Summary

Focal segmental glomerulosclerosis (FSGS) is the main pathology underlying steroid-resistant nephrotic syndrome (SRNS) and a leading cause of chronic kidney disease. Monogenic forms of pediatric SRNS are predominantly caused by recessive mutations, while the contribution of *de novo* variants (DNVs) to this trait is poorly understood. Using exome sequencing (ES) in a proband with FSGS/SRNS, developmental delay, and epilepsy, we discovered a nonsense DNV in *TRIM8*, which encodes the E3 ubiquitin ligase tripartite motif containing 8. To establish whether *TRIM8* variants represent a cause of FSGS, we aggregated exome/genome-sequencing data for 2,501 pediatric FSGS/SRNS-affected individuals and 48,556 control subjects, detecting eight heterozygous *TRIM8* truncating variants in affected subjects but none in control subjects ($p = 3.28 \times 10^{-11}$). In all six cases with available parental DNA, we demonstrated *de novo* inheritance ($p = 2.21 \times 10^{-15}$). Reverse phenotyping revealed neurodevelopmental disease in all eight families. We next analyzed ES from 9,067 individuals with epilepsy, yielding three additional families with truncating *TRIM8* variants. Clinical review revealed FSGS in all. All *TRIM8* variants cause protein truncation clustering within the last exon between residues 390 and 487 of the 551 amino acid protein, indicating a correlation between this syndrome and loss of the TRIM8 C-terminal region. Wild-type TRIM8 overexpressed in immortalized human podocytes and neuronal cells localized to nuclear bodies, while constructs harboring patient-specific variants mislocalized diffusely to the nucleoplasm. Co-localization studies demonstrated that Gemini and Cajal bodies frequently abut a TRIM8 nuclear body. Truncating *TRIM8* DNVs cause a neuro-renal syndrome via aberrant TRIM8 localization, implicating nuclear bodies in FSGS and developmental brain disease.

Nephrotic syndrome (NS [MIM: PS256300]) is the second leading cause of chronic kidney disease in the first three decades of life.¹ Children with NS manifest with edema and severe proteinuria, which arise from podocyte foot process effacement within the glomerular filtration barrier.^{2,3} Patients with steroid-resistant nephrotic syndrome (SRNS)

invariably progress to end-stage renal disease (ESRD) and frequently have focal segmental glomerulosclerosis (FSGS [MIM: PS603278]) on renal biopsy.^{1,2,4,5} In 11%–45% of children with FSGS/SRNS, pathogenic variants can be identified in one of 59 known monogenic disease genes.^{6–12} While these Mendelian etiologies predominantly exhibit

recessive modes of inheritance in 44/59 disease genes or dominant vertical inheritance with incomplete penetrance in much of the remainder,⁹ the contribution of *de novo* variants (DNVs) to NS is mostly unknown.

Monogenic NS genes are predominantly expressed in the glomerular podocyte.^{2,3,11,13} Their encoded proteins coalesce into molecular pathways, which are essential for podocyte development or homeostasis and impaired by patient mutations.^{2-4,11,13} Nucleoporins have been implicated in genetic forms of NS,¹⁴⁻¹⁸ thus suggesting that nuclear maintenance and homeostasis are key in the pathobiology of nephrotic syndrome. Nuclear bodies, which are defined sites within the nucleus for biochemical reactions and gene regulation, have not been linked to NS to date.¹⁹⁻²²

We started from the observation of an individual with a rarely observed clinical presentation. The index subject was a male child (case UC-023-1) of Asian ancestry with syndromic NS (Tables 1 and S1; Figures 1A–1C). He developed seizures at 2 years of life. At age 4 years, he developed NS that was resistant to steroid therapy. Renal biopsy revealed FSGS by light microscopy and electron microscopy (Figures 1A and 1B). Notably, electron microscopy showed extensive foot process effacement and distinctive alterations of the glomerular basement membrane (GBM), including thinning, lamellation, and blebbing (Figure 1B).

To identify the genetic cause of NS and, potentially, his epileptic encephalopathy, we performed parent-proband trio-based exome sequencing (ES). Evaluation of ES variant data under both dominant and recessive models did not reveal a causative variant in any gene from a curated list of 625 genes known to be associated to Mendelian kidney diseases,²⁴ which include 59 monogenic NS disease genes⁹

