~~Abstract~~ABSTRACT:

Photoelectrochemical (PEC) water splitting holds the potential as a direct route for solar energy conversation and storage. The performance of a PEC device is strongly influenced by the electronic properties of the photonanode surface. It has been shown that the synthesis methods can have profound impact on the electronic properties and PEC performance of various photo-electrode materials such as hematite. In this work, soft X-ray spectroscopic techniques, including O K-edge XAS, and Fe L-edge XAS/XES, have been employed to investigate how the synthesis methods impact the electronic structure of resulting hematite materials. It is found that the hematite samples via solution regrowth methods show dramatically increased 3d-4sp band ratios in O K-edge XAS spectra and decreased relative elastic peak intensities in Fe L-edge RIXS spectra compared to samples synthesized via ALD or solution grown. The difference observed in O-K and Fe-L spectra indicated that solution regrowth strategy alters the O 2p-Fe 3d hybridization and hence the electronic structure of the hematite films, which proves to be beneficial for PEC performance of the hematite photoanode. Our findings provided new insights and potentially useful strategies for enhancing the PEC performance of photoanode materials.

~~Introduction~~INTRODUCTION:

In the quest to reduce human's environmental footprint, it has become more crucial than ever to develop new and sustainable green energy technologies. Among the emerging energy technologies, photocatalysis deserves special attention, considering the vast abundance of solar light. Solar water splitting, one of the most important applications of photocatalysis, holds great promise for energy conversion and storage.[1-3] To achieve efficient and inexpensive PEC water splitting, finding the photo-catalyst materials with suitable electronic properties is the key but remains a challenge even after decades of intense research. [4-5] [6-10] Among the myriad of available materials, metal oxides, particularly the 3d transition metal oxides (TMOs), have established their prominence in this field due to their stability, cost-efficiency, and the tunability of their electronic characteristics.[11-13] Hematite is a prototypical photoanode material with a favorable band structure and high stability and thus has attracted intense attention.[14] However, hematite has not delivered its expected performance, as it typically shows small photovoltages and poor catalytic activity for the OER.[15-17] Therefore, these challenges must be investigated and understood in order to enhance the PEC performance of hematite materials.

36 Suitable surface/interface treatment can passivate deleterious surface states and reduce effects such as surface Fermi

37 level pinning and therefore has been regarded as an effective method to improve the water splitting performance.[18-20]

38 For example, the effectiveness of the surface modification by loading OER catalysts on the photoanode surface has

39 been demonstrated in numerous studies, such as Co-Pi on bismuth vanadate, and $NiFeO_x$ on hematite.[20-21] Inspired

40 by this approach, Ji-Wook et al., developed a solution regrowth strategy where additional hematite layers were

41 deposited onto the original hematite films via a few regrowth cycles inside the growth solution. This regrowth

42 strategies proves to be effective to reduce the surface states on hematite films and thus improves the photovoltages

43 by 27%. With the addition of the $NiFeO_x$ catalyst onto the regrown hematite surface, the photovoltage is further

44 improved to a value of 0.8 V, the highest reported photovoltage for hematite to date. This facile regrowth method

45 holds great promise in the optimization of other PEC systems and a better understanding on the mechanism for

46 performance improvement would be helpful for the adaptation in other systems. Several characterization techniques

47 have been employed to study the surface morphology and surface kinetics of hematite photoanode before and after

48 the regrowth process.[22] The impact of the growth methods on the electronic structures is another piece of useful

49 information to better understand the improvement mechanism.

50 X-ray spectroscopies are a series of powerful techniques to probe the electronic structure of materials.[23-24] X-ray

51 absorption spectroscopy (XAS) and X-ray emission spectroscopy (XES) are commonly employed to study

52 condensed-matter materials by probing element specific transitions from either the core level to conduction band or

53 from the valence band to the core level, respectively.[25-27] The 3d TMOs have been extensively investigated by XAS

54 and XES. Since oxygen has an electron configuration of $1s^2 2s^2 2p^6$ in a purely ionic model, the transition from O1s to

55 2p is prohibited due to the fully occupied 2p orbital. However, the 3d TMOs are not fully ionic, and the considerably

56 more covalent bond reduces the number of filled states of O 2p orbital. Therefore, the peak intensities in the O K-

57 edge XAS spectra are strongly correlated with the covalency in the TMO bond, especially for the peaks resulting

