Spin moiré superlattices (SMSs) have been proposed as a magnetic analog of crystallographic moiré systems and a source of electron minibands offering vector-field moiré tunability and Berry curvature effects. However, it has proven challenging to realize an SMS in which a large exchange coupling *J* is transmitted between conduction electrons and localized spins. Furthermore, most systems have carrier mean free paths  $I_{mfp}$  shorter than their spin moiré lattice constant  $a_{spin}$ , inhibiting miniband formation. Here, we discover that the layered magnetic semimetal EuAg<sub>4</sub>Sb<sub>2</sub> overcomes these challenges by forming an interface with *J* ~ 100 milli–electron volts transferred between a Eu triangular lattice and anionic Ag<sub>2</sub>Sb bilayers hosting a two-dimensional electron band in the ballistic regime ( $I_{mfp} >> a_{spin}$ ). The system realizes an SMS with  $a_{spin}$  commensurate with the Fermi momentum, leading to a marked quenching of the transport response from miniband formation. Our findings demonstrate an approach to magnetically engineering moiré superlattices and a potential route to an emergent spin-driven quantum Hall state.

### **INTRODUCTION**

A heterostructure of two-dimensional (2D) crystals with a relative twist or lattice mismatch produces a moiré superlattice potential. The conduction electrons form mini flat bands enhancing the effects of electronic correlation, resulting in a wealth of correlated electronic phases (1, 2). A distinct approach to the design and construction of moiré flat bands is to embed itinerant electrons in a spin modulation incommensurate with the atomic lattice to impose a superlattice exchange potential. Recent theoretical works have demonstrated that nontrivial spin structures such as skyrmion lattices (SkLs) (3-5) that form spin moiré superlattices (SMSs) may enable unique modulated electronic behavior (6). Similar to conventional moiré systems, the Fermi surface of the conduction electrons is strongly reconstructed into a magnetic Brillouin zone (BZ) defined by the periodicity of the SMS (5, 7). However, compared to crystallographic moiré lattices, it is expected that a magnetically derived moiré system could support relatively straightforward tunability (e.g., with magnetic field) and enable new phenomena with

the vector-like nature of the magnetism (compared to a scalar charge modulation) (8).

Despite these theoretical predictions, experimental realization of all of the necessary ingredients for SMSs has proven challenging. A first requirement is a modulated magnetic superlattice with a multi-q structure. Recent advances have established such textures in a growing number of thin films and bulk crystalline magnets (9). However, among the electrically conducting multi-q systems, there is a scarcity of electronically clean compounds or Fermi surfaces capable of nesting with the magnetic BZ of the underlying magnetic texture. A further challenge lies in the realization of relatively large exchange coupling constant J between conduction electrons and an underlying spin superlattice that can reconstruct the Fermi surface.

### RESULTS

Here, we study the SMS within magnetic layered semimetals, where a magnetic subsystem is alternately stacked with conductive semimetallic layers hosting highly mobile electrons and relatively low Fermi energy  $E_{\rm F}$  (10–12), as a route to overcome these challenges. A platform material which connects to these considerations is EuAg<sub>4</sub>Sb<sub>2</sub>, which crystalizes into the rhombohedral CaCu<sub>4</sub>P<sub>2</sub> type structure (*R*-3*m*, space group 166) (13). As shown in Fig. 1A, the crystal structure is the alternate stacking of triangular lattices of magnetic Eu atoms and Ag<sub>2</sub>Sb bilayers of Zintl-Klemm type {Eu<sup>2+</sup>[(Ag<sub>2</sub>Sb)<sup>-</sup>]<sub>2</sub>}. Previous studies reported successive magnetic transitions along with metamagnetism (14, 15), suggesting the presence of magnetic frustration in the Eu triangular lattice layer. The conduction bands are mainly composed of Sb-5s/5p orbitals on the anionic layer (13) coordinated with a neighboring Eu layer along the *c* axis.