and 20 glomerulonephritis disease genes.⁹ This suggested that the syndromic phenotype of this individual was likely caused by a variant in a gene not previously implicated in known Mendelian forms of kidney disease. Under a dominant *de novo* Mendelian genetic hypothesis, we identified a heterozygous nonsense variant (c.1375C>T [p.Gln459*]) in *TRIM8* (MIM: 606125) in subject UC-023-1, while his unaffected parents were wild type at this position (Table 1; Figures 1C and S1). The results were confirmed using CLIA-certified genome sequencing (GS), which also excluded pathogenic structural variants. *TRIM8* encodes a 551 amino acid tripartite E3 ubiquitin ligase, which regulates NF- κ B, interferon, and STAT signaling pathways in cancer and the immune system²⁵⁻³⁰ (Figure 1C). The variant was deemed deleterious and likely to be causal because (1) the variant is predicted to cause protein truncation, because the resulting mRNA transcript is likely to escape nonsense-mediated decay as it resides in the last exon; (2) it is exceedingly rare and, in fact, absent from the Genome Aggregation Database (gnomAD) population, which contains ES or GS data from 141,456 adults who are not known to have severe pediatric disease,^{31,32} and (3) the *TRIM8* locus exhibits high loss-of-function (LoF) intolerance (gnomAD probability for loss-of-function intolerance [pLI] 0.99; loss-of-function observed/expected upper bound fraction [LOEUF] 0.26), meaning LoF alleles are not frequently observed relative to gene size and expected mutation rate.³¹

To determine whether *TRIM8* DNVs are a monogenic cause of NS and establish whether NS and developmental delay/epilepsy are allelic in these cases, we aggregated and analyzed ES or GS from a cohort of 60,114 subjects, including 2,501 SRNS/FSGS-affected individuals, 48,556

^aPosition change corresponds to *TRIM8* transcript GenBank: NM_030912 and *TRIM8* protein GenBank: NP_112174.2.

^bThis patient was independently recruited and reported²³ while the current manuscript was in preparation.

^cFG-FA corresponds to a pair of monozygotic twins (genetically confirmed) who share the same *TRIM8* variant and a nearly identical phenotype.

