Abstract

Understanding the long-term course of problematic drinking is a fundamental concern for health services research in the alcohol field. The stability of, or change in, the course of drinking—especially heavy drinking—has both theoretical and applied relevance to alcohol research. We explore the application of latent class growth modeling to 5 years of survey data collected from dependent and problem drinkers—some not in treatment at baseline—in an attempt to uncover prototypical longitudinal drinking patterns. Results indicated that five profiles of drinkers can be used to represent their longitudinal course of alcohol consumption: early quitters ($N = 88$), light/non-drinkers ($N = 76$), gradual improvers ($N = 129$), moderate drinkers ($N = 229$), and heavy drinkers ($N = 572$). Significant baseline factors included ASI drug severity, dependence symptoms, and marital status. Attendance at AA meetings, the size of one's heavy drinking and drug using social network, past treatment, receiving suggestions about one's drinking, and contacts with the medical system were significant influences. The size of heavy drinking and drug using social networks was noticeably larger for the heavy drinkers. Findings also support the usefulness of a semi-parametric latent group-based approach as a tool for analyzing alcohol-related behaviors.

1. Introduction

Understanding the long-term course of problematic drinking is a fundamental concern for health services research in the alcohol field. The stability of, or change in, the course of drinking—especially heavy drinking—has both theoretical and applied relevance to alcohol research (Kerr et al., 2002). Characterizing these courses can help us illuminate the underlying roles that a wide spectrum of factors play in the course of drinking—in getting better, staying the same, or progressing to more serious problems over time. A brief

summary of the development of subtypes in alcohol consumption is provided by Jackson et al. (2000).

To address this issue and other research questions appropriate for a longitudinal design, the scientist has available a number of analytic options—many of only recent development. Each method may be more appropriate for different research questions, some methods overlap with each other, and many require a sophisticated approach. Overviews of some of the choices are given by Stoolmiller (1995), Windle (1997), Muthén and Muthén (2000), and Collins and Sayer (2001) among others. In related work we employed a hierarchical growth model to test the effects of various influences on the level of alcohol consumption over time (Weisner et al., 2003a; Matzger et al., in press). These influences included membership in groups such as those defined by gender and ethnicity. In such models those groups can be known a priori and these models can be thought of as modeling the “average” study participant. In the analysis reported here we focused instead on trying to uncover common or prototypical groups which are defined by their common pattern of

[☆] Weights were created to account for differences in sampling fraction, fieldwork duration across agencies and non-response differences. We did not use them in this analysis although it is possible to include weights. Preliminary runs suggested using them resulting in little differences on these findings.

54 drinking over 5 years. We asked: are there common drink-
55 ing trajectories, what do they look like, and what appears to
56 influence them?

57 The research reported here is part of an ongoing effort
58 designed to follow a large representative sample of treated
59 and untreated individuals with alcohol disorders drawn from
60 the same community in an effort to understand alcohol con-
61 sumption over time. Among its unique contributions is the
62 inclusion of a probability sample of untreated individuals
63 who met criteria for “problem drinking.” It also includes a
64 sample of people entering public and private chemical de-
65 pendency programs in the same county with good response
66 and follow-up rates.

67 Based on earlier work on this sample and the litera-
68 ture on long-term alcohol outcomes, we used a conceptual
69 framework from longitudinal outcome research, including
70 that of treatment careers and the natural course of treated
71 populations (Hser et al., 1997; Joe et al., 1990; Simpson,
72 1990; Stoolmiller, 1995) plus the medical utilization litera-
73 ture (Aday et al., 1999; Andersen and Newman, 1973). We
74 examined 5-year trajectories of profiles of drinking within a
75 framework of *individual factors* (demographic and problem
76 characteristics), *formal services* (substance abuse treatment
77 and community agency contacts), and *informal influences*
78 (12-step meeting participation and recovery-oriented social
79 networks) (Bond et al., 2003; Weisner and Matzger, 2003;
80 Weisner et al., 2003a).

81 1.1. Latent class growth models

82 To identify common drinking trajectories, we used latent
83 class growth modeling (LCGM), an analytic approach based
84 on finite mixture modeling (Muthén and Muthén, 2000;
85 Nagin, 1999). We sought to characterize profiles of drinkers
86 over time by constructing prototypical trajectories of the
87 variable of interest—alcohol consumption.

88 The underlying assumption is that the collection of ob-
89 served individual trajectories can be efficiently summarized
90 by a smaller set of latent clusters of those trajectories. A ra-
91 tionale for approaching longitudinal data in this manner is
92 provided by Nagin (1999) who uses the analogy of clinical
93 diagnostic classifications; we know that not everyone with
94 the same diagnosis is identical, but we also recognize that
95 such groupings are meaningful and helpful in both clinical
96 practice and research.

