27 We achieve a  $\sim 700$ -fold and  $\sim 10$ -fold increase in multi-carbon product formation by designing  
 28 roughened catalysts for both foil- and gas diffusion-type electrodes, respectively. We showcase  
 29 catalyst surface area as a key descriptor for understanding the interplay between the electrode  
 30 structure and local reaction environment on activity and selectivity. Both experimental and  
 31 computational modeling determine heightened reaction rates towards  $\text{CO}_2\text{R}$  at lower  
 32 overpotentials, which uncover a clear dependence on electrode roughness.

33  
34

### Highlights

35  
36  
37  
38  
39  
40

- Distinct catalyst morphologies are translated between electrode types
- Reaction rate toward  $\text{CO}_2\text{R}$  and  $\text{C}_{2+}$  products is enhanced at lower overpotentials
- Increase in  $J_{\text{geo}}$  up to  $\sim 735$ x and  $\sim 10$ x are observed with foil and GDEs, respectively
- Experiments and model show Tafel-like description of roughness and potential shift

## 41 **Summary**

42           Increased use of gas-diffusion electrodes for CO<sub>2</sub> electroreduction widens the  
43 experimental phase space (i.e., increased reaction rate and mass transport) that was previously  
44 inaccessible using foil electrodes. This raises fundamental questions over the impacts of key  
45 variables that translate between liquid- and vapor-fed CO<sub>2</sub> electrolysis systems, warranting  
46 comparisons to aid our understanding of the underlying processes that control performance. In  
47 this work, we studied the interplay of current-potential profiles and electrode roughness on  
48 product activity and selectivity for both liquid- and vapor-fed CO<sub>2</sub> reduction. We implement a Cu  
49 nanoflower morphology on both electrode architectures, allowing us to tune the  
50 electrochemically active surface area (ECSA) and thus overpotential. This results in decreased  
51 overpotentials as high as 460 and 174 mV for foil and gas diffusion electrodes, respectively, while  
52 maintaining or improving multi-carbon product current density. We further investigate these  
53 overpotential shifts and product activities by normalizing the current density by ECSA, uncovering  
54 current-potential relationships akin to those of the Tafel description. A continuum, 1D steady-  
55 state model rationalized the shifts, demonstrating that Tafel-like kinetics are useful for describing  
56 the roughness dependence for both liquid- and vapor-fed systems. This analysis establishes a  
57 holistic approach for establishing key catalyst design criterion that guide the development of  
58 improved materials and devices for CO<sub>2</sub> electrolysis technologies.

59

## 60 **The bigger picture**

61 CO<sub>2</sub> electrolysis is an attractive method for producing industrially relevant chemicals  
62 while reducing emissions coupled with renewable energy sources. Recent advancements have  
63 focused on evolving the electrode architecture from metal foils to porous gas diffusion electrodes  
64 for improving the reaction rate. However, the contributions from surface kinetics and local  
65 reaction environment are convoluted and vary when translating from liquid- to vapor-fed  
66 systems. Herein, we draw connections between these systems by evaluating identical catalyst  
67 structures of varying roughness for both electrode types. Our experimental and modeling  
68 approaches provide better understanding of the interplay between electrode structure and  
69 reaction environment on the activity and selectivity. We observe nominal changes in the intrinsic  
70 activity of Cu with significant overpotential savings corresponding to the roughness factors across  
71 electrode types.

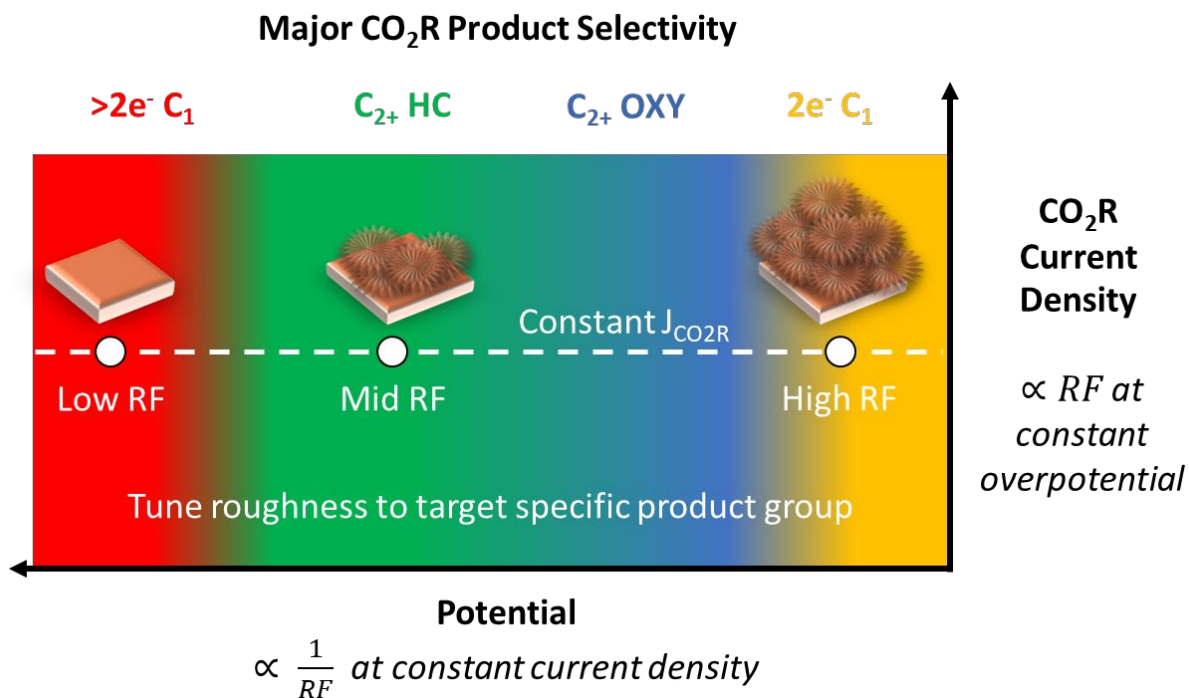

## 72 **1. Introduction**

73 Increased accessibility and rapidly declining costs of renewable technologies have  
74 incentivized gradual decarbonization in the global energy landscape.<sup>1,2</sup> However, other energy  
75 services essential to modern civilization cause emissions that will be more difficult to eliminate  
76 fully, such as aviation, long-distance transportation and shipping, and production of carbon  
77 intensive structural materials.<sup>3</sup> To address these and other remaining emissions, methods of  
78 carbon capture and sequestration are being developed to remove CO<sub>2</sub> from air and point sources  
79 of emissions, requiring further development and cooperative policy for economic viability.<sup>4,5</sup>  
80 Thus, there is great motivation to utilize CO<sub>2</sub> after it has been captured to make valuable  
81 products.<sup>6</sup> Electrochemical CO<sub>2</sub> reduction (CO<sub>2</sub>R) has risen as a promising candidate in that regard  
82 based on two criteria, including: (1) the ability to address emissions while producing essential  
83 carbon-based fuels and chemicals,<sup>7</sup> and (2) CO<sub>2</sub>R can be coupled with intermittent renewable  
84 technologies such as wind and solar power, to convert electricity to more versatile forms of  
85 chemical energy for storage and transportation.<sup>8</sup>