To shed light on the electronic structure of EuAg<sub>4</sub>Sb<sub>2</sub>, we performed ab initio density functional theory (DFT) calculations of the Fermi surfaces (Fig. 1B). These reproduce the hole pockets observed by the angle-resolved photoemission electron spectroscopy (ARPES) as shown in Fig. 1C for the Fermi surface at 104 eV. We observe intensity

for three pockets,  $\alpha$ ,  $\beta$ , and a surface state (SS) around the  $\Gamma$  point (section S1). The SS spectrum is reproduced by the DFT calculation as well in a slab geometry. The shape of the  $\alpha$  pocket is cylindrical with a minimal  $k_z$  dispersion, whereas the  $\beta$  pocket shows a stronger warping open along the  $k_z$  direction (see the photon energy dependence in Fig. 1D). The 2D nature of the electronic structure can also be inferred from a large anisotropy of single-crystal resistivity. We observed an enhanced out-of-plane to in-plane resistivity ratio, which is highly anisotropic  $\rho_{zz}/\rho_{xx} = 230$  at T = 1.8 K (section S2 and fig. S5). In high–magnetic field measurements, we observe Shubnikov–de Haas (SdH) oscillations from the  $\alpha$  and  $\beta$  pockets open along the out-of-plane ( $k_z$ ) direction with band parameters consistent with DFT calculations (section S3 and figs. S6 to S8).

We characterized the magnetic modulation of the SMS via singlecrystal small-angle neutron scattering (SANS). Three distinct incommensurately modulated phases (ICM1, ICM2, and ICM3) are observed at zero field (see Fig. 1, E to G) and subsequent application of external magnetic field B||c at T = 2.1 K (see Fig. 1, H to J; see also Fig. 1K for the field-temperature phase diagram and details in section S4). The ground (ICM1) state (Fig. 1E) exhibits a pattern with sixfold symmetry around the *c* axis for magnetic modulation vectors equivalent with  $q_{ICM1} \approx (0.165, 0, 0.014 \text{ Å}^{-1})$  in Cartesian  $(q_x, q_y, q_z)$  coordinates, potentially related to the *ab*-cycloid structure previously reported in the structurally similar system EuAg<sub>4</sub>As<sub>2</sub> (*16*).

From the ground state, the magnetic structure evolves with increasing *T* or *B* to a multiple-spot pattern in ICM2 represented by  $q_{\text{ICM2}} \approx (0.146, 0.031, \pm 0.007 \text{ Å}^{-1})$  (see, e.g., Fig. 1, F and I) with a corresponding magnetic modulation wavelength  $\lambda_{\text{ICM2}} = 4.6$  nm. Tilted field experiments demonstrate the ICM2 magnetic order to be multi-*q* in nature (see section S5 and figs. S13 and S14). The pattern can be described by the superposition of domains of equivalent double-*q* structures, each composed of *q* vectors, *q*<sub>1</sub> and *q*<sub>2</sub>, with a mutual angle  $\Phi \approx 84^{\circ}$  at T = 2.1 K and B = 1.8 T for B||c (Fig. 2A illustrates this arising from an azimuthal *q*-rotation  $\varphi_q \approx 12^{\circ}$ , leading to the near right angle configuration, i.e.,  $\Phi = 60^{\circ} + 2\varphi_q$ ). This state is followed by an additional ICM3 phase characterized by a

