20 **Abstract**

21 Leaf respiration in the dark ( $R_{\text{dark}}$ ) and light ( $R_{\text{day}}$ ) is poorly characterized in diverse  
22 tropical ecosystems, and little to no information exists on the degree of light  
23 suppression in common tree species within the Amazon basin, and their dependences  
24 upon plant functional traits and position within the canopy. We quantified  $R_{\text{dark}}$  and  
25 apparent  $R_{\text{day}}$  using the Kok method and measured key leaf traits in 26 tree species  
26 distributed in three different crown positions: canopy, lower canopy, and understory.  
27 We found that canopy trees had significantly higher rates of  $R_{\text{dark}}$  and  $R_{\text{day}}$  than trees in  
28 the understory. The difference between  $R_{\text{dark}}$  and  $R_{\text{day}}$  (the light suppression of  
29 respiration) was greatest in the understory ( $68 \pm 9\%$ , 95% CI) and lower canopy ( $49 \pm$   
30  $9\%$ , 95% CI) when compared to the canopy ( $37 \pm 10\%$ , 95% CI). We found that  $R_{\text{day}}$   
31 was significantly and strongly correlated with  $R_{\text{dark}}$  ( $r^2 = 0.76$ ).  $R_{\text{dark}}$  had a significant  
32 relationship to leaf mass area (LMA,  $r^2 = 0.26$ ), and phosphorus (P,  $r^2 = 0.18$ ) but no

33 significant relationship with nitrogen, sugars, and starch. Our results highlight the  
34 importance of including representation of the light suppression of leaf respiration in  
35 terrestrial biosphere models and also of accounting for vertical gradients within forest  
36 canopies and connections with functional traits.

## 37 **1 Introduction**

38 Autotrophic respiration is one of the processes that strongly ~~regulates~~~~contribute to~~  
39 both terrestrial and global carbon balances (Tang et al., 2019). However, large uncertainties  
40 remain in the magnitude of biological and environmental controls over tropical autotrophic  
41 respiration, largely due to limited observational studies requiring advanced technologies (*e.g.*  
42 portable photosynthesis systems) deployed to logistically challenging field sites. In tropical  
43 forests, limited estimates suggested that only 30% of the carbon fixed by photosynthesis is  
44 allocated to the formation of new tissues (biomass), with the rest being respired back into the  
45 atmosphere (Chambers et al., 2004; Malhi et al., 2014). Previous work has estimated that  
46 tropical in forests, autotrophic respiration contributes between 20 to 29 Mg C ha year<sup>-1</sup>, with  
47 leaf respiration being the major, but highly uncertain contributor at an estimated 32-56% of  
48 the total (Chambers et al., 2004; Metcalfe et al., 2010; Malhi, 2012; Malhi et al., 2014). Both  
49 field observations and modeling development of autotrophic respiration is substantially less  
50 studied than photosynthesis (Huntingford *et al.*, 2017). This might be explained by the  
51 difficulty in measuring foliar CO<sub>2</sub> release (Meir et al., 2001; Chambers et al., 2004; Heskell,  
52 2018) due to the lower fluxes and higher signal to noise ratio when compared to  
53 measurements of photosynthesis (Tcherkez et al., 2017a, 2017b).

54 ~~In addition,~~ Leaf respiration can be substantially inhibited by light (Kok, 1948, 1949)  
55 and this metabolism is dynamic and complex, and regulated by changes in enzyme activities  
56 and interactions with photosynthesis, photorespiration, and other pathways such as nitrate  
57 assimilation (Tcherkez et al., 2017a, 2017b). For example, (Heskell and Tang, 2018)  
58 determined that when the inhibition of leaf respiration in a temperate forest by light is not  
59 accounted for in land models, an overestimation of net primary productivity (NPP) occurs. In  
60 addition, current leaf respiration models generally do not take into account changes in the  
61 vertical gradient of light availability within the forest, which is known to greatly influence  
62 plant metabolism- (Weerasinghe et al., 2014; Heskell and Tang, 2018). Respiratory rates have  
63 also been associated with morphological and nutrient variation of leaves, such as leaf mass  
64 per area, ~~and~~ nitrogen and phosphorus content (Meir et al., 2001; Atkin et al., 2015; Crous et

65 al., 2017; Rowland et al., 2017), and can be regulated by the availability of respiratory  
66 substrates, such as non-structural carbohydrates including soluble sugars and starch (Collalti  
67 et al., 2019).

68 ~~\_\_\_\_\_ Light is considered a limiting resource in tropical forests (Wu et al., 2016) and  
69 it varies as a function of height in the canopy. For this reason, trees modify their resource  
70 capture and use strategies according to light availability, reflecting changes in their  
71 morphological and nutrient composition, due to the high competition for light (Wright et al.,  
72 2004). Studies such as those by (Kosugi et al., 2012; Weerasinghe et al., 2014; Heskell and  
73 Tang, 2018) reported a large effect of leaf position within the canopy on leaf respiration.  
74 However, little to no information exists on the magnitudes of leaf respiration in common tree  
75 species within the Amazon basin, and their dependence upon position within the canopy.~~

76 The difference between apparent respiration in the light ( $R_{\text{day}}$ ) and respiration in the  
77 dark ( $R_{\text{dark}}$ ) is known as the light suppression of leaf respiration. ~~Several hypotheses have been  
78 advanced to explain the phenomena ; enzyme deactivation by light which reduces the flux of  
79 carbon into the TCA cycle,  $\text{CO}_2$  re-fixation by photosynthesis, and interactions with other  
80 biochemical pathways during the day (Tcherkez and Ghashghaie, 2017; Tcherkez et al.,  
81 2017a; Gauthier et al., 2020).~~ The two main approaches used to estimate  $R_{\text{day}}$  and  
82 consequently light suppression are, the  $^{13}\text{CO}_2$  isotopic method (Loreto et al., 1999, 2001;  
83 Gong et al., 2018) and the Kok method (Kok, 1948, 1949). ~~This~~ isotopic method assumes  
84 that in an atmosphere of  $^{13}\text{CO}_2$ , all  $^{12}\text{CO}_2$  detected is from respiration, and is considered to be  
85 the most accurate method (Tcherkez et al., 2017a). ~~The Kok method uses the abrupt change in  
86 the gradient of the initial slope of the response of photosynthesis to irradiance. Regression  
87 photosynthesis against irradiance points above the Kok kink results in a shallower initial slope  
88 where the y intercept provides an estimate of  $R_{\text{light}}$  (Farquhar & Busch, 2017) (Tcherkez et al.,  
89 2017a, 2017b; Way et al., 2018; Yin et al., 2020).~~ ~~The Kok method uses the abrupt change in  
90 the gradient of the initial slope of the response of photosynthesis to irradiance. Regression  
91 photosynthesis against irradiance points above the Kok kink results in a shallower initial slope  
92 where the y intercept provides an estimate of  $R_{\text{day}}$  (Farquhar & Busch, 2017) (Farquhar and  
93 Busch, 2017; Tcherkez et al., 2017a, 2017b; Way et al., 2018; Yin et al., 2020).~~