86 Knowledge gained from liquid-fed systems has provided a strong foundation for vapor-  
87 fed devices using gas-diffusion electrodes (GDEs) as the field focuses on industrial  
88 implementation. For both systems – which use aqueous electrolytes – complicated surface  
89 kinetics and competing homogeneous and hydrogen-evolution reactions (HER) limit  
90 performance.<sup>9–11</sup> More recently, the concept of the microenvironment (i.e. local reaction  
91 environment) in cooperation with polarization and surface effects has helped frame our  
92 understanding of device performance.<sup>12</sup> For foil electrodes in liquid-fed devices, roughening likely  
93 does not increase the intrinsic activity of Cu towards CO<sub>2</sub>R;<sup>9,13</sup> yet, it does influence product  
94 selectivity due to nano- and meso-scale effects.<sup>14–17</sup> Differences in selectivity have been  
95 attributed to varying coordination number,<sup>18–23</sup> pore size and shape,<sup>24,25</sup> and subsurface  
96 oxygen.<sup>26</sup> Ren et al. demonstrated changing selectivity based on the potential window<sup>27</sup> and De  
97 Luna et al. have correlated C<sub>2</sub>H<sub>4</sub> activity with suppressed CH<sub>4</sub> formation,<sup>28</sup> both achieved via  
98 nanostructuring. This also changes the local pH<sup>14,15,29</sup>, which can suppress the HER rate and  
99 promote C<sub>2+</sub> selectivity.<sup>28,30–32</sup> Naturally, the strategy for operating at low overpotential in

100 alkaline electrolytes has resulted in nearly full selectivity towards multi-carbon products from CO  
101 reduction.<sup>33</sup> By extension, these criteria have been employed for enhanced CO<sub>2</sub>R performance in  
102 vapor-fed systems; GDEs permit highly active CO<sub>2</sub>R in alkaline electrolytes (e.g. KOH) while  
103 minimizing species diffusion lengths in thin catalyst layers.<sup>31,34</sup> Such systems have been able to  
104 target multi-carbon production at lower overpotentials by controlling the microenvironment;  
105 which there are likely many more when using GDEs compared to foil electrodes.<sup>12,31,34–36</sup> Yet, it  
106 is unclear what effects translate between environments by nanostructuring the catalyst layer.

107 In this work, we utilize catalyst surface area to provide insight and bridge knowledge gaps  
108 between two different systems; liquid- and vapor-fed CO<sub>2</sub>R electrolyzers that utilize foil  
109 electrodes and GDEs, respectively (Figure S1). We observe the complex interplay between  
110 overarching potential-dependent trends, microenvironment, and electrodes of varying design  
111 and roughness factor (RF). We propose that the CO<sub>2</sub>R selectivity trends and catalyst design  
112 strategies for tuning product formation in liquid-fed CO<sub>2</sub> electrolysis extend to the vapor-fed  
113 systems (Figure 1). That is, (1) at a constant overpotential, the geometric current density will  
114 increase with increasing RF and (2) at constant geometric current density, the overpotential will  
115 decrease with increasing RF, both of which can affect product selectivity. By utilizing Cu  
116 nanoflower (NF) catalysts with intermediate RFs (e.g. ~185), we observe enhancements in multi-  
117 carbon (C<sub>2+</sub>) production at lower overpotentials. Activity and selectivity trends are further  
118 explored by comparing the formation of products accounting for electrode RF. More importantly,  
119 the overpotential savings are proportional to the ratio of RFs between electrodes at similar  
120 geometric current densities, regardless of the electrode architecture. We corroborate and  
121 explain these findings via computational Multiphysics modeling of kinetics with local species  
122 transport to estimate differences in microenvironment. Tafel parameters derived from the foil  
123 electrodes are used to predict the current densities for GDEs of varying RF, showcasing RF  
124 dependence. In this way, a more generalized catalyst-design criterion is established; namely, the  
125 surface area should be targeted to specific current-potential regimes that enhance product  
126 selectivity or increase energy efficiency.

127

128 **Figure 1. CO<sub>2</sub>R electrode development strategy using RF**

129 Effect of electrode roughness on geometric current density, electrochemical potential, and  
 130 major CO<sub>2</sub>R product selectivity for liquid- and vapor-fed CO<sub>2</sub> reduction. Product groups are  
 131 defined as 2e<sup>-</sup> single-carbon (2e<sup>-</sup> C<sub>1</sub>), >2e<sup>-</sup> single-carbon (>2e<sup>-</sup> C<sub>1</sub>), multi-carbon hydrocarbon (C<sub>2+</sub>  
 132 HC), and multi-carbon oxygenate (C<sub>2+</sub> OXY).  $\eta$  and CO<sub>2</sub>R Current Density represent overpotential  
 133 and geometric current density, respectively. Relationships of potential and current density (x-  
 134 and y-axes, respectively) with respect to RF are depicted.

135 **2. Results and Discussions**

136 **2.1. Synthesis and characterization of electrode morphology**

137

142 (G) Roughness factor comparisons of foil and GDE samples before and after nanoflower

143 formation.