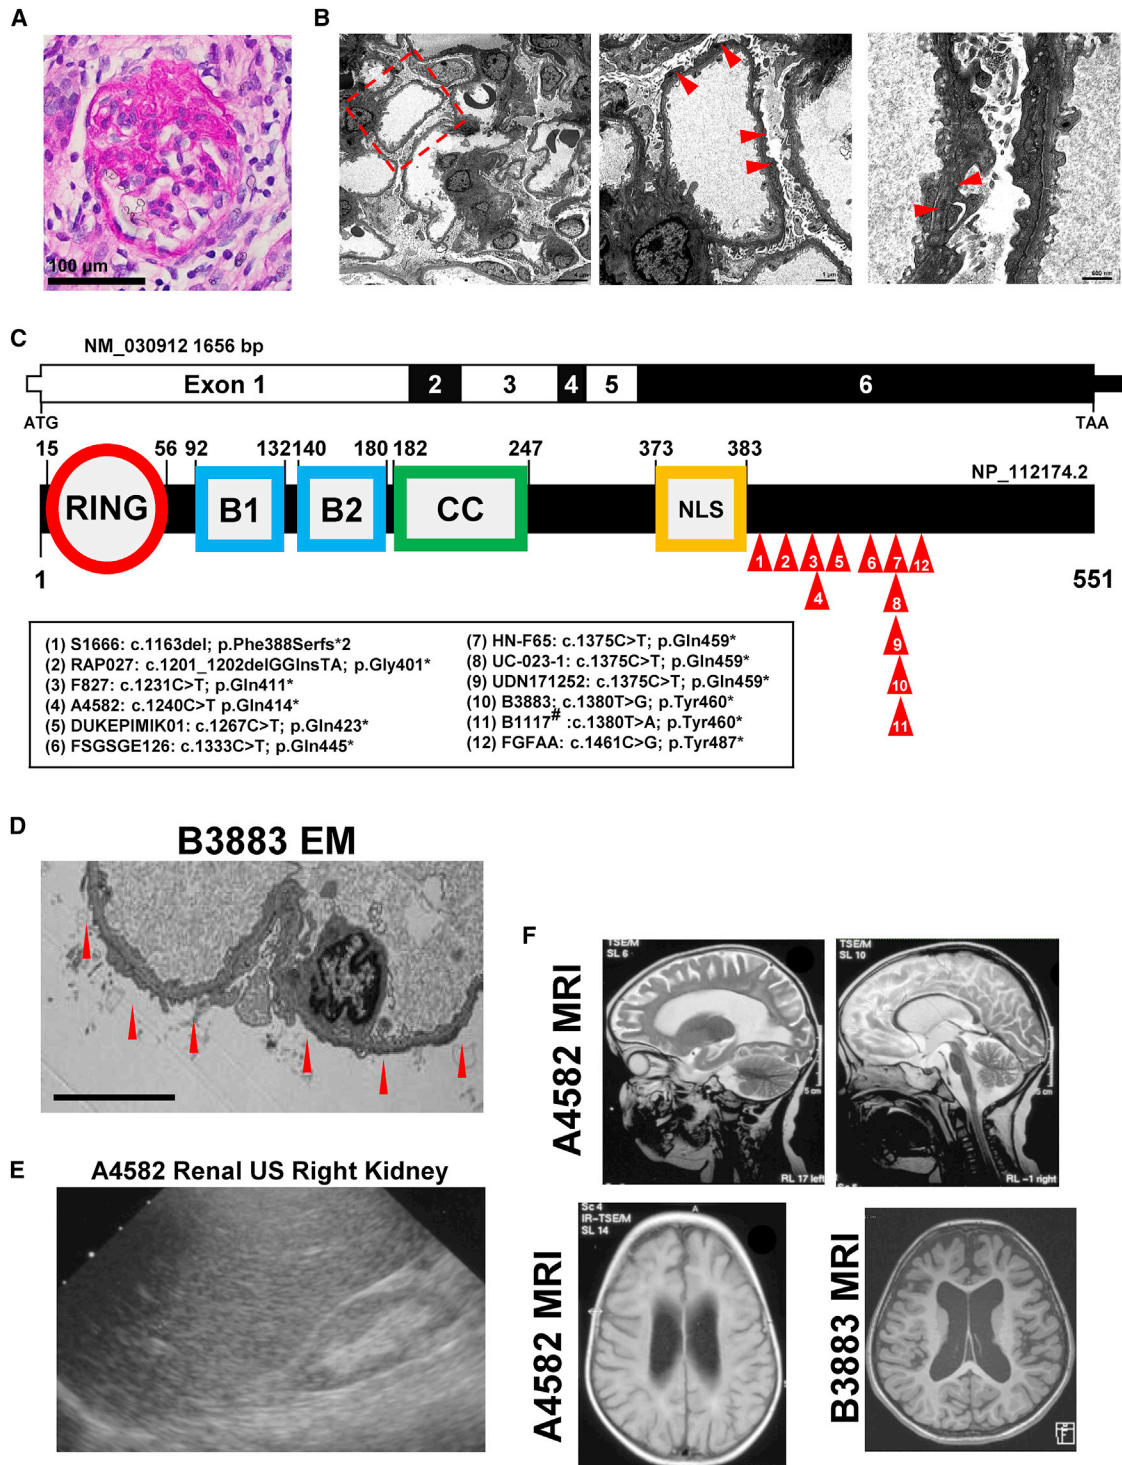

Figure 1. Truncating *TRIM8* mutations identified in 12 families with nephrotic syndrome and neurologic disease

(A) Periodic acid Schiff (PAS) staining of paraffin sections of kidney cortex from a renal biopsy of the index case subject UC-023-1 was performed. A representative glomerulus shows a lesion of focal segmental glomerulosclerosis with segmental obliteration of capillary lumina by extracellular matrix accompanied by loss of overlying podocytes and broad adhesions to Bowman's capsule (PAS, scale bar: 100 μ m).

(B) Ultrastructural analysis of kidney tissue from a renal biopsy of the index case UC-023-1 was performed by transmission electron microscopy. A low-power view (left, 2,500 \times) of the glomerular capillaries shows patent lumina and unremarkable mesangium. There is nearly complete (>90%) effacement of the podocyte foot processes with microvillous transformation of the podocyte cytoplasm. A higher-power view (middle, 6,300 \times) shows a glomerular capillary with thinning and irregularities of the glomerular basement membrane as well as marked foot process effacement with microvillous change. There are no immune-type electron dense deposits. In the highest-power view (right, 16,000 \times), two adjacent glomerular capillaries show thinning (124–131 nm) of their glomerular basement

control subjects, and 9,057 individuals with a broad diagnosis of epilepsy. First, we queried for truncating *TRIM8* variants in ES/GS data from 2,501 pediatric nephrosis subjects (defined as SRNS or nephrotic-range proteinuria with biopsy-proven FSGS) and from 48,556 control subjects (Table 2). The control subjects were children or adults without NS or related kidney disease, as determined by a clinical nephrologist and/or available clinical data.³³ We identified heterozygous truncating *TRIM8* variants in eight unrelated probands but no variants in control subjects, demonstrating statistically significant overrepresentation in affected individuals (two-sided Fisher's exact $p = 3.28 \times 10^{-11}$; OR = inf, CI 33.2-inf) and, thereby, establishing *TRIM8* truncating variants as a monogenic cause of NS (Tables 1 and 2; Figures 1C and S1). Accordingly, all *TRIM8* variants were absent from the gnomAD (N = 141,456 individuals). Furthermore, variant data from all cases did not reveal pathogenic variants in known NS disease genes. Importantly, segregation analysis confirmed *de novo* inheritance of *TRIM8* variants in all six families with available parental DNA ($p = 2.21 \times 10^{-15}$) (Table 1, Figure S1). *Post hoc* review of the clinical data demonstrated that all eight NS-affected individuals also had presented with developmental delay and seven of eight developed epilepsy (Tables 1, S1), strongly indicating that the renal and neurodevelopmental phenotypes are not coincidental but indeed caused by pathogenic variants in the same gene.

