**Abstract** A significant event happened for electrical engineering in 2008, when researchers at HP Labs announced that they had found "the missing memristor," a fourth basic circuit element that was postulated nearly four decades earlier by Dr. Leon Chua, who was also instrumental in developing the mathematical theories of memristive, memcapacitive, and meminductive systems, resulting in an entire class of "mem-models" that are the foundation of the present work. By applying well-known mechanical–electrical analogies, the mathematics of mem-models may be transferred to the setting of engineering mechanics, creating the mechan-

We study these memmodels, which are characterized by a "zero-crossing" property that has interesting implications for nonlinear constitutive modeling, particularly hysteresis, and we identify some examples of "mem-dashpots" and "memsprings," which include displacement-dependent and variable dampers, the superelasticity found in shapememory alloys, and the pinched hysteresis loops associated with self-centering structures. This work adds to the fast-growing body of literature on elements and systems labeled with "mem," which is a basic branch of study in nonlinear dynamics.

### **1 Introduction**

1.1 Motivations of this study

Modeling hysteresis (e.g., [\[4](#page-34-1)[,15](#page-34-2),[29,](#page-34-3)[39](#page-35-0)[,40](#page-35-1)[,46](#page-35-2)]) is inherently challenging; however, it is necessary in that it has broad utility in many engineering disciplines, including smart structures, robotics, mechatronics, structural control, structural health monitoring, damage detection, and earthquake engineering. Rapid advances in sensor technology are providing researchers in different fields of science and engineering with valuable data collected from real-world measurements. Facing formidably large streams of such data, researchers are expected to extract the most useful and accurate information to enable rapid assessment for decision-making, and modeling plays a central role. This study explores one possibility for very generally modeling hysteresis, adopted from another discipline.

Development of a fundamental circuit element, the memristor, was announced recently [\[43](#page-35-3)], nearly four decades after its prediction [\[9\]](#page-34-0). Equally important, there is a mathematical theory involving memristor devices and memrisitive systems [\[10](#page-34-4)] and, more recently, this theory was extended to include memcapacitors and meminductors [\[13](#page-34-5)], thereby significantly enlarging this family of "mem-models." These developments have inspired us to explore whether these nonlinear constitutive models, all of which are characterized by a "zero-crossing" property, have a role to play in engineering mechanics.

Two obvious but related conceptual gaps need to be bridged first in this study: from electronics to mechanics, and from nano- to macro-scale modeling. Bridging these gaps is made possible, in part, by applying mechanical–electrical system analogies. Bond graph theory [\[32,](#page-35-4)[36\]](#page-35-5) also helps to bridge the gaps. Starting from these well-established techniques, we identify the mechanical counterparts of the memristor, memcapacitor, memrisitive systems, etc., and identify some examples of these mem-models found in recent engineering mechanics literature.

The transfer from one knowledge domain to another is not straightforward. The mem-models defined in Chua [\[9\]](#page-34-0), Chua and Kang [\[10\]](#page-34-4), and Di Ventra et al. [\[13\]](#page-34-5) are mathematically abstract, demanding significant effort to translate the terminology and mathematical notation from electrical systems theory to other physical domains. Also, many functional forms need to be examined in order to develop mem-models usable in practical data analysis and modeling. Georgiou et al. [\[17\]](#page-34-6) is one of the few recent studies with specificity in functional form; however, it covers a relatively simple situation and is not from the field of engineering mechanics. Jeltsema and Dòria-Cerezo [\[23\]](#page-34-7) discuss difficulties that may arise when introducing mem-models in classical Lagrangian or Hamiltonian mechanics and propose a "port-Hamiltonian" approach as a way to overcome these difficulties. Other references are cited in the literature review (Sect. [2\)](#page-5-1) and in subsequent sections, but generally speaking, there are very few published studies relevant to the engineering mechanics community. This is mainly because these mem-models are so "new," even though the physical and mathematical basis of memristors was first presented many years ago. We are thus motivated to investigate these models and to examine their potential for dealing with engineering mechanics problems.

<span id="page-5-5"></span>

As a preview, consider a single-degree-of-freedom (SDOF) model:

<span id="page-5-0"></span>
$$
m\ddot{x}(t) = u(t) - r(t) \tag{1}
$$

where  $x(t)$  is the displacement of mass *m*,  $u(t)$  is its driving force,  $r(t)$  is its restoring force, and

$$
r(t) = c\dot{x}(t) + kx(t), \text{ for a linear dashpot and spring}
$$
\n(2)

 $r(t) = M(x)\dot{x}$ , for a memristor (3)

<span id="page-5-4"></span> $r(t) = M(a)x$ , for a memcapacitor (4)

The restoring force in Eq. [\(2\)](#page-5-2) is widely studied and understood, whereas the nonlinear damper in Eq. [\(3\)](#page-5-3) is not so well known, and certainly not by the name "mem-ristor." In Eq. [\(4\)](#page-5-4),  $a(t)$  is the integral of  $x(t)$  with respect to time; we are unaware of any such "memcapacitor" in engineering mechanics. Equations [\(3\)](#page-5-3) and [\(4\)](#page-5-4) are the simplest examples of mem-models to be studied herein. Figure [1](#page-5-5) presents four pinched hysteresis loops, taken from computational results that will be discussed later. It is worth noting that the abscissa of each panel in Fig. [1](#page-5-5) has two labels, velocity or displacement, due to the fact that Eqs. [\(3\)](#page-5-3) and [\(4\)](#page-5-4) have identical mathematical form, although the physical units of the two functions  $M(\cdot)$ differ.

### 1.2 Contributions and structure of this paper

This paper demonstrates the usefulness of memristive and memcapacitive theories for modeling some important nonlinear hysteretic systems in engineering mechanics. Specifically, displacement-dependent and variable dampers are memristive systems. Also, the superelasticity of shape-memory alloys (SMA) and the pinched hysteresis of self-centering structures may be modeled as memcapacitive systems, a premise justified (in part) by devising and presenting quantitative mem-models using simulations and experimental data in Sect. [5.](#page-20-0) This paper also connects mem-models with broader classes of constitutive models in engineering mechanics in Sects. [5.4](#page-23-0) and [6,](#page-26-0) thereby highlighting future research directions.

<span id="page-5-3"></span><span id="page-5-2"></span>The literature review in Sect. [2](#page-5-1) summarizes basic concepts and translates mem-model theories from electrical engineering to engineering mechanics. Memdampers and mem-springs are formally introduced in Sect. [3.](#page-9-1) Due to their newness, mem-springs subjected to two typical kinds of periodic inputs are the main focus when deriving various properties. These properties not only illuminate understanding but also are instrumental in modeling. Significant portions of this paper focus on detailed case studies, presented in Sects. [4](#page-15-0) and [5.](#page-20-0) Because mem-models are nonlinear (and thus lack many linear system properties and simplicity), such case studies are both necessary and enlightening. Moreover, we must pay attention to time and state events that arise in the case studies, where time events are the discontinuities inherent in nearly all excitation signals, and state events are the discontinuities inherent in a model's state variables. Regarding modeling technique, Sect. [4.6](#page-19-1) outlines an approach, involving time-varying secants, which was first tested on mem-dashpot models, and later utilized to devise the quantitative mem-spring models discussed in Sect. [5.](#page-20-0)

In this paper, a *Remark* gives a brief review of existing knowledge. A *Property* presents useful results, put forth in detail for the first time in this study, and derived mainly for mem-models subjected to two classes of periodic excitation. Finally, an *Example* augments the case studies, providing specific mathematical expressions or numerical results of mem-model simulations.

### <span id="page-5-1"></span>**2 Literature review**

### 2.1 Memristors, bond graphs, and physical analogies

Chua's seminal memristor paper is Chua [\[9](#page-34-0)]. Two years later, Oster and Auslander [\[31\]](#page-35-6) proposed the memristor as a new bond graph element by interpreting Chua's idea in the context of Paynter's tetrahedron

<span id="page-6-0"></span>

	Electrical system	Translational mechanical system
-1.	Current $i$	Velocity $\dot{x}$
2.	Voltage $v$	Restoring force $r$
3.	Charge q, $dq = idt$	Displacement x, $dx = \dot{x}dt$
4.	Flux linkage $\varphi$ , $d\varphi = v dt \implies \varphi = \int_{-\infty}^{t} v(\tau) d\tau$	Momentum p, $dp = rdt \implies p = \int_{-\infty}^{t} r(\tau) d\tau$
5.	Resistor $dv = Rdi$	Dashpot $dr = cdx$
6.	Capacitor $dq = Cdv$	Spring $dx = \frac{1}{k} dr$
7.	Inductor $d\varphi = Ldi \implies v = L\frac{di}{dt}$	Mass $dp = md\dot{x} \Longrightarrow r = m\frac{dx}{dt}$
8.	Memristor $d\varphi(q) = M(q) dq \implies M(q) = \frac{v}{r}$ [9]	Memristor $dp(x) = M(x)dx \implies M(x) = \frac{r}{x}$
9.	Memristor $dq(\varphi) = W(\varphi)d\varphi \Longrightarrow W(\varphi) = \frac{i}{v}$ [9]	Memristor $dx(p) = W(p)dp \implies W(p) = \frac{\dot{x}}{p}$
10.	$i - v$ for hysteresis [9]	$\dot{x} - r$ for hysteresis
11.	$q - \varphi$ for additional insights [9]	$x - p$ for additional insights

**Table 1** Force–Voltage Analogy used to translate from electrical to mechanical terminology

of state [\[32](#page-35-4)] and using the Force–Current Analogy to explain a mechanical device called a "tapered dashpot." As told by Paynter [\[33\]](#page-35-7), bond graphs were born in 1959 as a result of his training and experience in hydroelectric power, which greatly reinforced his awareness of physical analogies. Physically different systems that have the same mathematical model are called analogous systems [\[30](#page-34-8)]. In other words, analogous systems are expressed by the same set of algebraic, differential (or integro-differential) equations, but the specific physical meaning of each parameter or state variable is different. Analogies are available for many kinds of mechatronic (i.e., electro-mechanical) systems, including translational and rotational mechanical systems, fluid power systems, electrical power systems, and heat transfer systems [\[19](#page-34-9)]. Today, bond graph models are routinely used when analyzing mechatronic systems with many degrees of freedom, and when appropriate, they incorporate finite element models [\[11,](#page-34-10)[44](#page-35-8)[,45](#page-35-9)]. Another analogy—involving springs (capacitors), dashpots (resistors), and masses (inductors)—is the Force– Voltage Analogy [\[30\]](#page-34-8), which is applicable to translational mechanical systems and was used during this study (in addition to the Force–Current Analogy) to "translate" memristor theory and its extensions into mechanical notation and terminology; e.g., see Table [1.](#page-6-0)

*Remark 1* (On  $p =$  momentum or impulse) It is challenging to name *p* in Table [1](#page-6-0) without a bit of thought. In classical mechanics, a particle's momentum is defined as the product of its mass and velocity, so in analytical mechanics, *p* and *q* are called generalized momenta and generalized coordinates, respectively. This supports the naming of *p* and *x* as momentum and displacement, respectively, in engineering mechanics. It also supports the naming of *p* as momentum in Oster and Auslander [\[31\]](#page-35-6) or Jeltsema and Scherpen [\[24](#page-34-11)], but there are reasons to support the naming of *p* as impulse (also mentioned in those two references). In classical mechanics, an impulse is defined as the time integral of force, resulting in a change of momentum, and thus impulse and momentum have the same physical units. No matter how we name *p*, the mathematical relationship between *p* and *r* is the same as between *x* and  $\dot{x}$ , in the sense that the first quantity is the time integral of the second. Paynter's tetrahedron of state includes both of these relationships.

*Remark 2* (On  $r =$  restoring force) The force  $r$  in Table [1](#page-6-0) is not an applied (i.e., external) force. Rather, it is an internal force that characterizes a particular element (or system) in a constitutive equation. For example, for a spring or damper, *r* is a restoring force [\[28\]](#page-34-12); for a mass, *r* is its inertia force. An applied force is denoted in this paper by  $u(t)$ , as in Eq. [\(1\)](#page-5-0).