97 To illustrate, Fig. 1 displays several individual 5 year tra-
98 jectories from our data which exemplify the wide variation
99 in drinking patterns observed. Baseline levels varied, some
100 increased the volume they drank over time, some drank less
101 as time went on and some both increased and decreased how
102 much they consumed. Thus, we cannot assume any change
103 is necessarily monotonic.

104 The statistical method itself has a long history (Bauer and
105 Curran, 2003) and has recently been developed by Nagin
106 (1999), Nagin and Tremblay (2001), Roeder et al. (1999) as
107 LCGM and in the context of structural equation modeling as

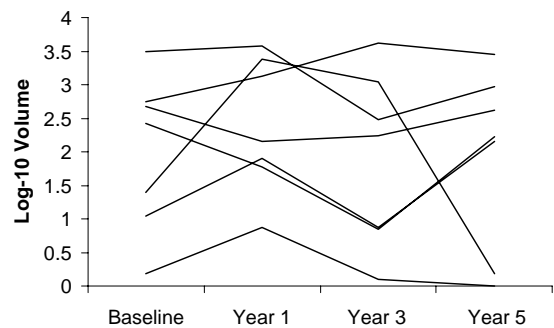

Fig. 1. Examples of drinking trajectories across 5 years.

108 growth mixture modeling (GMM) by Muthén and Muthén
109 (2000). LCGM is a semi-parametric, group-based approach
110 which uses a multinomial modeling strategy to identify ho-
111 mogeneous clusters of individual trajectories and to test the
112 effects of covariates on those profiles. GMM is a multivariate
113 normal method for reaching the same goal. While con-
114 strained, currently, to the multivariate case, GMM allows one
115 to incorporate heterogeneity within the trajectories whereas
116 LCGM does not. The LCGM approach, however, can be
117 applied to a wider range of distributions of the dependent
118 variable such as dichotomous indicators and counts.

119 In addition to estimating the number of latent profiles,
120 one can test and fit separate polynomial terms to character-
121 ize the shape of each profile. It is also possible to test po-
122 tential baseline factors which influence which latent profile
123 an individual is assigned to as well as testing time-varying
124 covariates which may influence the shape of each profile.

125 One important aspect of LCGM is that it provides an
126 improvement on the “classify-then-analyze” procedure in
127 which subjects are first classified to groups by some method
128 such as a cluster analysis using a distance metric, and then
129 the clusters are compared on various measures (e.g., Burgess
130 et al., 2002). Such a method, in effect, assumes group/cluster
131 membership is measured without error (Roeder et al., 1999).
132 Not accounting for the error in cluster assignment in those
133 comparisons may result in statistical bias. By *simultaneously*
134 estimating group membership and testing for group differ-
135 ences, however, it takes the uncertainty of group member-
136 ship into account in estimating the standard errors used in
137 testing for differences.

138 A challenge to the application of this mixture-of-distribut-
139 ions approach is that there are many possible models to
140 choose from with no clear, best procedure for searching
141 among them. So determining the number of latent profile
142 clusters, which and how many polynomial terms to include,
143 and what baseline and covariate measures to include all form
144 competing models. As a guide, Nagin advocates the use of
145 Bayes factor to compare models (Kass and Raftery, 1995).
146 Computed from the Bayesian information criteria (BIC), min-
147 us two times the change in BIC between models is an ap-
148 proximate Bayes factor which can then be used to select a
149 parsimonious model. Reference to other criteria can be found

150 in Bauer and Curran (2003) and Muthén (2003). LCGM has
 151 been used to date primarily in studies of adolescent behavior
 152 (e.g., Brame et al., 2001; Cote et al., 2002; Lacourse et al.,
 153 2002) where change is more the norm. In studies of drug
 154 use White et al. (2002) recently applied LCGM to adoles-
 155 cent smoking as did Colder et al. (2001) using GMM. Hill
 156 et al. (2000), Tapert et al. (2003), Chassin et al. (2002) and
 157 Oxford et al. (2003) used latent trajectories to study alco-
 158 hol use among adolescents and Muthén and Muthén (2000)
 159 modeled heavy drinking using GMM.