To confirm this hypothesis, we analyzed ES data for *TRIM8* truncating variants from 9,057 individuals with a broad diagnosis of epilepsy, aggregated from multiple investigators and consortia and hosted at the genetic warehouse at the Institute for Genomic Medicine (IGM) at Columbia University (see supplemental material and methods). We identified three additional subjects with heterozygous *de novo* truncating *TRIM8* variants and with complete clinical data available to interrogate for kidney disease (Tables 1 and 2; Figures 1B and S1). Strikingly, clinical chart review and reverse phenotyping revealed that nephrotic syndrome arose in all three individuals after the diagnosis of epilepsy/developmental delay (Tables 1 and S1). Altogether, these findings establish that *de novo* truncating *TRIM8* variants are the genetic basis of a neuro-renal syndrome in children characterized by early-

onset developmental delay with epileptic encephalopathy and FSGS and distinctive glomerular basement membrane alterations.

Phenotypic evaluation of all 12 individuals revealed a common natural history in individuals with *TRIM8* variants. They all exhibited early-onset developmental delay (onset <1 to 2.5 years) and 11/12 developed epilepsy (onset <1 to 4.5 years) (Tables 1 and S1). All individuals developed NS with variable age of onset (onset birth to 13.7 years) but generally delayed compared to the onset of neurologic disease (Tables 1 and S1). Only one monozygotic twin pair did not develop epilepsy (FG-FA) and had a relatively mild developmental brain phenotype. Brain atrophy was observed in six of eight individuals with available imaging (Tables 1 and S1; Figure 1F). SRNS developed in 8 of 12 subjects (Tables 1 and S1). FSGS was observed in 10 of 12 biopsies, whereas diffuse mesangial sclerosis was noted in RAP027 and in A4582 (Tables 1 and S1; Figures 1D and 1E). Five subjects underwent renal transplantation; follow-up studies showed that none of them developed clinical or pathological FSGS recurrence with up to 24 years of follow up, and one individual (S1666) developed rejection at 8 years (Tables 1 and S1).

These specific phenotypes suggested a strong correlation with patient genotypes. All 12 *TRIM8* variants cause truncation between amino acids 390 and 487, which is C-terminal to a nuclear localization signal (NLS) (Table 1, Figure 1C). Because all variants reside within the last exon, the mRNA transcripts are predicted to escape nonsense-mediated decay.^{34,35} In addition, we interrogated *TRIM8* LoF variants in gnomAD and identified 7 heterozygous truncating variants out of 141,456 subjects. These gnomAD variants were identified in subjects ranging from ages 30 to 75 years and are spatially distinct from *TRIM8* subject variants, causing truncation prior to the NLS or farther C-terminal than the cluster of variants we identified (amino acids 390–487) (Figure S3). This supports a cluster effect for *TRIM8* variants, in which earlier or later *TRIM8* truncating events are less likely to cause the full neuro-renal syndrome and suggests that *TRIM8* subject variants do not cause disease through haploinsufficiency.

Furthermore, we observed the same recurrent variant (c.1375C>T [p.Gln459*]) in three independent subjects, who were confirmed to be unrelated by genome-wide

membranes accompanied by textural irregularities with focal mild lamellation (arrowhead). Scale bars: 4 μ m in left, 1 μ m in middle, 600 nm in right.

(C) Coding exon (upper bar) and protein domain (lower bar) structures of *TRIM8* are shown with arrows indicating position of heterozygous mutations identified in nine subjects. B1, B-box domain 1; B2, B-box domain 2; CC, coiled-coil domain; NLS, nuclear localization signal; RING, ring finger domain. #This patient was independently recruited and published, while the current manuscript was in preparation.

(D) Renal biopsy was performed in subject B3883 at age 8 years. Ultrastructural findings by electron microscopy (EM) at 3,000 \times include diffuse podocyte foot process effacement (red arrows) and thin glomerular basement membranes. Scale bar: 6 μ m.

(E) Renal ultrasound (RUS) is shown for subject A4582 at 2.75 years, demonstrating a hyperechogenic and atrophied (4.68 cm) right kidney after progression to ESRD.