### 2.2 Flow- and effort-controlled systems

Bond graph practitioners distinguish a flow-controlled element (or system) from an effort-controlled element. Paynter's tetrahedron of state depicts relations among four state variables which, for electric circuit elements, are  $e = \text{effort} = v = \text{voltage}, f =$ flow  $= i =$  current,  $q =$  charge, and  $p = \varphi =$  $\phi$  = flux linkage. These various symbols and terms are briefly mentioned here because they (and others) appear in Chua [\[9](#page-34-0)], Oster and Auslander [\[31](#page-35-6)], or Jeltsema and Scherpen [\[24](#page-34-11)]; see Table [7](#page-27-1) in "Appendix 1." For electrical systems, charge- or current-controlled are aliases for flow-controlled, while flux-, voltage-, or impulse-controlled are aliases for effort-controlled. Thus, when exercising the Force–Voltage Analogy, we see that Paynter's tetrahedron depicts relations among four state variables that govern translational mechanical elements:  $e = \text{effort} = r = \text{restoring force}, f =$ flow =  $\dot{x}$  = velocity,  $x$  = displacement, and  $p$  = momentum. So for mechanical elements (or systems) under this analogy, displacement- or velocitycontrolled are aliases for flow-controlled, while forceor momentum-controlled (or impulse-controlled) are aliases for effort-controlled.

As discussed in Rosenberg and Karnopp [\[36](#page-35-5)], pages 20 and 21, flow (velocity) and effort (force) are called power variables because their product equals power, which is the time derivative of energy. Conversely, energy is the time integral of power. Momentum and displacement are called energy variables because instantaneous energy quantities (kinetic or potential) can be expressed naturally in terms of them. Displacement is the time integral of flow, while momentum is the time integral of effort. These four state variables (flow, effort, displacement, and momentum), which are fundamental in power flow and energy conservation considerations for dynamical systems, are the vertices of Paynter's tetrahedron of state, regardless of the type of physical system of interest.

Loosely speaking, a flow-controlled system involves connecting two or more basic elements in parallel where the total kinetic quantities are summations of individual ones while all elements share the same kinematic quantities. In this case, the kinematic quantities need to be solved (or calculated) first. The contrary can be said about the kinetic quantities in an effort-controlled system where two or more basic elements are connected in series. An example is given in "Appendix 1"; see Fig. [25](#page-27-0) and corresponding equations in Table [8.](#page-28-0)

### 2.3 Mem-elements and mem-systems

The constitutive equations for all mem-models (i.e., memristor, memcapacitor, meminductor, as well as memristive, memcapacitive, and meminductive systems) are summarized in Table [2.](#page-7-0) Both the timeinvariant elements and their time-varying systems definitions are included, but hereafter, we will restrict this study to time-invariant mem-models.

*Remark 3* (On  $a =$ absement and  $\rho$ ) The quantity  $a$  in Table  $2$  is the time integral of displacement  $x$ , while ρ is the time integral of momentum *p*. Although the name "absement" for *a* appears in Jeltsema [\[22](#page-34-13)], it is not widely known or accepted. An online search uncovered "absition" as an alternative to absement. Another search uncovered "time integral of momentum" in Bellenger and Duvel [\[3\]](#page-34-14), but this article is not about memcapacitors, and  $\rho$  was not given a name. Rather,  $\rho$  was used to estimate an "average value" of the diurnal water layer over the course of many days. This article is cited as an example of a study of time series data that might (eventually) lead to an engineering model of nonlinear behavior that is of interest in the field of meteorology.

<span id="page-7-1"></span>*Remark 4* (Passivity) Chua [\[9\]](#page-34-0) provides necessary and sufficient conditions for a memristor (in isolation) to be

<span id="page-7-0"></span>

	Element or system	Flow-controlled	Effort-controlled
1.	Memristor (element)	$p = G(x)$ or $r = M(x)\dot{x}$	$x = F(p)$ or $\dot{x} = W(p)r$
2.	Memcapacitor (element)	$p = G(a)$ or $r = M(a)x$	$a = F(p)$ or $x = W(p)r$
3.	Meminductor (element)	$\rho = G(x)$ or $p = M(x)\dot{x}$	$x = F(\rho)$ or $\dot{x} = W(\rho)p$
4.	Memristive system <sup>†</sup>	$\dot{\mathbf{y}} = \mathbf{g}(\mathbf{y}, \dot{x}, t)$ and $r = M(\mathbf{y}, \dot{x}, t) \dot{x}$	$\dot{\mathbf{y}} = \mathbf{f}(\mathbf{y}, r, t)$ and $\dot{x} = W(\mathbf{y}, r, t) r$
5.	Memcapacitive system <sup>†</sup>	$\dot{y} = g(y, x, t)$ and $r = M(y, x, t)x$	$\dot{y}$ = <b>f</b> ( <b>y</b> , <i>r</i> , <i>t</i> ) and <i>x</i> = <i>W</i> ( <b>y</b> , <i>r</i> , <i>t</i> ) <i>r</i>
6.	Meminductive system <sup>†</sup>	$\dot{\mathbf{v}} = \mathbf{g}(\mathbf{v}, \dot{x}, t)$ and $p = M(\mathbf{v}, \dot{x}, t) \dot{x}$	$\dot{\mathbf{y}} = \mathbf{f}(\mathbf{y}, p, t)$ and $\dot{x} = W(\mathbf{y}, p, t)$ p

**Table 2** Two forms of mem-models (element or system)

All expressions were translated from Chua [\[9\]](#page-34-0), Oster and Auslandar [\[31\]](#page-35-6), Chua and Kang [\[10](#page-34-4)], and Di Ventra et al. [\[13\]](#page-34-5) by using mechanical–electrical system analogies

† **y** denotes a state variables vector, **g** and **f** denote vector functions, and *M* and *W* are scalar functions

passive such as  $M(x) > 0$  for "any admissible input"  $\dot{x}$  and output *r* for all time  $t \geq t_0$ . Similarly, Chua and Kang [\[10](#page-34-4)] give  $M(y, \dot{x}) \ge 0$  for time-invariant memristive systems, the generalization of memristors. However, this passivity condition is only sufficient if a memristor (element or system) is part of a more complicated system containing other elements that dissipate energy. (For example in the case of Fig. [25\(](#page-27-0)2a), the weaker condition  $M(x) \geq -c$  is sufficient for passivity of the combined system; see "Appendix 1.") Nonetheless, the passivity condition will be adopted in this paper, despite contrary considerations in Di Ventra and Pershin  $[12]$  $[12]$ . Together with Remark [9,](#page-8-0) the passivity condition restricts all memristor or memristive system paths to the first or third quadrants of the  $(\dot{x}, r)$  plane.

<span id="page-8-5"></span>*Remark 5* (Mathematical parallelism) As was mentioned in the introduction after Eq. [\(4\)](#page-5-4), and as Table [2](#page-7-0) shows, mem-models possess mathematical (i.e., functional) parallelisms that are noteworthy. However, physical units and energetics must also be considered; see Sect. [3.1.](#page-9-2) Also, see Table [9](#page-28-1) in "Appendix 1" for an example.

*Remark 6* (On invertibility) The mathematical relationship between *F* and *G* in Tables [2](#page-7-0) and [7](#page-27-1) is the same as for any basic element (electrical or mechanical) in the sense that one is the inverse of the other:  $F^{-1} = G$  and  $G^{-1} = F$ . Also, *W* is the reciprocal of *M* (and vice versa) at any given point in time *t*.

*Remark 7* (Reduction of memristive system to memristor) Chua and Kang [\[10\]](#page-34-4) defines memristive systems in terms of two equations, called the state equation and the input–output equation, from which the time-invariant version can be obtained. As a conceptual example of a flow-controlled memristive system, we have the following:

State equation: 
$$
\dot{\mathbf{y}} = \mathbf{g}(\mathbf{y}, \dot{x}, t)
$$
  
\n
$$
\xrightarrow{\text{time inv.}} \dot{\mathbf{y}} = \mathbf{g}(\mathbf{y}, \dot{x}) \xrightarrow{\text{for element: } \mathbf{y} = x} \dot{x} = \dot{x}
$$
\n(5)

Input–output equation:  $r = M(y, \dot{x}, t) \dot{x}$ 

$$
\stackrel{\text{time inv.}}{\Longrightarrow} r = M(\mathbf{y}, \dot{x}) \dot{x} \stackrel{\text{for element: } \mathbf{y} = x}{\Longrightarrow} r = M(x) \dot{x}
$$
\n(6)

where **y** is the state vector, **g** is a vector function, and *M* is a scalar function. In this case, the velocity  $\dot{x}$  is the input, while the restoring force  $r$  is the output. Trivial sufficient conditions for a time-invariant memristive system to reduce to a simple memristor are:  $y = x$ ,  $g(x, \dot{x}) = \dot{x}$ ,  $M(x, \dot{x}) = M(x)$ . These conditions are assumed in Eqs.  $(5)$  and  $(6)$ . The final result in Eq.  $(6)$  is

*Remark 8* (Reduction of memcapacitive system to memcapacitor) Di Ventra et al. [\[13\]](#page-34-5) introduce another basic mem-model, a memcapacitive system in which *a* is the integral of displacement *x* with respect to time. As a conceptual example of a flow-controlled memcapacitive system, we have the following:

Eq.  $(3)$ , which is a memristor, a subclass of memristive

systems (as expected).

State equation: 
$$
\dot{\mathbf{y}} = \mathbf{g}(\mathbf{y}, x, t)
$$
  
\n
$$
\xrightarrow{\text{time inv.}} \dot{\mathbf{y}} = \mathbf{g}(\mathbf{y}, x) \xrightarrow{\text{for element: } \mathbf{y} = a} x = x \tag{7}
$$

<span id="page-8-3"></span>Input–output equation:  $r = M(\mathbf{y}, x, t) x$ 

<span id="page-8-4"></span>
$$
\xrightarrow{\text{time inv.}} r = M(\mathbf{y}, x) x \xrightarrow{\text{for element: } \mathbf{y} = a} r = M(a) x
$$
\n(8)

where **y** is the state vector, **g** is a vector function, and *M* is a scalar function. In this case, the displacement *x* is the input, while the restoring force *r* is the output. Trivial sufficient conditions for a time-invariant memcapacitive system to reduce to a simple memcapacitor are:  $\mathbf{y} = a$ ,  $\mathbf{g}(a, x) = x$ ,  $M(a, x) = M(a)$ . These conditions are assumed in Eqs. [\(7\)](#page-8-3) and [\(8\)](#page-8-4). The final result in Eq.  $(8)$  is Eq.  $(4)$ , which is a memcapacitor, a subclass of memcapacitive systems (again as expected). Another example is Eq. [\(15\)](#page-13-2) in Di Ventra et al. [\[13](#page-34-5)].

<span id="page-8-0"></span>*Remark 9* (Zero-crossing property) For a memristor,  $r = 0$  when  $\dot{x} = 0$  and vice versa. This means that the  $(\dot{x}, r)$  intersection always goes through the origin, which is called the "zero-crossing" property in Chua and Kang [\[10](#page-34-4)]. In fact, all mem-models in Table [2](#page-7-0) have a zero-crossing property, determined by the corresponding pair of input and output in the input–output equation.

<span id="page-8-2"></span><span id="page-8-1"></span>*Remark 10* (On nonlinearity) It is important to note that the memristor is intrinsically nonlinear, not merely a classical resistor (constant), which is a linear timeinvariant electrical engineering element; see page 511 of Chua [\[9](#page-34-0)]. By analogy, a classical viscous damper (constant) should not be considered a mechanical memristor, nor should a classical spring (constant) be called a mechanical memcapacitor.