**Fig. 2. Matching between the Fermi surface and magnetic modulation period of EuAg<sub>4</sub>Sb<sub>2</sub>. (A)** Schematic *q*-vector configuration for the ICM2 state. Rhombic double*q* domains are color coded (red, blue, and black). Plus and minus signs in each circle denote that of the *q*<sub>z</sub> coordinate.  $\varphi_q$  is the azimuthal rotation of *q* vectors away from high-symmetry directions.  $\Phi$  is the mutual angle of rhombic double-*q* vectors, *q*<sub>1</sub> and *q*<sub>2</sub>. (B) 3D configuration of the *q* vectors of the ICM2 state in reciprocal space reproduced from SANS experiments (see section S5). The *q*-vector positions, *q*<sub>1</sub> and *q*<sub>2</sub>, belonging to a double-*q* domain are highlighted in red. Note the *q*<sub>z</sub> scale is expanded for visibility. (C) Magnetic field–dependent in-plane magnetic modulation  $q_{xy} = (q_x^2 + q_y^2)^{1/2}$  in units of Å<sup>-1</sup> for each magnetic state at *T* = 2.1 K in *B*||*c*. Bar with caps is width of the peak comparable to the instrumental resolution (~0.008 Å<sup>-1</sup>). (D) Diameter of the Fermi surface (2*k*<sub>F</sub>) for the  $\alpha$  pocket estimated with ARPES and for the  $\alpha_1$  and  $\alpha_2$ estimated from SdH and dHvA oscillations in each sample (#1-#4) with *B*||*c* (see table S1). The open symbol is the central value, and the bar with caps is the SD. (E) Top: Schematic  $\alpha$ -Fermi surface in the lattice BZ. Bottom: Geometric relationship (viewed from the *k*<sub>z</sub> axis) for the extremal cross sections of the  $\alpha$  pocket (pink and blue circles) and the magnetic BZ for an SMS (double-*q*) domain (red polygons) at *T* = 2.1 K and *B* = 2 T for the *c* axis, where  $\varphi_q \approx 12^\circ$  and  $\Phi \approx 84^\circ$ .

12-spot pattern, which can be decomposed into two inequivalent six-spot patterns of larger ( $q_{ICM3}$ ) and smaller ( $q_{ICM3'}$ ) |q|. The former and the latter are proximate to  $q_{ICM1}$  and  $q_{ICM2}$  in length, respectively. The double-q spin structure in the ICM2 phase breaks the symmetry of the original atomic lattice. Whereas contrary to the tendency observed in Gd-based centrosymmetric materials (17-19), such a lowered symmetry SMS has been reported in Eu-based magnets, e.g., the rhombic SkL in EuAl<sub>4</sub> (20) and distorted triangular SkL in a tetragonal EuNiGe<sub>3</sub> (21).

Although the *q* vectors of the ICM2 state are nearly confined in the layer plane, they have nonzero  $q_z$  (see Fig. 2B), which enriches the magnetic texture. The four peaks highlighted in red belong to a single double-*q* domain of the ICM2 state (see section S5). Because of the small  $q_z$  component, the plane spanned by the two *q* vectors is tilted from the  $a^*b^*$  plane, resulting in a horizontal shift of spin texture at each Eu triangular lattice layer. The length scale of the out-ofplane modulation ( $\lambda_{ICM2z} \sim 90$  nm at T = 2.1 K and B = 1.8 T) is much longer than the in-plane modulation ( $\lambda_{ICM2} \sim 4.6$  nm), consistent with the quasi-2D nature of the Fermi surface (see also sections S5 and S10). In the following, we focus on the in-plane interaction of electronic and magnetic structure and impact of the electronic commensuration on the transport response.

In Fig. 2 (C and D), we compare the low-temperature, magnetic field–dependent in-plane magnetic modulation  $(q_{xy})$  with the  $\alpha$  pocket Fermi surface diameter  $(2k_F)$  estimated from ARPES, SdH, and dHvA measurements. Quantum oscillation measurements observed two branches  $\alpha_1$  and  $\alpha_2$  associated with the  $k_z$  warping of a quasi-2D pocket (figs. S6 and S7). Upon increasing magnetic field, the relatively large  $q_{ICM1}$  evolves to  $q_{ICM2}$  in the SMS phase, with the latter agreeing well with  $2k_F$  estimated from these methods. This commensuration relation between  $q_{ICM2}$  and  $2k_F$  for the cylindrical  $\alpha$  pocket (viz.  $q_{ICM2} = 2k_{F\alpha}$ ) suggests a strong coupling between the magnetic and electronic degrees of freedom and may offer insight

gradually evolves [a similar phenomenology has been seen in other centrosymmetric rare earth systems (17, 19)] and weakens the commensuration. At higher fields, the q vectors for ICM3 are more poorly matched and evolve away from  $2k_{\rm F}$  upon approaching the fieldinduced ferromagnetic phase. Figure 2E illustrates a schematic relationship between the Fermi surfaces and the magnetic BZ defined with two q vectors for the double-q structure of the ICM2 state. In an electronically clean system with much longer electron mean free path than the period of spin modulation ( $l_{\rm mfp} >> a_{\rm spin}$ ), electrons at the  $\alpha$ pocket are expected to respond to the periodic potential produced by the SMS for the ICM2 state, resulting in a reconstructed electronic structure.