(F) Brain magnetic resonance imaging is shown for subject A4582 at 2.75 years and B3883 at 6 years of life. T2 transverse images of A4582 show deep sulci, atrophied gyri, and thin corpus callosum (top left) and atrophy of corpus callosum, pons and midbrain, while cerebellum preserved (top right). T2 flare axial image of A4582 (bottom left) shows atrophied white matter and hyperintense periventricular signal intensity. T1 axial image of B3883 shows increased ventricle size and sulcal spaces.

analysis for hidden relatedness and principal component analysis for ancestry. Two additional affected individuals harbor p.Tyr460* variants, arising from two different nucleotide changes at the same position (Table 1). Recurrent *de novo* truncating variants affecting the same nucleotide are exceedingly rare events. The observation of three of such variants (in the case of c.1375C>T [p.Gln459*]) would have a probability below 0.94×10^{-18} , even if we assume we had conducted ES in trios from all 60,114 subjects studied here. This further supports a hotspot effect for *TRIM8* DNVs causing the clinical syndrome of FSGS and developmental brain disease.

To assess the biological role of *TRIM8* in renal disease, we interrogated published single-cell RNA sequencing (scRNA-seq) datasets for its endogenous expression in mammalian kidneys. Consistent with prior literature,²⁷ we observed that *TRIM8/Trim8* mRNA is predominantly expressed in podocytes in scRNA-seq data from two independent human fetal kidney studies,^{36,37} mouse fetal kidney,³⁸ and adult mouse glomeruli³⁹ (Figures 2A, S4A, and S4B). By immunohistochemistry, we determined that TRIM8 protein localized to the renal cortex and, particularly, glomerular podocytes of adult human kidneys (Figure 2B). Of note, we also observed that TRIM8 staining localized to discrete nuclear foci, especially within proximal tubular epithelium (Figure S4C). Overall, these findings indicate that *TRIM8* is expressed in podocytes, suggesting its variants may cause a primary podocytopathy.

To assess the molecular consequence of *TRIM8* case-associated variants on its protein localization, we performed transient overexpression of N-terminally GFP-tagged cDNA constructs modeling the wild-type allele and two independent *TRIM8* variants (p.Gln411* and p.Gln459*) in an immortalized human podocyte cell line. These two variants are representative of our described allelic series, which truncate the C terminus of the protein. This region is not well conserved across human TRIM paralogs in contrast to the N-terminal region, which contains the well-conserved tripartite domains (Figure S5). Immunofluorescence (IF) and confocal microscopy showed that wild-type TRIM8 localized to discrete nuclear bodies (NBs) in

94% of transfected nuclei (Figures 2C, 2D, and S6), consistent with the literature.²⁷ Expression of MYC-tagged wild-type *TRIM8* demonstrated similar localization to nuclear bodies (Figure S8A). In contrast, TRIM8 bearing the case-associated variants p.Gln411* or p.Gln459* mis-localized diffusely to the nucleoplasm in transfected cells (Figures 2C, 2D, and S6). This pattern of localization of GFP-tagged wild-type and case-associated variant *TRIM8* constructs was confirmed in immortalized mouse podocytes and the neural BE(2)-M17 cell line (Figures S8B and S8C). To determine the identity of TRIM8 NBs, we co-stained for established markers of Gemin bodies, Cajal bodies, PML bodies, cleavage bodies, or nuclear speckles but did not observe colocalization with wild-type TRIM8. However, we found that 72.5% of endogenous SMN1-positive Gemini bodies and 56.4% of p80 Coilin-positive Cajal bodies abutted a TRIM8 NB by confocal microscopy (Figures 2E and 2F). These findings suggest that TRIM8 can aggregate into NB that are likely disrupted by variants that truncate in a critical region from amino acid 390–487.

It still remained unclear whether *TRIM8* variants cause disease by haploinsufficiency, dominant-negative, gain-of-function, or toxic effects. To explore this question indirectly, we simultaneously targeted TRIM8 orthologs in zebrafish (79% and 78% similarity to trim8a [GenBank: NP_001265783.1] and trim8b [GenBank: NP_001135847.1], respectively) via CRISPR-Cas9 single-guide RNAs (sgRNAs) that target N-terminal regions likely to induce nonsense-mediated decay (exon 5 and 3, respectively; Figure S7A). After determining high targeting efficiency using heteroduplex analysis in F0 mosaic mutants (~100%; Figures S7B–S7E), we simultaneously disrupted both genes and assessed (1) gross morphology indicative of renal function impairment, which include pericardial and periorbital edema and (2) glomerular filtration defects using dextran-FITC conjugates according to our established procedures.⁴⁰ Double F0 mosaic mutants showed no significant lethality and no gross morphological anomalies (n = 30–45 larvae/experiment, repeated twice) and did not display any detectable increase in proteinuria when compared to gRNA alone injected larval batches (n = 21–25 larvae/