94  
95 It is known that the Kok method can underestimate rates of light respiration (Gong et  
96 al., 2018; Way et al., 2018; Yin et al., 2020), but on the other hand is the most practical

97 | method to apply in logistically challenging field conditions (Tcherkez et al., 2017a). The Kok  
98 | “effect” has been described as due to not only changes in respiratory rates with light, but also  
99 | other physiological and biochemical process (Gauthier et al., 2020; Yin et al., 2020). At least  
100 | three phenomenon can explain the Kok “effect”, as decrease in the photochemical efficiency,  
101 | refixation of CO<sub>2</sub> by photosynthesis, and a decrease of mitochondrial respiration due to light  
102 | inhibition (Yin et al., 2020). CO<sub>2</sub> reassimilation has been widely discussed, but there are still  
103 | disagreements regarding its importance in the Kok “effect” (Buckley et al., 2017; Farquhar  
104 | and Busch, 2017).

105 | Light is considered a limiting resource in forests understory varying as a function of  
106 | height in the canopy (Mulkey et al., 1996). For this reason, trees modify their resource capture  
107 | and use strategies according to light availability, reflecting changes in their morphological and  
108 | nutrient composition, due to the high competition for light (Wright et al., 2004). Studies such  
109 | as those by (Kosugi et al., 2012; Weerasinghe et al., 2014; Heskell and Tang, 2018) reported a  
110 | large effect of leaf position within the canopy on leaf respiration. However, little to no  
111 | information exists on the magnitudes of leaf respiration in common tree species within the  
112 | Amazon basin, and their dependence upon position within the canopy.

113 | Given the great biodiversity of tropical forests (Cardoso et al., 2017; ter Steege et al.,  
114 | 2020), the scarcity of leaf respiration measurements in the tropics, and the known high  
115 | sensitivity of leaf respiration to canopy position ((Griffin et al., 2002) REF), there is an urgent  
116 | need to quantify both  $R_{\text{dark}}$  and the suppression of respiration that occurs in the light. In  
117 | particular, we need in situ measurements to know how it varies across common tree species,  
118 | as a function of height within the forest.

119 | canopy.

120 | Due to the great importance of the Amazon rainforest in the global climate context,  
121 | this study aims to quantify the ~~biosphere-atmosphere CO<sub>2</sub> fluxes resulting~~  $R_{\text{dark}}$  and  $R_{\text{day}}$  from  
122 | leaf autotrophic respiration; the component that most contributes to total autotrophic  
123 | respiration, and is the most sensitive to environmental change (Chambers et al., 2004; Malhi  
124 | et al., 2014; Cavaleri et al., 2017). Thus, the questions that guided this work were: **i)** Does the  
125 | Kok method, which can be applied in the field, compare quantitatively to <sup>13</sup>CO<sub>2</sub> labeling  
126 | method?; **ii)** What are the  $R_{\text{dark}}$  and  $R_{\text{day}}$  leaf respiration rates of common “Terra-firme” tree  
127 | species in the Central Amazon basin and what is the degree of light suppression?; **iii)** Does  
128 | canopy position influence the variation of leaf respiration rates and light suppression? and **iv)**

129 What are the relationships between respiratory rates and leaf functional traits? In the  
130 laboratory we compared estimates of  $R_{\text{dark}}$  and  $R_{\text{day}}$ , using two methods: the  $^{13}\text{CO}_2$  method  
131 based on a portable photosynthesis system coupled to a cavity ringdown isotopic analyzer for  
132  $^{13}\text{CO}_2$  and  $^{12}\text{CO}_2$ , and the Kok method. In the field, we used the Kok method to measure  $R_{\text{dark}}$   
133 and  $R_{\text{day}}$  in 26 trees occupying three different canopy positions including the canopy, lower  
134 canopy, and understory where we also measured key leaf traits.

## 135 2 Material and methods

### 136 Determination of leaf dark adapted $R_{\text{dark}}$ and $R_{\text{day}}$ using the Kok and $^{13}\text{CO}_2$ methods