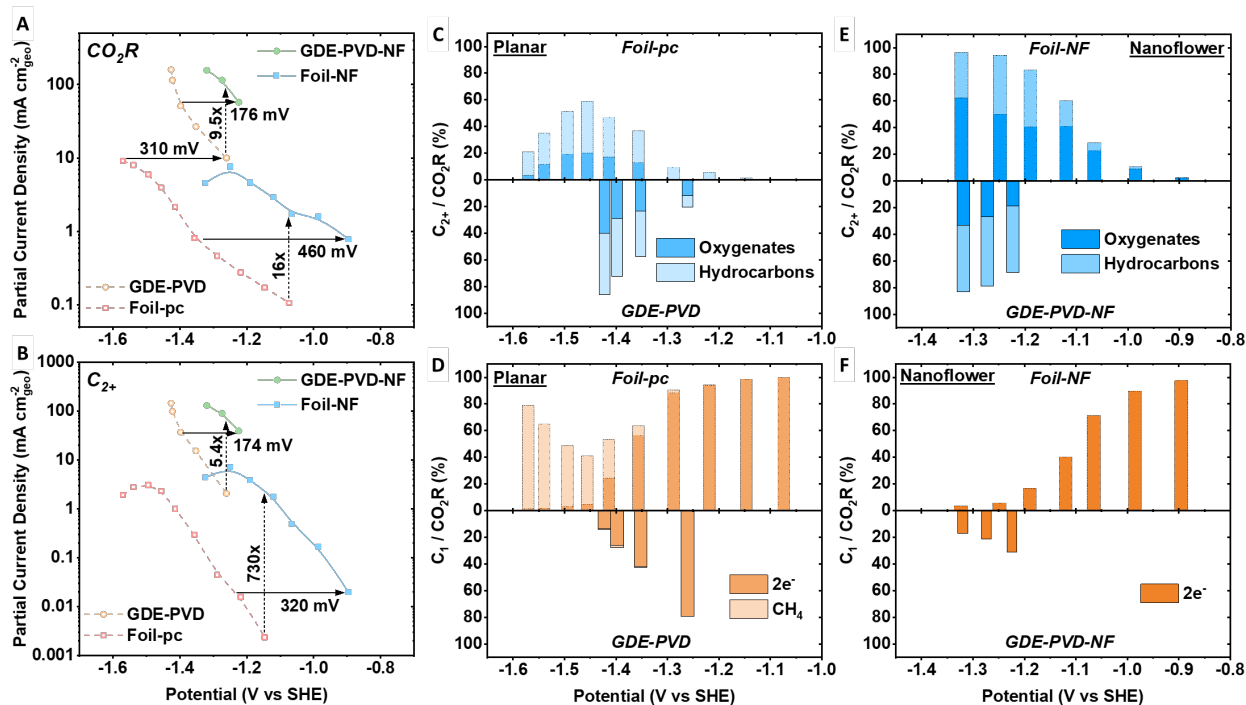

144 To modulate the surface area of the active catalyst layer readily, we employed a facile  
145 etching technique based on a previously reported procedure,<sup>33</sup> where  $(\text{NH}_4)_2\text{S}_2\text{O}_8$  oxidatively  
146 etches the surface of polycrystalline copper foil<sup>37</sup> (foil-pc) to form 3-dimensional self-assembled  
147 nanoflower structures (foil-NF) (Figure S2). The surface conversion from foil-pc (Figure 2A) to foil-  
148 NF (Figure 2B) was characterized by a scanning electron microscope (SEM), revealing significant  
149 reconstruction from a smooth surface to a roughened porous flower-like network. For GDEs, we  
150 formed electrodes containing Cu on porous expanded polytetrafluoroethylene (ePTFE)  
151 substrates via physical vapor deposition (PVD) (Figure 2C), denoted as either GDE-275 or GDE-  
152 1000 depending on the deposited Cu thickness in nm. NF formation was translated to a GDE by  
153 employing the same procedure used on electrodes (referred to as GDE-275-NF and GDE-1000-  
154 NF), as exposure time and solution composition can modulate the electrode nanostructure and  
155 surface area.<sup>33</sup> Both top (Figure 2D) and cross-section (Figure 2F) SEM images of these electrodes  
156 further show that the dense Cu layer formed by PVD (Figure 2E) results in a nanoflower structure,  
157 similar in feature and pore size ( $\sim 100\text{-}200$  nm) as foil-NF (Figure 2B and S3). Additionally, we  
158 validated the stability of this structure by conducting SEM after electrochemical testing, which  
159 showed some sintering while the major morphological features are maintained (Figure S4). The  
160 X-ray photoelectron spectroscopy (XPS) spectra of the Cu 2p region for the NF electrodes  
161 exhibited a broad peak at  $\sim 933.5$  eV and satellite features in the range of 940-945 eV, both  
162 corresponding to the  $\text{Cu}^{2+}$  oxidation state (Figure S5). Similarly, the corresponding X-ray  
163 diffraction (XRD) patterns reveal the presence of CuO in agreement with  $\text{Cu}^{2+}$  observed via XPS  
164 (Figure S6).

165 To estimate the ECSA of each electrode, we performed cyclic voltammetry to measure  
166 the double-layer capacitance in a non-Faradaic potential window (Figure S7). The RF, defined as  
167 the ratio of ECSA to geometric area of the electrode, resulted in values of 2 and 185 for foil-pc  
168 and foil-NF, respectively (Figure 2G). This substantial increase of 92x in ECSA is likely due to large  
169 amounts of Cu available within the foil-pc electrode that converted to NF. In comparison, GDE-  
170 275 and GDE-1000 resulted in comparable RFs of 11 and 13 before NF formation, respectively,  
171 despite their difference in the catalyst-layer thickness; as bulk Cu atoms are shielded from the  
172 electrolyte, they do not affect the ECSA measurements nor participate in  $\text{CO}_2\text{R}$ . After NF

173 formation the average RFs scaled with the PVD Cu thickness, with values of 33 (GDE-275-NF) and  
174 185 (GDE-1000-NF). We found that nanostructuring an initial PVD layer of 1000 nm thickness  
175 (GDE-1000) led to a near identical roughness as that of the foil-NF. It is noted that while the wet  
176 etching process increases the ECSA, it does so by simultaneously altering both catalyst thickness  
177 and porosity (Figure 2E-F). The resulting increase in the ECSA for GDEs (3x and 14x as rough) is  
178 notably less relative to the foil electrodes due to higher ECSA of non-nanostructured GDE-275  
179 and GDE-1000 samples (Table S7).

180

## 2.2. Understanding potential-dependent selectivity trends

182

183 **Figure 3. Potential shifts and fractional selectivity towards C<sub>2+</sub> and C<sub>1</sub> products from CO<sub>2</sub>**  
 184 **reduction**

185 (A and B) CO<sub>2</sub>R (A) and C<sub>2+</sub> (B) partial current densities for foil electrodes (foil-pc and foil-NF)  
 186 and GDEs (GDE-1000 and GDE-1000-NF) at various operating potentials.

187 (C-F) Fraction of C<sub>2+</sub> products (C) and C<sub>1</sub> products (D) for foil and GDEs with planar morphology.  
 188 Fraction of C<sub>2+</sub> products (E) and C<sub>1</sub> products (F) for foil and GDEs with nanoflower morphology.  
 189 C<sub>2+</sub> products divided into multi-carbon oxygenate (C<sub>2+</sub> OXY) and multi-carbon hydrocarbon (C<sub>2+</sub>  
 190 HC). C<sub>1</sub> products divided into two electron single carbon (2e<sup>-</sup> C<sub>1</sub>) and CH<sub>4</sub>. Foil-pc data adapted  
 191 from previous work.<sup>27</sup>

192 To understand the changes in the electrocatalytic activity and selectivity with changing  
 193 electrode structure, we tested CO<sub>2</sub>R performance under both liquid- and vapor-fed conditions  
 194 using the same corresponding electrochemical reactor and underlying substrate. These  
 195 comparisons are done by plotting the applied potential with respect to the standard hydrogen  
 196 electrode (V<sub>SHE</sub>), which allows for the assessment of trends based on an absolute potential  
 197 reference and thus circumventing variable pH corrections and differences in electrolyte  
 198 concentration. It is important to note that the GDEs can operate at much greater geometric

199 current densities ( $J_{\text{geo}}$ ) for  $\text{CO}_2\text{R}$  than the foils due to substantially increased diffusivity and  
200 smaller diffusion lengths of  $\text{CO}_2$  in vapor- and aqueous phase, respectively.<sup>39</sup> Thus, any  
201 improvements in applied potential or  $J_{\text{geo}}$  will be conservative compared to those on the RHE  
202 scale (denoted as  $V_{\text{RHE}}$ ), as the GDEs will result in a higher shift due to increased pH from higher  
203  $J_{\text{geo}}$ . When comparing electrodes of the same architecture, we use  $V_{\text{RHE}}$  where appropriate (see  
204 SI). Additionally, the results shown at each current density were repeated three times to establish  
205 statistical significance, which exhibited reasonable standard deviations of the data (Table S1-S6).

