(Dated: 25 February 2022)

Ion-scale magnetospheres have been observed around comets, weakly-magnetized asteroids, and localized regions on the Moon, and provide a unique environment to study kinetic-scale plasma physics, in particular in the collisionless regime. In this work, we present the results of particle-in-cell simulations that replicate recent experiments on the Large Plasma Device at the University of California, Los Angeles. Using high-repetition rate lasers, ion-scale magnetospheres were created to drive a plasma flow into a dipolar magnetic field embedded in a uniform background magnetic field. The simulations are employed to evolve idealized 2D configurations of the experiments, study highly-resolved, volumetric datasets and determine the magnetospheric structure, magnetopause location and kinetic-scale structures of the plasma current distribution. We show the formation of a magnetic cavity and a magnetic compression in the magnetospheric region, and two main current structures in the dayside of the magnetic obstacle: the diamagnetic current, supported by the driver plasma flow, and the current associated to the magnetopause, supported by both the background and driver plasmas with some time-dependence. From multiple parameter scans, we show a reflection of the magnetic compression, bounded by the length of the driver plasma, and a higher separation of the main current structures for lower dipolar magnetic moments.

I. INTRODUCTION

A vast range of space and astrophysical scenarios are driven by the rapid expansion of plasmas through space. Such examples include interplanetary coronal fast ejecta[1], the expansion of the stellar material from supernova remnants[2], and artificial magnetospheric releases of tracer ions[3]. When these expanding plasmas encounter obstacles of magnetic nature, the resultant interaction leads to highly nonlinear and complex dynamics. In the solar system, the interaction between the plasma flow (*i.e.* the solar wind) and planetary-sized magnetic obstacles leads to the formation of magnetospheres[4].

The effective size of the magnetic obstacles is determined by the equilibrium position between the kinetic pressure of the solar wind and the magnetic pressure exerted by the planetary magnetic fields[5]. The region of equilibrium, called the magnetopause, can be described using the pressure balance derived from magnetohydrodynamics (MHD)

$$n_d m_{i,d} v_0^2 = \frac{B^2}{8\pi} , \qquad (1)$$

where n_d is the density of the solar wind, v_0 is its flow velocity, $m_{i,d}$ is the mass of its ions, and B is the total magnetic field at the magnetopause. The total magnetic field can be written as $B = B_0 + B_{\rm dip}$, where B_0 is the collective magnetic field and $B_{\rm dip} = M/L_0^3$ is the magnetic

field of the obstacle, often well described by a dipolar profile of magnetic moment M. The distance L_0 between the center of the dipole and the magnetopause, often referred to as the plasma standoff distance, measures the effective size of the magnetic obstacle.

For planetary-sized magnetospheres, the obstacle size is typically tens of thousands of kilometers. However, magnetospheres with a few hundreds of kilometers are also observed in space environments such as the lunar surface. When the magnetic obstacle size is smaller or of the order of the ion kinetic scales of the plasma, *i.e.* the ion skin depth or the ion gyroradius, the interaction with the solar wind results in ion-scale magnetospheres, or mini-magnetospheres.

The study of mini-magnetospheres in past years was mainly motivated by the observation of crustal magnetic anomalies on the lunar surface[6–10]. Although the Moon does not have a global magnetic field like Earth, it does have small localized regions of crustal magnetic field, of 10-100 nT over distances of 100-1000 km[6], which are of the same order as the gyroradius of solar wind ions near the Moon's surface. As a result, when these regions of the lunar surface are exposed to the solar wind, mini-magnetospheres can form. Several studies associated the deflection of particles off lunar mini magnetospheres to the formation of the "lunar swirl" structures[10,11]. Other interactions between the solar wind and small-sized patches of magnetic field also occur in other regions of the solar system. Such examples include Mars[12], where the induced magnetosphere interacts with the crustal fields; Mercury[13] and Ganymede[14], where the small magnetospheres interact with the solar wind and Jupiter's magnetosphere, respectively, and comets and

asteroids[15], when interacting with the solar wind.