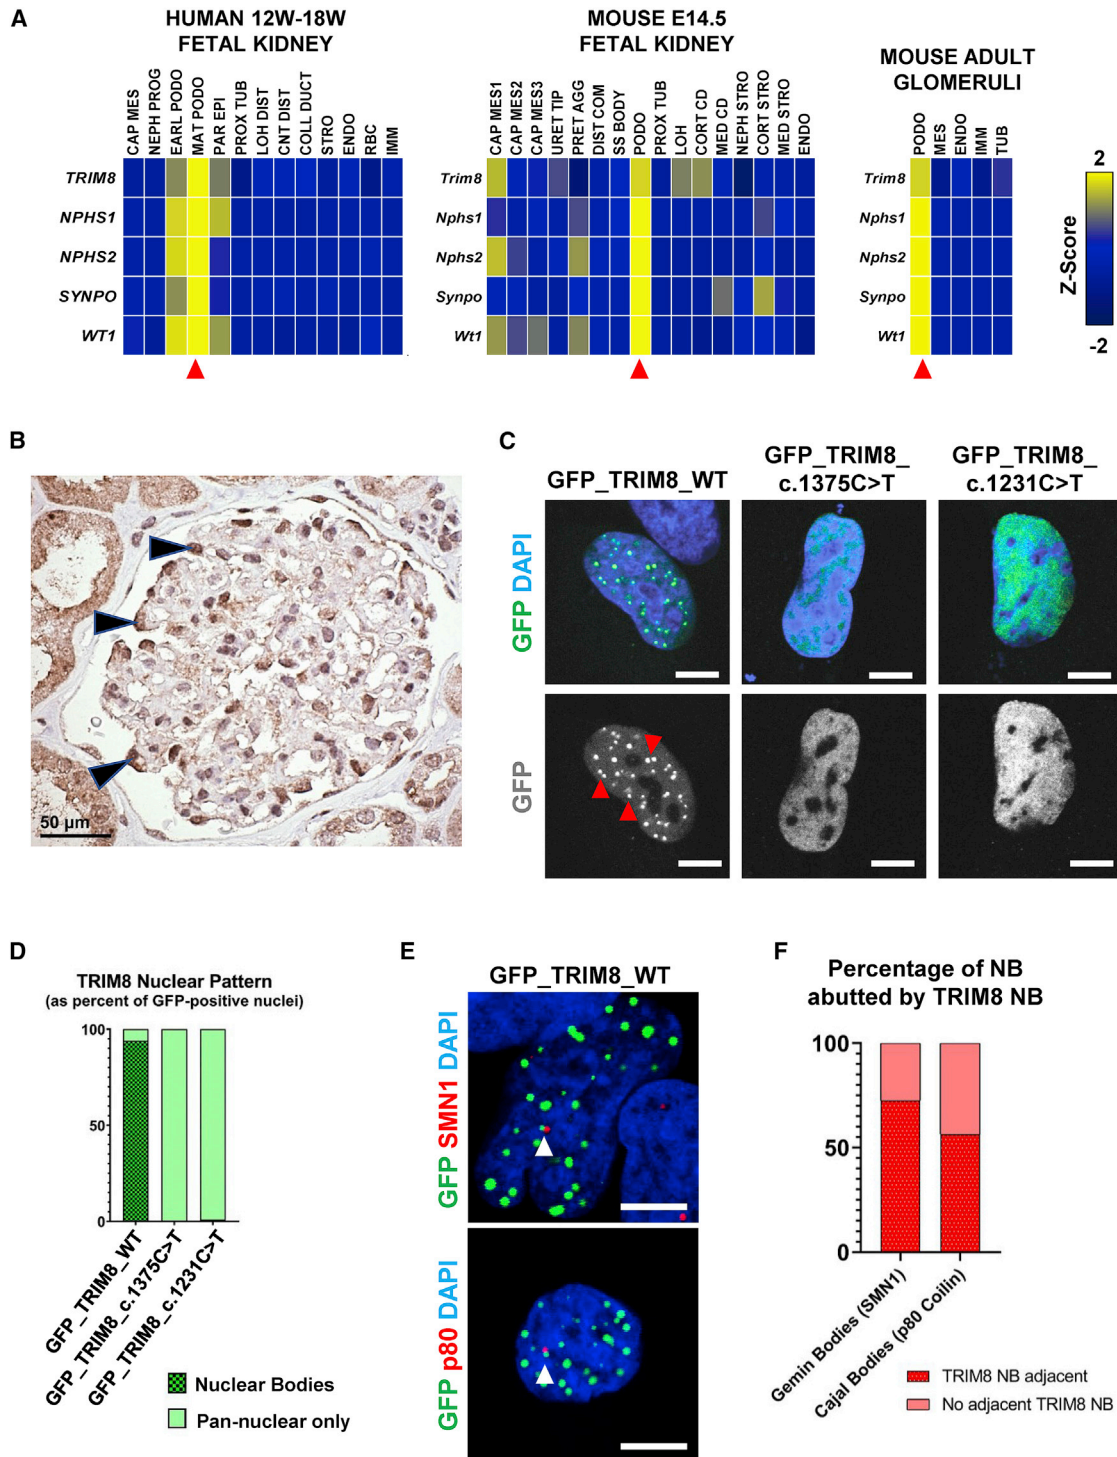

Figure 2. *TRIM8* is expressed in podocytes of mammalian kidneys and localizes to nuclear bodies
 (A) *TRIM8* mRNA (z-score) was predominantly expressed by podocytes (red arrows) from single-cell mRNA sequencing data.^{26,28,29} In human fetal kidneys from 12 to 19 weeks gestation (left), *TRIM8* expression was highest in the mature podocyte cluster, marked by expression of *NPHS1*, *NPHS2*, *SYNPO*, and *WT1*, relative to other developmental cell-type and nephron segment clusters. *Trim8* expression in E14.5 mouse kidneys (middle) was, similarly, highest in the podocyte cluster (*Nphs1*, *Nphs2*, *Synpo*, *Wt1*) with lower expression in one cap mesenchyme cluster and two tubular segment clusters. In adult mouse glomeruli (right), *Trim8* mRNA was predominantly expressed in podocytes relative to other clusters. CAP MES, cap mesenchyme; CNT DIST, distal connecting tubule; COLL DUCT, collecting duct; CORT CD, cortical collecting duct; CORT STRO, cortical stroma; DIST COM, distal comma shaped body; EARL_PODO, early podocyte; ENDO, endothelium; IMM, immune cells; LOH, Loop of Henle; LOH DIST, distal Loop of Henle; MAT_PODO, mature podocyte; MED CD, medullary collecting duct; MED STRO, medullary stroma; NEPH PROG, nephron progenitor; NEPH STRO, nephrogenic stroma; PAR EPI, parietal epithelial cell; PODO, podocyte; PRET AGG, pretubular aggregate; PROX TUB; proximal tubule; RBC, red blood cells; SS Body, mid S-shaped body; STRO, stroma; TUB, tubule; URET TIP, ureteric tip.

(legend continued on next page)

condition, repeated; Figures S7F and S7G). These findings argue against the possibility that *TRIM8* variants cause epilepsy and nephrotic syndrome through loss-of-function mechanisms (haploinsufficiency or dominant-negative effects) and support our genetic and cell-based studies that implicate gain-of-function or toxic effects.

In summary, beginning with the observation of a rare clinical presentation, we show that *de novo* truncating variants in *TRIM8* cause a neuro-renal syndrome through the analysis of genomic sequencing of 60,114 subjects from world-wide cohorts (Table 2). We detected a genotype-phenotype correlation between C-terminally truncating *TRIM8* variants and syndromic nephrotic syndrome, in which variants clustered within a restricted region of the *TRIM8* C terminus (Figure 1C, Table 1). At the cellular level, we found that case-associated variants disrupt *TRIM8* localization to nuclear bodies, which might associate proximally to Gemini and Cajal bodies. Our combined *in vitro* data suggest nuclear sub-compartments as candidates in NS pathogenesis.