206 Between the foils and GDEs, we observe a >310 mV potential difference between foil-pc  
207 and GDE-PVD at a  $\text{CO}_2\text{R}$   $J_{\text{geo}}$  of  $10 \text{ mA cm}^{-2}$ , highlighting the impact of increased  $\text{CO}_2$  mass  
208 transport and higher ECSA within the GDEs.<sup>39,40</sup> Within the same electrode architecture, there is  
209 a positive shift in the operating potential window with the higher RF (NF morphology) electrodes  
210 (Figure 3A and B), alluding to the activation overpotential dependence on RF. At a  $\text{CO}_2\text{R}$   $J_{\text{geo}}$  of  
211  $\sim 0.8 \text{ mA cm}^{-2}$ , the foil electrodes resulted in a maximum potential shift of 460 mV. The GDEs  
212 resulted in a smaller shift of 176 mV, as the RF ratio is smaller than that of the foil. For the thinner  
213 GDE-275, there was an even smaller shift of 62 mV at the same  $\text{CO}_2\text{R}$   $J_{\text{geo}}$  of  $57 \text{ mA cm}^{-2}$  (Figure  
214 S10). At a constant potential, the  $\text{CO}_2\text{R}$   $J_{\text{geo}}$  increases by up to 16x with the foil-NF electrodes,  
215 whereas up to 9.5x is achieved with the GDEs. In terms of  $\text{C}_{2+}$   $J_{\text{geo}}$ , the shift in the potential range  
216 for the foil electrodes is reduced to 320 mV, whereas the GDEs have largely maintained the  
217 potential shift of 174 mV. Thus, the degree of overpotential shift can vary depending on the  
218 electrode type and operating potential window. We infer that the greater difference (460 – 320  
219 mV) between the foil electrodes is due to  $\text{CO}$ ,  $\text{HCOO}^-$ , and  $\text{CH}_3\text{COO}^-$  being formed at lower  
220 overpotentials due to an increased ECSA (Figure S11). Overall, this indicates that the increased  
221 catalyst surface area helps to decrease the overpotentials in the predominantly activation-  
222 controlled regime, and thus increase energy efficiency, while maintaining the rate at which  $\text{CO}_2\text{R}$   
223 products are generated for both GDEs and foil electrodes.

224 The foil-NF electrode is highly selective towards two-electron single-carbon ( $2e^- \text{ C}_1$ )  
225 products starting at  $-0.49 V_{\text{RHE}}$  ( $-0.89 V_{\text{SHE}}$ ) (Figure S8). Peak selectivity towards  $\text{CO}$  (72.2%) and  
226  $\text{HCOO}^-$  (31.8%) are observed along with a modest 8.5% FE toward  $\text{H}_2$ ; formation of these  $2e^-$   
227 products is due to the low overpotential similar to other reported high RF systems operating in