137 For all gas exchange measurements, branches were cut and recut in a bucket with  
138 water to restore hydraulic conductivity (Weerasinghe et al., 2014; Albert et al., 2018). For all  
139 leaf gas exchange measurements, the leaf temperature was set ( $T_{\text{block-}}$ ) at  $31 \pm 1$  °C (Slot and  
140 Winter, 2017) and the air flow rate through the chamber was maintained at  $300 \mu\text{mol s}^{-1}$  (Crous et  
141 al., 2012; Weerasinghe et al., 2014; Heskell and Tang, 2018) and the reference  $\text{CO}_2$  concentration maintained at 400  
142 ppm (Crous et al., 2012; Weerasinghe et al., 2014; Heskell and Tang, 2018). For the Kok  
143 method, the respiratory  $\text{CO}_2$  flux of the sampled leaves was measured using a portable  
144 photosynthesis system (Li-6400XT, Li-Cor®, Lincoln, USA). Following the introduction of a  
145 leaf into the chamber with  $100 \mu\text{mol m}^{-2} \text{s}^{-1}$  of photosynthetically active radiation (PAR), the  
146 two IRGAs were matched. Net photosynthetic assimilation values ( $A_{\text{net}}$ ) were subsequently  
147 recorded for PAR values of 100, 90, 80, 70, 60, 50, 40, 30, 20, 15, 10 and  $5 \mu\text{mol m}^{-2} \text{s}^{-1}$  (with  
148 IRGA matching before each recording). Following this, the light source was switched off ( $0$   
149  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) and the leaf was allowed 10 minutes to acclimate in the dark before matching the  
150 IRGAs and recording the dark adapted respiration rate ( $R_{\text{dark}}$ ). Due to the interactions that  
151 occur in the presence of light, the Kok method (Kok, 1948) was used to estimate the  
152 “apparent” respiratory rates in the light. The Kok method consists of determining  $R_{\text{day}}$  at low  
153 irradiance, due to the “break” that occurs in the light curve near the light compensation point.  
154 In this method,  $R_{\text{day}}$  is estimated as the intercept, on the “y” axis, of the net photosynthesis rate  
155 as a function of PAR, at low light intensity. For each leaf, a linear regression using at least  
156 three points between 5 and 20 PAR was performed to estimate  $R_{\text{day}}$ . With data from the dark  
157 adapted measurement of  $R_{\text{dark}}$  and the “apparent” estimate of light respiration ( $R_{\text{day}}$ ), was used  
158 to calculate the light suppression, according to **Equation 1**:

159 **Eq. 1.**  $Suppression (\%) = \left[ \frac{(R_{dark} - R_{day})}{R_{dark}} \right] * 100$  \_\_\_\_\_

160 For the <sup>13</sup>CO<sub>2</sub> method (Loreto et al., 2001), two modifications were made to the  
161 portable photosynthesis system including 1) a 400 ppm atmosphere of 99% <sup>13</sup>CO<sub>2</sub> (Cambridge  
162 Isotopes) was delivered to the leaf chamber and 2) a fraction (50 ml/min) of the air exiting the  
163 leaf chamber was routed to a cavity ringdown isotopic analyzer for CO<sub>2</sub> (G2131-i, Picarro)  
164 which measured the concentration of <sup>13</sup>CO<sub>2</sub> and <sup>12</sup>CO<sub>2</sub> exiting the leaf chamber. This method  
165 assumes that the leaf uses the <sup>13</sup>CO<sub>2</sub> atmosphere for photosynthesis with any <sup>12</sup>CO<sub>2</sub> detected  
166 deriving from leaf respiration (Loreto et al., 2001). The experiment was carried out with a  
167 tropical tree species in the family Chrysobalanaceae growing near the laboratory and exposed  
168 to natural sunlight for 6-7 hours per day. To compare the Kok and <sup>13</sup>CO<sub>2</sub> methods for  
169 determining R<sub>day</sub>, R<sub>dark</sub>, and the degree of suppression by light (%), both methods were  
170 performed on six different leaves from the same individual, but each on a different branch.

## 171 **Field Study Site**

172 Field data of 26 trees was collected at the Tropical Silviculture Experimental Station  
173 (E.E.S.T - ZF2), managed by the National Institute for Amazon Research (INPA), located  
174 approximately 60 km NW of Manaus, Brazil. The ZF-2 has an area of approximately 21,000  
175 ha adjacent to extensive areas of undisturbed tropical forest. Data was collected in a  
176 permanent plot installed in 1996, known as North–South transect (2°35'40.3"S,  
177 60°12'28.7"W), located at km 33 of the local road, covering an area of 5 ha (20m x 2,500m)  
178 (Araújo et al., 2020). The predominant vegetation in the reserve is ~~of the typetype of~~ Dense  
179 Tropical Rainforest of "Terra Firme" with a great diversity of woody and herbaceous species.  
180 The North-South transect presents in the plateau areas a predominance of species belonging to  
181 the families Lecythidaceae, Sapotaceae, Burseraceae, and Fabaceae. Among these families,  
182 the most common species belonged to the genera *Eschweilera*, *Pouteria*, *Protium*, *Swartzia*,  
183 **and** *Inga* (Carneiro, 2004).

## 184 **Tree Species selection in the field**

185 We sampled 26 trees (**Table 1**), all located along the North-South Transect, between  
186 200 and 400 meters, in plateau areas. Access to the canopy leaves was obtained by a tree  
187 climber who scaled trees with a pole pruner and removed a branch. Thus, the trees were  
188 selected taking into consideration: i) ecological aspects, with a focus on highly abundant tree

189 species in the Amazon basin (Ter Steege et al., 2013; Cardoso et al., 2017) and ii) practical,  
190 related to climber access to the individual's branches. The classification of crown illumination  
191 index was performed according to (Clark and Clark, 1992). In the 26 individuals studied,  
192 crowns were distributed in different classes (see **Table 1**). For analysis ~~they-eight trees~~ were  
193 classified in understory, nine in the lower canopy and nine in the canopy groups. The ones  
194 with low, medium and high lateral light ~~was/were~~ associated to understory trees, the ones with  
195 some overhead light are lower canopy and trees with full overhead light belong to the canopy.

196

### 197 **Determination of leaf $R_{\text{dark}}$ and $R_{\text{day}}$ using the Kok method in the field**

198 The measurements were made in 2019 during three different field campaigns, in  
199 June/July, September and November. Data was collected between 8 am and 2 pm Local Time.  
200 The measurements were made using mature, fully expanded leaves with a good visual aspect.  
201 A fully expanded leaf per tree was selected for each field campaign. Due to the method of  
202 access to the canopy, the orientation for obtaining branches was not standardized and  
203 branches were collected on positions North, South, East, and West of the crown.