### <span id="page-9-1"></span>**3 Passive mem-springs and mem-dashpots**

### <span id="page-9-2"></span>3.1 Terminology and scope of this study

The point of departure for the rest of this paper is Table [2,](#page-7-0) which summarizes three classes of nonlinear constitutive equations where the elements in Lines 1–3 are subclasses of the corresponding systems in Lines 4–6. In the context of engineering mechanics, a classical dashpot model resists motion by means of a force that is directly proportional to velocity. By analogy and for brevity in this paper, memristors (elements) or memristive systems will often be called "memdashpots" because the ratio of resisting force to velocity is nonconstant and explicitly depends on "memory" via the state vector **y**. Similarly, the class of mem-models in Lines 2 and 5 will often be called "mem-springs" because the ratio of restoring force to displacement is nonconstant and explicitly depends on "memory" via the state vector **y**, *not* simply on the current value of displacement. Hence, as an example, the cubic term in the Duffing equation is *not* considered a mem-spring. The mem-models in Lines 3 and 6 will not be discussed further. Table [3](#page-9-0) gives sample notation and physical units (see caption) that will be used as needed.

The scope of this study is limited to case studies of mem-springs and mem-dashpots in isolation, meaning not in combination with other elements (or systems). Moreover, thermodynamically passive memdashpots and mem-springs are of primary interest here. The focus is on discovering what the engineering mechanics literature holds regarding these two special mem-models. Due to their mathematical parallelism (Remark [5\)](#page-8-5), insights gained about one should prove useful for the other. Therefore, plots of force *r* versus velocity  $\dot{x}$  and force  $r$  versus displacement  $x$  can be presented together (as in Fig. [1\)](#page-5-5), despite the fact that memsprings and mem-dashpots differ significantly in their physical interpretations, particularly their energetics.

Thus far, various passive mem-dashpot models have been found in the engineering mechanics literature, but no unified studies, which simultaneously study passive mem-spring models, have been found (although perhaps these appear, and other researchers will find them). Since their energetics are path-dependent, arrows that show increasing time have been added to the plots.

As noted in Remark [4,](#page-7-1) the passivity condition  $D(y, \dot{x}) \geq 0$  will be assumed for mem-dashpots, which along with the zero-crossing property restricts all paths in the  $(\dot{x}, r)$  plane to the first and third quadrants. Consequently, mem-dashpot power is never negative, and mem-dashpot energy cannot be created as time goes forward. In addition, the passivity condition  $S(y, \dot{x}) \geq 0$  will be assumed for mem-springs, which along with the zero-crossing property restricts all paths in the  $(x, r)$  plane to the first and third quadrants. Assuming the mem-spring displacement is zero at some point in time (sometimes called an initial or reference state), the amount of energy removed at any time thereafter cannot exceed the amount already stored up to that time; see the discussion pertaining to Fig. 3 in [\[13\]](#page-34-5).

The condition  $D \geq 0$  alone suffices to prove that mem-dashpot models are passive, whereas the parallel condition  $S \geq 0$  is insufficient by itself to do the same for mem-springs. Clearly, it is more difficult to prove that mem-spring models (as a class) are passive, which presumably accounts for the lack of unified studies. This observation has motivated us to examine memspring models in more detail in Sects. [3.3](#page-10-0) and [3.4,](#page-14-0) and to devise the quantitative mem-spring models presented in Sect. [5.](#page-20-0)

	Mem-dashpots	Mem-springs					
State Eqs.	$\dot{y} = g(y, \dot{x})$	$\dot{y} = g(y, x)$					
I/O Eq.	$r = D(y, \dot{x})\dot{x}$	$r = S(y, x)x$					
Power	$P(t) = r(t)\dot{x}(t)$ for element $D(x(t))\dot{x}^2(t)$	$P(t) = r(t)\dot{x}(t)$ for element $S(a(t))x(t)\dot{x}(t)$					
Energy	$U(t) = \int_0^t P(\tau) d\tau$ <sup>for element</sup> $\int_0^t D(x(\tau)) \dot{x}^2(\tau) d\tau$	$U(t) = \int_0^t P(\tau) d\tau$ <sup>for element</sup> $\int_0^t S(a(\tau))x(\tau) \dot{x}(\tau) d\tau$

<span id="page-10-1"></span>**Fig. 2** Illustrations for **a** analytic and **b** piecewise continuous displacement and their corresponding absement defined in Table [4](#page-13-1)

3.2 Examples of mem-dashpots

An example of a mem-dashpot is the "tapered dashpot" [\[24](#page-34-11)[,31\]](#page-35-6). Table [10](#page-28-2) in "Appendix 2" summarizes other examples from the literature.

On the other hand, many commonly discussed types of damping are not mem-dashpots (memristors or memristive systems), such as linear viscous, air, Coulomb, displacement-squared, and solid or structural damping (e.g., [\[21\]](#page-34-16)).

### <span id="page-10-0"></span>3.3 Mem-springs  $r = S(a)x$  subject to periodic input

This subsection discusses several properties of memsprings of the form  $r = S(a)x$  subject to periodic input. The properties are illustrated via examples in Figs.  $3, 4, 5, 6, 7$  $3, 4, 5, 6, 7$  $3, 4, 5, 6, 7$  $3, 4, 5, 6, 7$  $3, 4, 5, 6, 7$  $3, 4, 5, 6, 7$  $3, 4, 5, 6, 7$  $3, 4, 5, 6, 7$ , and  $8$ . Table [4](#page-13-1) summarizes two different but related types of periodic input, displacement  $x(t)$  and absement  $a(t)$ , plotted in Fig. [2.](#page-10-1) Table [11](#page-29-0) in "Appendix 2" gives the secant stiffnesses *S*(*a*) and their differentiability classifications for all examples.

Due to mathematical parallelisms evident in Table [2,](#page-7-0) some of these mem-spring properties can be reinterpreted as properties of mem-dashpots of the form  $r = D(x)\dot{x}$  by replacing *x*, *a*, and *S* with  $\dot{x}$ , *x*, and *D*, respectively. Other useful results and insights can be obtained from these examples and properties by translating concepts, terminology, and notation from flowcontrolled elements to effort-controlled elements.

One type of periodic input is defined by a pair of analytic functions, Eqs.  $(9)$  and  $(10)$  in Table [4,](#page-13-1) where  $A > 0$  is the amplitude of the sinusoidal displacement

with period  $T = \frac{2\pi}{\omega}$ , and  $a_0 = \frac{A}{\omega}$  is the value about which the analytic absement  $a(t)$  oscillates. The related type of periodic input is defined by a pair of piecewise continuous functions, Eqs. [\(13\)](#page-13-5) and [\(14\)](#page-13-6) in Table [4.](#page-13-1) Equation [\(13\)](#page-13-5) is the piecewise linear  $(\mathcal{C}^0)$  displacement whose extrema coincide with the maxima and minima of the sinusoidal displacement. The related piecewise parabolic  $(\mathcal{C}^1)$  absement is the time integral of Eq. [\(13\)](#page-13-5) with  $a(0) = 0$  (consistent with the analytic absement). Hence,  $a_0$  for the related absement differs by a factor of  $\frac{\pi}{4}$  from  $a_0$  for the analytic absement. These quantities are defined for notational convenience and insight into analysis, and all examples are plotted with respect to  $A, \omega$ , and  $a_0$  as a way of "normalizing" and comparing results. In many figures, dissipated energy is indicated by a plus sign inside a clockwise hysteresis loop in the  $(x, r)$  plane, whereas stored (or created) energy is indicated by a minus sign inside a counter-clockwise loop.

Note that in certain situations when  $t = 0, \frac{T}{4}, \frac{T}{2}, \frac{3T}{4}$ , *T* , the corresponding values of *r*(*t*) (or other variables) are not always unique, meaning one-sided limits must be considered at those times. Thus, for notational convenience, the four quarter periods—called Phases 1,2,3, and 4—are detailed in Eqs.  $(17)$ – $(20)$  along with  $\bar{a}(t)$  in Eqs. [\(11\)](#page-13-7) and [\(15\)](#page-13-2).

This is to illustrate the impact of Situation (1) to the tangent stiffness of (*x*, *r*)

<span id="page-12-1"></span>**Fig. 7** One element model (see Table [11\)](#page-29-0) subject to  $x(t) = A \sin(\omega t)$ , and  $x(t) = \frac{4A}{T} \left(t - \frac{T}{2} \left[ \frac{2t}{T} + \frac{1}{2} \right] \right)$  $(-1)^{\lfloor \frac{2t}{T} + \frac{1}{2} \rfloor}$ , with  $a(0) =$ 0,  $T = \frac{2\pi}{\omega}$ , respectively, with  $A = 1$ , and  $\omega = 1$ . This is to illustrate the impact of Situation (2) to the tangent stiffness of  $(x, r)$ 

<span id="page-12-2"></span>

*Property 1* (*Asymmetry of secant stiffness S(a) about a*0) Under certain conditions, a mem-spring model can degenerate into a nonlinear (or even linear) spring without memory, meaning there is no hysteresis loop in the  $(x, r)$  plane. As an example, if  $S(a)$  is an even function with respect to  $a_0$  (i.e.,  $S(a_0-\xi) = S(a_0+\xi)$  for all  $\xi$ ), such degeneracy happens, as Fig. [3](#page-11-0) illustrates. Hence, the remaining examples involve secant stiffnesses *S*(*a*) which, by design, are not even functions about *a*0.

*Property 2* (*Orientation of hysteresis loops*) If *S*(*a*) decreases in a strictly monotonic fashion about  $a_0$  (i.e.,  $S(a_0 + \xi) < S(a_0 - \xi)$  for all  $\xi > 0$ ), then the orien<span id="page-13-1"></span>**Table 4** Two related periodic motions (displacements and absements) used in Sect. [3.3](#page-10-0)

<span id="page-13-10"></span><span id="page-13-7"></span><span id="page-13-4"></span><span id="page-13-3"></span>

<span id="page-13-11"></span><span id="page-13-6"></span><span id="page-13-5"></span><span id="page-13-2"></span>tation of the hysteresis loop in the first quadrant of the  $(x, r)$  plane is clockwise (since  $A > 0$ ), whereas the loop in the third quadrant is counter-clockwise. If, on the other hand, the secant stiffness increases monotonically, the orientation is counter-clockwise in the first quadrant, but clockwise in the third quadrant. See Fig. [4.](#page-11-1)

*Property 3* (*Smoothness of r, S, x and a*) The smoothness (i.e., differentiability classification) of*r*(*t*) depends on the smoothness of both  $x(t)$  and  $S(a(t))$ . If  $S(a)$  and  $x(t)$  are analytic functions, then:

<span id="page-13-8"></span>
$$
\frac{dr}{dt} = \frac{d}{dt} (S(a)x) = S(a)\dot{x} + \frac{dS(a)}{da}x^2,
$$
 (21)

where  $\dot{a} = x$  was used. However, if  $S(a)$  or  $x(t)$  are nondifferentiable at any point in time, then care must be taken when interpreting Eq. [\(21\)](#page-13-8). For example, the sharp outer tips of the "petals" (hysteresis loops) in Fig. [5](#page-11-2) are due solely to the nondifferentiability of the piecewise linear displacement in Eq. [\(13\)](#page-13-5) at  $t = \frac{T}{4}, \frac{3T}{4}$ , whereas the outer tips are smooth in Fig. [4.](#page-11-1)

<span id="page-13-0"></span>*Property 4* (*Tangent stiffness K along (x, r) curve*) The tangent stiffness  $K(t) = \frac{dr}{dx}(t)$  along the  $(x, r)$  path is symbolically obtained by dividing Eq.  $(21)$  by  $\dot{x}(t)$  with the proviso that the velocity is not zero (although it is at  $t = \frac{T}{4}, \frac{3T}{4}$ :

<span id="page-13-9"></span>
$$
K(t) = \frac{dr}{dx} = \frac{d}{dx} (S(a)x) = S(a) + \underbrace{\frac{dS(a)}{da}}_{Factor1} \underbrace{\frac{x^2}{\dot{x}}}_{Factor1} \tag{22}
$$

Equation [\(22\)](#page-13-9) shows that the tangent stiffness *K* and the secant stiffness *S* differ by a term that is critically sensitive (analytically and numerically) in the vicinity of times when  $\dot{x} = 0$ . This sensitivity is one of the reasons that it is important to examine both *S* and *K* when analyzing test data with mem-models in mind (see Sect. [4.6\)](#page-19-1). Moreover, if hysteresis is to be modeled well, it is important to study *S* and *K* separately from *x* and  $\dot{x}$  in order to understand their effects on the restoring force *r*.