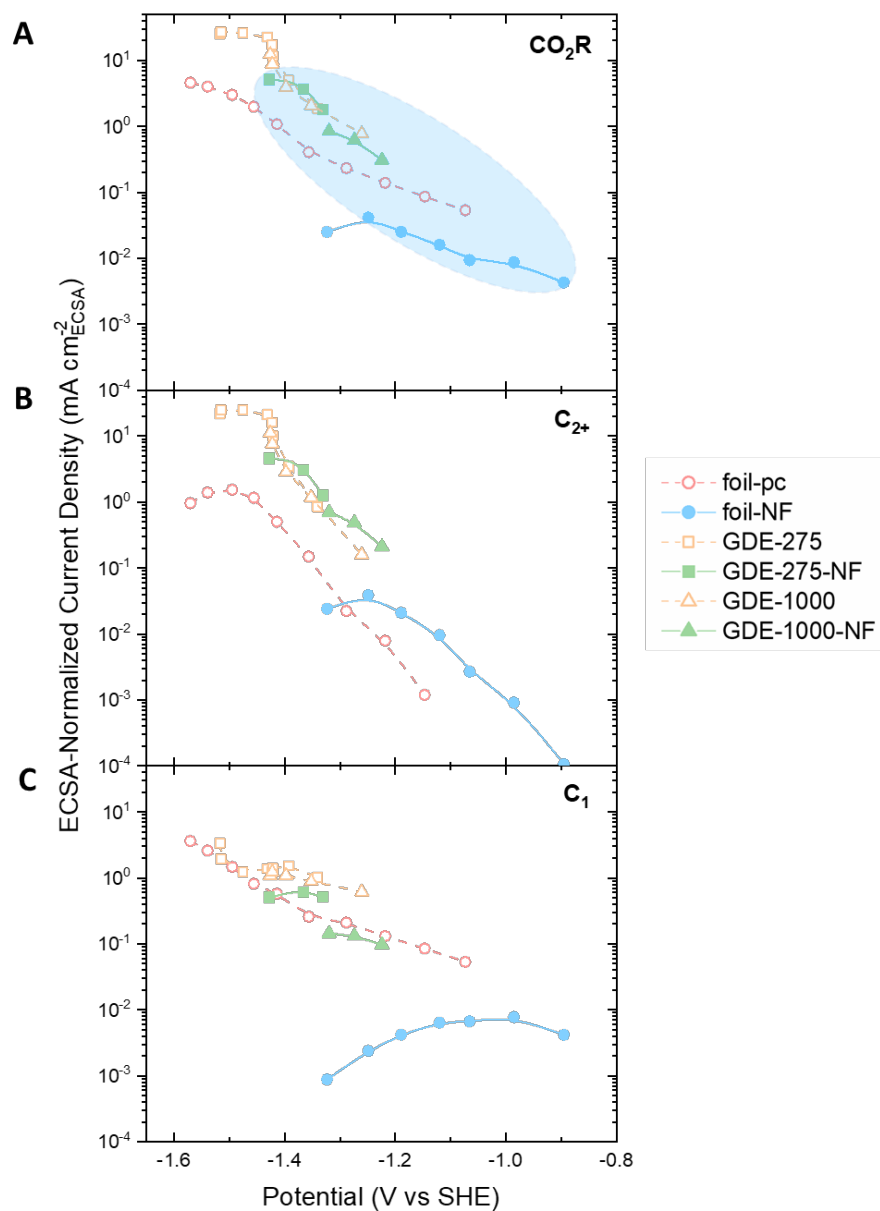

228 similar to more positive potentials.<sup>18,22,22,41-43</sup> With increasing overpotentials ( $< -0.58 V_{\text{RHE}}$  or -  
229  $0.98 V_{\text{SHE}}$ ), higher selectivity towards  $C_{2+}$  products including  $C_2H_4$ ,  $C_2H_5OH$ ,  $C_3H_7OH$ ,  $CH_3COO^-$ , and  
230 small quantities of  $C_2H_6$  are measured. Furthermore, an oxygenate-to-hydrocarbon ratio of up to  
231 11.8 is measured on the foil-NF at lower overpotentials (Figure S17). Previously, we observed this  
232 enhanced  $C_{2+}$  oxygenate formation for  $CO_2R$  and  $CO$  reduction correlating with increased ECSA  
233 and low overpotentials.<sup>18,33</sup> Additionally, the combination and increased quantity of oxide-  
234 derived active sites present in foil-NF may promote selectivity towards oxygenates.<sup>26,44,45</sup> For GDE  
235 samples,  $C_2H_4$  formation on the NF samples exceeds that of both PVD samples at  $71 \text{ mA cm}^{-2}$ ,  
236 with lower selectivity towards  $C_2H_5OH$  and  $H_2$  (Figure S9). Effects due to internal diffusion within  
237 the pores such as trapping<sup>46</sup> and local pH changes may aid in the formation of further-reduced  
238 products at low  $J_{\text{geo}}$ .<sup>33,47</sup> Our modeling analysis shows that sufficient  $CO_2$  concentration ( $>21 \text{ mM}$ )  
239 and less alkaline pH are expected throughout the rougher, more porous catalyst layers,  
240 supporting the aforementioned effects (Figures S38-39). However, the effects of decreasing pH  
241 and  $CO_2$  concentration are more pronounced at the higher current densities of 143 and  $214 \text{ mA}$   
242  $\text{cm}^{-2}$ , resulting in the NF samples exhibiting lower selectivity towards  $C_{2+}$  products compared to  
243 the thinner PVD catalyst layers.

244 To better understand the distribution of  $CO_2R$  products, the fractional selectivity for both  
245 the foil and GDE is given in Figure 3C-F. The GDE-PVD demonstrates significantly greater  $C_{2+}/CO_2R$   
246 ratio compared to that of the foil-pc electrode at similar applied potentials (Figure 3C).  
247 Remarkably,  $C_{2+}$  oxygenates are observed at potentials as positive as  $-1.26 V_{\text{SHE}}$  with the GDE,  
248 whereas only  $C_{2+}$  hydrocarbons are found in the case of the foil. This earlier onset corresponds  
249 to higher oxygenate-to-hydrocarbon ratios on the GDE-PVD than the foil (Figures S17-18).  
250 Additionally, the GDE shows a lower preference for  $C_1$  formation compared to the foil (Figure 3D).  
251 We posit this is due to enhanced C-C coupling with higher average  $CO_2$  concentration throughout  
252 GDEs (Figures S35 and S38) and a local pH effect caused by increased current density.<sup>29</sup>  
253 Comparing foil electrodes,  $CH_4$  is not observed on the foil-NF due to the overpotential shift being  
254 in the positive direction while activation-controlled. For the foil-pc,  $CH_4$  increases at potentials  
255  $< -1.28 V_{\text{SHE}}$ , becoming the majority  $CO_2R$  product due to limited solubility of  $CO_2$ .<sup>37</sup> Despite these

256 differences, exclusive formation towards  $2e^-$  products for both foil and GDE is observed at  
257 potentials  $>-1.28 V_{SHE}$ , which is again attributed to the low overpotential.

258 Unlike the planar Cu morphology, greater  $C_{2+}/CO_2R$  fractions are obtained with the foil-  
259 NF electrode under liquid-fed aqueous conditions compared to those of the GDE-1000-NF in a  
260 similar potential window ( $-1.20$  to  $-1.32 V_{SHE}$ ) (Figure 3E). Relative to the foil, we see greater  
261 fractions towards  $2e^-$  product formation at higher overpotentials on the GDE due to  $*CO$   
262 desorption when higher concentrations of  $CO_2$  are present (Figure 3F).<sup>48</sup> However, this is  
263 opposite for the NF morphology, which results in a higher oxygenate-to-hydrocarbon ratio for  
264 the foil compared to the GDE (Figures S17-18). Because both electrodes exhibit similar  
265 morphology, porosity (Figures 2F and S2), and RF ( $\sim 185$ ), we deduce that the increased oxygenate  
266 fraction on the foil-NF is likely influenced by differences in the microenvironment.<sup>12</sup> The  
267 concentration and residence times of adsorbates can vary between electrode architectures at  
268 lower current densities. For example, the GDE architecture may result in more effective removal  
269 of hydroxide than the foil setup due to flowing electrolyte and  $CO_2$  being fed on the GDL side,  
270 which reduces local oxygen concentration and the propensity for oxygenate production. We  
271 observe a clear preference towards  $C_{2+}$  production for all NF electrodes at potentials  $>-0.95 V_{RHE}$   
272 (Figures S14-S16), with up to 10x enhancement in  $C_{2+}/CO_2R$  for the foil NF at  $\sim -0.9 V_{RHE}$  ( $-1.3 V_{SHE}$ ).  
273 Thus, the influence from the combination of both electrode RF and microenvironment lead to  
274 the observed enhancements in  $C_{2+}$  formation, not just the potential. Furthermore, the increase  
275 of the  $C_{2+}/CO_2R$  ratios associated with the GDE-NF samples are not observed at potentials  $<-0.95$   
276  $V_{RHE}$  ( $<-1.41 V_{SHE}$ ) (Figures S14-16). The effects of ECSA on the current density-potential behavior  
277 and product selectivity are more prominent in liquid-fed systems as compared to vapor-fed  
278 systems at potentials more positive than  $-0.95 V_{RHE}$ , which may suggest decreasing influence  
279 from local reaction environments in GDEs.

280

282

283 **Figure 4. Comparison of foil and gas-diffusion electrode samples.**284 (A-C) ECSA-normalized partial current density towards (A) CO<sub>2</sub>R products, (B) C<sub>2+</sub> products, and285 (C) C<sub>1</sub> products as a function of potential (V vs SHE) for foil and GDE samples. Blue oval in (A)286 indicates J-V slopes towards CO<sub>2</sub>R appear similar while activation-controlled.