204

### 205 **~~Determination of leaf $R_{\text{dark}}$ and $R_{\text{day}}$ using the Kok and $^{13}\text{CO}_2$ methods~~**

206 ~~For all gas exchange measurements, branches were cut and recut in a bucket with~~  
207 ~~water to restore hydraulic conductivity (Weerasinghe et al., 2014; Albert et al., 2018).~~  
208 ~~For all leaf gas exchange measurements, the leaf temperature was maintained at  $31 \pm 1$~~   
209  ~~$^{\circ}\text{C}$  (Slot and Winter, 2017) and the air flow rate through the chamber was maintained at~~  
210  ~~$300 \mu\text{mol s}^{-1}$  and the reference  $\text{CO}_2$  concentration maintained at 400 ppm (Crous et al.,~~  
211 ~~2012; Weerasinghe et al., 2014; Heskell and Tang, 2018). For the Kok method, the~~  
212 ~~respiratory  $\text{CO}_2$  flux of the sampled leaves was measured using a portable~~  
213 ~~photosynthesis system (Li-6400XT, Li-Cor®, Lincoln, USA). Following the introduction~~  
214 ~~of a leaf into the chamber with  $100 \mu\text{mol m}^{-2} \text{s}^{-1}$  of photosynthetically active radiation~~  
215 ~~(PAR), the two IRGAs were matched. Net photosynthetic assimilation values ( $A_{\text{net}}$ ) were~~  
216 ~~subsequently recorded for PAR values of 100, 90, 80, 70, 60, 50, 40, 30, 20, 15, 10 and 5~~  
217  ~~$\mu\text{mol m}^{-2} \text{s}^{-1}$  (with IRGA matching before each recording). Following this, the light~~  
218 ~~source was switched off ( $0 \mu\text{mol m}^{-2} \text{s}^{-1}$ ) and the leaf was allowed 10 minutes to acclimate~~  
219 ~~in the dark before matching the IRGAs and recording the dark respiration rate ( $R_{\text{dark}}$ ).~~  
220 ~~Due to the interactions that occur in the presence of light, the Kok method (Kok, 1948)~~

was used to estimate the “apparent” respiratory rates in the light. The Kok method consists of determining  $R_{day}$  at low irradiance, due to the “break” that occurs in the light curve near the light compensation point. In this method,  $R_{day}$  is estimated as the intercept, on the “y” axis, of the net photosynthesis rate as a function of PAR, at low light intensity. For each leaf, a linear regression using at least three points between 5 and 20 PAR was performed to estimate  $R_{day}$ . With data from dark respiration  $R_{dark}$  and the “apparent” estimate of light respiration ( $R_{day}$ ), was used to calculate the light suppression, according to Equation 1:

$$\text{Eq. 1. } \text{Suppression}(\%) = \left[ \frac{R_{dark} - R_{day}}{R_{dark}} \right] * 100$$

For the  $^{13}\text{CO}_2$  method (Loreto et al., 2001), two modifications were made to the portable photosynthesis system including 1) a 400 ppm atmosphere of 99%  $^{13}\text{CO}_2$  (Cambridge Isotopes) was delivered to the leaf chamber and 2) a fraction (50 ml/min) of the air exiting the leaf chamber was routed to a cavity ringdown isotopic analyzer for  $\text{CO}_2$  (G2131-i, Picarro) which measured the concentration of  $^{13}\text{CO}_2$  and  $^{12}\text{CO}_2$  exiting the leaf chamber. This method assumes that the leaf uses the  $^{13}\text{CO}_2$  atmosphere for photosynthesis with any  $^{12}\text{CO}_2$  detected deriving from leaf respiration (Loreto et al., 2001). The experiment was carried out with a tropical tree species in the family Chrysobalanaceae growing near the laboratory and exposed to natural sunlight for 6-7 hours per day. To compare the Kok and  $^{13}\text{CO}_2$  methods for determining  $R_{day}$ ,  $R_{dark}$ , and the degree of suppression by light (%), both methods were performed on six different leaves from the same individual, but each on a different branch.

## Leaf traits

Leaves used for gas exchange measurements and others were collected and obtained six discs of known diameter (1.7 cm). These were dried in an oven at 65 °C for 72 hours until the constant mass was obtained and was calculated the leaf mass per area (LMA  $\text{g m}^{-2}$ ). For leaf nitrogen and phosphorus content, leaves were collected, following the same drying process and subsequently the leaf samples were ground in a Wiley mill. The nitrogen (N) content was determined by the Kjeldahl method and the phosphorus content (P) obtained by colorimetry and the absorbance readings made at 660 nm in a spectrophotometer using ammonium molybdate and 3% ascorbic acid. For nonstructural carbohydrates, the leaf samples were collected only in the first campaign (June/July), kept, and transported for 3

252 hours in a box with ice with a temperature between 0-4 °C to the laboratory in Manaus, Brazil  
253 (consistent with guidelines from (Landhäusser et al., 2018)Landhausser et al. 2018). In the  
254 laboratory, they were placed in microwaves for 90 seconds and dried in an oven for 72 hours  
255 at 65 °C. The processed leaf samples were ground in a ball mill and sent to the Pacific  
256 Northwest National Laboratory in Washington state, USA for the quantification of non-  
257 structural carbohydrates including sugars, starch and total carbohydrates (NSC) as previously  
258 described (Dickman et al., 2019; Zhang et al., 2021).

## 259 Data analysis

260 All statistical analysis was performed using R version 3.6.0 (R Development Core  
261 Team, 2019) and IGOR Pro, version 6.37 (WaveMetrics, Inc., United States). ~~A statistical To~~  
262 ~~compare the methods used to estimate -comparison of~~  $R_{\text{day}}$ ,  $R_{\text{dark}}$ , and the degree of suppression  
263 by light (%) obtained from the Kok and  $^{13}\text{CO}_2$  methods, ~~were -was~~ performed a non-  
264 parametric t-test to compare the two methods (n = 4-6). ~~In the field study, T~~to verify the effect  
265 of canopy position on the studied variables, we performed a Kruskal-Wallis test, considering  
266 significant differences if  $p \leq 0.05$ . To access the relations between  $R_{\text{dark}}$  and other variables  
267 (*i.e* LMA, N and P content, sugars, starch and total NSC concentrations), we used linear  
268 regression analysis and a Spearman correlation matrix (Supplementary Figure S1) to see the  
269 correlations for all the data (n = 77). ~~All the results are presented as mean ± 95% CI.~~

## 270 3 Results

### 271 Comparison between Kok and $^{13}\text{CO}_2$ methods for estimating $R_{\text{day}}$ and the degree of light 272 suppression

