowly focused on the relative frequencies of noun and verb types and tokens in the input and in children’s vocabularies. Instead, we ask a subtler question: Do the marked differences among languages in verb meanings have consequences for children’s understanding of nouns? We present evidence on this issue by examining verbs of transfer verbs in English and Japanese and their effect on young children’s attention to object properties and generalization of object names.

Verbs of transfer in English and Japanese are a good starting point for answering the question of how differences in verbs may influence children’s acquisition of nouns. Specifically, the verb “put” in English is used for all sorts of transfer events -- from putting water in the tub, a cup on a table, a ring on a finger, a hat on a head, mail into a slot, and thread through a needle. In contrast, Japanese has a set of more specific transfer verbs. Thus, for water in the tub it is “haru”, for a cup on a table, it is “oku”, for a ring on to a figure it is “hameru”, for a hat on the head, it is “kaburu,” for mail into a slot, it is “sashikomu,” and thread through a needle, it is “toosu.” These verbs in contrast to the more abstract meaning of English “put” focus attention on the objects in the event and on their relation to each other. Here, then, is the question: Do these more specific verbs of transfer in Japanese modulate Japanese children’s interpretation of object names?

## Experiments

Prior to the test phase, the child was introduced to test objects with each paired containers and how the each test object fit into or through the container. As shown in Figure 1, one test pair, the same-Fit choice, contained an object and container that matched the exemplar in the fit as described by the Japanese verb. One test pair, the same-Shape choice, contained an object the same shape as the exemplar. However, the fit of this object into the provided container would

not be instance of the Japanese verb “hameru.” The third test pair, the distracter, presented an object and a fit into the provided container that was unlike the exemplar. During the test phase, the child was presented with an exemplar and their respective containers with its appropriate action. For example, the exemplar for a “Hameru” set was demonstrated by a pushing motion how it snapped into the same shaped container, a manner outcome that would be referred to by the Japanese verb “hameru.” Then, children were asked to select one from these three choices. The specific conditions across the three experiments 1 through 3 differed in the verbal descriptions of the events, the verbal requests to make a choice and whether the exemplar had a name or not.

Figure 1. Actual stimuli

## Conclusion

This series of experiments suggest that language a child learns emphasize or de-emphasize action information.

Figure 2. Japanese-speaking children’s performance

As you can see in Figure 2., Japanese-speaking children’s attention to shape of objects increased when they generalize name of the object, and decreased when they generalize object without name. Explicit action information comes to guide the naming of novel objects. However, English speaking-children did not affected by the verbal cues as much as Japanese-speaking children did.