To clarify the relationship between secant and tangent stiffness, Table [5](#page-14-1) gives the values of *S* and *K* for a few examples at  $t = 0$ ,  $\frac{T}{4}$ ,  $\frac{T}{2}$ ,  $\frac{3T}{4}$ , *T*. These are the times when the  $(x, r)$  path either crosses the origin (when  $x(t) = 0$ ), or the path reaches an extremum of  $x(t)$  (when  $\dot{x}(t) = 0$ ,  $a(t) = a_0$ ), sometimes called a "turning point" in hysteresis modeling articles.

At the origin: For mem-springs of the form  $r = S(a)x$ , Eqs. [\(12\)](#page-13-10) and [\(16\)](#page-13-11) are continuous and equal to zero when  $x(t) = 0$  while  $\frac{dS}{da}$  is finite at those times, so one-sided limits exist and are continuous, leading to:

$$
K(0) = S(a(0)) = S(0)
$$
\n(23)

$$
K\left(\frac{T}{2}\right) = S\left(a\left(\frac{T}{2}\right)\right) = S(2a_0) \tag{24}
$$

$$
K(T) = S(a(T)) = S(0)
$$
 (25)

for all examples in Figs. [3,](#page-11-0) [4,](#page-11-1) [5,](#page-11-2) [6,](#page-12-0) [7,](#page-12-1) and [8.](#page-12-2) At both turning points: Three situations are illustrated in Figs [6,](#page-12-0) [7,](#page-12-1) and [8,](#page-12-2) respectively. The situations are: (1) *S* is continuously differentiable with  $\frac{dS}{da} = 0$ ; (2) *S* is continuous piecewise linear with  $\frac{dS}{da} \neq 0$ ; and (3) *S* has an integrable discontinuity with  $\frac{dS}{da} = 0$ . One-sided limiting values of *S* and *K* are given in Table [5](#page-14-1) at each junction of Phases 1–4.

Under Situation (1) with the sinusoidal excitation— Fig. [6a](#page-12-0)—the product of Factors 1 and 2 in Eq. [\(22\)](#page-13-9) may be determined by using L'Hospital's rule. Under Situation (1) with the piecewise excitation—Fig. [6b](#page-12-0)—Factor 1 is continuously differentiable and equal to zero, while Factor 2 is zero—so their product is zero. Thus, the tangent stiffness is continuous and equal to the secant stiffness.

Under Situation (2) with the sinusoidal excitation— Fig. [7a](#page-12-1)—the tangential stiffness line becomes vertical.

**Table 5** Values and *S*, *K*, and *U* at the controlling points within a cycle for selected models given in Sect. [3.3](#page-10-0)

If the hysteresis loop in the first quadrant is considered a flower petal, its outer tip is rounded. This may be a disadvantage of this kind of excitation as it could mask discontinuities in the model in this situation. In Situation (2) with the triangular excitation[—7b](#page-12-1)— $\dot{x} \left( \frac{T}{4}^{-} \right) \neq 0$ ,  $\dot{x}\left(\frac{T}{4}^+\right) \neq 0$  and  $\dot{x}\left(\frac{T}{4}^-\right) \neq \dot{x}\left(\frac{T}{4}^+\right)$ . The last condition leads to  $\frac{dr}{dx} \left( \frac{T}{4}^{-} \right) \neq \frac{dr}{dx} \left( \frac{T}{4}^{+} \right)$ , under which we will always have a flower petal with a sharp outer tip.

Under Situation (3)—Fig. [8—](#page-12-2) $r$  has a  $C^0$  discontinuity at *a*0, regardless of excitation.

<span id="page-14-2"></span>*Remark 11* (Rate dependence of mem-spring models) Generally speaking, mem-spring models are ratedependent, behaving as linear (constant) springs "in the limit of infinite frequency" [\[13\]](#page-34-5). In particular, as  $\omega \rightarrow \infty$  for models of the form  $r = S(a)x$  subject to periodic input, we have, e.g.,  $a_0 = \frac{A}{\omega} \rightarrow 0$ , so  $r(t) \rightarrow S(0)x(t)$ , which is a linear spring.

<span id="page-14-3"></span>*Property 5 (Energy stored or dissipated)* For most examples in Figs. [4–](#page-11-1)[8,](#page-12-2) Table [5](#page-14-1) gives the values of the energy  $U(t)$  at the end of Phases 1–4. The results are in accord with passivity at the end of a full period, meaning  $U(T) = U(0)$  as noted in Di Ventra et al. [\[13](#page-34-5)]. In particular for  $r = S(a)x$  subject to periodic input, energy is stored (created) during the first half period and then dissipated by an equal amount during the second half period (or vice versa). Moreover, because memsprings degenerate to linear springs as the frequency goes to infinity (Remark [11\)](#page-14-2), *U*(*t*) goes to zero in the same limit.

### <span id="page-14-0"></span>3.4 The usefulness of system models

According to Property [5,](#page-14-3) the simplest mem-spring models show energy storage in either the first or the third quadrant, whereas data from many structural (macro-scale) tests show only energy dissipation (in

<span id="page-15-2"></span>**Fig. 9 b** Following Fig. 1 in [\[37\]](#page-35-10), a schematic hysteretic loop is formed for SMA subject to  $x(t)$  =  $\frac{4A}{T}\left(t-\frac{T}{2}\left\lfloor\frac{2t}{T}+\frac{1}{2}\right\rfloor\right)(-1)^{\left\lfloor\frac{2t}{T}+\frac{1}{2}\right\rfloor}$ , with  $a(0) = 0$ ,  $T = \frac{2\pi}{\omega}$ ,

 $A = 1$ , and  $\omega = 1$ . **a**, **c**, and **d** Other insights developed in this study. See "Appendix 4" including Fig. [30](#page-33-0) for more explanations

<span id="page-15-1"></span>

both quadrants); e.g., see Dolce et al. [\[14](#page-34-17)], Santos and Cismașiu [\[37\]](#page-35-10), Christopoulos et al. [\[8\]](#page-34-18), Ricles et al. [\[35\]](#page-35-11), and Fig. [9](#page-15-2) for one such example. A different insight can be gained by contrasting Eqs. [\(17\)](#page-10-2) and [\(19\)](#page-11-4) while observing that an element model cannot produce the same behavior in the first and third quadrants when subjected to the specified cyclic input. In other words, the  $(x, r)$  path is "anti-symmetric with respect to the origin," as stated in [\[13](#page-34-5)].

One way to tackle this issue within the framework of mem-models is to utilize system models, Table [2,](#page-7-0) Line 5. The basic approach is to include *x* in *S* and introduce a switching mechanism whenever  $x(t) = 0$ . Section [5](#page-20-0) presents examples of such mem-spring system models. The rest of this subsection gives a few examples of mem-springs of the form  $r = S(a, x)x$  subject to the same two types of periodic input as were used in the previous subsection (Table [4\)](#page-13-1). In "Appendix 2," Table [12](#page-30-0) contains the secant stiffness  $S(a, x)$  and Table [13](#page-30-1) lists values of *S*, *K*, and *U* (for comparison with Table [5\)](#page-14-1). Contrasting Fig. [10](#page-15-1) with [4,](#page-11-1) and Fig. [11a](#page-16-0) with b, one can see the difference that the switching in these models can make in terms of modeling capability. Properties [1](#page-11-5) to [4](#page-13-0) may be extended from elements to systems; see Figs. [26](#page-32-1) and [27](#page-32-0) in "Appendix 2" for an example.

### <span id="page-15-0"></span>**4 Case studies of mem-dashpots**

### 4.1 Overview of mem-dashpot case studies

As a case study of a mem-dashpot in the engineering mechanics literature, details of a controllable hydraulic damper in Scruggs and Gavin [\[38](#page-35-12)] are presented and discussed in this section. For comparison purposes, results from three nano-device models (two memristors and one memristive system in [\[7](#page-34-19),[42,](#page-35-13)[43\]](#page-35-3)) are also summarized and discussed. The three nano-device models, designated herein as Case Studies #1, 2 and 3 (see "Case studies from nano-field" of Appendix [3\)](#page-29-1), can be viewed as mem-dashpots by means of the Force– Voltage Analogy. Instead of using the Simulation Program with Integrated Circuit Emphasis (SPICE) as in Chang et al. [\[7](#page-34-19)], MATLAB<sup>TM</sup> was used for all computa<span id="page-16-0"></span>**Fig. 11** One element contrasted with one system model (see Table [12\)](#page-30-0) to illustrate the behavior of  $(x, r)$  in the third quadrant;  $x(t) = A \sin(\omega t)$  with  $A = 1$  and  $\omega = 1$ 

tions herein. Throughout this study, ode45 (a MATLAB ODE solver based on RK45) was used with RelTol  $=$  $10^{-6}$ , AbsTol =  $10^{-3}$  and MaxStep =  $10^{-3}$ .

This section focuses on the governing state and input–output equations. Naturally, the input (i.e., excitation) plays an important role in understanding the nonlinear input–output equations. Although the response to many different kinds of excitation is of interest, only a few signal types have actually been used thus far, namely periodic, ordered, or amplitudemodulated forms, which are often used to probe both memristive devices and engineering mechanics devices.

### 4.2 A controllable hydraulic damper

Equations  $(30.59)$ – $(30.62)$  in  $[38]$  are simplified versions of a more general form of variable damper, also reviewed in that same paper. Following the notation for flow-controlled memristive systems in Tables [2](#page-7-0) and  $3$ , Eqs. (30.59) to (30.62) can be rewritten as timeinvariant state and input–output Eqs.  $(26)$  and  $(27)$ ,

where the state vector has two components  $y(t)$  =  $[y_1(t), y_2(t)] = [x(t), w(t)]$  with  $w \in [0, 1]$ .  $T_w$ ,  $K_w$ ,  $c_{\text{min}}$  and  $c_{\text{max}}$  are design parameters, while sat and *H* denote the saturation and Heaviside functions, respectively. Thus, this model is included as a key memdashpot case study. Some snapshots of this nontrivial model from Scruggs and Gavin [\[38\]](#page-35-12) are reproduced in Fig. [12,](#page-17-0) while more details and insights are provided in Figs. [12](#page-17-0) and [13.](#page-17-1)

### <span id="page-16-2"></span>4.3 Regarding variable(s) in state vector **y**

The selection of variable(s) in state vector **y** is, in general, a subjective matter that depends on the physical mechanism(s) perceived to underlie the observed nonlinear behavior. In some cases encountered in the literature, a mem-model expressed in terms of a state vector does not necessarily mean the model is a system as defined in Table [2.](#page-7-0) Instead, the model may actually be an element (as in Case Study #1). Two interesting observations can be made regarding Case Study #2. First, it is straightforward to show that:

<span id="page-16-1"></span>State Eq.: 
$$
\dot{\mathbf{y}} = \underbrace{\left[\frac{1}{T_w} \text{sat}_{[-1,1]}\left\{K_w\left[50|y_1|^{\frac{3}{2}}\mathcal{H}\left(-[(1-y_2)c_{\text{min}} + y_2c_{\text{max}}]A_p^2\dot{x} \cdot y_1 - y_2\right]\right\}\right]}_{\mathbf{g}(\mathbf{y},\dot{x})}
$$
\n  
\n*U*O Eq.:  $r = \underbrace{[(1-y_2)c_{\text{min}} + y_2c_{\text{max}}]A_p^2\dot{x}}_{D(\mathbf{y},\dot{x})}\dot{x}$ \n  
\n(27)

<span id="page-17-0"></span>

<span id="page-17-1"></span>**Fig. 13** Time histories of the input, output, internal variable, power, and energy in Fig. 30.6 in Scruggs and Gavin [\[38](#page-35-12)]

$$
v(t) = \left[ y + \frac{R_{\text{ON}}}{R_{\text{OFF}}} (1 - y) \right] \frac{D^2}{\mu_V} \frac{\dot{y}}{y(1 - y)}
$$
  
= 
$$
\underbrace{\frac{D^2}{\mu_V} \left[ \frac{1}{1 - y} + \frac{R_{\text{OFF}}}{R_{\text{ON}}} \frac{1}{y} \right]}_{M(y)} \dot{y}
$$
(28)

where  $y = \frac{w}{D}$ , which may have a physical meaning of being a normalized width according to Chang et al. [\[7](#page-34-19)]. It can be seen that  $y$ ,  $\dot{y}$ —joined with  $v$ —form a memristor (not a memristive system). We have:

$$
G(y) = \int M(y)dy
$$
  
=  $\frac{D^2}{\mu V} \left[ -\ln(1 - y) + \frac{R_{\text{OFF}}}{R_{\text{ON}}} \ln y \right]$   
+  $\frac{D^2}{\mu V} \left[ \ln(1 - y_0) - \frac{R_{\text{OFF}}}{R_{\text{ON}}} \ln y_0 \right]$  (29)

where  $\ln y$  and  $\ln(1 - y)$  require  $0 < y < 1$ .