273 In order to validate the Kok method for the determination of  $R_{\text{day}}$  in the remote central  
274 Amazon field site, an inter-comparison between Kok and  $^{13}\text{CO}_2$  methods for estimating  $R_{\text{day}}$   
275 and the degree of light suppression was performed at the National Institute for Amazon  
276 Research (INPA) campus in Manaus, Brazil by taking advantage of a cavity ringdown  $\text{CO}_2$   
277 isotope spectrometer that we interfaced to the portable photosynthesis system supplied with  
278  $^{13}\text{CO}_2$  (see Material and methods). Due to its proximity to the laboratory, we utilized a tree in  
279 the family Chrysobalanaceae and observed statistically identical mean values of dark  
280 respiration between the methods ( $p = 0.94$ , n = 6). The mean values of dark adapted  $R_{\text{dark}}$   
281 ~~and determined using the Kok and~~  $^{13}\text{CO}_2$  methods was  $0.67 \pm 0.17$  and  $0.68 \pm 0.27$   $\mu\text{mol CO}_2$

282  $\text{m}^{-2} \text{s}^{-1}$  (95% CI), respectively (**Figure 1A**). Both Kok and  $^{13}\text{CO}_2$  methods also observed that  
283 estimates of  $R_{\text{day}}$  were lower than  $R_{\text{dark}}$  (**Figure 1B**). The mean  $R_{\text{day}}$  values, determined by the  
284 Kok method was  $0.36 \pm 0.17 \mu\text{mol CO}_2 \text{m}^{-2} \text{s}^{-1}$  and the  $^{13}\text{CO}_2$  method  $0.27 \pm 0.03 \mu\text{mol CO}_2 \text{m}^{-2}$   
285  $\text{s}^{-1}$ . Thus, statistically identical mean values of  $R_{\text{day}}$  were observed between the methods ( $p =$   
286  $0.73$ ,  $n = 4$ ). Finally, the percentage of leaf dark respiration suppression by light was also  
287 statistically equal between the Kok and  $^{13}\text{CO}_2$  methods ( $p = 0.41$ ,  $n = 4$ ), with  $44 \pm 17\%$  (Kok)  
288 and  $54 \pm 17\%$  ( $^{13}\text{CO}_2$ ) (**Figure 1C**).

### 289 **Effect of crown position on respiratory rates and degree of light suppression in a central** 290 **Amazon forest transect**

291 Given the favorable comparison between the Kok and  $^{13}\text{CO}_2$  methods for estimation of  
292  $R_{\text{day}}$  and the light suppression of  $R_{\text{dark}}$ , we utilized the Kok method to determine these leaf  
293 respiratory rates in an established north-south forest transect with identified species in the  
294 central Amazon. **Figure 2** summarizes the leaf respiration measurements from 26 individuals  
295 across 18 common species in the Amazon forest, and grouped according to canopy position  
296 (understory, lower canopy, and canopy). The mean values of  $R_{\text{dark}}$  observed among the 26  
297 individuals ranged from  $0.19 \pm 0.04 \mu\text{mol CO}_2 \text{m}^{-2} \text{s}^{-1}$  to  $0.90 \pm 0.26 \mu\text{mol CO}_2 \text{m}^{-2} \text{s}^{-1}$  (95%  
298 CI), whereas mean estimated values of  $R_{\text{day}}$  using the Kok method showed reduced values  
299 ranging from  $0.01 \pm 0.01$  to  $0.69 \pm 0.27 \mu\text{mol CO}_2 \text{m}^{-2} \text{s}^{-1}$ . Thus, the light suppression of  $R_{\text{dark}}$   
300 ranged between  $17 \pm 6\%$  to  $95 \pm 4\%$ . Moreover, the pattern of reduced  $R_{\text{day}}$  relative to  $R_{\text{dark}}$   
301 was observed for each of the 26 individuals. Overall, a general pattern emerged that higher  
302 rates of  $R_{\text{dark}}$  and  $R_{\text{day}}$  were associated with lower values of light suppression of  $R_{\text{dark}}$ .  
303 Moreover, lower rates of  $R_{\text{dark}}$  and  $R_{\text{day}}$  were associated with higher values of light suppression  
304 of  $R_{\text{dark}}$ . Relative to canopy species, understory species tended to have lower rates of  $R_{\text{dark}}$  and  
305  $R_{\text{day}}$  but higher values of light suppression of  $R_{\text{dark}}$ .

306 **Figure 3** shows the mean  $A_{\text{net}}$  versus PAR leaf gas exchange response curves for  
307 species in the canopy (**Figure 3A**), lower canopy (**Figure 3B**), and understory (**Figure 3C**).  
308 All three canopy positions showed the classic Kok effect where a sudden change in the  
309 gradient of the initial slope of net photosynthesis ( $A_{\text{net}}$ ) occurred at low PAR intensities (0-15  
310  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) which corresponded to the light compensation point (1-6  $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ ).  
311 When the mean rate of  $R_{\text{dark}}$  and estimates of  $R_{\text{day}}$  and the percent light suppression of  $R_{\text{dark}}$  was  
312 obtained for each of the three canopy positions, a large effect of canopy position was

313 observed.  $R_{\text{dark}}$  was the highest in canopy trees ( $0.50 \pm 0.07 \mu\text{mol of CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) and lowest in  
314 the understory trees ( $0.25 \pm 0.03 \mu\text{mol of CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) with the lower canopy trees with  
315 intermediate values of  $R_{\text{dark}}$  ( $0.36 \pm 0.04 \mu\text{mol of CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) (**Figure 3D**). A similar pattern  
316 was observed for estimates of  $R_{\text{day}}$  using the Kok method with canopy trees showing the  
317 highest rates ( $0.32 \pm 0.07 \mu\text{mol of CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ), understory trees showing the lowest rates  
318 ( $0.10 \pm 0.02 \mu\text{mol of CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ), and intermediate rates in lower canopy trees ( $0.18 \pm 0.03$   
319  $\mu\text{mol of CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) (**Figure 3E**). Thus, there was a decrease in both  $R_{\text{dark}}$  and  $R_{\text{day}}$  with depth  
320 into the canopy. In contrast, the light suppression of  $R_{\text{dark}}$  showed a different trend with respect  
321 to canopy position with canopy trees showing the lowest values ( $37 \pm 10\%$ ), understory trees  
322 showing the highest values ( $68 \pm 9 \mu\text{mol of CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ), and lower canopy trees showing  
323 intermediate values ( $50 \pm 5 \mu\text{mol of CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) (**Figure 3F**). Thus, while  $R_{\text{dark}}$  and  $R_{\text{day}}$   
324 decreased with depth into the forest canopy, the light suppression of  $R_{\text{dark}}$  increased. These  
325 trends were found to be statistically significant ( $p < 0.001$ ,  $n = 74 - 77$ ).