160 We asked three primary questions: (1) are there underly-
 161 ing groups of prototypical profiles in the data; (2) what are
 162 the shapes of those profiles; and (3) are there variables, be-
 163 yond drinking volume, which influence both which profile a
 164 subject is classified to and how the profile is shaped? Also,
 165 as this methodology has not yet been widely applied, we
 166 wanted to determine the feasibility of applying this approach
 167 to the field of alcohol research for questions such as these.

168 2. Method

169 2.1. Subjects

170 The study sample resulted from combining two sampling
 171 procedures. Details can be found in Weisner and Matzger
 172 (2002) and Weisner et al. (2002) and are summarized here.
 173 In-person interviews were conducted with individuals enter-
 174 ing a county's public and private chemical dependency
 175 programs (the *treatment sample*) and with problem drinkers
 176 from the general county population (*general population*
 177 *sample*) who had not received treatment in the prior year.
 178 The *treatment sample* ($n = 927$) included consecutive ad-
 179 missions in the ten public and private programs in the county
 180 that met the following inclusion criteria (Kaskutas et al.,
 181 1997): (1) at least one new intake per week; (2) drugs other
 182 than alcohol were not the primary focus (e.g., methadone
 183 maintenance programs were not included); and (3) first
 184 line treatment entry (i.e., programs limited to aftercare or
 185 programs were excluded).

186 Data collection for the treatment sample was conducted
 187 by trained interviewers who were independent of the treat-
 188 ment agencies. They administered structured in-person
 189 questionnaires to all participants by the end of their third day
 190 of residential treatment or third outpatient visit. Informed
 191 consent was obtained and participation was independent of
 192 receiving agency services. The overall response rate for in-
 193 dividuals in all programs participating in the study was 80%.
 194 The *general population sample* of dependent and problem
 195 drinkers not entering treatment ($n = 672$) was collected in
 196 the same county. Telephone interviews using random digit
 197 dialing methods were conducted with a probability sample
 198 of 13,394 individuals age 18 and over. Individuals were
 199 recruited for an in-person interview if they met problem
 200 drinking criteria (described below) and had not received
 201 substance abuse treatment during the previous 12 months.

202 Individuals met criteria for problem drinking by reporting
 203 at least two of the following during the previous 12 months:
 204 (1) drinking five or more drinks on a day at least once a
 205 month for men (three drinks on a day weekly for women);
 206 (2) one or more alcohol-related social consequences (from
 207 a list of eight); and (3) one or more alcohol dependence
 208 symptoms (from a list of nine). This measure is consistent
 209 with the predominant approach taken in research on alco-
 210 hol epidemiology and similar measures have been used in
 211 a wide variety of published studies (Institute of Medicine,
 212 1990; Schmidt et al., 1998; Weisner, 1990; Weisner and
 213 Schmidt, 1992; Wilsnack et al., 1991). Alcohol-related so-
 214 cial consequences cover a range of ways that individuals
 215 with substance abuse problems come to the attention of
 216 others in the community (Hilton, 1987; Weisner, 1990;
 217 Weisner et al., 1995; Weisner and Schmidt, 1992). This
 218 included drinking-driving arrests, public drunkenness ar-
 219 rests, other alcohol-related criminal arrests, traffic accidents
 220 when drinking, other (non-traffic) alcohol-related accidents,
 221 and/or confrontations about an alcohol-related health prob-
 222 lem by a medical practitioner, serious alcohol-related family
 223 problems caused by respondents' drinking, confrontations
 224 about an alcohol-related job problem by a supervisor or
 225 employer. The count of dependence items included nine
 226 criteria commonly used in clinical and general population
 227 research (American Psychiatric Association, 2000; Caetano
 228 and Weisner, 1995).

229 To select those individuals who met criteria for *alcohol de-*
 230 *pendence*, our measure consisted of a checklist of questions
 231 based on criteria from the Diagnostic Interview Schedule for
 232 Psychoactive Substance Dependence, DSM-IV (American
 233 Psychiatric Association, 2000) that has been used in other
 234 published studies (Humphreys and Weisner, 2000; Weisner
 235 et al., 2000a,b, 2001). We established whether each symp-
 236 tom was present or absent during the 30 days prior to the
 237 baseline interview.

238 2.2. Data collection

239 In-person baseline interviews were conducted in 1995 and
 240 1996. One-, three- and five-year follow-up interviews were
 241 conducted using computer assisted telephone interviewing.
 242 Baseline respondents were tracked every three months us-
 243 ing postcard mailings and telephone check-ins. Respondents
 244 who could not be reached by telephone were referred to a
 245 fieldwork agency for further searching. Follow-up response
 246 rates (based on the baseline survey) were 84% for year 1,
 247 82% for year 3, and 79% for year 5.