Multiple experiments have been performed in laboratory environments that replicate the interaction between plasma flows and magnetic obstacles. With a proper re-scaling of parameters[16], these experiments represent highly controlled configurations where a large variety of diagnostics can be used to obtain more accurate measurements than those obtained from the direct probing of astrophysical events. In experimental studies, fast-moving plasma flows are usually driven resorting to high-intensity lasers focused onto solid targets of plastic or metal composition[17,18]. These laser-ablated plasmas can be mildly collisional or collisionless, replicating astrophysical conditions[19,20]. By adding dipole field sources against the plasma flow, previous experiments of mini magnetospheres studied possible applications for spacecrafts[21–23], the formation of lunar swirls[11], and the conditions for the formation of magnetosphere features[24–27]. Although these experiments achieved important breakthroughs in the study of ion-scale magnetospheric physics, they were limited to i) 1D measurements of the magnetic field and plasma density profiles and ii) fixed properties of the obstacle and plasma flow.

Numerical simulations play a key role in interpreting and designing experiments. Early MHD simulations attempted to explain the formation and characteristics of lunar mini-magnetospheres and validate experimental and analytical models[25,28,29]. Hybrid simulations were used to study the role of ion kinetic effects, and obtain conditions for the formation of magnetospheres[30] and replicate previous experimental results[31]. However, these simulations do not resolve the electron scales and do not capture important kinetic effects on the magnetosphere's boundary, *e.g.* charge separation effects and nonthermal particle distributions. Fully kinetic simulations, such as particle-in-cell (PIC), were used to resolve the microphysics of these systems and study its role in the formation of lunar mini-magnetospheres[32–36], the scaling of their properties with solar wind speed and magnetic field orientation[37] and the conditions for the formation of collisionless shocks[38].

In this work, we use PIC simulations of ion-scale magnetospheres driven by super-Alfvénic plasma flows to interpret the results of recent experiments[39] performed at the LArge Plasma Device (LAPD), University of California, Los Angeles. In these experiments, fast collisionless plasma flows generated by high-repetition-rate lasers were collided with the magnetized ambient plasma provided by the LAPD and with a dipolar magnetic field obstacle, leading to the formation of ion-scale magnetospheres. Using motorized probes, high spatial and temporal resolution measurements of the magnetic field allowed characterization of 2D magnetic field and current density structures. Apart from validating the experimental results, the simulations presented in this work explore a set of upstream and magnetic parameter scans and configurations not accessible in the laboratory to determine the importance of each system parameter on the mag-

netospheric properties. The simulations show that the background ions, and then the driver ions, are responsible for the formation of the magnetopause observed in the experiments. They also show that a reflection of the downstream magnetic compression is observed for certain parameters of the driver plasma, and that the distance between the main current features is dependent on the dipolar and driver plasma parameters. Both experiments and simulations studied scenarios where the magnetic fields were perpendicular to the plasma flows. This configurations leads to higher jumps of density and bigger effective obstacle sizes[28,38], than in parallel configurations.

This paper is organized as follows. In Sec. II, we briefly review the LAPD experiments and their main results. In Sec. III, we present PIC simulations of ion-scale magnetospheres. In Sec. III A, we outline the standard configuration and parameters used for the simulations. In Sec. III B, we provide an overview of the temporal evolution of these systems and show that the simulations agree with the results of the LAPD experiments. We discuss the origin of the structures observed in current density and magnetic field synthetic diagnostics and use particle phase spaces to interpret them. In Sec. III C, we present the results for different lengths of the plasma flow and define the conditions required to reproduce the features observed experimentally. The coupling between the laser-ablated driver and background plasmas is characterized in Sec. III D with simulations with different driver densities. In Sec. III E, different magnetic moments are considered, and we show that the main current density features are highlighted and more easily visible for weaker magnetic obstacles. In Secs. III F and III G, we discuss and illustrate the validity of the key simplifications and approximations used for the parameter scans presented in Secs. III B-III E. Finally, we outline the conclusions of this work in Sec. III G.

This paper is the second part of a two part series. Detailed experimental results are presented in Part I[39].