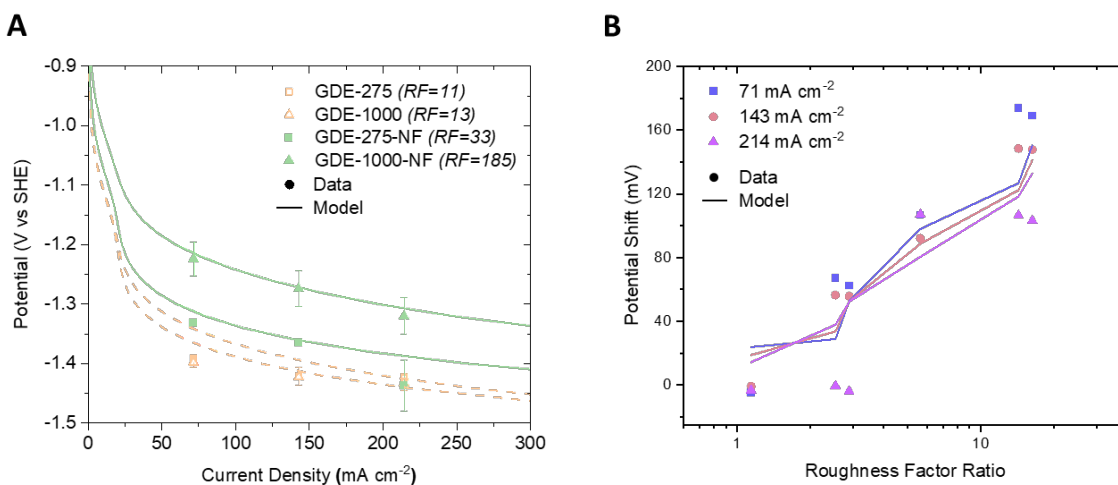

287 Due to the importance of the local microenvironment and conditions on CO<sub>2</sub>R selectivity,  
288 we examine the data in terms of the local current density (i.e., ECSA-normalized) or average  
289 turnover frequency per active site for each electrode.<sup>49</sup> There is an increase in the ECSA-  
290 normalized current density ( $J_{\text{ECSA}}$ ) towards CO<sub>2</sub>R for the GDEs compared to foil electrodes (Figure  
291 4A).<sup>40</sup> We identify the slopes for CO<sub>2</sub>R activity to be similar for all the samples in this study prior  
292 to mixed-control (shaded blue). Furthermore, the  $J_{\text{ECSA}}$  towards CO<sub>2</sub>R for all GDE samples collapse  
293 onto a single curve, validating the observed potential shift associated with  $J_{\text{geo}}$  under activation-  
294 control. Thus, we observe little to no enhancement in the intrinsic activity of Cu towards CO<sub>2</sub>R  
295 with increasing ECSA in the form of a GDE, similar to what is observed in liquid-fed systems using  
296 foil electrodes.<sup>9,13</sup>

297 To assess changes in product activity, we provide results for the individual products  
298 (Figures S19-S26), and C<sub>2+</sub> (Figure 4B) and C<sub>1</sub> (Figure 4C) product groupings. The current-voltage  
299 (J-V) slopes for C<sub>2</sub>H<sub>4</sub>, C<sub>2</sub>H<sub>5</sub>OH, and C<sub>3</sub>H<sub>7</sub>OH appear consistent across all samples while in the  
300 activation-controlled regime, suggesting the rate-limiting step plausibly remains unaffected  
301 (Figure S22-S24).<sup>50</sup> The changing slope for CH<sub>3</sub>COO<sup>-</sup> compared to other C<sub>2+</sub> products (Figure S25)  
302 reinforces the hypotheses regarding ECSA and pH effects resulting in divergent reaction  
303 mechanisms for these products.<sup>51,52</sup> However, the activities towards C<sub>2+</sub> products show light  
304 promotion ascribed to the NF GDEs. While the foil-NF sample appears to suppress both CO<sub>2</sub>R and  
305 HER (Figure S26) when compared to foil-pc, it promotes C<sub>2+</sub> product formation by an order of  
306 magnitude (~10x at -1.15 V vs SHE). The average number of electrons per molecule reaffirms  
307 that the formation of C<sub>2+</sub> products is achieved with the rougher NF samples at lower  
308 overpotentials (Figure S28). We infer the contribution on C<sub>2+</sub> product activity from changing ECSA  
309 and morphology may be larger for liquid-fed CO<sub>2</sub>R on foil electrodes than vapor-fed CO<sub>2</sub>R on  
310 GDEs. Additionally, the discernable asymptotic and/or decreasing  $J_{\text{ECSA}}$  indicates the samples may  
311 be entering a mixed-control regime at varying potentials.

312 The enhancements in C<sub>2+</sub> products suggest a corresponding suppression of C<sub>1</sub> product  
313 formation with all NF electrodes (Figure 4C). The NF samples show poor activity towards HCOO<sup>-</sup>  
314 compared to the planar counterparts (Figure S20). The suppression of this terminal reaction  
315 pathway leads to the formation of \*CO, the common intermediate for all other CO<sub>2</sub>R products.<sup>9</sup>

316 The overall product distribution supports the preference for \*CO dimerization, as CO formation  
317 is also suppressed on the NFs like HCOO<sup>-</sup> (Figure S19). Additionally, little to no formation of CH<sub>4</sub>  
318 on the NFs leads to a combined lower J<sub>ECSA</sub> towards C<sub>1</sub> products (Figure S20). Interestingly, the  
319 GDE-1000-NF has a lower fraction of products going through the COR pathway compared to foil-  
320 NF (Figure S29); we posit the effects of concentration overpotential and lower residence times  
321 of adsorbed intermediates on the NF GDEs may allow for more facile \*CO desorption.  
322 Additionally, this may be related to the quantity of hydrogen evolving; the activity towards  
323 hydrogen results in similar J-V slopes for all NF electrodes, whereas asymptotic regions are  
324 present on the foil-pc and PVD electrodes where CO<sub>2</sub>R is dominant (Figure S26). Based on this  
325 analysis, we provide insight onto the varying contributions of microenvironment and morphology  
326 on product activity and selectivity.

327 **2.4. Investigating RF influence on overpotential shift via analytical and modeling**  
 328 **approaches**

329  
 330 **Figure 5. Relationship between roughness factor ratio and overpotential shift derived from**  
 331 **experimental results and predicted by 1D steady-state model.**  
 332 (A) Potential (V vs. SHE) resulting from various applied current densities obtained with the four  
 333 GDEs from experiment (scatter), and the predicted relationship from the model using an  
 334 average of 6e<sup>-</sup> per CO<sub>2</sub> (solid and dashed lines).  
 335 (B) Potential shift resulting from six possible combinations of RF ratios from the four GDE  
 336 samples (scatter) and the model prediction using the Tafel parameters extracted from Figure 5A  
 337 (line).