248 2.3. Measures

249 The variables used in this analysis were selected based
 250 both on our previous research and selected for theoretical
 251 reasons (Hser et al., 1997; Weisner et al., 2003a). Also, these
 252 measures have been used in several published papers (Bond
 253 et al., 2003; Kaskutas et al., 2002; Weisner and Matzger,

254 2003; Weisner et al., 2003a). The behavior we sought to
 255 model was the change in the total number of drinks taken
 256 in the year prior to each assessment—the total volume of
 257 alcohol consumed. Given the skewed nature of the observed
 258 data, we used the base-10 log of the volume throughout the
 259 analysis. The resulting distribution fit much closer to the
 260 normal distribution and resulted in better fit statistics than
 261 the untransformed measure throughout our work with this
 262 data.

263 *Baseline variables* included age, gender, marital status,
 264 ethnicity, family income, alcohol-related social conse-
 265 quences, number of dependence symptoms, and whether
 266 respondents reported any alcohol treatment in the year prior
 267 to the interview. *Time-varying* measures covering the year
 268 prior to each interview included an indicator of whether
 269 they had received any suggestions about their drinking from
 270 anyone (family member or friend, as well as provider from
 271 a welfare, medical, criminal justice or workplace setting),
 272 whether they had any contact with any community agency
 273 system (i.e., welfare, medical, criminal justice, workplace)
 274 about their drinking, the size of their heavy drinking and
 275 drug using social network, the number of days they at-
 276 tended an AA meeting, and whether they had received any
 277 substance abuse treatment (Cote et al., 2002).

278 2.4. Procedure

279 The literature suggests that those whose problems are
 280 more severe may have less reduction in consumption and
 281 problems over time and those whose problems are less se-
 282 vere are at less risk for having their problems addressed or
 283 entering treatment (Finney and Moos, 1992; Shaw et al.,
 284 1997; Simpson, 1990; Simpson et al., 2002). However, it
 285 is unknown if this would effect the latent classifications so
 286 instead of modeling dependent and non-dependent respon-
 287 dents separately we tested baseline dependence as one of
 288 the candidate variables.

289 Given the very large set of possible models and the lack of
 290 a fully objective method of model selection, we proceeded
 291 with model building and testing in four steps: (1) estimating
 292 the number of profiles; (2) screening for candidate baseline
 293 variables; (3) screening for time-varying covariates; and (4)
 294 testing a final model. To implement the work we employed
 295 a user-written SAS procedure, Proc Traj (Jones et al., 2001).

296 More specifically, in the first step, five different latent
 297 class growth models of alcohol volume were estimated: the
 298 first fitting only two latent profiles, the next three profile
 299 groups, and so on up to a model with six latent profiles.
 300 Each model contained no covariates but did include terms for
 301 linear and quadratic time effects—a decision based on the
 302 examination of the data (see Fig. 1) and the four-time point
 303 design. Using the Bayes Factor as a guide to compare model
 304 fit, we selected the most parsimonious model. Part of this
 305 decision included the relative size of each resulting profile
 306 so that, ideally, no one cluster held less than approximately
 307 5% of the total sample.

308 Second, once the optimal number of latent profiles was
 309 established, we screened among the baseline variables for
 310 candidates to add to the model using a method similar
 311 to the model-building strategy discussed by Hosmer and
 312 Lemeshow (1989) for logistic regression (p. 86) and Nagin
 313 (1999). To do this, a multinomial logistic regression model,
 314 with predicted latent profile group membership from the
 315 first step as the dependent variable and the candidate base-
 316 line variables as covariates was estimated and tested. All
 317 candidate predictors with $P < 0.10$ were kept and placed
 318 in a new latent trajectory model. We then re-fit the latent
 319 trajectory model, again constraining it to have the same
 320 number of profiles found optimal in step one, but now
 321 including the baseline variables selected through the screen-
 322 ing. This provided us with a test of each of the candidate
 323 baseline variables. For the next step, we retained only those
 324 baseline variables which were statistically significant. By
 325 adding the baseline variables to the model, some subjects
 326 may be assigned to a different latent profile.

327 In the third step the—estimated latent profile group
 328 membership from step 2 was used in a second screening
 329 analyses—this time to select candidates from among the
 330 time-varying covariates. Given that each covariate was
 331 measured four times (once per assessment), we used a
 332 set of repeated measures general linear models for the
 333 screening—one per candidate measure—in place of a sin-
 334 gle multinomial logistic regression. Measures where the
 335 profile-by-time interaction was significant were retained for
 336 inclusion in the final model. Then, in the forth and final
 337 step, a model was estimated and tested which now included
 338 both the baseline variables and the time-varying covariates.