TRIM8 variants cause a unique subgroup of syndromic nephrotic syndrome. All subjects were diagnosed with renal disease after (10/12) or at the time of (2/12) the development of neurologic disease. Previous case reports have described truncating DNVs in *TRIM8* in a total of eight children with developmental delay and epilepsy, but only three of these subjects were described to have nephrotic syndrome (Figure S2),^{23,41–43} which left it unsolved whether the renal disease was associated to *TRIM8* variants or just coincidental. The early ascertainment of these cases is also consistent with our observation that renal disease presents later in the course of these patients and may not have been apparent yet at the time of these reports. This underscores the importance of establishing a molecular genetic diagnosis in *TRIM8* affected subjects with neurologic manifestations and should prompt clinicians to screen immediately for features of nephrosis.

While 44 of 59 known NS disease genes exhibit recessive modes of inheritance⁹ and the remainder 15 mostly cause dominantly inherited forms of FSGS with age of onset later

in adolescence or adulthood, the contribution of *de novo* variants to pediatric NS is poorly understood. This may reflect ascertainment bias due to the genetic approaches employed previously to discover these etiologies, mostly in consanguineous families. Our approach of combining trio-ES/GS with large cohort analysis to validate *TRIM8* DNVs offers a useful framework to be applied for SRNS-affected individuals lacking a molecular diagnosis to potentially discover causative *de novo* variants and/or support a rare genetic finding. This is especially critical as *de novo* variants are increasing in prevalence in society in association with advanced paternal age.^{44–46}

TRIM8 disease-associated variants are restricted to the last exon (Figures 1C and S2).^{23,41–43} Combining our findings with previous reports showed that four individuals from distinct ethnic backgrounds share the identical variant at position c.1375 and two share nonsense variants at position c.1380 (Figure S2).^{23,41} This observation suggests that this region is a recurrent germline variant hotspot (Figure S2, Table 1), as has been demonstrated for other rare dominant monogenic causes of syndromic epilepsy⁴⁷ and nephrotic syndrome.⁴⁸