Alternatively, it is again straightforward to show that the state and input–output equations in Case Study #2 define another memristor. We can also show that:

<span id="page-18-0"></span>**Fig. 14** Typical smooth and nonsmooth excitation time histories and their corresponding phase plots. Here, a mem-dashpot is used as an example. **a** Follows Fig. [2,](#page-10-1) **b** mimics [\[7\]](#page-34-19), the analytic signal in (**c**) follows [\[38\]](#page-35-12), while the piecewise signal in (**c**) mimics [\[35](#page-35-11)]

$$
v = \left[\frac{R_{\rm ON} - R_{\rm OFF}}{e^{-\left(\mu_V \frac{R_{\rm ON}}{D} q + C\right)} + 1} + R_{\rm OFF}\right] i \tag{30}
$$

where *C* is an integral constant to be determined (i.e., a memristor, not a memristive system).

Considering what variable(s) a state vector might include, the internal state variable  $w$  in [\[38\]](#page-35-12) has a physical interpretation, being the normalized viscosity coefficient with  $w \in [0, 1]$ , which is quite noteworthy because in Case Study #3 from [\[7](#page-34-19)], a similar choice occurs for the internal state variable w. The normalized  $w$  has a clear physical interpretation, being an area index varying between 0 and 1.  $w$  can be solved as a nonlinear function involving an integral of  $v$ . Using the notation in Table [2,](#page-7-0) w is a nonlinear function of  $\phi$ , while *W* is an affine combination of  $w$  and a nonlinear function of v. Ultimately, *W* can be expressed as a nonlinear bivariate function of v and  $\phi$ ; see "Understanding case" study #3" in Appendix [4.](#page-31-0)

### 4.4 Regarding excitations

The first (and maybe foremost) challenge in studying mem-models is the dependence of their responses on

their excitations, which is due to their intrinsic nonlinearity (so long as the amplitude of excitation is high enough to meet some nonlinearity observability criteria). See Figs. [17](#page-21-0) to [19](#page-23-1) (later) for simulated results of Case Studies #1 to 3 as well as the hydraulic damper from [\[38\]](#page-35-12). To symbolically illustrate excitation dependency, let  $r = D(x, \dot{x}) \dot{x}$ , which is a simple example of a flow-controlled time-invariant system model for a mem-dashpot, we have:

$$
p = \int r \, dt = \int D(x, \dot{x}) \, \dot{x} \, dt
$$

$$
= \int D(x, \dot{x}) \, dx = \int D(x, h(x)) \, dx \tag{31}
$$

where  $\dot{x} = h(x)$  has a piecewise-defined expression according to the phase plot  $(\dot{x}, x)$ —as discussed in Sect. [3.3](#page-10-0) especially Table [4](#page-13-1) and Eqs.  $(17)$  to  $(20)$  but for a mem-dashpot. Thus, it can be seen that *p* is piecewise defined, depending on *x*. Also, it can be seen that  $(x, p)$  (or, equivalently, G in Table [2\)](#page-7-0) is phase plotdependent, i.e., excitation-dependent.

Together with Fig. [2,](#page-10-1) Fig. [14](#page-18-0) exemplifies typical time histories and phase plots in terms of  $x$  and  $\dot{x}$  used as input to a flow-controlled mem-dashpot. Similar phase plots, but in terms of *p* and *r*, could be applied to an effort-controlled mem-dashpot. (For a mem-spring, we could use pairs of *a* and *x*, and *p* and *r*, respectively, for a flow-controlled and an effort-controlled situation.)

Each of the three typical signals illustrated in Fig. [14](#page-18-0) has its pros and cons. In terms of propagating in phase space, the sinusoidal signal seems to be the least efficient given that only one circle is explored (assuming constant amplitude). An amplitude-modulated signal would be more efficient in contrast in this regard.

The difference between a smooth signal and its sawtooth counterpart needs to be clarified: The former is differentiable, thus facilitating analytical manipulation, while the latter does not possess this convenience but enjoys popularity in practice, e.g., in pseudo-dynamic tests in earthquake engineering (such as the excitation in Fig. [20a](#page-24-0) following Applied Technology Council [\[2\]](#page-34-20)). Of course, these excitation forms are not exhaustive. Ultimately, responses under random excitations need to be studied; studying periodic and/or ordered excitations is a necessary preliminary stage.

<span id="page-19-2"></span>**Table 6** State events in case study of controllable hydraulic damper

### 4.5 Regarding solving state and input–output equations

State and input–output equations, such as Eqs. [\(5\)](#page-8-1) and [\(6\)](#page-8-2) and others presented elsewhere as typical examples of flow/effort-controlled mem-dashpot and memspring systems, can be sometimes be solved uncoupled. For example, Case Studies #1 to 3 are simple enough that they can be solved uncoupled (as they were in this work; see Sect. [4.3](#page-16-2) and "Case studies from nano-field" in "Appendix 3"). On the other hand, the hydraulic damper equations from Scruggs and Gavin [\[38](#page-35-12)] were solved coupled.

In particular, Eq.  $(5)$  is a nonlinear ODE to be solved. The smoothness condition for numerically integrating this ODE can easily be violated by discontinuities in the nonlinear operator **g** and/or those in the input  $\dot{x}$ . The former leads to state events while the latter to time events. See Fig. [14,](#page-18-0) where a sawtooth wave is an example involving time events; typically, a displacement time history with sawtooth features is popular in earthquake engineering tests. Mathematically, this means that  $\frac{dx}{dt}$ is discontinuous at certain times. On the other hand, nonsmooth operators **f** include, but are not limited to, piecewise-defined functions or generalized functions. Time events, which are (by definition) known prior to the start of computations, are associated with excitations (assuming they are deterministic, not random). Some locations when  $\dot{x} = 0$  (or  $i = 0$ , or  $v = 0$ ) are highlighted with red circles in most plots in Sect. [4.](#page-15-0) In contrast, state events cannot be known in advance because they are caused by nonlinearities in the constitutive relations. Both directly affect the smoothness of the state equation, an ODE.

An interesting and a challenging point for the controllable hydraulic damper is the subtlety of state events. There are no time events in this case because the prescribed excitation is analytic. However, there are state events, caused by four situations, detailed in

<span id="page-19-0"></span>**Fig. 15** Cartoons showing time-varying secants of  $\mathbf{a}$  ( $\dot{x}$ ,  $r$ ) and  **(** $x, r$ **) for memristive and memcapacitive systems, respectively** 

Table [6.](#page-19-2) Numerically solving the case study of controllable hydraulic damper can be quite challenging. We need to pay attention to the time instances when  $x(t) = 0$ ,  $\dot{x}(t) = 0$ ,  $\ddot{x}(t) = 0$  and those time instances when sat applies. One of the challenges—for the specified excitation time histories—is that  $x(t) = 0$  and  $\ddot{x}(t) = 0$  do not line up. Some locations when  $\ddot{x} = 0$ (or  $\dot{v} = 0$ ) are highlighted with blue squares in most plots in Sect. [4.](#page-15-0)

### <span id="page-19-1"></span>4.6 Using time-varying secants in modeling

For modeling purposes, it is worth noticing that the quotient of  $r(t)$  and  $\dot{x}(t)$  has the physical meaning of a time-varying viscous damping coefficient. Likewise, the quotient of  $r(t)$  and  $x(t)$  is a time-varying stiffness. In other words, the quotients  $D =$  $rac{r(t)}{\dot{x}(t)}$ and  $S = \frac{r(t)}{x(t)}$  are time-varying secants, illustrated in Fig. [15,](#page-19-0) which are defined for all *t* except when the denominator is zero which should not hinder physical interpretation.

Given a time-varying  $(x, r)$  plot, the physical interpretation of secant stiffness *S* clearly differs from the tangent stiffness  $K$ , as discussed in Property  $4$  and shown in Tables [5](#page-14-1) and [13.](#page-30-1) Secant modulus is also well-known in engineering mechanics as, for example, Young's modulus for concrete which is typically estimated for a stress-strain curve by connecting the origin with the point corresponding to 45% of its ultimate strength in accord with the recommendation of ACI [\[1\]](#page-34-21). However, time-varying secants are not so widely used as time-varying tangents when modeling pathdependent engineering mechanics systems. Nevertheless, when applying mem-models to experimental data, we must pay attention to time-varying secants . For the reader's convenience, time-varying secant plots of all four mem-dashpots are presented together in Fig. [16.](#page-21-1) Note that Cases #1 to 3 are effort-controlled with  $v(t)$ specified as the excitation;  $M = \frac{v(t)}{i(t)}$  and  $W = \frac{i(t)}{v(t)}$ in these case studies are analogous to  $\frac{r(t)}{\tilde{x}(t)}$  and  $\frac{\dot{x}(t)}{r(t)}$ , respectively, for mem-dashpots.

*Example 1* (Using  $M = \frac{v(t)}{i(t)}$  for modeling memristors: Case Studies #1 and 2) Figures [17](#page-21-0) and [18](#page-22-0) show results from Case Studies #1 and 2. Even though different excitations are used, each quotient  $M = \frac{v(t)}{i(t)}$  stays on its own secant curve, which is a constitutive curve. Moreover, since these are memristors (elements), each flux–charge relationship is one-to-one for the specified excitation, which in general does not happen for systems (either memristive or memcapacitive).

*Example 2* (Using  $W = \frac{i(t)}{v(t)}$  for modeling a memristive System: Case Study  $\#3$ ) Figure [19](#page-23-1) shows results from Case Study #3 [\[7](#page-34-19)], which is a memristive system (not an element). For this model, the secant (i.e., quotient) is a bivariate function that depends on the voltage v and its time integral  $\phi$ . In addition, both  $(q, \phi)$ and  $(W, \phi)$  are not one-to-one mappings—even though these facts are not obvious without careful study of the model and Fig. [19.](#page-23-1) While "Understanding Case Study #3" of Appendix [4](#page-31-0) discusses these claims, intuitively we explain them as a result of the model not being an element but a system, the former of which would guarantee  $(q, \phi)$  and  $(W, \phi)$  to be one-to-one mappings according to Table [7.](#page-27-1)

*Example 3* (Using  $D = \frac{r(t)}{\dot{x}(t)}$  for modeling a memdashpot: Scruggs and Gavin [\[38](#page-35-12)]**)** It should not be a surprise to learn that, for memristive systems, the secant damping *D* is not a single-valued function of *x*. For example, under the excitation given in Scruggs and Gavin [\[38\]](#page-35-12), the secant damping in  $(\dot{x}, r)$  is not a simple function. In fact, the internal state variable,  $w$ , is actually a normalized time-varying damping coefficient that follows its own dynamics; see Fig. [13.](#page-17-1)

### <span id="page-20-0"></span>**5 Case studies of mem-springs**

#### 5.1 Overview of mem-spring case studies

In this section, we present mem-spring models that reproduce the features of some fascinating nonlinear hysteresis, which we believe have underlying memcapacitive nature. In contrast to memristors, memcapacitors are relatively new, yet we believe there is no lack of examples. Two possibilities are self-centering structures and flag-shaped hysteresis, which have captured attention in earthquake engineering and shape-memory alloy (SMA) communities (e.g.,  $[8,35]$  $[8,35]$  $[8,35]$ ). However, they are neither memristors nor memristive systems. The zero-crossing property of memristors is expressed in terms of  $(\dot{x}, r)$ , whereas the zero-crossing property of self-centering structures (or flag-shaped hysteresis) is expressed in terms of  $(x, r)$  manifesting superelasticity, i.e., having zero residual displacement upon unloading. Perhaps, their behavior could be modeled as memcapacitors or, more likely, memcapacitive systems. While simulated data are used for SMA as described in "Appendix 4," experimental data are examined for a self-centering test structure in this section. In both cases, the resulting mem-spring models utilized the switching mechanism discussed in Sect. [3.4.](#page-14-0)

There are of course other mechanical capacitors (i.e., springs) that include memory effects; however, many of them are neither memcapacitors nor memcapacitive systems. For example, the Ramberg-Osgood model  $[25]$  is not a memcapacitor, nor is it a memcapacitive system. The same can be said for the well-known bilinear model [\[5](#page-34-23)[,6](#page-34-24)[,26](#page-34-25)].