### 326 Relationships between respiratory rates and leaf traits

327 ~~While the~~ The mean values of leaf mass area (LMA) ~~for canopy trees decreased from a~~  
328 ~~maximum in~~ were  $99 \pm 5 \text{ g m}^{-2}$  in canopy trees ( $99 \pm 5$ ,  $88 \pm 4 \text{ g m}^{-2}$  in lower canopy trees and  
329  $86 \pm 2 \text{ g m}^{-2}$  in the understory trees. There was ~~this trend was not~~ no statistically difference ( $p$   
330  $= 0.069$ ,  $n = 77$ ) ~~between the groups~~ (**Supplementary Figure S2A**). For N and P leaf content  
331 (**Supplementary Figures S2 B,C**), no clear variation with canopy position was observed ( $p =$   
332  $0.29$ ;  $p = 0.28$ ,  $n = 77$ ). We ~~also~~ observed no statistical difference in concentration of sugars  
333 ( $p = 0.13$ ,  $n = 26$ ) and total NSC ( $p = 0.19$ ,  $n = 26$ ; **Supplementary Figures S2D-F**). Also,  
334 for starch there was no statistical difference between the groups (**Supplementary Figures**  
335 **S2E**;  $p = 0.47$ ,  $n = 26$ ), but the mean values for the canopy ( $0.68 \pm 0.19\%$ ) was higher when  
336 compared to the lower canopy ( $0.44 \pm 0.11\%$ ) and understory ( $0.40 \pm 0.14\%$ ).

337 The relationship between  $R_{\text{day}}$  and  $R_{\text{dark}}$  (**Figure 4A**) shows a strong positive correlation  
338 ( $r^2 = 0.76$ ,  $p < 0.001$ ). The  $R_{\text{day}} \times$  Light suppression had a different trend and significant  
339 relationship ( $p < 0.001$ ), with a strong explanation ( $r^2 = 0.59$ ,  $p < 0.001$ ), demonstrating that  
340 higher values of daytime respiration have lower values of light suppression (**Figure 4B**).

341 When assessing the relationship between  $R_{\text{dark}}$  and leaf mass per area (LMA), we found  
342 26% of explanation ( $p < 0.001$ ) (**Figure 5A**). For  $R_{\text{dark}}$  and N content the relationship is non-  
343 significant ( $r^2 = 0.01$ ,  $p = 0.37$ ; **Figures 5B, C**) while the relationship between  $R_{\text{dark}}$  and P is

344 significant ( $r^2 = 0.18$ ,  $p < 0.001$ ). In addition, no significant correlations were observed  
345 between  $R_{\text{dark}}$  and any of the components of NSCs (**Figures 5D-F**), including sugars ( $r^2 =$   
346  $0.053$ ,  $p = 0.26$ ), starch ( $r^2 = 0.00053$ ,  $p = 0.91$ ), and total NSC ( $r^2 = 0.047$ ,  $p = 0.29$ ).

#### 347 **4 Discussion**

348 Here we observed that using Kok method we can have an accurate estimate of  
349 apparent light respiration when compare with  $^{13}\text{CO}_2$  labelling (Figure 1). It is important to  
350 highlight in this case that  $^{13}\text{CO}_2$  labelling also does not consider the internal recycling of  $\text{CO}_2$ .  
351 In the field work, our results highlight the influence of the crown position in the rates of  $R_{\text{day}}$   
352 and  $R_{\text{dark}}$ . The physiological variables related to photosynthesis and respiration in the dark and  
353 in the light, differ according to the crown position (**Figures 3D, E**). In addition to  
354 physiological variables, light suppression was also influenced by crown position (**Figure 3F**),  
355 with higher values in the understory and lower values in the canopy trees.  $R_{\text{dark}}$  has a strong  
356 relationship with  $R_{\text{day}}$  (**Figure 4A**) and medium correlation with leaf mass area (**Figure 5A**),  
357 which indicates that the higher respiration is associated with higher LMA. Trees in the canopy  
358 have higher LMA (**Supplementary Figure S2A**), which may be associated with the plant's  
359 strategies for using light. In this study, no relationships were found for N (**Figure 5B**) and  
360 carbohydrates (**Figures 5 D-F**). Otherwise, relationships with P content were significant  
361 (**Figure 5C**). All these results are very important and have great implications on dynamics  
362 models of carbon assimilation in tropical forests.

#### 363 **Crown position and the effect on leaf respiration and light suppression of $R_{\text{dark}}$**

364 Leaf respiration is affected by the availability of light (Meir et al., 2001; Kosugi et al.,  
365 2012; Asao et al., 2015; Araki et al., 2017), as the microenvironment along the vertical  
366 gradient of the forest is different, especially when comes to temperature and light (Mulkey et  
367 al., 1996; Marengo et al., 2014; Rey-Sánchez et al., 2016). The need for light varies  
368 continuously between species and influences their life strategies, directing the investment of  
369 their resources, whether for growth or survival (Poorter and Bongers, 2006). These results  
370 demonstrate the importance of the vertical gradient in the physiological characteristics of the  
371 leaves (Kosugi et al. 2012, Weerasinghe et al. 2014, Heskell and Tang 2018).