II. LAPD EXPERIMENT

A new experimental platform has been developed on the LAPD to study mini-magnetospheres. The platform combines the large-scale magnetized ambient plasma generated by the LAPD, a fast laser-driven plasma, and a pulsed dipole magnet, all operating at high-repetition-rate (~ 1 Hz). In the experiments, a supersonic plasma is ablated from a plastic target and then expands into the dipole magnetic field embedded in the ambient magnetized plasma. By measuring 2D planes of the magnetic field over thousands of shots, detailed maps of the magnetic field evolution are constructed. Additional details on the platform and results can be found in Part I.

Example results are shown in Fig. 1 for the measured change in magnetic field $\Delta B_z = B_z - B_{z,\text{initial}}$ and the current density $J_x = \partial \Delta B_z / \partial y$. Here, B_z is the total

magnetic field, $B_{z,\text{initial}} = B_0 + B_{\text{dip}}$ is the total initial magnetic field, B_0 is the background LAPD field, and B_{dip} is the dipole magnetic field. These results are taken along y at $x = 0$ from the $z = 0$ plane probed experimentally. In the experiments, the dipole is centered at $(x, y, z) = (0, 0, 0)$ and has a magnetic moment $\mathbf{M} = -M\,\hat{\mathbf{z}}$ with $M = 475\,\text{Am}^2$. The laser-driven plasma moves in the positive y direction.

As seen in Fig. 1(a), the expanding laser-driven plasma creates a leading magnetic field compression followed by a magnetic cavity. The cavity reaches a peak position of $y \approx -13$ cm, while the compression propagates closer to the dipole before being reflected back towards the target. The current density in Fig. 1(b) shows two prominent structures. Following the expansion of the magnetic cavity is a diamagnetic current, which reaches a peak position of $y \approx -15$ cm before stagnating for approximately 1 μs and then dissipating. Ahead of the diamagnetic current is the magnetopause current near $y \approx -13.5$ cm, which lasts for about 0.5 μs.

Here, we aim to qualitatively model these experiments in order to address key questions that aid in the interpretation of the experimental results. In particular, simulations can explain the role of each system component in the features observed, address which plasma component (ambient or laser-driven) is responsible for the features observed and which pressure balances are most relevant.

In the experiments the ions are nearly collisionless and the electrons are highly collisionless, with $\nu_{ci}/\omega_{ci} = 0.5$ and $\nu_{ce}/\omega_{ce} = 6 \times 10^{-4}$, where ν_{cj} is the thermal collision frequency, and ω_{cj} the gyrofrequency, for the ions ($j = i$) and the electrons ($j = e$) of the background plasma. The ion-ion collision length, for the driver and background, is approximately 176 d_i, which is much larger than the size of the system. For this reason, we used PIC simulations of collisionless plasmas to model the experiments.

III. PIC SIMULATIONS

A. Configuration of the simulations

Motivated by the results of experiments described in Sec. II, we performed 2D simulations with OSIRIS, a massively parallel and fully relativistic PIC code[40,41]. With PIC simulations, we can accurately resolve the plasma kinetic scales characteristic of mini-magnetospheres dynamics.

The numerical simulations presented in this work stem from a simplified description of the LAPD experimental setup, represented in Fig. 2. In these simulations, a driver plasma moves against a background plasma permeated by a uniform magnetic field $\mathbf{B_0}$ and a dipolar magnetic field $\mathbf{B_{dip}}$. $\mathbf{B_0}$ and $\mathbf{B_{dip}}$ are oriented along the z direction and are transverse to the driver plasma flow. Since the most relevant dynamics of the simulations occurs at the ion kinetic scales, all the spatial scales are normalized to the ion skin depth of the back-

FIG. 1. LAPD experimental results for the temporal evolution of a) the variation of the magnetic field ΔB_z and b) the current density J_x at $x = z = 0$. The experimental results are discussed with more detail in Part I.