### <span id="page-20-1"></span>5.2 Experimental PC4 data modeled as a mem-spring

PC4 in Ricles et al. [\[35\]](#page-35-11) is a specimen typifying the potential of self-centering structures.  $T = 8$  s is assumed for every cycle of an amplitude-modulated sawtooth displacement excitation as shown in Fig. [20a](#page-24-0). Four colors are used to indicate loading and unloading in both the positive and negative directions. Digitized data are only obtained for the positive direction, while antisymmetry is used for the negative direction.  $a(t)$  is obtained through calculating the area under  $x(t)$ . Figure [21a](#page-24-1) recovers Ricles et al. [\[35](#page-35-11)]'s Fig. 8(a), while Fig. [20b](#page-24-0)–d and Fig. [21b](#page-24-1), c provide other quantities that are not presented in Ricles et al. [\[35\]](#page-35-11), but useful in our modeling.

For the assumed excitation, the secant stiffness *S* shown in Fig. [22](#page-24-2) was extracted by analyzing test data. To clarify this, we select  $a$  and  $\dot{x}$  as state variables and assume the following input–output equation:

$$
r = S(\underbrace{a, \dot{x}}, x)x
$$
\n(32)

**Fig. 16** *Top row* Secants for all four case studies; the complexity increases from elements (*first two plots*) to systems (*last two plots*). For an element, the secant is a one-to-one mapping. For

<span id="page-21-2"></span>

a system, it is not. For Case Study #3, the secant is a bivariate function (see Fig. [19\)](#page-23-1). For the controllable hydraulic damper, it is a dynamic quantity. *Bottom row*: The integrals of the secants

<span id="page-21-1"></span>

<span id="page-21-0"></span>**Fig. 17** Figure [2b](#page-10-1), c in Case Study #1 from Strukov et al. [\[43](#page-35-3)] is reproduced by using the two different memristor models subject to two different excitations. See Tables [14](#page-30-2) and [15](#page-31-1) in "Case studies from nano-field" of Appendix [4](#page-31-0) for details

<span id="page-22-0"></span>**Fig. 18** A parametric study based on the model given in Strukov [\[42](#page-35-13)], Page 17, subject to  $v = \pm v_0 \sin^2 \left(\frac{1}{2} 2.5 \pi t\right)$  with  $v_0 = 1, 2, 2.2$ , respectively. These exercises reveal the oneto-one mapping  $M$  (or, equivalently,  $G$ ) as the excitation gets

$$
= \left[\frac{1}{4}(\text{sgn}(x) + 1)(\text{sgn}(x) + 1)S_1(x) + \frac{1}{4}(\text{sgn}(x) + 1)(1 - \text{sgn}(x))S_2(a, x) + \frac{1}{4}(1 - \text{sgn}(x))(1 - \text{sgn}(x))S_3(x) + \frac{1}{4}(1 - \text{sgn}(x))(\text{sgn}(x) + 1)S_4(a, x)\right]x
$$
(33)

For this example, having  $\dot{x}$  as a state variable is very helpful in defining the switching mechanism for a memcapacitive system. For each of the four zones selected by the joint signs of  $x$  and  $\dot{x}$ , the value of  $S$  is either a function of *x* alone (when it seems to be simply a nonlinear spring) or a function of both *a* and *x* (when it seems to be a memcapacitive system).

stronger. They also show that a memristor may not display its nonlinearity when the excitation is very weak. This is our Case Study #2; see Tables [14](#page-30-2) and [15](#page-31-1) in "Case studies from nano-field" of Appendix [4](#page-31-0) for details

Our proposed model works with the specified amplitude and rate of the input. It is a black-box model that is quite a simplification since it involves only a singledegree-of-freedom. Since each nonlinear model would be different, our model must be checked against additional test data. In addition, we anticipate the need for a damage index bounded within a range, to be introduced as an internal state variable.

### <span id="page-22-1"></span>5.3 A proposed qualitative mem-spring model for flag-shaped hysteresis

When an input  $x(t)$  with a period of  $T = 4$  s is used, we have the following model and simulation shown in

<span id="page-23-1"></span>**Fig. 19** An illustration of the secant *W* being a bivariate function of  $\phi$  and v in Case Study #3 from Chang et al. [\[7\]](#page-34-19). The threedimensional surface  $W = W(\phi, v)$  contains two trajectories that resulted from two distinct excitations. In addition, the first and

Figs. [23](#page-25-0) and [24](#page-25-1) by introducing an intermediate variable, which is *not* a state variable:

$$
w(t) = a(t) - a(t_i) [\mathcal{H}(t - t_i) - \mathcal{H}(t - t_{i+1})]
$$
  
\n $t \in [t_i, t_{i+1}], \text{ where } x(t_i) = 0, \quad i = 1, 2, 3, ...$  (34)

leading to  $w(t) = a(t)$  when  $x(t) > 0$ , and  $w(t) =$  $a(t)$ − a local maximum value for  $a(t)$  when  $x(t) < 0$ . All local maximum values can be considered values of a memory parameter [\[49](#page-35-14)]. The input–output equation then becomes  $r(t) = S(t) x(t)$  with:

third quadrants in  $(v, i)$  correspond to two different curves in  $(\phi, i)$ *W*) and  $(\phi, q)$ , even though these facts may not be easily seen here. See "Understanding Case Study #3" of Appendix [4\)](#page-31-0)

$$
S(t) = \begin{cases} S_0 e^{-a_0}, & |w(t)| \le a_0 \\ S_0 e^{-|w(t)|}, & |w(t)| > a_0 \end{cases}
$$
(35)

where  $a_0 > 0$ . Comparing Figs. [20](#page-24-0) with [23,](#page-25-0) and [21](#page-24-1) with [24](#page-25-1) indicates both the promise and limitation of this proposed mem-spring model in capturing the flagshaped hysteresis given in the PC4 data in Ricles et al. [\[35\]](#page-35-11).

### <span id="page-23-0"></span>5.4 Comment on generalizing mem-springs

Many continuum mechanics texts introduce constitutive models by discussing linearly elastic materials that obey tensorial stress-strain equations

*Author's personal copy*

**Fig. 21**  $(x, r)$ ,  $(a, r)$ ,  $(a, x)$ , and  $(a, S)$  are shown here, where a matches Ricles et al. [\[35\]](#page-35-11)'s Fig. 8(a), and **b**–**d** are derived from **a** and to reveal the insights into modeling in this study

<span id="page-24-2"></span><span id="page-24-1"></span>

**Fig. 23** Behaviors and inner workings of the proposed qualitative system model under multiple cycles of amplitude-modulated sawtooth excitation—in terms of time histories—in contrast to those in Fig. [20](#page-24-0)

<span id="page-25-0"></span>

<span id="page-25-1"></span>**Fig. 24** Behaviors and inner workings of the proposed qualitative system model under multiple cycles of amplitude-modulated sawtooth excitation—in terms of hysteretic loops—in contrast to those in Fig. [21](#page-24-1) and more

$$
\sigma = \mathbf{E} : \boldsymbol{\varepsilon} \tag{36}
$$

where **E** denotes a constant tensor called the secant modulus [\[47](#page-35-15)]. These are called Hookean models because they generalize Hooke's law, which is a scalar equation, just as each input–output equation in Table [2](#page-7-0) is scalar. By analogy, one way to generalize memsprings is to embed them in continuum mechanics by defining a secant modulus tensor which depends on strain as well as other state variables **y** that enable history dependence  $\mathbf{E} = \mathbf{E}(\mathbf{y}, \boldsymbol{\varepsilon})$ .

For example, consider a long thin uniform cylindrical wire, made of SMA, having length *L* and crosssectional area *A*. Assume infinitesimal strain theory, let the axial displacement be denoted by

$$
\delta = \delta(\xi, t) \tag{37}
$$

where  $\xi \in [0, L]$  is the axial coordinate, and let

$$
\varepsilon = \varepsilon(\xi, t) = \frac{\partial \delta(\xi, t)}{\partial \xi} \tag{38}
$$

be the axial strain. Assume the SMA material obeys a uniaxial stress-strain equation of the form

$$
\sigma = E(\alpha, \varepsilon)\varepsilon \tag{39}
$$

where  $\alpha = \alpha(\xi, t)$  is the integral of the strain with respect to time, called the "strain absement," thereby enabling history-dependent response under certain axial loading conditions. Furthermore, since SMA is known to be rate-dependent [\[50\]](#page-35-16), the secant modulus

should also depend on strain rate  $\varepsilon_t = \frac{\partial \varepsilon(\xi, t)}{\partial t}$ , so generalize further by letting

$$
E = E(\alpha, \varepsilon_t, \varepsilon) \tag{40}
$$

which highlights the distinction between history- and rate-dependent response. The local axial stiffness of this model is

$$
S(\alpha, \varepsilon_t, \varepsilon) = \frac{E(\alpha, \varepsilon_t, \varepsilon)A}{L} \tag{41}
$$

which is analogous to the secant stiffness in Eq.  $(32)$ . Dynamically, this SMA wire model would satisfy the nonlinear wave equation

$$
\mu \frac{\partial^2 \delta}{\partial t^2} = \frac{\partial}{\partial \xi} \left[ E(\alpha, \varepsilon_t, \varepsilon) \frac{\partial \delta}{\partial \xi} \right]
$$
(42)

where  $\mu$  is the mass density of the SMA material.

In addition to nonlinear material behavior, nonlinear geometric behavior (finite strain) must ultimately be considered in three-dimensional configurations. As stated on page 609 of Willam [\[47](#page-35-15)], "the three versions of nonlinear elasticity" (algebraic, integral, differential) "lead to constitutive formulations which exhibit fundamental differences when we consider triaxial conditions." Constitutive models for SMA (and other materials) must be generalized beyond nonlinear elasticity, thereby enabling hysteretic dissipative response under diverse loading conditions. These are challenging topics which have been, and will continue to be, important areas of engineering mechanics research for many decades.