372 The relationship between higher respiration rates and the availability of light may be  
373 related to a higher demand for energy for possible repairs due to photodamage (Weerasinghe  
374 et al., 2014; Santos et al., 2018). In contrast, the lower values in the understory, indicate that

375 these trees do not require as much energy. This promotes a positive carbon balance under  
376 light-limited conditions, a typical characteristic of understory species that invest in survival,  
377 waiting for the moment of increased resources to invest in growth (Poorter and Bongers,  
378 2006; Lambers et al., 2008). Light suppression of  $R_{\text{dark}}$  is higher in the understory trees  
379 (**Figure 3F**). However, most studies have not observed differences in light suppression when  
380 assessing the effect of upper and lower position of the same canopy (Weerasinghe et al. 2014,  
381 Heskell and Tang 2018). This divergence between studies can be explained using different  
382 species in different crown positions, since the studies mentioned worked with the intraspecific  
383 variation of the individuals.

384         The rate of light suppression of respiration and the canopy position had an different  
385 behavior when compared to respiratory rates in light and in the dark. Suppression is higher on  
386 species in the understory and is lower in species in the canopy (**Figure 3F; Figure 4B**).  
387 Respiratory activity throughout the day is regulated by the demand for energy and structural  
388 carbohydrates during the photosynthesis process (Lambers et al., 2008; Tcherkez and  
389 Ghashghaie, 2017; Collalti et al., 2019). Thus, suppression rates are lower in species that have  
390 greater metabolic activity. Higher irradiance results in greater demand for respiratory  
391 products, such as ATP, NADH, and carbon skeletons, reflecting higher rates of respiration in  
392 the presence of light (Weerasinghe et al. 2014), and this also might vary in function of  
393 temperature (Way et al., 2018). To elucidate which factors influences the variation in light  
394 suppression, it is necessary to know the effect of temperature and irradiance on leaf  
395 respiration (Atkin et al., 2000; Lambers et al., 2008; Way et al., 2015, 2018).

396         The rate of leaf respiratory inhibition can vary under conditions of water availability  
397 (Crous et al., 2012; Turnbull et al., 2017) and depending on the age of the soils, being higher  
398 in old and P-deficient soils (Atkin et al., 2013). In temperate forests, the inhibition of  
399 respiration varies seasonally (Heskell et al., 2014; Heskell and Tang, 2018), as they have  
400 defined seasons. In addition, apparent suppression may vary depending on the method of  
401 estimating daytime respiration (Way et al., 2018; Keenan et al., 2019). Knowing the light  
402 suppression of respiration in different ecosystems allows inferring carbon use efficiency  
403 (CUE). However, specific studies are necessary, since suppression varies in each type of  
404 ecosystem (Atkin et al., 2013; Turnbull et al., 2017).

405         In the context of climate change, a higher occurrence of extreme events is expected,  
406 which will cause an increase in the frequency of natural disturbances in the forest and,

407 consequently, might benefit individuals from the understory, promoting and an increase in  
408 their respiratory rates, as evidenced by this work. Emission of respiratory CO<sub>2</sub> is higher in  
409 canopy trees being two times higher than those in the understory. Species in the understory  
410 have slower growth, which is why they invest more in the carbon economy, whereas canopy  
411 species have more light and higher temperatures available, respire more, emitting more  
412 amount of atmospheric CO<sub>2</sub> through the forest.

413 — Although the Amazon rainforest is of great importance for the global carbon cycle, the  
414 quantification of light suppression of respiration in this biome is still limited. Inhibition of leaf  
415 respiration strongly influences the respiration estimates of the ecosystem and when not  
416 considered in the models, they cause overestimations and, consequently, underestimate the  
417 NPP (Kroner and Way, 2016; Wehr et al., 2016; Keenan et al., 2019). Studies that estimated  
418 autotrophic respiration of the ecosystem in the Amazon rainforest (Chambers et al., 2004;  
419 Malhi et al., 2014), considered the inhibition of light respiration through correction factors  
420 obtained in studies not developed in the Amazon.

#### 421 **Relationships between respiratory rates and leaf traits**

422 Canopy trees, which have a relatively exposed canopy, have higher values of  
423 respiration, leaf mass per area, and nitrogen rates (Asao et al., 2015; Araki et al., 2017;  
424 Rowland et al., 2021). Those individuals in the canopy invest in a smaller area and higher  
425 mass to protect them from damage by excessive irradiance, while those in the understory  
426 invest in a specific leaf area for light interception (Wright et al., 2004; Poorter and Bongers,  
427 2006; Lambers et al., 2008). Respiration in the dark correlates with the levels of phosphorus  
428 (**Figure 5C**). Respiratory substrates participate in nitrogen assimilation pathways and  
429 phosphorus, present in the ATP molecule, the main respiratory product (Tcherkez et al.,  
430 2017a; Tcherkez and Ghashghaie, 2017).

431 Levels of nitrogen and phosphorus prove to be important for improve modeled carbon  
432 fluxes and dynamics in the forest (Zhu et al., 2019) and also can help to understand the  
433 response of plants to global warming (Tang et al., 2018). In this study no relationships were  
434 found for N (**Figure 5B**), but for P we found a significant relationship (**Figure 5C**). A similar  
435 result was observed by (Meir et al., 2001). It is known that Amazonian soils are limited by  
436 this nutrient (Quesada et al., 2010), and this nutrient is linked to  $R_{\text{dark}}$  through multiple  
437 processes, is essential for the formation of proteins, nucleic acids, phosphate trioses and ADP

438 phosphorylation (Tcherkez and Ghashghaie, 2017). On the respiratory process it can restrict  
439 glycolysis and function of the electron transport chain (Atkin et al., 2015; Rowland et al.,  
440 2017; Tcherkez and Ghashghaie, 2017).

441 The relations of  $R_{\text{dark}}$  and N and P levels are higher in areas with soils with lower P  
442 concentration (Crous et al., 2017; Rowland et al., 2017). This can be explained by the high  
443 respiratory cost for investment in leaf nutrients. Saturated photosynthesis is less sensitive than  
444 respiration at low concentrations of P in the soil (Crous et al., 2017; Rowland et al., 2017).  
445 However, (Meir et al., 2001), when comparing the behavior of dark leaf respiration in the Jaru  
446 forest in Rondônia and in a forest in Cameroon, observed that in Brazil (Jaru), LMA  
447 explained 20% of the variation of  $R_{\text{dark}}$ . In Brazil, the best predictor variables were LMA and  
448 P content. The relationships between the main characteristics of the leaf (N, P, and LMA or  
449 SLA) with respiration shows a significant biogeographic variation (Atkin et al., 2015; Crous  
450 et al., 2017; Rowland et al., 2017).