339 3. Results

340 In comparing model fit among the two-class (BIC =
 341 -6558.29), the three-class (BIC = -6432.63), the
 342 four-class (BIC = -6328.72), the five-class (BIC =
 343 -6261.71), and the six-class (BIC = -6496.08) models,
 344 a five-latent profile model was selected. The probability of
 345 correct model for the five-class solution was equal to 1.0
 346 (Nagin, 1999, formula 6). Examination of the mean pos-
 347 terior probabilities of assignment to profile are displayed
 348 in Table 1 and indicate a strong separation among the
 349 profiles.

Table 1
 Mean posterior probability of latent profile group membership (row) by
 latent profile group assigned to (column)

	Early quit	Non-drinkers	Gradual improvers	Moderate drinkers	Heavy drinkers
Group 1	0.96	0.01	0.01	0.01	0.00
Group 2	0.00	0.96	0.00	0.01	0.00
Group 3	0.01	0.00	0.89	0.02	0.00
Group 4	0.03	0.03	0.07	0.82	0.10
Group 5	0.00	0.00	0.03	0.15	0.90

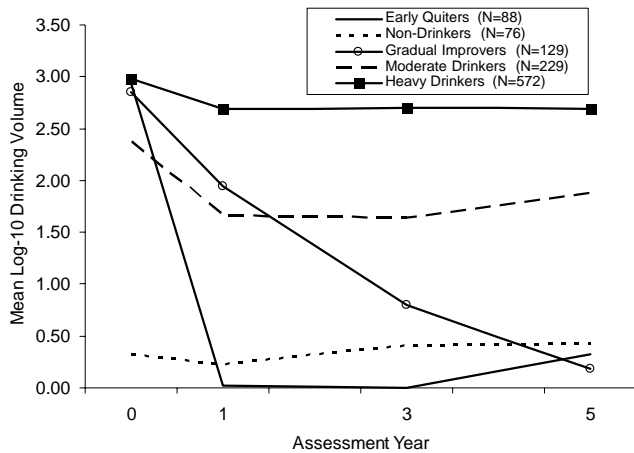

Fig. 2. Latent group profiles of mean log 10 number of drinks consumed in the prior year.

For descriptive purposes we labeled the latent profiles, displayed in Fig. 2, as early quitters ($N = 88$), light/non-drinkers ($N = 76$), gradual improvers ($N = 129$), moderate drinkers ($N = 229$), and heavy drinkers ($N = 572$). That is not to say respondents assigned to the moderate drinkers profile, for example, were all drinkers at all time points. The proportion in each group who reported no drinking in the previous year, as shown in Table 2, however, suggests these labels are reasonable.

Table 3 displays the parameter estimates and tests of significance for the final modeling step. Though not displayed in the figures, the predicted latent group profiles were close to the observed.

As in any longitudinal study, survey respondents dropped out of the study for various reasons or did not answer all baseline questions resulting in missing data. As this methodology requires full data to estimate the latent trajectories, this analysis was run on a final sample size of 1094. The question then is whether a model including the missing cases, had they been available, would have resulted in a different solution. There is no way of knowing that or how the dropouts are distributed among the five latent classes. Comparisons on baseline measures between those with full data and those without found some statistical differences. Those without full data were more likely to be male, have higher ASI psychiatric, drug and employment severity scores, less ASI alcohol severity,

Table 2
Proportion of group membership reporting no drinks consumed in prior year

	Baseline	Year 1	Year 3	Year 5
Early quit	0.0	96.6	100	77.3
Non-drinkers	67.1	76.3	65.8	65.8
Gradual improvers	0.0	13.2	48.1	73.6
Moderate drinkers	1.3	16.2	13.5	4.8
Heavy drinkers	0.17	1.6	0.7	0.5

more AA attendance, and smaller sized drinking networks (all $P < 0.05$).

We also used a variation on multiple imputation to address this matter. Proc MI in SAS was employed to generate five imputed datasets using MCMC. For each of the imputed datasets we re-estimated a five-class model and cross-classified group membership in one model against another's. For each of the resulting ten contingency tables, we computed the percentage of respondents not assigned to the same profile in both models. The average discordance was only 11.6% with the majority of that resulting from switching between the heavy and moderate trajectories. This is consistent with the off-diagonal mean posterior probabilities seen in Table 1.