into the origins of the SMS itself (5, 7). As the field increases,  $q_{ICM2}$ 

A comparison of this evolution in magnetic structure to that of magnetotransport reveals an acute coupling between the two. As shown in Fig. 3A, for B||c, the integrated intensity for each incommensurate phase tracks changes in M(H) before entering the fieldinduced ferromagnetic phase (see fig. S9 for details). Schematic q positions in reciprocal space for each magnetic phase are depicted in insets in Fig. 3A. The magnetoresistivity (MR) (Fig. 3B) and Hall conductivity ( $\sigma_{xy}$ ; Fig. 3C) in the same parameter range (see section S6 for analysis) show prominent changes upon entering the ICM2 region, with the former undergoing a sharp enhancement with a peak at the optimal  $2k_{\rm F} = q_{\rm ICM2}$  and the latter being quenched nearly to zero. As can be seen by comparing with the nonmagnetic analog SrAg<sub>4</sub>Sb<sub>2</sub> [see the insets in Fig. 3, B and C, and section S7; a similar result has been reported in Green et al. (22)], the high mobility transport response is insensitive to the magnetism in ICM1, begins to recover in ICM3, and reemerges in the FM state. Given their similarity, the large Hall conductivity anomaly exceeding 10<sup>5</sup> S/m is difficult to reconcile with changes in spin-scattering across these phases. We measured the anomalous magnetotransport properties at various temperatures and fields (fig. S18) and confirmed that this

behavior persists across the magnetic phase diagram (see the color plot of magnetoresistance; Fig. 1K), indicating instead a superzone gap opening of the electron bands renormalized in the SMS states. We note that the magnitude of MR (~250%) is remarkably large compared with the other multi-q compounds (17, 23–25), signifying the impact of the electronic commensuration with the SMS state.

We hypothesize that the remarkable interplay between the magnetic and electronic properties of the present system can be understood within the common framework of geometrical moiré superlattices and SMS as incommensurate potentials. A bilayer of 2D crystals with a small twist ( $\theta$ ) produces a moiré superlattice with a periodicity  $a_{geo}$  $\approx a_0/\theta$  incommensurate to the underlying lattice constant  $a_0$  (Fig. 4A). By comparison, the superposition of multiple single-q spin modulations forms a variety of SMSs depending on the moment modulation (3-6, 8). Under finite magnetic field, this includes a rhombic SkL, composed of the superposition of two helices with identical handedness and finite homogeneous magnetization (Fig. 4B): the associated anti-SkL (aSkL; Fig. 4C), and the double-q vortex lattice (VL; Fig. 4D) (see section S5). Such multi-q modulations impart a periodic exchange potential on the conduction electrons at  $a_{spin} = a_0/|\mathbf{q}_{rlu}|$ (where  $|\mathbf{q}_{\rm rlu}|$  is the length of one of the magnetic q vectors in reciprocal lattice units). This periodic potential reconstructs the electron band yielding a new (magnetic) BZ of width  $2\pi/a_{spin}$ . In the case of

**Fig. 3. Magnetic field–induced transitions and quenched transport response.** (**A** to **C**) Magnetic field dependence of (A) magnetization (*M*) per formula unit (f.u.) and the scattering intensity for each phase as depicted in the inset, (B) MR, and (C) Hall conductivity ( $\sigma_{xy}$ ) for  $B||_C$ . For MR, ( $\rho_{xx} - \rho_{poly}$ )/ $\rho_{xx0}$  is obtained by subtracting a smooth polynomial background ( $\rho_{poly}$ ) from  $\rho_{xx}$  and normalized by  $\rho_{xx0}$ , the value at zero field. Inset in (B) and (C) is the field dependence of  $\rho_{xx}$  and  $\sigma_{xy}$  for nonmagnetic isomorph SrAg<sub>4</sub>Sb<sub>2</sub> at *T* = 1.8 K.

a large SMS exchange potential *J* on the order of the Fermi level  $E_{\rm F}$ , a conventional band (see Fig. 4E and Eq. 1 below) is converted to a set of folded bands (see Fig. 4F) with reduced dispersion separated across  $E_{\rm F}$ . DFT calculations here yield  $J/E_{\rm F} \approx 0.93$ , consistent with this energetic regime (this estimate is consistent with that determined from analysis of magnetic scattering, confirming the physical relevance of  $J \sim E_{\rm F}$ ; see section S8).