338  
 339 To probe further the relationship between RF and overpotential shift, we simulate the  
 340 effects using a 1D, steady-state GDE catalyst-layer model for CO<sub>2</sub>R and HER reactions (complete  
 341 description in Section S3). We account for CO<sub>2</sub>R and HER by using single electrochemical reactions  
 342 with the average electrons passed per product; two electrons for HER and 5-6 electrons per CO<sub>2</sub>  
 343 molecule reduced. This is based on the observation that the majority species are two-carbon  
 344 products within the potential range that was tested as shown in the experimental data (Figure  
 345 S28)):

348 This reaction kinetics are modeled using the Tafel expressions,

$$j_{CO_2R} = j_{CO_2R,0} \left( \frac{c_{CO_2}}{c_{CO_2}^{ref}} \right) \exp \left( \frac{\alpha_{CO_2R} F}{RT} \left( \phi_s - \phi_l - \left( U_{CO_2R}^0 - \frac{2.303RT}{F} \text{pH} \right) \right) \right) \quad (1)$$

$$j_{HER} = j_{HER,0} \exp \left( \frac{\alpha_{HER} F}{RT} \left( \phi_s - \phi_l - \left( U_{HER}^0 - \frac{2.303RT}{F} \text{pH} \right) \right) \right). \quad (2)$$

349 The Tafel parameters ( $\alpha_{CO_2R}$ ,  $\alpha_{HER}$ ,  $j_{CO_2R,0}$  and  $j_{HER,0}$ ) are determined using a pH-  
 350 corrected foil electrode model (complete description in Section S3.1). Piecewise-linear and linear  
 351 fits accurately describe the foil data from the foil-pc and foil-NF samples, respectively (Figure  
 352 S35). The electrochemical reaction rate for species  $i$  is calculated as

$$R_i = \sum_h \frac{a_v v_{i,h} j_h}{n_h F} \quad (3)$$

353 where  $v_{i,h}$  is the stoichiometric coefficient for species  $i$  in electrochemical reaction  $h$ ,  $n_h$  is the  
 354 number of electrons in electrochemical reaction  $h$ . The specific surface area is calculated using  
 355 the dimensions and measured ECSA of each catalyst layer, which is normalized by the roughness  
 356 factor of the foil electrode data that was used to fit the kinetics,

$$a_v = \frac{RF_{GDE}}{RF_{foil}} \cdot \frac{1}{L_{CL}} \cdot S \quad (4)$$

357 where  $S$  is the saturation. The saturation accounts for the fraction of the catalyst layer surface  
 358 that is not wetted by the electrolyte and a value of 0.64 is assumed for an ideally-wetted catalyst  
 359 layer.<sup>53</sup> Dividing the RF of the GDE by the RF of the foil-NF electrode normalizes the exchange  
 360 current densities to the ECSA at which the kinetic parameters were extracted. By incorporating  
 361 CO<sub>2</sub> and ion-transport effects, electrode parameters, and bulk electrolyte reactions (as described  
 362 by Weng et al.),<sup>53</sup> we predict the J-V relationships for the four GDEs labeled by their RFs (Figure  
 363 5A). The results show that the Tafel fit to the foil-NF data, when scaled by ECSA, give an accurate  
 364 prediction of the J-V relationships for all GDE samples. Additionally, there was little sensitivity to  
 365 the average number of electrons between five and six (Figure S41). This suggests that our  
 366 utilization of ECSA in the modified Tafel description is a valid method for estimating the trend of  
 367 decreasing overpotential with increasing RF for the GDEs.

368 We then determined six RF ratios (dividing any two electrode RFs) from combinations of  
 369 the four GDE samples (Figure S31A). Further comparison of the modeling results provided a semi-

370 logarithmic relationship between the ratio of RFs and the difference in applied potentials at 71  
371 and 143 mA cm<sup>-2</sup> (Figure 5B). The computational model predicts similar shifts in potential for the  
372 various RF ratios, further corroborating the use of the number of electrons per CO<sub>2</sub> molecule as  
373 an effective approach towards understanding activity relationships between HER and CO<sub>2</sub>R.  
374 Furthermore, these results suggest some proportional dependence of overpotential shift on the  
375 ratio of RFs (Figure S31), despite the complex reaction networks on the catalytic surface. These  
376 differences are exacerbated at a J<sub>geo</sub> of 214 mA cm<sup>-2</sup>, where a notable deviation from linearity is  
377 observed along with increased deviations between sample potentials (Figure S32). The surface  
378 CO<sub>2</sub> concentration from the model indicates a drastic decrease with thicker electrodes and a  
379 commensurate increase in the local pH at high current densities (Figures S38-39). Additionally,  
380 we posit observations including increased overpotential (due to low CO<sub>2</sub> concentration) and  
381 hydrogen evolution are indicative of entering a mixed-control regime.

382         The resulting slopes of 151 mV dec<sup>-1</sup> (at 71 mA cm<sup>-2</sup>) and 128 mV dec<sup>-1</sup> (at 143 mA cm<sup>-2</sup>)  
383 vary due to the differences in catalyst-layer thickness, morphology, and product selectivity within  
384 each combination of electrodes. Additionally, the contributions from surface faceting cannot be  
385 ignored and are also tied to the applied potential.<sup>28</sup> We extend this analysis by measuring the  
386 current-potential slopes from the J<sub>ECSA</sub> of the total and CO<sub>2</sub>R reactions showing 123 and 116 mV  
387 dec<sup>-1</sup>, respectively (Figure S30). This is in agreement with the slopes of potential shift vs RF ratio,  
388 which are in fact both *b* according to the definition of the Tafel expression (full the derivation in  
389 the SI). Specifically, the slopes obtained using potential shifts at a total J<sub>geo</sub> of 143 mA cm<sup>-2</sup> from  
390 both the experiment (128 mV dec<sup>-1</sup>), and the model (123 mV dec<sup>-1</sup>) are comparable. This is likely  
391 due to the majority of total current being comprised of CO<sub>2</sub>R current, thereby the slope derived  
392 from J<sub>CO<sub>2</sub>R</sub> results in a similar value of 116 mV dec<sup>-1</sup>. We observe that the above trends in potential  
393 shift and RF ratio apply across all electrodes in this work, regardless of electrode architecture  
394 (Figure S33). At any near-equivalent value of J<sub>geo</sub> for total and CO<sub>2</sub>R reactions, the range of  
395 potential shifts increases with RF. These results signify RF/ECSA as an important descriptor for  
396 developing computational models that deepen our understanding of current-potential  
397 relationships. A more robust model including microkinetic parameters for various intermediates  
398 and mechanisms can further elucidate the dependence on RF.

### 399 3. Conclusion

400 In this work, we identify and bridge knowledge gaps between liquid- and vapor-fed CO<sub>2</sub>  
401 reduction systems, using active surface area as a descriptor to understand the effects of changing  
402 local environments and resultant activity and selectivity trends. For the liquid-fed CO<sub>2</sub>R system,  
403 the Cu foil-NF electrode demonstrates up to 735x increase in geometric current density towards  
404 CO<sub>2</sub>R (−0.75 V vs RHE) and an overpotential shift up to 460 mV compared to the foil-planar. A  
405 preference towards multi-carbon products (>95% of CO<sub>2</sub>R is C<sub>2+</sub>) is observed as compared to the  
406 foil-pc from previous work. Within vapor-fed devices, rougher GDEs provide similar overpotential  
407 shifts (~170 mV) and geometric current-density enhancements (~10x towards CO<sub>2</sub>R). Such  
408 overpotential shifts can lead to increased energy efficiency while maintaining a desired current  
409 density, however, selectivity trends do not necessarily extend between electrode architectures.  
410 Additionally, the NF morphology prefers multi-carbon product formation on an activity basis,  
411 even though the J-V slopes from the ECSA-normalized current densities from different electrodes  
412 are similar. With a 1D computational model using a simplified Tafel-description, the observed  
413 potential shifts are strongly suggested to be related to the RF ratios of electrodes when  
414 activation-controlled. Through this comparative investigation, we demonstrate a general  
415 strategy that utilizes electrode engineering efforts to translate foil electrodes from liquid-fed to  
416 GDEs for more industrially relevant operating conditions. Our approach towards understanding  
417 the interplay of current-potential relationships, electrode formulation, and local reaction  
418 environment can be applied to a variety of systems and reactions for improved design and  
419 performance.