3.1. Profile shape

As expected, given the study recruitment methods, all profiles (Fig. 2) begin at a high level of drinking with one exception. The light/non-drinkers are characterized by relatively little drinking throughout the 5-year period. In reviewing the data it appears that these participants were, at the time of their baseline interviews, in treatment for drug problems other than alcohol. The fact that this group was separated out supports the usefulness of the LCGM approach to modeling trajectories.

The early quitters are mainly respondents who went from heavy drinking to a very low level of alcohol consumption and maintained that low level with a rise in year 5. The gradual improvers displayed a steady drop in mean alcohol consumption over time. In contrast, both the moderate and heavy drinker groups continued their consumption across time. The moderate drinker group, however, began at a lower level at baseline (a profile group mean of 1.7 drinks per day versus 4.5 for the heavy profile) and appeared to have declined more at year 1. The difference in consumption is striking. The mean number of drinks for the moderate drinkers at year 1 is down to 0.8 drinks per day while it only dropped to a mean of 3.2 drinks per day for the heavy drinkers. Also of note is that the heavy drinkers form the largest group ($N = 572$, or 52.3% of the sample).

3.2. Baseline variables

Among the baseline variable candidates, ASI drug severity, number of dependence symptoms, family income, and marital status (constructed as two contrasts comparing those never married to those formerly married and to those currently married) all passed the screening step. In testing these four variables among the five latent profiles, only family income was not significant. Then light/non-drinkers and gradual improvers had the highest mean ASI drug severity scores at intake (0.14 and 0.11) while the heavy drinkers had the lowest (0.05). Interestingly, the early quitters had the highest number of dependence symptoms (mean = 5.23) and the light/non-drinkers had the lowest (0.08).

Table 3
Estimates, standard errors and tests of significance of the final model for the problem drinking sample

Group	Parameter ^a	Estimate	Standard error	T-value	P > T
Baseline variables					
Non vs. early	Constant	2.57	0.355	7.23	0.0000

BIC = −5704.4 (N = 1094).

^a ASI drug: alcohol severity index drug severity; dependence symptoms: number of dependence Sx; formerly married: formerly vs. never married; married: married vs. never married; contacts: contacts with formal services; AA meetings: number of AA meeting attended in previous year; network size: number of heavy drinking and drug using individuals in respondents social network; prior Txt: received treatment for alcohol dependence in prior year; suggestions: received suggestions about their drinking from anyone.

428 3.3. Time-varying covariates

429 The number of AA meetings, drinking cohort size, treat-
430 ment in the past year, receiving suggestions from others
431 and contacts with the medical system were retained by the
432 screening procedure for testing. Plots of the means for each
433 of these four covariates over time for each of the five latent
434 profile groups are shown in Fig. 3.

435 The means for the moderate and heavy drinkers track in
436 a consistent fashion, with the exception of the size of the
437 drinking cohort which is larger for the heavy drinkers. The
438 early quitters had the highest AA attendance at year 1 and
439 the gradual improvers had the highest number of suggestions
440 received throughout.

441 4. Discussion

442 These results indicate that the course of drinking over
443 a 5-year period is variable and influenced by several fac-
444 tors. Yet, while there appears to be substantial variation, a
445 limited number of prototypical profiles emerged. From the
446 standpoint of health services research, the single dominant
447 profile—the largest group which did not appreciably change
448 drinking consumption—is an important finding. In their re-
449 view of studies of the stability of alcohol consumption over
450 time, Kerr et al. (2002) point out that the question of the
451 stability of consumption is key to questions of mortality and
452 diseases attributable to heavy consumption.

453 While this is the first LCGM of this sample and requires
454 replication, these findings suggest that dependent and prob-
455 lem drinkers may be, initially, divided into two general cat-
456 egories: those that continue to drink at a steady pace over
457 time (i.e., the heavy and moderate drinking) and those for
458 whom their drinking declines. More effort on understand-
459 ing who comprises the “stable” group is clearly needed. The
460 tests of the baseline measures suggest those who substan-
461 tially reduced their drinking were most likely to be those
462 who were the most heavily dependent at baseline. This may
463 be driven to some degree by regression to the mean.

464 The covariates indicate that, in general, those who had
465 gone to fewer AA meetings and those who had received
466 fewer suggestions about help for their drinking were less
467 likely to have been in treatment, and were more likely to
468 display a steady level of drinking over time. The apparent
469 influence of the size of one’s cohort of heavy drinkers and
470 drug users can also be seen in these findings.