ground plasma $d_i = c/\omega_{pi} = \sqrt{m_{i,0}c^2/4\pi n_0 e^2}$, where c is the speed of light in vacuum, ω_{pi} is the ion plasma frequency, $m_{i,0}$ is the mass of the background plasma ions, n_0 is the background density, and e is the electron charge. In turn, the temporal scales are normalized to $1/\omega_{ci}$, where $\omega_{ci} = eB_0/m_{i,0}c$ is the ion cyclotron frequency of the background. The simulation box is a 12 d_i × 12 d_i area with periodic and open boundary conditions in the x and y directions, respectively. The flow is in the y direction and the size of the simulation domain in the x direction is large enough to avoid re-circulation of the particles through the whole interaction. The simulations considered 25 particles per cell per species. To resolve the dynamics of the electron kinetic scales, we used 10 grid cells per electron skin depth $d_e = d_i\sqrt{m_e/m_{i,0}}$ in both x and y directions, where m_e is the electron mass.

The driver plasma, shown in region I in Fig. 2, represents ideally the plasma ablated from the plastic target in the experiments. We assume that this driver has a length L_y that is typically 2 d_i, and a width L_x that is typically infinite. It has a constant density n_d, and it is initialized moving to the right side with initial flow velocity v_0. The driver is composed of an electron species and a single ion species, with ion mass $m_{i,d}$. Because the driver plasma is reflected during the interaction with the background, an empty region at the left of the driver was added to accommodate the reflecting particles. Although the experimental driver plasma has a non-uniform density and velocity, and it is performing a 3D expansion, the relevant evolution of the system occurs in such a short amount of time that only a small portion of the driver ends up interacting with the background. Over this region and time scale, a 1D driver expansion with constant
FIG. 2. Schematic illustration of the initial setup of the 2D PIC simulations performed. The system considers a vacuum region at the left, a driver plasma (I) of density n_d and length L_y, travelling to the right with flow velocity v_0, and a background plasma (II) with constant density n_0 and with an internal magnetic field B_0. A dipole is included at the center of the background region. Both the uniform and the dipolar magnetic fields are oriented in the z direction. An illustration of the effective magnetic obstacle created by the dipole and of the magnetic field profile at $x = 0$ are also shown in a dashed circumference and in a solid black line, respectively.

velocity and density is a good model of the experiments. Additionally, in this paper, we are mainly interested in the plasma dynamics along the axis of symmetry $x = 0$, where the 3D expansion is less relevant. A more realistic driver was considered on Sec. III G.

The background plasma is represented in region II. It is an 8 d_i length and infinite width plasma and it has uniform density n_0. The initial interface between the driver and background plasma is located at $y_B = -4\ d_i$. Like the driver plasma, it has an electron species and a single ion species, of mass $m_{i,0}$. The background plasma is magnetized with an internal uniform magnetic field $\mathbf{B_0} = B_0\hat{\mathbf{z}}$, and its magnitude is defined such that the Alfvénic Mach number of the flow, $M_A \equiv v_0/v_A = v_0\sqrt{4\pi n_0 m_{i,0}}/B_0$, where v_A is the Alfvén velocity, matches the super-Alfvénic value $M_A = 1.5$, of interest to the experiments.

A dipolar magnetic field is externally imposed in our simulations (i.e., it is added to the plasma self-consistent electromagnetic fields to advance particle momenta but is not included in Maxwell's equations to advance the fields). The dipole is centered at $(x, y) = (0, 0)$ and its associated magnetic field is $\mathbf{B_{dip}} = B_{dip}\hat{\mathbf{z}}$, with $B_{dip} = M/r^3$, where M is the dipolar magnetic moment, $r = \sqrt{x^2 + y^2 + \delta^2}$ is the distance to the origin of the dipole and $\delta = 0.25\ d_i$ is a regularization parameter, that prevents the field from diverging at $x = y = 0$. For

most simulations, the magnetic moment M was chosen such that the expected standoff, obtained from Eq. (1), is similar to the experimental value $L_0 = 1.8\ d_i$. For this particular magnetic moment, the total initial magnetic field $B_0 + B_{dip}$ is $\approx 3.0\ B_0$ at the standoff distance. Near the interface between the driver and background plasmas, the magnetic field of the dipole is relatively small and the initial magnetic field is $\approx 1.2\ B_0$.