In order for the SMS to reconstruct the electronic band structure, a further requirement is that the carrier mean free path  $(l_{mfp})$  sufficiently exceeds the magnetic superlattice constant  $(a_{spin})$ , viewed naturally as a momentum-space reconstruction (26). Figure 4G shows the comparison between the  $l_{mfp}$  and  $a_{spin}$  for various spin texture–hosting materials (see section S9) (17–20, 23, 24, 27–44). Several 3d transition metal–based chiral magnets show relatively lower mobility compared with rare earth intermetallics. Carrier transport in EuAg<sub>4</sub>Sb<sub>2</sub> is in the ballistic regime ( $l_{mfp} \approx 250 \text{ nm} > \lambda_{ICM2} = a_{spin} \approx 4.6 \text{ nm}$ ); analysis of the SdH oscillations (fig. S8) shows that the average quantum mean free path ( $l_q$ ) of the  $\alpha$  pocket among various EuAg<sub>4</sub>Sb<sub>2</sub> samples is estimated to be  $l_q = 48 \text{ nm}$  (table S1), which is more than 10 times the SMS modulation wavelength and among the cleanest ever reported.

To examine the emergent SMS electronic structure, we construct an effective model simulating the electronic miniband in the magnetic BZ for a 2D system. We start with the double-exchange model

$$H = -t \sum_{\langle r \ r' \rangle} \left( c_{r\sigma}^{\dagger} c_{r'\sigma} + \text{h. c.} \right) - \sum_{r} J c_{r\alpha}^{\dagger} \left( \vec{s}_{r} \cdot 1/2 \vec{\sigma}_{\alpha\beta} \right) c_{r\beta} + Bg s_{r}^{z} (1)$$

where  $t = (3m^*a_0^2)^{-1}$  is the nearest-neighbor hopping on the triangular lattice with lattice constant  $a_0$ , which reproduces the dispersion of the  $\alpha$  pocket and  $\vec{s}_r$  is the vector field describing a spin moiré texture of the Eu local spins with lattice constant  $a_{\rm spin}$  (see also section S10). We also include a Zeeman field *B*. The Fermi wave number  $k_{\rm F\alpha}$  and exchange coupling  $J/E_{\rm F} \approx 0.93$  are based on the DFT calculations.

As shown in Fig. 4H, we find that the SkL, aSkL, and VL all fold bands in the moiré BZ and are thus capable of strongly renormalizing the transport response. Because of their  $S^2$  winding density, the SkL and aSkL further produce folded Chern bands (3, 45). For each texture, we find folded bands confirmed by the peak of the density of states. This implies an effective mass renormalization capable of quenching of high mobility bulk transport. This model also highlights the importance of the matching between  $q_{\rm ICM2}$  and  $2k_{\rm F}$  as it guarantees a near integer filling of the magnetic BZ and suppressed band dispersion transport response (see section S10).

### DISCUSSION

Among the key factors in realizing the present SMS response, we highlight the significance of the "resonant condition"  $J \approx E_F$  (46, 47) along with a large mean free path. When the Ruderman-Kittel-Kasuya-Yosida (RKKY) mechanism is the driving force for magnetic ordering, the uniform ferromagnetic state is unstable to a twisted texture below a critical  $J/E_F \approx 1.8$ , a universal ratio at low densities (section S10). Therefore,  $J > 2E_F$  favors a ferromagnetic state whereas  $J << E_F$  favors a spiral phase but does not strongly alter the band structure (i.e., nearly free electron behavior is expected). Meanwhile,  $J \approx E_F$ , the regime of EuAg<sub>4</sub>Sb<sub>2</sub>, features a noncollinear phase with largely reconstructed minibands and a large overall effect of ~100 meV (fig. S25), which can effectively reduce the dispersion across the magnetic BZ.