58 from O 2p – Fe 3d hybridizations.[28] The TM L-edge can also be probed, where the XAS measures the transition

59 from 2p to 3d orbital, which represents the state of the valence electrons in TMOs. Resonant inelastic X-ray

60 emission spectroscopy (RIXS) and non-resonant X-ray emission spectroscopy (Nr-XES) use resonant and non-

61 resonant excitation energy, respectively, to excite the core electrons in the materials. X-ray spectroscopic techniques

62 have previously been employed to investigate various hematite systems, including size and shape effect on the

63 electronic structures in the hematite systems and hematite-TiO_2 heterojunction systems,[29-31] from which detailed

64 understanding of the XAS and XES transitions for hematite has been established. In this work, we aim to use x-ray

65 spectroscopies to reveal how the growth methods impact the electronic structures of hematite materials and its

66 correlation with PEC performance.

67 ~~Experimental~~EXPERIMENTAL:

68 The hematite films characterized here were synthesized via two different methods, i.e., atomic layer deposition

69 (ALD) and solution-based regrowth methods. The ALD samples were obtained via reactions by alternating pulses of

70 iron precursors (iron tert-butoxide, heated to 125 °C) and water (kept at 25 °C), both delivered in N_2 carrier gas at a

71 rate of 10 ml/min. 500 ALD cycles were used to produce the pre-formed iron oxide films, which then went through a

72high-temperature annealing step to ensure the complete conversion to crystalized hematite films. The pre-formed
73ALD films annealed at 500 and 800 °C are denoted as ALD 500 and ALD 800, respectively.

74Solution-derived samples are synthesized in the solution containing 0.15 M iron (III) chloride hexahydrate ($FeCl_3$,
7597%, Alfa Aesar) and 1 M sodium nitrate ($NaNO_3$, 99%, Alfa Aesar) at 100 °C for 1 hr. The as-synthesized FeOOH
76films were further converted to Fe_2O_3 film by thermal annealing at 800 °C for 5 mins. The sample obtained with this
77method is named as sdH (solution-derived Hematite). To obtain the solution-regrowth hematite (rgH I) samples, the
78sdH films were further immersed ~~the sdH sample~~ in the above-mentioned solution at 100 °C for 1 hr and then
79annealed again at 800°C for 5 mins. Additional one and two cycles of reaction-annealing process were applied to the
80sample labeled as rgH II and rgH III, respectively. The thickness of the hematite films varies as a function of the
81growth method, which was summarized in Table S1 in the supporting information. Among all six samples, rgH II
82showed the highest photovoltage and lowest turn-on voltage in PEC measurements, as shown in the Figure S1.

83The X-ray spectroscopies measurements are performed on beamline 8.0.1 at the Advanced Light Source, Lawrence
84Berkeley National Laboratory. The photon energy resolution was set to be 0.1, 0.2 and 0.5 eV for O K-edge XAS, Fe
85L-edge XAS, and Fe L-edge XES, respectively. TEY and TFY signals were recorded simultaneously in XAS
86measurements, providing surface and bulk sensitive characterizations, respectively. TEY signals were recorded by
87monitoring the sample drain current, whereas TFY signals were collected using a channeltron detector. XES spectra
88were acquired using a grazing-incidence grating spectrometer.

89Both TEY and TFY XAS spectra were normalized to the incoming photon flux, represented by drain current
90measured from an upstream gold mesh. A linear background based on the slop in the pre-edge region was subtracted
91from each flux-normalized XAS spectra, which was then normalized again to the post-edge region. The XES spectra
92were normalized to the high-energy region. Quantitative deconvolution of spectra was performed by using software
93Athena Demeter version 0.9.24.

94As shown, with gray lines in Figure 1, the individual absorption events contributing to a XAS spectrum were fit in
95order to separate the hematite signal from the substrate signal in a quantitative fashion. After subtracting an
96arctangent background, several Gaussian functions, corresponding to signals from both the hematite films and FTO
97substrate, were employed to fit the XAS spectrum.