### <span id="page-26-0"></span>**6 Summary and conclusions**

In brief, Chua proposed the memristor in [\[9](#page-34-0)], presented memristive systems theory with Kang 5 years later in Chua and Kang [\[10](#page-34-4)], and presented memcapacitive and meminductive theories with Di Ventra and Pershin in Di Ventra et al. [\[13\]](#page-34-5). Table [2](#page-7-0) summarizes the results of transplanting these theories to the field of engineering mechanics by following the lead of Oster and Auslander [\[31](#page-35-6)] and Jeltsema and Scherpen [\[24](#page-34-11)]. Many examples of memristors and memristive systems, called mem-dashpots, were found in the literature; however, the same could not be said of memcapacitors or memcapacitive systems, called mem-springs. Mathematical parallelisms between mem-dashpots and mem-springs were recognized and exploited, but physical differences and the newness of mem-springs led to the realization that these newer models deserve deeper study, in part because of a little-studied quantity called absement which allows mem-spring models to display hysteretic response in great abundance. However, it is nontrivial to devise mem-spring models that, when subjected to arbitrary excitations, are passive. Even for periodic excitations, a switching mechanism was needed so that simulations with prototype mem-spring models could maintain passivity, as in Fig. [1.](#page-5-5) Moreover, the input–output equations for all mem-models in Table [2](#page-7-0) are scalar, as is Hooke's law, which implies that embedding mem-models in continuum mechanics is a nontrivial task. The mathematical form of the stressstrain equations that arise from such considerations involves secant modulus rather than tangent modulus, so these inherently nonlinear models are partly algebraic (the input–output equation) and partly differential (the state equation). In other words, the stress-strain equations that emerge from generalizing a scalar memspring model would involve total stress and strain (not incremental relations as in plasticity). As [\[47\]](#page-35-15) notes, different versions (algebraic, differential) of nonlinear elasticity alone (to say nothing of inelasticity) lead to constitutive formulations that display fundamental differences under triaxial conditions. Clearly, these nonlinear constitutive models merit more study.

**Acknowledgments** This study is partially funded by NSF CMMI 0626401 with Program Office, Dr. S.C. Liu. Part of this work was initiated during the first author's sabbatical leave; she would like to thank Professor Jim Beck and Professor Jeff Scruggs for their hospitality. The authors would like to thank Professor Jim Beck for providing us with Eq. [\(48\)](#page-28-3) and helpful comments to earlier drafts, Professor Jeff Scruggs, Professor Dennis Bernstein, and Dr. Giovanni Paziena for referring us to the following references, respectively, Ogata [\[30](#page-34-8)], Jeltsema and Scherpen[\[24](#page-34-11)], and Strukov [\[42\]](#page-35-13). The first author wishes to thank Professor Shirley Dyke for assistance in finding data for the PC4 specimen in Ricles et al. [\[35\]](#page-35-11).

### **Appendix 1 for Sect. [2](#page-5-1)**

Table [7](#page-27-1) lists various definitions of the memristor and the publications from which they were taken. First, these seemingly different definitions are indeed all consistent once notational differences are taken into account. Next, they are for either a general or a specific electrical system. Last, they distinguish a flow-controlled electrical device from an effort-controlled electrical device. For electrical systems, charge- or current-controlled

### Understanding memristors and memcapacitors

<span id="page-27-1"></span>

<span id="page-27-0"></span>**Fig. 25 1a** A Kelvin model connected in series with a mass, **1b** a Maxwell model connected in series with a mass, **2a** a Kelvin model connected with a memristor in parallel and then connected in series with a mass, **2b** a Maxwell model connected with a memristor in series and then connected in series with a mass. Each is subject to a prescribed force  $u(t)$ 

are aliases for flow-controlled, while flux-, voltage-, or impulse-controlled are aliases for effort-controlled.

Figure [25](#page-27-0) depicts some simple situations where the necessity to contrast flow- and effort-controlled mechanical systems becomes evident. After all, basic elements like springs, dampers, or memristors are made to be used repetitively and in a well-organized manner in order to form a "system" that models a complex realworld device or structure. For translational mechanics, the connectivity of these basic elements can be reduced to either parallel or serial connections, the roots of the concepts of flow- and effort-controlled systems.

Figure [251](#page-27-0)a and 1b shows the Kelvin and Maxwell models, each connected in series with a mass. Jeltsema and Scherpen [\[24\]](#page-34-11) reveal the duality between these flow- and effort-controlled systems, expressed in terms of integro-differential equations. In a flow-controlled device, the natural state variables are displacement *x* and velocity  $\dot{x}$ . These state variables should be solved (or calculated) first by integrating the differential equation based on force equilibrium. In contrast, in an effort-controlled device, the natural state variables are

momentum  $p$  and restoring force  $r$ , where momentum is the time integral of restoring force. These state variables should be solved (or calculated) first from the equation based on deformation compatibility.

These two linear time-invariant flow- and effortcontrolled systems may be extended by introducing a new element—such as the memristor (nonlinear timeinvariant)—as shown in Fig. [25](#page-27-0) 2a and 2b. Table [8](#page-28-0) presents the state variables and state equations for the corresponding models in Fig.  $25$ , where  $u(t)$  is an applied force as in Eq. [\(1\)](#page-5-0). For systems in general, the constitutive relations of all components—either elements or systems—need to be "assembled" in accord with the connectivity of the components. In the absence of other important details, the need for two different mathematical expressions for the same memristor to fit into these two different systems may be seen clearly. In other words, when doing computations, we may need to deal with either a flow-controlled memristor or an effort-controlled memristor, depending on the element or system connectivity.

Table [9](#page-28-1) lists expressions that are analogous to the set of  $(v, i)$  plots in Strukov  $[42]$  under the title of "Curious Lay Person's Viewgraph—II," plus one more for the memcapacitor. Table [9](#page-28-1) also illustrates the underlying mathematical parallelism in the case of sinusoidal excitation.

The proof to Remark [4](#page-7-1) is given below. The equation of motion corresponding to Fig.  $25(2a)$  $25(2a)$  is:

<span id="page-27-2"></span>
$$
m\ddot{x} + kx = u - [c + M(x)]\dot{x}, \text{ with } x(0) = x_0,
$$
  
\n
$$
\dot{x}(0) = \dot{x}_0
$$
\n(43)

Assume free vibration; i.e.,  $u = 0$ . Multiply both sides of Eq.  $(43)$  by  $\dot{x}(t)$ . Note that

$$
(m\ddot{x} + kx)\dot{x} = \frac{d}{dt}E(t)
$$
\n(44)

Other damper equations may be used

**Table 10** Examples of mem-dashpots

<span id="page-28-2"></span>ID Application and governing Eq.

1. The Van der Pol oscillator and Liénard equation contain mem-dashpots. The Van der Pol oscillator can be viewed as a memdashpot connected in parallel with a linear dashpot and a linear spring before connecting in series with a mass, as illustrated in Fig. [25\(](#page-27-0)2a):

$$
\ddot{x} - \varepsilon [1 - x^2] \dot{x} + x = 0, \text{ with } \varepsilon > 0 \implies \underbrace{\ddot{x}}_{\text{unit mass classical dashpot}} + \underbrace{\varepsilon \dot{x}}_{\text{mem-dashpot}} + \underbrace{x}_{\text{classical spring}} = 0 \quad (46)
$$

 $(47)$ 

A more general expression for a mem-dashpot in a flow-controlled mechanical system is the term  $D(x)\dot{x}$  in the Liénard equation:

$$
\underbrace{\ddot{x}}_{\text{unit mass}} + \underbrace{D(x)\dot{x}}_{\text{mem-dashpot}} + \underbrace{f(x)}_{\text{nonlinear spring}} = 0
$$

The Liénard equation, which includes the Van der Pol oscillator, is one of the most theoretically studied nonlinear dynamics equations (e.g., [\[18](#page-34-26)[,29](#page-34-3)[,41](#page-35-18)]).

<span id="page-28-3"></span>2. Displacement-dependent dampers, which have been investigated for earthquake mitigation [\[16,](#page-34-27)[34](#page-35-19)], are mem-dashpots. A general form is:

$$
D(x) = \sum_{n=1}^{\infty} \alpha_n |x|^n, \ \alpha_n \ge 0 \qquad (48)
$$

where the use of the absolute function and the requirement of nonnegativity of  $\alpha_n$  are to ensure passivity of the memristor (Remark [4\)](#page-7-1). Ilbeigi et al. [\[20](#page-34-28)] studied nonlinear displacement-dependent dampers of the type:

$$
D(x) = \lambda \left[ \mu^2 \left( \frac{1}{1 - \beta x^{\left( \frac{1}{\delta} \right)}} \right)^2 - 1 \right]^2 \tag{49}
$$

#### Understanding memristors and memcapacitors

#### **Table 10** continued

### ID Application and governing Eq.

where  $\lambda > 0$  satisfies the passivity property, Remark [4](#page-7-1) ( $\mu$ ,  $\beta$ , and *s* are other design parameters). This formula is approximated using Taylor series expansion in Ilbeigi et al. [\[20\]](#page-34-28), resulting in two other damper formulas as follows:

$$
D(x) = \alpha_1 + \alpha_2 |x|^{\frac{1}{s}} + \alpha_3 |x|^{\frac{2}{s}} + \alpha_4 |x|^{\frac{3}{s}} + \alpha_5 |x|^{\frac{4}{s}} \qquad (50)
$$
  

$$
D(x) = \alpha_1 + \alpha_2 x^2 + \alpha_3 x^4 + \alpha_4 x^6 + \alpha_5 x^8 \qquad (51)
$$

Each of these can be considered a linear viscous damper connected with memristors (mem-dashpots) in series. The passivity conditions  $\alpha$ 's  $\geq 0$  are satisfied in Ilbeigi et al. [\[20](#page-34-28)] but not mentioned.

3. Variable dampers have been studied for earthquake mitigation as well. Unlike the displacement-dependent dampers discussed above, they are not memristors but they are memristive systems. For example, setting  $y = x$ , the two-step viscous damping in Madhekar and Jangid [\[27\]](#page-34-29) is of the form:

$$
r = \underbrace{\left[\frac{1}{2} \left(1 + \text{sgn}\left(x\dot{x}\right)\right) c_{d_1} + \frac{1}{2} \left(1 - \text{sgn}\left(x\dot{x}\right)\right) c_{d_2}\right]}_{D(y,\dot{x})} \dot{x} \tag{52}
$$

where  $c_{d_1}$  and  $c_{d_2}$  are two different viscosity values. This is an input–output equation of a time-invariant flow-controlled memdashpot as in Table [3;](#page-9-0) also see the two (*x*˙, *r*) plots with prominent zero-crossing feature in Madhekar and Jangid [\[27](#page-34-29)].

where  $E(t) = \frac{1}{2}m\dot{x}^2 + \frac{1}{2}kx^2$ . Multiply this equation by *dt* and integrate from  $t = 0$  to  $t = T$  to obtain  $E(T) = E(0) - \Delta(T)$ , where

$$
\Delta(T) = \int_0^T \left[c + M(x)\right] \dot{x}^2 dt \tag{45}
$$

is a dissipation function. If  $c + M(x) \geq 0$ ,  $\forall x(t)$ , then  $\Delta(T) \geq 0$ . Thus,  $M(x) \geq -c$  is sufficient for passivity (i.e., no produced energy).

### **Appendix 2 for Sect. [3](#page-9-1)**

Examples of mem-dashpots are given in Table 10. See Tables [11](#page-29-0) and [12](#page-30-0) for some models used in Sects. [3.3](#page-10-0) <span id="page-29-1"></span>and [3.4,](#page-14-0) respectively. Table [13](#page-30-1) and Figs. [26](#page-32-1) and [27](#page-32-0) are also referred to in Sect. [3.](#page-9-1)

<span id="page-30-2"></span>**Table 14** Three case studies on nano-devices selected as case studies herein with the equation or page numbers appeared in these papers

function of  $w(t)$  and  $v(t)$ . Applying the fundamental existence-uniqueness theorem for ODEs (e.g., in [\[18](#page-34-26)]) to Eq. [\(57\)](#page-31-3), the solution exists and is unique on an open set for v; i.e.,  $(w, \phi)$  is one-to-one (since the hyperbolic sine in Eq. [\(57\)](#page-31-3) is analytic and thus satisfies the Lipschitz condition). Hence,  $W = f(w(\phi), v)$  =  $g(\phi, v)$ .