An ultimate goal of the combination of spin textures and 2D electron sheets is a designer renormalization of the electronic

structure. The present system provides important design principles for this, in particular the matching of exchange and Fermi energies and long electronic mean free paths. Furthermore, in contrast to 3d element-based materials, where electronic structure and magnetic properties are derived from the same atomic orbitals, the present lanthanide-based systems are composed of rare earth magnetic layers spatially separated from semimetal layers with low carrier density. Combining such functional components in a single material facilitates an augmented material design space, here enabling high electron mobility and exfoliatability (11, 48). In the pursuit of magnetic texture-driven quantum Hall effect (3, 4), crucial next steps would be to evaluate and control the detailed spin texture in this family of compounds, overcome the large negative bandgap, and obtain a truly 2D form via exfoliation or thin film synthesis (the latter enabling the use of strain and electric/displacement fields). This system provides design principles for realizing emergent magnetic textures in centrosymmetric materials that are strongly coupled to exotic electronic systems.

## METHODS

Single crystals of EuAg<sub>4</sub>Sb<sub>2</sub> and SrAg<sub>4</sub>Sb<sub>2</sub> were grown via a self-flux method. The starting materials Eu/Sr, Ag, and Sb were mixed in the molar ratio Eu/Sr:Ag:Sb = 1:24:12. They were loaded into a 2-ml alumina crucible and sealed in an evacuated quartz tube. The growth ampoule was heated to  $1100^{\circ}$ C and slowly cooled to  $650^{\circ}$ C at a rate of  $1.5^{\circ}$ C/hour. The single crystals were separated by decanting the flux in a centrifuge. The typical size of the crystals is 2 by 2 by 0.5 mm<sup>3</sup> with the wide *ab* planes. The single phase nature of the crystals was checked by powder x-ray diffraction, and the orientation of single crystals was checked by a single-crystal x-ray diffractometer.

Electrical transport measurements were performed by a conventional five-probe method with a typical ac excitation current of 1 mA at typical frequency near 15 Hz. The transport response in low temperatures and a magnetic field was measured using a commercial superconducting magnet and cryostat. The obtained longitudinal and transverse signals were field symmetrized and antisymmetrized to correct for a contact misalignment, respectively. Magnetization measurements were performed using a commercial SQUID (superconducting quantum interference device) magnetometer.

SANS experiments were performed using the SANS-I beamline at the Paul Scherrer Institute, Switzerland. Magnetic SANS patterns were obtained from a 44-mg single crystal of size 6 by 6 by 0.2 mm<sup>3</sup>. The (001) plane was the widest and aligned perpendicular to the neutron beam. The crystal was mounted inside a superconducting cryomagnet that provided temperatures down to 2 K and horizontal magnetic fields up to 6.8 T along the *c* axis. The background measured at 15 K and 0 T was subtracted from the SANS data. The 3D SANS plot is generated by using the GRIP (GRASP Integrated 3D Plotter) (49). Single-crystal unpolarized neutron diffraction measurements were carried out using the double focusing triple-axis spectrometer BT-7 at the NIST Center for Neutron Research (50) and PONTA at JRR-3. Details are described in section S5.

High–magnetic field magnetization measurements were performed in the National High Magnetic Field Laboratory (NHMFL) pulse field (Los Alamos National Laboratory) facilities. Measurements in fields up to 50 T were performed in both <sup>3</sup>He and <sup>4</sup>He atmospheres. Temperatures between 1.5 and 4 K were taken with the sample immersed in <sup>4</sup>He liquid. High–magnetic field transport measurements were carried out in the NHMFL at the dc field (Tallahassee, FL). Measurements in the dc field up to ±31.65 T were performed using standard ac lock-in techniques. To obtained longitudinal resistivity, the signals were field symmetrized.