98~~Results~~ RESULTS and ~~discussion~~ DISCUSSION:

99Figure 1 shows both TFY and TEY XAS spectra of hematite films obtained via different methods. All spectra can be
100divided two regions: the O2p-Fe3d hybridization region (528-534 eV) and O2p-Fe4s4p hybridization region (534-
101546 eV). In the O2p-Fe3d region, two well-resolved peaks are originated from the t_{2g}/e_g splitting from crystal field
102effect.[27, 29] Because the inelastic mean free path for fluorescence photons (few hundred nm) are much larger than that
103of secondary electrons (few nm), TFY spectra, as well as XES spectra, are typically considered bulk-sensitive while
104TEY spectra are more surface sensitive. For each sample, TEY and TFY spectra are substantially different, which
105can be better visualized in the overlayed spectra shown in Figure S1. The most prominent difference is the ratio of
106the peaks in the two regions ~~significantly~~. Among these six samples, the TEY spectra are quite similar and in line

107with the previous reported hematite spectra, further confirming that the measured films synthesized by ALD method

108and solution based method are indeed pure hematite films.[10] The TFY spectra, however, show an additional peak

109located at 533.8 eV for samples ALD-500, ALD800, sdH, and rgH1. This feature could correspond to the signal

110from the FTO substrate [27] or the impurities in the film bulk. Given the fact that this addition peak decrease with film

111thickness (from sample ALD-500 to rgH I), we can rule out the contribution from bulk impurities, which should be

112independent of the film thickness. The O K-edge XAS signal from the substrate has also been displayed in the

113Figure S2. Such interference from the substrate is not present in the spectra of thick samples (rgH II and rgH III), but

114their TEY and TFY spectra still show substantial difference, suggesting that there are differences in the surface and

115bulk electronic structures of the solution samples.
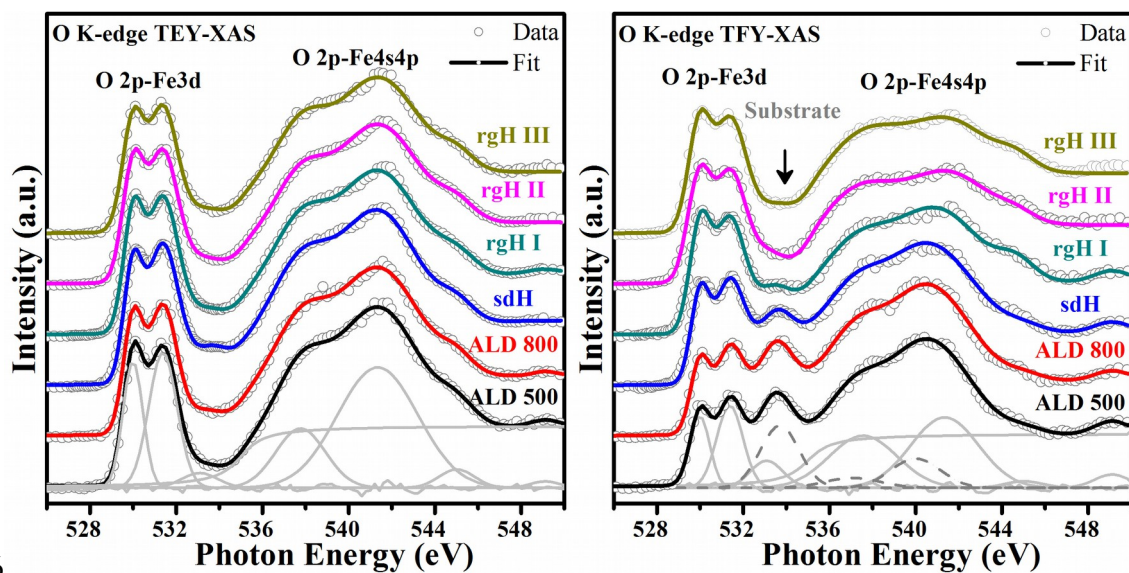

116

117*Figure 1: O K-edge XAS signals of Hematite films synthesized by different methods, the peak decomposition has also indicated in*
118*the figure. The experimental data is shown with the open circles and the fitted results are shown with the solid line.*
119*The substrate signals are included to fit the TFY spectra and displayed by dash lines.*

120

121To further reveal more details in the electronic structural differences among the samples, the XAS spectra were

122analyzed by peak deconvolution, as shown in Figure 1, S4 2, and S3S5. Based on the peak fitting results, the 3d-4sp

123band ratios can be quantitatively compared among the six samples, as shown in Figure 2. For the two ALD samples,

124the band ratios in the surface (in black) and in the bulk (in red) are very close (the inset of Figure 2). This is because

125the ALD samples are thin enough to be fully detected under both TEY and TFY modes. A much larger difference

126between surface and bulk band ratios was observed for the solution-grown samples and the difference increase with

127numbers of regrowth cycles.