471 The results found here are in agreement with and compli-
472 ment the analysis of Weisner et al. (2003a) who found
473 that in addition to treatment status and formal influences,
474 recover-oriented social networks are key influences on lower
475 levels of drinking. They expand upon those results by de-
476 scribing the underlying common patterns of that drinking.
477 Such patterns cannot be identified by the more common
478 mixed-effects repeated measures analysis.

479 In preliminary analyses we noticed continuing improve-
480 ment in model fit as models with greater numbers of cluster
481 profiles were applied to the data by splitting out respondents
482 from the heavy and moderate drinking groups into smaller
483 groups. This may indicate that this large group of steady
484 drinkers have a common pattern of steady consumption,
485 varying only in their level of how much they consume. Such
486 a notion is supported by the mean group probabilities just
487 off the diagonal in the lower right corner of Table 1 and the
488 variations seen among the multiply-imputed model results.

489 The continuing improvement in model fit as the number of
490 latent profiles is increased has been discussed by Nagin and
491 Tremblay (2001) and Bauer and Curran (2003). This reflects
492 a basic statistical problem that if the underlying distribution
493 of profiles is not distinct but continuous, one is attempting to
494 approximate that continuity by a discrete function. However,
495 the distinction between those two groups may be important
496 if the relationship between amount of alcohol consumed
497 and health-related consequences is non-linear such that the
498 adverse consequences accelerate once some level of daily
499 drinking is surpassed.

500 As in any research, this study has some limitations includ-
501 ing the use of a sample drawn from a single US county’s
502 population and the reliance on self-report. The county was
503 chosen to be representative; it was selected on the basis of