420

## 421 **4. Methods**

### 422 **4.1. Electrode Preparation and Characterization**

423 A cleaned and polished copper foil was immersed in an aqueous solution containing 0.25  
424 M sodium hydroxide and 62.5 mM ammonium persulfate at 60 °C for one hour to form cupric  
425 oxide nanoflowers (See SI for full preparation procedure). The same procedure was used to make  
426 the nanostructured GDE samples from a layer of copper deposited via e-beam physical vapor  
427 deposition on the expanded polytetrafluoroethylene (ePTFE) gas-diffusion-layer (GDL) substrate.  
428 The as-prepared electrodes were characterized by scanning electron microscopy (SEM) to  
429 confirm nanoflower morphology, and focused ion-beam (FIB) SEM was used to measure  
430 electrode thicknesses. X-ray photoelectron spectroscopy (XPS) and X-ray diffraction (XRD) were  
431 used to confirm the oxidation and crystal structure of the copper catalyst, respectively. The  
432 electrodes were electrochemically pre-reduced prior to performing CO<sub>2</sub> reduction at a potential  
433 of -0.75 V vs Ag|AgCl, the electrochemically active surface area (ECSA) was determined by  
434 performing double-layer capacitance measurements via cyclic voltammetry (CV).

### 435 **4.2. Electrochemical Evaluation**

436 For the liquid-fed system, a CO<sub>2</sub>-saturated 0.1 M KHCO<sub>3</sub> electrolyte was fed with  
437 humidified CO<sub>2</sub> at the flow rate of 20 sccm. For the vapor-fed system, CO<sub>2</sub> gas at 10 sccm is  
438 directly introduced to the backside of the GDE in addition to the CO<sub>2</sub>-saturated 1 M KHCO<sub>3</sub>  
439 electrolyte at the front of the GDE. For the liquid-fed system, chronoamperometry was used for  
440 1 hour, while chronopotentiometry was used for vapor-fed analyses. IR-compensation was  
441 performed by an average of measured resistances (taken every three minutes) over the  
442 electrolysis period. The entire protocol was repeated three times to confirm reproducibility for  
443 each condition.

### 444 **4.3. Reactor and System Set Up**

445 A custom polycarbonate electrochemical cell and advanced manufactured  
446 electrochemical cell was used for liquid-fed and vapor-fed CO<sub>2</sub>R experiments, respectively.<sup>33,38</sup>

447 Both cells formed a three-electrode system: (1) foil and gas diffusion electrodes were used as  
448 working electrodes and exposed to the electrolyte; (2) a platinum foil (Alfa Aesar; 99.99% trace  
449 metals basis) and IrO<sub>2</sub> (Dioxide Materials) were used as counter electrodes for liquid-fed and  
450 vapor-fed systems, respectively; (3) an Ag/AgCl electrode was used as the reference electrode  
451 through a Luggin capillary. Anion-exchange membranes comprised of (Selemion AMV, AGC Inc.)  
452 and Fumasep were used in between the working and counter electrode compartments for liquid-  
453 and vapor-fed systems, respectively.

#### 454 **4.4. Product Analysis**

455 Product identification and quantification were conducted according to protocols  
456 described in detail in our previous work.<sup>29,37,38</sup> For each tested operating condition, 1 mL of  
457 reactor exhaust gas was injected multiple times into a GC (SRI Instruments; Multiple Gas #3,  
458 8610C) during the electrolysis period to analyze the concentration of products in the gas phase.  
459 After CA/CP measurements, the electrolyte was collected, and then the liquid-phase products  
460 were analyzed by using water suppression <sup>1</sup>H NMR (600 MHz, Varian Inova and 500 MHz, Avance  
461 III HD Bruker with Prodigy cryoprobe). The anolyte was also analyzed in the same way to account  
462 for acetate and formate species that crossed over the membrane due to their anionic character.

## 610 **6. Acknowledgements**

611 This work was performed at both the Department of Chemical Engineering at Stanford University  
612 and Lawrence Livermore National Laboratory, funded by a cooperative research and  
613 development agreement with TOTAL American Services, Inc. (affiliate of TOTAL SE) under  
614 agreement number TC2307. This work was performed under the auspices of the U.S. Department  
615 of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 and  
616 was supported by Laboratory Directed Research and Development funding under project 19-SI-  
617 005. Project conceptualization and liquid-fed CO<sub>2</sub> reduction experiments was performed by  
618 Daniel Corral, Stephanie Nitopi, and Lei Wang with the Joint Center for Artificial Photosynthesis,  
619 a DOE Energy Innovation Hub, supported through the Office of Science of the U.S. Department  
620 of Energy under Award Number DE-SC0004993. Alex King was supported by a NSF Graduate  
621 Fellowship (DGE 1752814) and along with Adam Weber acknowledge support from the Liquid  
622 Sunlight Alliance, which is supported by the U.S. Department of Energy, Office of Science, Office  
623 of Basic Energy Sciences, Fuels from Sunlight Hub under Award Number DE-SC0021266. Daniel  
624 Corral thanks the Stanford Graduate Fellowship, as well as the GEM Fellowship at Stanford  
625 University and Lawrence Livermore National Laboratory. The authors thank and appreciate  
626 guidance and discussions from colleagues including Julie Hamilton, Dr. Alan Landers, David Koshy,  
627 Kabir Abiose, Dr. McKenzie Hubert, Kyra Yap, Prof. Carlos Morales-Guio, Prof. Andrew Wong,  
628 Prof. Drew Higgins, Dr. Shaffiq Jaffer, and Dr. Amitava Sarkar. The authors thank Alex King and  
629 Dr. Adam Weber for modeling guidance and helpful discussions. The authors thank the Nuclear  
630 Magnetic Resonance Spectroscopy Facilities, and part of this work was performed at the Stanford  
631 Nano Shared Facilities (SNSF), supported by the National Science Foundation under award ECCS-  
632 2026822. The authors thank Maryann C. Tung for collecting SEM images using FIB. The authors  
633 thank the Nuclear Magnetic Resonance Spectroscopy and Cleanroom Facilities at Lawrence  
634 Livermore National Laboratory.