128Extensive XAS/XES studies on various 3d TMOs suggested a quantitative linear relationship between the 3d-3sp

129band ratio and the number of 3d electrons: A higher 3d-4sp band ratio corresponds to fewer 3d electrons in the 3d

130TMOs, and vice versa.[23, 30, 32-33]

Figure 2: 3d-4sp band ratio of different hematite films obtaining from O K-edge XAS. Signals obtained from TEY and TFY detection modes have been denoted as surface-band ratio (black) and bulk-band ratio (red), respectively. For the two ALD samples, the surface- and bulk- band ratio values are close to each other and has been included in the inset of Figure 2.

According to the linear relationship reported in the literature, the band ratio of ~0.43 for the ALD samples corresponds to an average 3d electron number of 5.5,[23, 30] which is higher than the expected number of 5 in hematite. The sample sdH shows similar surface-band ratio in comparison with the ALD samples, while the bulk-band ratio is significantly higher. After the regrowth cycles, the samples rgH I, II, and II show a mild change in the surface band ratio whereas the bulk band ratio changes dramatically. The surface band ratios grows from 0.43 for sdH to 0.52 for rgH II, corresponding to 3d electron numbers from 5.5 to 5.1. As a comparison, the bulk band ratio increased from 0.54 for sdH to 0.78 for rgH II, corresponding to 3d electron numbers from 5 to 3.5.[23, 30] The abnormal d electron number indicates the complication that arises after the hybridization between Fe 3d, 4sp and O 2p.

To better understand the Fe-O hybridization, the Fe L-edge was further investigated. For these experiments only the TEY data were recorded, because TFY spectra were severely distorted due to self-absorption effect. As shown in Figure S64, the Fe L-edge TEY spectra appear very similar among all samples and resemble hematite spectra reported in the literature.[34] For quantitative comparison, the L_3 peak intensities in the normalized spectra are plotted in Figure 3. The intensities of L_3 peaks were calculated by integrating under L3-edge spectra preceded by

149subtracting a linear background between 705 and 713 eV. [33] From sample ALD 500 to sample rgH II, the L3 peak

150intensity decreases continuously, but shows slight increase for the rgH III sample. The decrease in L3 intensity can

151be ascribed to the reduction of the density of the unoccupied states, indicating that more d states are filled. The trend

152shown in Figure 3 suggest that more electrons occupy the Fe 3d orbital in the solution-grown samples compared

153with the ALD samples and the first two regrowth cycles further increase the 3d electron numbers. This is in contrary

154to the conclusions derived from O K-edge TEY spectra, which suggest slightly fewer electrons occupying the 3d

155orbital with each regrowth, which will be discussed in more details later.
156

157   *Figure 3: Fe L-edge TEY-XAS signals of the hematite films, the L3 edge has been enlarged to show a clear comparison.*

158Since the Fe 3d orbital is partially filled, to get a complete picture of Fe 3d configurations, it is necessary to

159investigate both the conduction band and valence band of hematite films. XAS spectra only provide information of

160the conduction band, XES techniques (including RIXS and Nr-XES), on the other hand, can provide insight to the

161valence band states. As has been well documented before, the relative intensity of the elastic peak in RIXS spectra is

162an indicator of the degree of localization of the valence electrons. The inset of Figure 4 shows two representative

163RIXS spectra of sample ALD 500, excited at t_{2g} and e_g peak energies, respectively. For relative peak intensity

164calculations, the inelastic peak was fitted with a Gaussian function (as shown in the inset of Figure 4 and Figure

165S5S7) and the relative intensities of the inelastic peaks for all the samples are plotted in Figure 4. The elastic peak

166ratios for solution-grown samples are smaller than the ALD samples, suggesting a more delocalized characteristic of

167 Fe 3d electrons in the solution samples.[35] The higher level of delocalization is most likely a results of stronger

168 hybridization between O 2p and Fe 3d states, which leads to additional electrons transfer from the O site to the Fe