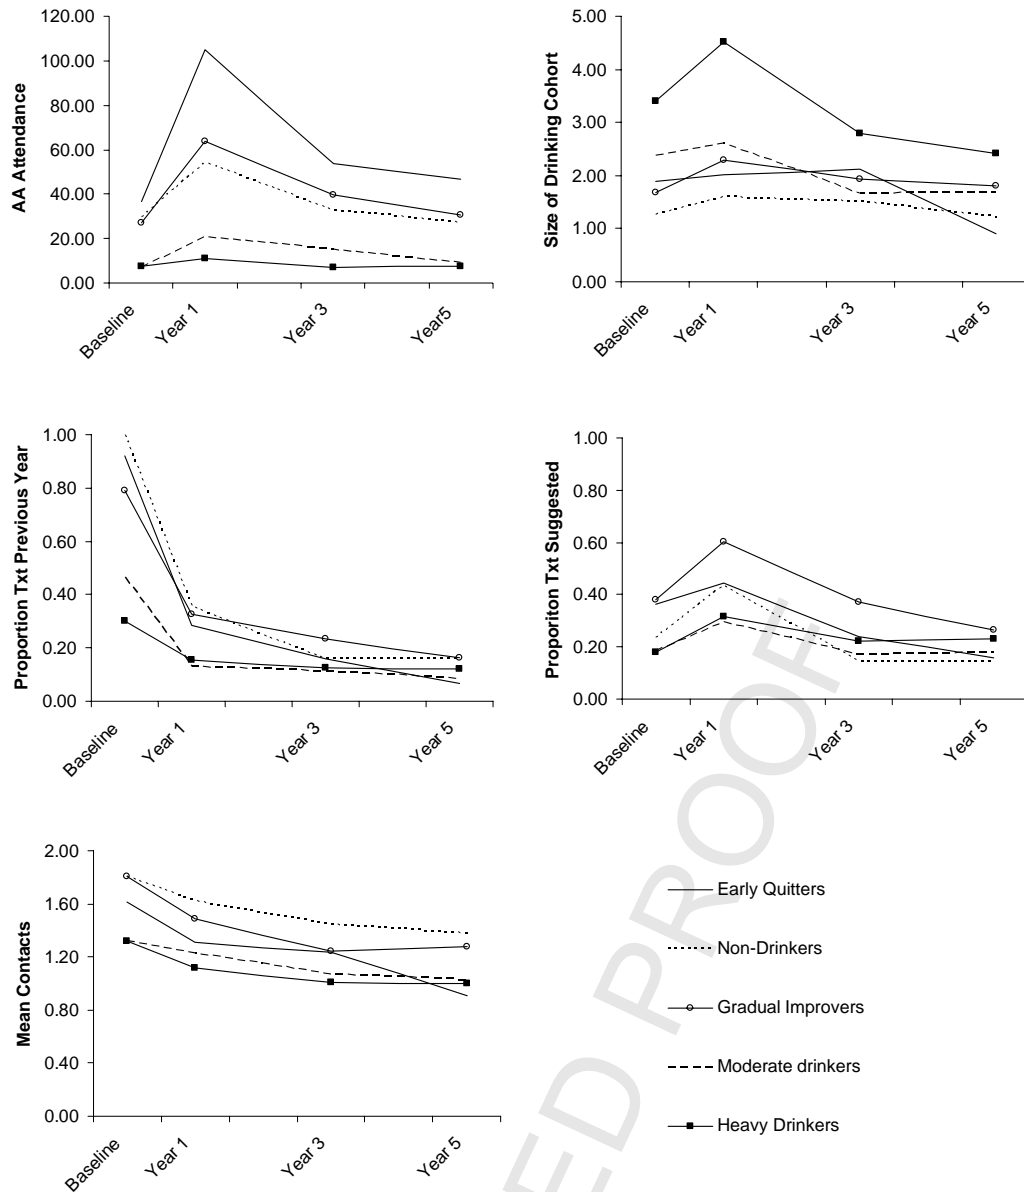

Fig. 3. Plots of time-varying covariate means by latent group over time. Legend for all plots in low left plot.

504 diversity in its population characteristics and mix of rural
 505 and urban areas. For the self-reports the study used robust
 506 questions and well-established interview techniques devel-
 507 oped through the Community Epidemiology Laboratory and
 508 clinical studies. Both of these issues are discussed further in
 509 Weisner et al. (2003a).

510 Complete baseline and alcohol consumption data at each
 511 assessment required the deletion of some respondents' data
 512 (time-varying covariates, however, could be missing). If the
 513 data are missing completely at random, then we suffered
 514 a loss of statistical power. If not, the latent structure may
 515 be different had those missing cases not been lost. While
 516 some differences were found between those not in the anal-
 517 ysis and those retained as indicated previously, the differ-
 518 ences were not, on the average, substantial (i.e., small sized

519 effects—most less than $d = 0.20$). Also, the lack of varia-
 520 tion in results from one imputation to another, except for the
 521 mixing between the heavy and moderate drinking groups,
 522 argues for the generalizability of the groupings.

523 As with any new and complex method, the application of
 524 it can be daunting and has some limitations as pointed to
 525 in Nagin (1999). The analysis can be somewhat time con-
 526 suming both in time to choose and test the appropriate mod-
 527 els and, to a lesser extent, in computer time. A number of
 528 possible models were not tested and the method of model
 529 selection may have allowed a more parsimonious model to
 530 be missed. Not all data will provide a clear point at which
 531 to set the number of profiles to fit. It may be difficult for
 532 the iterative process to find a maximum likelihood solution,
 533 the algorithm is sensitive to starting values, and respondents

534 missing baseline factors are not included in the analysis.
 535 While the use of the change in BIC decreases the subjectiv-
 536 ity in model selection, more objective help would be wel-
 537 comed. Also methods for selecting candidate baseline and
 538 time-varying covariates could be extended.

539 Further, by approaching this modeling through the
 540 semi-parametric LCGM approach over the parametric
 541 GMM method, we were forced to use a more cumbersome
 542 model selection procedure. GMM is applicable to this data
 543 because we used a response variable, log volume, which
 544 is normally distributed. We chose the LCGM approach for
 545 three reasons. First, there are other non-normally distributed
 546 measures we are interested in such as alcohol abstinence
 547 and AA attendance. As this time, GMM is restricted to
 548 the multivariate normal case. Second, as this method has
 549 seldom been used in this arena (and not on a sample such
 550 as this) we were not certain we would have sufficient data
 551 to estimate within-class heterogeneity or that it would be
 552 informative. Finally, we have been working in SAS and this
 553 Proc is available at no cost.

554 The broader case for using methods such as LCGM in
 555 this context is discussed by Muthén and Muthén (2000).
 556 It has been successfully used in the field of adolescent
 557 behavior by Nagin and colleagues and appears well suited
 558 for an application such as this. The results, at least in these
 559 data, are useful and interpretable. The ability to detect
 560 and describe underlying common longitudinal trajectories
 561 should help bring greater insight to understanding behav-
 562 ioral changes over time as serve as a complimentary method
 563 to the more standard mixed-effects ANOVA approach to
 564 longitudinal data. Nagin and Tremblay (2001) have ex-
 565 tended LCGM to modeling separate but related outcomes
 566 and version 3 of Mplus promises several improvements
 567 (<http://www.statmodel.com/mixtureaddon.html>). In general,
 568 LCGM and GMM, as well as longitudinal studies using
 569 more than only two time points (Fillmore, 1988) will benefit
 570 alcohol and drug abuse research in the future.