Hereafter, consider only prescribed piecewise linear  $v(t)$  as in [\[7\]](#page-34-19). Assume  $v(t) = bt + c$  for a generic section of the excitation and proceed as follows:

$$
\frac{d\phi}{dv} = \frac{\phi}{\dot{v}} = \frac{v(t)}{b} \tag{59}
$$

leading to the following piecewise relation for the phase plot  $(\phi, v)$ :

$$
\phi(t) = \frac{v^2(t)}{2b} + \phi_0 \Longrightarrow v(t) = \pm \sqrt{2b(\phi(t) - \phi_0)}
$$
\n(60)

#### Understanding memristors and memcapacitors

<span id="page-31-1"></span>**Table 15** Case studies: Both the state and input–output equations are from the original papers where they are cited from

ID	State and input-output Eqs. and Inter. Var.							
----	---	--	--	--	--	--	--	--

1 Equations [\(6\)](#page-8-2) and [\(5\)](#page-8-1) from Strukov et al. [\[43](#page-35-3)] are the state and input–output equations to produce Fig. [2](#page-10-1) in that paper:

State Eq.:  $\frac{dw}{dt} = \mu_V \frac{R_{ON}}{D}$ *<sup>D</sup> i* (53)

 $I/O$  Eq.:  $v = (R_{ON} \frac{w}{D} + R_{OFF} (1 - \frac{w}{D}))$ *i* (54)

where  $v(t) = v_0 \sin(\omega_0 t)$  and  $v(t) = \pm v_0 \sin^2(\omega_0 t)$  for Fig. [2b](#page-10-1), c, respectively, with  $v_0 = 10$ , and  $\omega_0 = 10\pi$  - differing from Strukov et al. [\[43](#page-35-3)], where  $v_0$  and  $\omega$  of being 1 and 200 $\pi$ , respectively. In addition,  $\frac{R_{\text{OFF}}}{R_{\text{ON}}}$  = 160 and  $\frac{R_{\text{OFF}}}{R_{\text{ON}}}$  = 380 for Fig. [2b](#page-10-1), c, respectively,  $R_{\text{ON}} = 100$ ,  $\frac{D^2}{\mu V} = 0.01$ , and  $\frac{w}{D}|_{t=0} = 0.1$ .

2 Strukov et al. [\[43](#page-35-3)] points that Chua does not anticipate w being bounded by 0 and *D*. A term called "window function" is used to simulate nonlinear drift when w approaches 0 and *D*. The expression for the term,  $\frac{w(1-w)}{D^2}$ , unfortunately, has a typo. The correct one is given in Strukov [\[42\]](#page-35-13):

State Eq.: 
$$
\frac{dw}{dt} = \mu_V \frac{R_{ON}}{D} i \frac{w}{D} (1 - \frac{w}{D})
$$
 (55)  
UO Eq.:  $v = (R_{ON} \frac{w}{D} + R_{OFF} (1 - \frac{w}{D})) i$  (56)

where  $\frac{R_{\text{OFF}}}{R_{\text{ON}}}$  = 50,  $R_{\text{ON}}$  = 100,  $\frac{D^2}{\mu_V}$  = 0.01, and  $\frac{w}{D}|_{t=0}$  = 0.001 assumed by the authors—not being zero as  $w \in (0, D)$ <br>on pp. 17 of Strukov [\[42\]](#page-35-13). To reproduce the response given on pp. 17 i specified frequency but not amplitude.

<span id="page-31-3"></span><span id="page-31-2"></span>3 From Chang et al. [\[7\]](#page-34-19):

State Eq.:  $\frac{dw}{dt} = 2\lambda \sinh(\eta v)$  (57) I/O Eq.:  $i = \left(1 - \frac{w}{D}\right) \alpha \left[1 - e^{-\beta v}\right] + \frac{w}{D} \gamma \sinh(\delta v)$  (58) where  $\lambda = 4.5$ ,  $\eta = 4$ ,  $\alpha = 0.5 \times 10^{-6}$ ,  $\beta = 0.5$ ,  $\gamma = 4 \times 10^{-6}$ , and  $\delta = 2$ .  $D = 412.5$  was obtained by trial and error in this study with  $\frac{w}{D}$  as given in Eq. [\(58\)](#page-31-2) (instead of Eq. (4) in Chang et al. [\[7](#page-34-19)] which gives a different range for *i*).

The general solution to Eq. [\(57\)](#page-31-3) with  $v(t) = bt + c$ is:

$$
w(t) = w(t_0) + \frac{2\lambda}{\eta b} \left[ \cosh(\eta v(t)) - \cosh(\eta bt_0 + \eta c) \right]
$$
\n(61)

$$
\stackrel{\text{Eq. (60)}}{=} w(t_0) + \frac{2\lambda}{\eta b} \left[ \cosh\left(\pm \eta \sqrt{2b\left(\phi(t) - \phi_0\right)}\right) - \cosh(\eta bt_0 + \eta c) \right]
$$
\n(62)

where the sign  $\pm$  remains the same within each piece as before. Clearly,  $(w, \phi)$  is a one-to-one mapping *within each piece* of the solution curve separated by the time events. Given that cosh is an even function, the first and third quadrants in  $(v, i)$  share the same  $(w, \phi)$ . These can be verified in Fig. [28.](#page-32-2)

Substituting Eqs.  $(58)$  to  $(61)$ , it can be seen that, for a pair of v and −v, the absolute values of their *i* differ, so do their *q* and *W* values—as stated in the caption for Fig. [19.](#page-23-1) Indeed, this system is not a memristor; rather, it is a memristive system.

In fact, the pair of  $\dot{w}$  and v defined in Eq. [\(57\)](#page-31-3) represents a relationship in a nonlinear resister with  $\dot{w}$  and w corresponding to current and charge, respectively.

Having said this,  $(w, \phi)$  must be a one-to-one mapping as stated above and illustrated in Fig. [28.](#page-32-2) Alternatively (and at the risk of unnecessary length), the one-to-one'ness and inflection points on  $(w, \phi)$  shown in Fig. [28](#page-32-2) can be understood as follows:

<span id="page-31-4"></span>
$$
\frac{\mathrm{d}w}{\mathrm{d}\phi} = \frac{\dot{w}}{\dot{\phi}} = \frac{2\lambda\sinh(\eta v)}{v} \tag{63}
$$

For all  $v(t)$ ,  $\frac{dw}{d\phi} > 0$ , which explains the monotonic  $(w, \phi)$ ; i.e.,  $(w, \phi)$  is one-to-one *for all t*. Furthermore, the continuity of sinh can be used to explain the continuity of  $(w, \phi)$  even when  $v(t)$  is only  $\mathcal{C}^0$  continuous.

### <span id="page-31-0"></span>**Appendix 4 for Sect. [5](#page-20-0)**

A prototype mem-spring model for SMA wire is given herein. While the models in Figs. [26](#page-32-1) and [27](#page-32-0) could be candidates for SMA wire in tension (e,g., those in [\[14\]](#page-34-17)), there is a useful methodology for establishing a memcapacitor model for any individual set of SMA wire data under a clearly defined excitation—if we adopt the philosophy of Sect. [4.6](#page-19-1) by paying attention to timevarying secants. For the piecewise-defined displace-

<span id="page-32-1"></span>

<span id="page-32-0"></span>**Fig. 27** Same system models as in Fig. [26](#page-32-1) (see Table [12\)](#page-30-0) but subject to  $x(t) = \frac{4A}{T}$   $\left(t - \frac{T}{2} \left[ \frac{2t}{T} + \frac{1}{2} \right] \right)$  $(-1)^{\lfloor \frac{2t}{T} + \frac{1}{2} \rfloor}$ , with  $a(0) = 0, T = \frac{2\pi}{\omega}, A = 1,$ and  $\omega = 1$ . This is to illustrate the behavior of (*x*, *r*) at  $x = 0$  and the impact of **a** Situation (1), and **b** Situation (2) to the tangent

<span id="page-32-2"></span>**Fig. 28** More insights in terms of  $\frac{w}{D}$  to understand Chang et al.'s [\[7\]](#page-34-19) Fig. 5a and Fig. 5b

<span id="page-33-1"></span>**Fig. 29** Illustrations of the procedure of developing a memcapacitor model by using an arbitrary set of SMA wire under a piecewise linear displacement as in Eqs.  $(13)$  to  $(16)$ 

ment in Eqs.  $(13)$  to  $(16)$ , this methodology is illustrated in Fig. [29](#page-33-1) and explained hereafter.

The mathematical expressions involved in modeling —for the example illustrated in Fig. [29—](#page-33-1)are given as follows:

<span id="page-33-2"></span>
$$
r_1(x) \Rightarrow s_1(x) = \frac{r_1(x)}{x} = s_1(h_1(a)) = S_1(a) \quad (64)
$$

<span id="page-33-3"></span>
$$
r_2(x) \Rightarrow s_2(x) = \frac{r_2(x)}{x} = s_2(h_2(a)) = S_2(a) \quad (65)
$$

To clearly demonstrate this modeling method, Fig. [9](#page-15-2) presented previously is utilized again. The restoring force versus displacement plot in the first quadrant is examined first. As shown in Fig. [30,](#page-33-0) the model parameters  $x_1$ ,  $r_1$ , and  $x_2$  are to be given in advance. Others can be conveniently obtained from geometry:  $r_2 = R - \frac{A - x_2}{x_1} r_1$  and where *R* is the restoring force corresponding to A, and  $x_3 = x_2 - (A - x_1)$ ;  $r_3 = \frac{x_3}{x_1}r_1$ . The corresponding absement values are:  $a_1 = \frac{T}{8A}x_1^2$ ;  $a_2 = 2a_0 - \frac{T}{8A}x_2^2$ , and  $a_3 = 2a_0 - \frac{T}{8A}x_3^2$ . By varying the values of  $x_1$ ,  $r_1$  and  $x_2$ , a set of these submodels are obtained. In all these sub-models, applying Eqs. [\(64\)](#page-33-2) and [\(65\)](#page-33-3) but considering a total of five pieces that characterize an experimental restoring force versus displacement plot, we have the following equations to define *S*(*a*) in a piecewise manner:

$$
S_1(a) = \frac{r_1}{x_1},
$$
  
  $a \in [0, a_1]$ , red lines in Fig. 30, (66)

$$
S_2(a) = \left(r_1 - \frac{x_1}{A - x_1}(R - r_1)\right)\sqrt{\frac{T}{8Aa}} + \frac{R - r_1}{A - x_1},
$$
  
 $a \in [a_1, a_0]$ , orange lines in Fig. 30, (67)

<span id="page-33-0"></span>**Fig. 30** To expand on Fig. [9,](#page-15-2) different variations in the hysteric loop in the first quadrant (subject to a piecewise linear displacement) and their corresponding models. The piecewise linear dis-

placement is defined in Eqs. [\(13\)](#page-13-5) to [\(16\)](#page-13-11) with  $a(0) = 0$ ,  $A = 1$ , and  $\omega = 1$ . Five sets of values are used for  $x_1, r_1$ , and  $x_2$ 

$$
S_3(a) = \left(R - \frac{A}{x_1}r_1\right)\sqrt{\frac{T}{8A(2a_0 - a)}} + \frac{r_1}{x_1},
$$

 $a \in [a_0, a_2]$ , green lines in Fig. [30,](#page-33-0) (68)

$$
S_4(a) = \left(r_3 - \frac{x_3}{x_2 - x_3}(r_2 - r_3)\right)\sqrt{\frac{T}{8A(2a_0 - a)}} + \frac{r_2 - r_3}{x_2 - x_3},
$$

$$
a \in [a_2, a_3], \text{ blue lines in Fig. 30,}
$$
 (69)

$$
S_5(a) = \frac{r_1}{x_1},
$$
  
\n
$$
a \in [a_3, 2a_0], \text{ black lines in Fig. 30,}
$$
 (70)

After finishing modeling the first quadrant, the model in the third quadrant must be made "anti-symmetric with respect to the origin" following [\[13\]](#page-34-5) (see Sect. [3.4\)](#page-14-0), which is conveniently carried out, say, using vector concatenation under MATLAB<sup>TM</sup>. Mathematically, this could be done using either of two approaches given in Sects. [5.2](#page-20-1) and [5.3.](#page-22-1) Data sets from other analytic or piecewise continuous displacements can be treated in a similar manner.