169 site.[36] Such additional electron transfer between O and Fe can explain the opposite trends of 3d electron numbers

170 deduced from O-K and Fe-L XAS spectra.
171

172 *Figure 4: Elastic peak intensity ratio of Fe L-edge RIXS spectra excited at t_{2g} and e_g energies, the RIXS spectra of sample ALD*
173 *500 have been included as an inset, the fitted elastic peak region has been shown in a dash line.*

174 In addition to the Fe L-edge RIXS data, the Nr-XES data were also investigated. As shown in representative Nr-XES

175 spectra of ALD 500 in the inset of Figure 5 and spectra in the Figure S8, the two peaks represent the transitions from

176 occupied 3d orbitals to $2p_{1/2}$ and $2p_{3/2}$ core levels, respectively. The branching ratio of $I(L_3)/I(L_2)$, summarized in

177 Figure 5, provides another indicator for the difference in the electronic structure among these samples. The L_3/L_2

178 branching ratio of note that the branch ratio of solution samples appears substantially larger than that of ALD

179 samples. It has been reported that the intensity ratio $I(L_3)/I(L_2)$ varies due to the occupancy of L_3 and L_2 levels,

180 which depends on the chemical state of the probed elements. Such $I(L_3)/I(L_2)$ ratio of 3d transition metals and alloys

181 is typically large owing to the non-radiative Coster-Kronig transition between L_2 and L_3,[37] and the probability of

182 such transition is distinctly lower for 3d metal oxides because of the presence of an energy gap. The higher

183 branching ratio of $I(L_3)/I(L_2)$ for solution-grown samples possibly suggests a smaller bandgap compared to the ALD

184 samples. Samples rgH I and rgH II shows even higher branching ratios, indicating that the first two regrowth cycles

13

7

14

185lead to a slightly decreased bandgap in the resulting hematite film. Such decreasing trend is reversed in the third

186regrowth cycle. The change in band gap is another strong indication of significant electronic structure change in

187solution-grown samples, which may also be due to the changes of the hybridization degree between O and Fe.
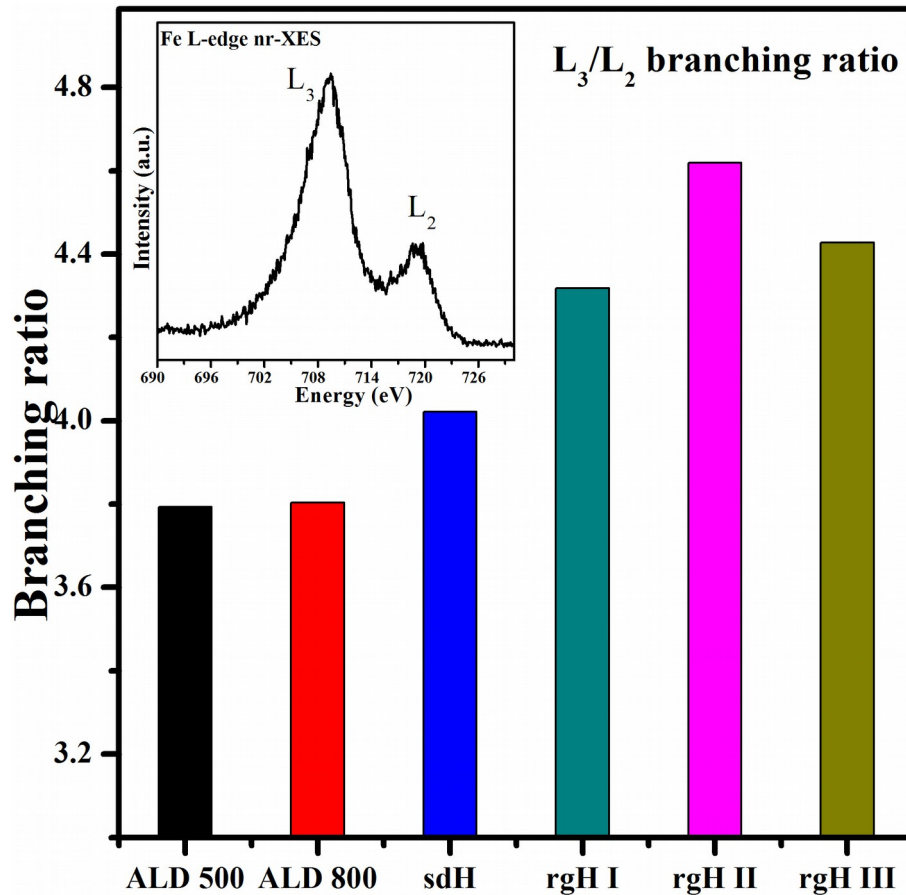