The mechanisms by which *TRIM8* variants cause disease are likely complex. While LoF intolerance metrics for *TRIM8* support haploinsufficiency, the presence of adult gnomAD subjects with earlier truncating events (Figure S3) do not support this genetic mechanism for this severe neuro-renal syndrome caused by C-terminal *TRIM8* variants. Moreover, these metrics are not always definitive, as there are other examples of *de novo* variants causing disease through a gain-of-function mechanism despite strong LoF intolerance at the locus.⁴⁹ Alternatively, *TRIM8* variants may cause dominant-negative loss-of-function of the wild-type allele, given that *TRIM8* can dimerize through its coiled-coil domain²⁷ and that we observe that C-terminal case-associated variants cause *TRIM8* mis-localization (Figures 2C, 2D, and S6). However, the absence of a phenotype in *trim8a/trim8b* knockout models supports the hypothesis that human variants cause disease through gain-of-function or toxic effects, as do the absence of reported neurologic and renal phenotypes in other *TRIM8*

(B) Immunohistochemistry of adult human kidney tissue demonstrates immunoreactivity for *TRIM8* within the nuclei, as well as the cytoplasm, of individual glomerular podocytes (arrowheads). There is also staining of the adjacent tubular epithelial cells. Scale bar: 50 μ m.

(C) A human podocyte cell line was transfected with N-terminal GFP-tagged wild-type *TRIM8* or *TRIM8* mutant constructs based on NS patient variants c.1375C>T and c.1231C>T. Cells were imaged by confocal microscopy. Representative images of GFP-tagged protein and DAPI localization are shown, revealing that wild-type *TRIM8* localizes to nuclear bodies (NBs) (red arrows) while patient mutants exhibit pan-nuclear staining overlapping with DAPI signal. Scale bars: 7 μ m.

(D) The presence of *TRIM8* NBs in (C) is determined from the sum of three independent experiments, as the percentage of 100 GFP-positive cells with NB localization versus those with pan-nuclear staining. Wild-type *TRIM8* localized to NBs in 94% of GFP-positive cells (94/100). In contrast, mutated *TRIM8* localized diffusely to the nucleoplasm in 100% (100/100) and 99% (99/100) of cells for the c.1375C>T and c.1231C>T constructs, respectively.

(E) A human podocyte cell line was transfected with N-terminal GFP-tagged wild-type *TRIM8*. IF and confocal microscopy was performed for endogenous Gemini body marker SMN1 (top) or Cajal body marker p80 Coilin (p80, bottom), demonstrating these bodies frequently abut a GFP-*TRIM8* NB (white arrow). Representative images are shown. Scale bars: 7 μ m.

(F) The percentage of endogenous SMN1-positive Gemini bodies or p80 Coilin-positive Cajal bodies that are abutted by a GFP-*TRIM8* nuclear body, as in (E), is determined from the sum of three independent experiments. 72.5% of Gemini bodies (58/80 NB in 38 transfected cells) and 56.4% of Cajal bodies (57/101 NB in 21 transfected cells) abutted a *TRIM8* NB.

loss-of-function zebrafish³⁰ and mouse^{29,50} models. Still, caution is warranted in translating such observations from zebrafish to human because there are established compensatory mechanisms for truncating variants in *Danio rerio* that may confound these results.⁵¹ Further studies employing knock-in models and mammalian organisms are warranted to delineate the precise mechanism of human *TRIM8* variants.

Based on our findings (Figures 2C–2F, S4C, and S6), *TRIM8* may play a critical role in nuclear bodies that are abrogated by disease-associated variants. The precise identity of these NB is not known, although Gemini and Cajal bodies can associate proximally to them (Figures 2E and 2F) and have broad functions in snRNP biogenesis, histone mRNA processing, and telomere maintenance.^{19–22} Furthermore, our findings suggest that the C-terminal *TRIM8* variants may impair the normal condensation of *TRIM8* protein into liquid droplets, although it remains unclear how the C-terminal region regulates liquid-liquid phase separation,^{52–54} thus posing intriguing questions and opening a new avenue of research in renal diseases. It will be critical to understand the cellular role of endogenous *TRIM8* in these NBs and how its functions are impacted by disease-associated variants introduced in podocytes.

In conclusion, we provide insight into the genetic and molecular etiology of a neuro-renal syndrome caused by a cluster of *de novo* variants in *TRIM8*, which reveal a yet unexplored mechanism of cellular pathogenesis in SRNS, FSGS, and developmental brain disease.

Data and Code Availability

The datasets supporting the current study have not been deposited in a public repository due to restriction by patient consent but are available from the corresponding author on request.