451 Although some studies report a strong relationship between respiratory rates and  
452 nitrogen content, the characteristics of the study site, such as soil fertility, must be considered  
453 (Crous et al., 2017; Rowland et al., 2017). As for respiration responses, biogeographic  
454 variation is large, which indicates that soil fertility has a strong influence on these responses,  
455 being inversely proportional to the availability of P in the soil (Atkin et al., 2015; Crous et al.,  
456 2017; Rowland et al., 2017). These results are relevant to the modeling of the carbon cycle in  
457 tropical forests, as they support the hypothesis that nutrient limitations affect photosynthetic  
458 and respiratory rates (Lambers et al., 2008; Peng et al., 2021) at different scales.

459 Non-structural carbohydrates are important for plant metabolism since they provide  
460 carbon skeletons for plant metabolism (*e.g* growth, reproduction, protection, defense) and are  
461 substrate for respiration process (Hartmann and Trumbore, 2016; Landhäusser et al., 2018;  
462 Dickman et al., 2019). Here in this study, we found no relationship between soluble sugar  
463 concentration and respiratory rates (**Figure 5D**), where higher respiratory demand shows a  
464 lower concentration of sugars. For starch concentrations, the relationship with respiration was  
465 also not evident (**Figure 5E**). Asao and Ryan, (2015) report that changes in carbohydrate  
466 levels did not directly affect the responses of photosynthesis and respiration in trees under  
467 branch girdling. However, (Collalti et al., 2019) state that the variation in plant respiration is  
468 dependent on the demand for substrates, demonstrating that respiratory rates vary depending  
469 on the need of the plant, varying between photoassimilates products or investment in biomass.

470 The variation within canopy position did not affect sugar, starch and total NSC  
471 concentration (**Supplementary Figures S2 D-F**). Leaves more exposed to sun usually have  
472 higher levels of soluble sugars when compared to shade leaves (Weerasinghe et al., 2014;  
473 Dayer et al., 2021). Starch is a reserve carbohydrate and not a fast consumption like sugars  
474 (Dickman et al. 2019), this perhaps can explain why there is higher concentration of starch  
475 and lower concentration of sugars in canopy trees. Other explanation is because our samples  
476 were collected during the early morning and because leaf NSCs peak of accumulation occurs  
477 at midday (Dickman et al., 2019; Gersony et al., 2020) we did not verify the effect of canopy  
478 position on NSCs concentrations.

## 479 **5 Conclusion**

480 Light suppression of leaf respiration varies according to the degree of canopy position.  
481 So, trees from the canopy had higher rates of light and dark respiration than trees from the  
482 understory. In the opposite light suppression is higher in the understory and lower on canopy  
483 trees. In addition, leaf respiration shows a positive and strong relationship with LMA and P  
484 content. These changes in physiology as a function of light availability have a great  
485 importance in carbon assimilation and can influence drought responses (Rowland et al., 2021).  
486 When the suppression is not considered in the models, it may cause an underestimation of  
487 NPP. Furthermore, knowledge about the impact of canopy position on inhibition of  
488 respiration will allow the refinement of the parameterization of climate models, as canopy  
489 trees have lower suppression and, consequently, have higher exchange of CO<sub>2</sub> with the  
490 atmosphere than the understory.

748 **FIGURE 1. Comparison between Kok and <sup>13</sup>CO<sub>2</sub> method** for estimating leaf respiration  
749 rates in the dark ( $R_{\text{dark}}$ , **A**); in the light ( $R_{\text{day}}$ , **B**), and the suppression of  $R_{\text{dark}}$  (Suppression, **C**).  
750 The line inside the box indicates the median of the data, the colored bar represents the 50%  
751 variation of the data, the vertical lines represent the 90 % of the variation, and the square point  
752 inside the colored box represents the mean. (n =4-6). The test used was non-parametric t-test.

**FIGURE 2. Respiration rate measured** in the light ( $R_{\text{day}}$ , brown bars) and in dark adapted leaves (purple bar), and light suppression (black point) for each individual studied. The number after the specie name represent the number of individuals per specie studied. Values are mean  $\pm$  standard error (n = 2-3). Data are organized in function of crown position, understory, lower canopy and canopy.

786 **FIGURE 3. Light response curve showing the Kok effect** for each class of crown position. **A** - canopy, **B** - lower canopy, and **C** - understory,  
787 showing linear regression for points above the abrupt change in the quantum yield (QY) of net CO<sub>2</sub> assimilation. Dotted lines show points 5 to  
788 20, that was used to obtain apparent light respiration (below), estimated using the Kok method. Data are averages of leaves measured during  
789 2019 in three different campaigns. Points are the average, and the vertical line represents the standard error. (understory, n = 24; lower canopy, n  
790 = 27; canopy, n = 26). The second part of the figure represents boxplots of **D** - respiration rates in the dark ( $R_{\text{dark}}$ ), **E** - apparent respiration rates  
in the light ( $R_{\text{day}}$ ), and **F** - apparent suppression of light respiration relative to the dark. The line inside the box indicates the median of the data,  
the colored bar represents the 50% variation of the data, the vertical lines represent the nineteenth percent of the variation, and the square point  
inside the colored box represents the mean (understory, n = 24; lower canopy, n = 27; canopy, n = 24-26). p values are shown for the non-  
parametric, Kruskal-Wallis test.

916

917

918

919

920 **FIGURE S3 (Graphical abstract):** resume of the main findings of this work. Respiration  
 921 rates are higher in trees from the canopy than trees in the understory. But the light suppression  
 922 had an opposite behavior, being higher in the understory trees. This may happen because of  
 923 higher metabolic activity in sun exposed leaves.