188

189 *Figure 5: The L3/L2 branching ratio of Fe L-edge Nr-XES of various hematite samples, the Fe L-edge Nr-XES spectrum of ALD*
190 *500 has been displayed in the inset.*

191The comparison between the surface-sensitive TEY XAS spectra (both O-K and Fe-L) and the bulk-sensitive TFY

192XAS and XES/RIXS spectra suggests that the electronic structure difference is more prominent in the bulk than on

193the surface. The surface sensitive Fe L-edge XAS peaks showed mild intensity changes (around 10% variation

194among the spectra shown in Figure 3), similar to the level of intensity variation in the O K-edge TEY-XAS. On the

195other hand, the bulk sensitive Fe L-edge RIXS features showed much larger variations in intensity (around 50%

196variation among the spectra shown in Figure 4), also consistent with the large variations observed in the O K-edge

197TFY-XAS. These similarities between O-K and Fe-L spectra observed both in the bulk and on the surface of the

198hematite films further suggested the changes of the electronic structures across the entire film were influenced by

199both O and Fe sites as a results of stronger O2p-Fe3d hybridization.

200As discussed in the previous section, the surface modification on photoanode surface has been proven to be an

201effective method to improve the PEC performance. One may claim that, in this work, the bulk electronic structure

202has been more affected than the surface by the regrowth method, which seems to suggest that the bulk electronic

203 structure changes is the driving factor for the performance enhancement. This is due to that the detection depth of
204 the TEY signal is more surface sensitive than the electrode/electrolyte interfacial layer where PEC reactions take
205 place. As well known, the photovoltage in hematite only develops within the space charge region, which is around
206 20-30 nm wide. The space charge region layer is thicker that the TEY detection depth (ca. 5-10nm) and within the
207 region of the TFY detection depth (ca. hundreds nm). Therefore, the observed growth method induced changes of
208 both the surface and bulk electronic structures are the driving factor for the performance enhancement.

209 The origin of the strong hybridization between O and Fe in solution-grown samples is still unclear, but may be
210 connected to structure of the hematite films. According to the previously reported structural and electrochemical
211 characterizations, the solution growth method produces hematite films with lower degree of surface disorder, which
212 may be a contributing factor contributing for the suppression of hybridization. From all the X-ray spectroscopic
213 data, the samples with the best PEC performance, rgH II, shows strongest O 2p- Fe 3d hybridization among all the
214 samples. It is possibly because strong hybridization between the cation sites and O anion sites can facilitate the
215 charge injection/extraction on the electrode surface during the electro-catalytic reaction. Such electronic structure-
216 performance correlation suggests that the significant impact of the occupancy of the Fe 3d orbitals and the O 2p- Fe
217 3d hybridization on the electronic properties of the hematite materials and their PEC performance in water splitting
218 reactions,[33] providing new insights and possible strategies for the performance enhancement of photoanode materials
219 for PEC water splitting reactions.

220 ~~Conclusion~~CONCLUSIONS:

221 The hematite films synthesized by ALD method and solution-derived growth method have been investigated using
222 X-ray spectroscopies. Analysis of XAS and XES/RIXS spectra revealed that performance ~~improved~~ improvement
223 observed in regrown solution samples is possibly related to a stronger hybridization between O 2p-Fe 3d
224 hybridization. The hybridization level increases with each regrowth cycle~~, and it maximizes~~ until maximizing after
225 the second cycles and then decreases with further regrowth. The stronger hybridization between the cation sites with
226 O enhances the capability of the oxygen electro-catalysis, providing useful information to understand the mechanism
227 of improvement in the PEC performance. This study indicates that the solution regrowth method can not only alter
228 the morphological structure but also change the intrinsic electronic structure of the materials, establishing a
229 possibility of a broad application of this strategy in materials synthesis. This work also illustrated the capability of
230 synchrotron X-ray technique to provide unique information regarding the electronic structure and its potential to
231 help understanding the properties of the materials in many other applications.