ARPES measurements were performed at two different beamlines of the Advanced Light Source: the beamline 4.0.3 (MERLIN) and the beamline 7.0.2 (MAESTRO). The two endstations are equipped with R8000 and R4000 hemispherical electron analyzers (Scienta Omicron), respectively. EuAg<sub>4</sub>Sb<sub>2</sub> crystals were cleaved inside ultrahigh vacuum chambers with a base pressure better than  $5 \times 10^{-11}$  torr using conventional the top-post cleaving method. All spectra were measured with linear horizontal light polarization. The photon energy-dependent experiments were performed while tuning the photon energy from 70 to 150 eV, which covers the complete BZ of EuAg<sub>4</sub>Sb<sub>2</sub> along  $k_z$ . The Fermi surface and energy-momentum dispersions were measured with 104-eV photon that maximizes the matrix elements of the bands centered at  $\Gamma$ .

DFT calculations were performed with the Vienna ab initio simulation package and further processed by Wannier90 to use Wannier transformation in analyzing the electronic structure. The electronic structures of  $EuAg_4Sb_2$  and  $SrAg_4Sb_2$  were converged with a nonmagnetic ground state with spin-orbit coupling. In contrast, calculations with ferromagnetic  $EuAg_4Sb_2$  ground states based on LDA+U treatment for Eu f electrons were used to motivate the magnetic interaction energies.

Funding: This work was funded, in part, by the Gordon and Betty Moore Foundation EPiQS Initiative, grant no. GBMF9070 to J.G.C. (instrumentation development, and DFT calculations); the US Department of Energy (DOE) Office of Science, Basic Energy Sciences, under award no. DE-SC0022028 (material development); the Office of Naval Research (ONR) under award no. N0014-21-1-2591 (advanced characterization); and the Air Force Office of Scientific Research (AFOSR) under award no. FA9550-22-1-0432 (magnetic structure analysis). T.K. acknowledges the support by the Yamada Science Foundation Fellowship for Research Abroad and JSPS Overseas Research Fellowships. N.P., L.F., S.F., and E.K. acknowledge support from the STC Center for Integrated Quantum Materials (NSF grant DMR-1231319) (theoretical modeling). S.F. acknowledges support by a Rutgers Center for Material Theory Distinguished Postdoctoral Fellowship, M.K. acknowledges support by the National Research Foundation of Korea, Ministry of Science, ICT grant 2016K1A4A4A01922028 and support by Samsung Scholarship from the Samsung Foundation of Culture. This work is based partly on experiments performed at the Swiss spallation neutron source SINQ, Paul Scherrer Institute, Villigen, Switzerland. J.S.W.

acknowledges funding by the Swiss National Science Foundation (SNF) under grant no. 200021\_188707. The neutron scattering experiments at JRR-3 were performed under a user program (proposal no. 22401). This research used resources of the Advanced Light Source, which is a DOE Office of Science User Facility under contract no. DE-AC02-05CH11231. A portion of this work was performed at the National High Magnetic Field Laboratory, which is supported by the National Science Foundation Cooperative Agreement no. DMR-1644779, the State of Florida, and the DOE. Pulsed magnetic field measurements at the Los Alamos National Laboratory were supported by the US Department of Energy BES "Science at 100T" grant. The identification of any commercial product or trade name does not imply endorsement or recommendation by the National Institute of Standards and Technology. Author contributions: T.K. synthesized the single crystals and performed and analyzed the transport experiments with D.G., L.Y., and T.S. supporting (dc field) and L.Y. and M.K.C. supporting (pulsed field). N.P. and L.F. constructed the theoretical model, and S.F. performed the DFT calculations with E.K. M.K. performed and analyzed the ARPES experiments with the support from J.D., C.J., A.B., and E.R. T.K. performed and analyzed the neutron diffraction experiments with J.W.L., Y.Z., and T.N. for neutron experiments. P.M.N. performed and analyzed the SANS experiments with J.S.W. T.K. and J.G.C. wrote the manuscript with contributions from all authors. R.C., L.F., and J.G.C. supervised the project. Competing interests: The authors declare that they have no competing interests. Data and materials availability: All data needed to evaluate the conclusions in the paper are present in the paper and/or the Supplementary Materials.