In this work, we present simulations with different drivers and magnetic dipole moments. All the simulations presented here, and their respective parameter sets, are listed in Table I. Simulations B-G are discussed through Sec. III on equally labeled subsections (i.e. simulation B for Sec. III B; simulations labeled with C for scan of Sec. III C, and so forth). Simulation B is used to discuss the overall dynamics of the system, while simulations C, D, and E illustrate the role of the driver length, the density ratio, and the magnetic moment, respectively. Simulations F show the results for more realistic choices of parameters and simulation G for a more realistic driver shape. The physical parameters of the simulations (e.g. M_A, L_0/d_i) were adjusted to be similar to the LAPD experiments, whereas other parameters (e.g. m_i/m_e, v_0, v_{the}) were chosen to make simulations computationally feasible. The experimental and numerical parameters are presented in Table II and compared with lunar mini-magnetospheres.

In most simulations, we considered a reduced mass ratio $m_i/m_e = 100$, a flow velocity $v_0/c = 0.1$, and cold plasmas to reduce the required computational resources, allow extended scans over the different parameters of the system, and simplify our analysis. Although these parameters are different in the experiments, they can still be used in the simulations to compare with the experimental results. v_0 is low enough to ensure a non-relativistic regime and OSIRIS operates in normalized plasma units, where n_0 is the independent variable. By using similar physical parameters (e.g. M_A, L_0/d_i) and proper space and time scales, (d_i, ω_{ci}^{-1}) the comparison between the simulations and the experiments remains valid. The thermal effects are negligible for the main results, and the chosen ion-to-electron mass ratio is high enough to ensure sufficient separation between electron and ion spatial and temporal scales. We confirm the validity of our assumptions in Sec. III F.

In most of the simulations presented in this work, we have assumed that ions and electrons are initially in thermal equilibrium, and considered cold ion and electron temperatures to neglect thermal effects, and thus used the electron thermal velocities v_{the} shown in Table I, to compute the ion thermal velocities v_{thi}. In the experiments, the driver plasma is composed of both hydrogen and carbon ions while the background is composed of hydrogen ions. Here, we aim to study the role of the hydrogen ions of the experimental driver (as they they are more relevant than the carbons ions) in the interaction with the hydrogen ions of the background plasma. More specifically, we aim to study simulations where equal ion

TABLE I. List of simulations performed and their parameters. $v_{the,y}$ and $v_{thi,y}$ represent the y component of the electron and ion thermal velocities, respectively. All the runs considered $v_{th,x} = v_{th,y} = v_{th,z}$ for the electrons and ions. The names of the simulations correspond to the subsections where they are presented. All the simulations consider $v_0 = 0.1\ c$ and $M_A = 1.5$.

masses were used for the driver and background plasmas, *i.e.* $m_{i,d} = m_{i,0}$.

Because the magnetic field in the xy plane of the experiments and of the simulations is mostly composed by the z component, we expect that the motion of the particles is mostly described in this xy plane, where our 2D simulations are defined. Also, previous works have suggested that similar 3D dynamics of mini magnetospheres can be investigated in such 2D simulations[38]. As a first approach, we can, therefore, use 2D simulations to study the 3D setup of the LAPD experiments.

B. Evolution and main features of the system

To identify the main magnetospheric and kinetic-scale structures that arise from the initial configuration, simulation B was performed. It considered a driver with length $L_y = 2\ d_i$ and density $n_d = 2\ n_0$ (twice the background density). The choice of these parameters considered the results of the parameters scans shown later in Secs III C and III D. Figs. 3 a1-3) represent the total ion density $n_i = n_{i,d} + n_{i,0}$, for three different times, and Figs. 3 b1-3) show the variation of the z component of the magnetic field, from its initial value, $\Delta B_z = B_z - B_{z,\text{initial}}$.

In Fig. 3 a1), we see the total ion density for an early time ($t\omega_{ci} = 1.5$). Given the small distance propagated by the driver plasma at this time, the dipolar magnetic field does not significantly affect the interaction between the plasmas. For this reason, we can express the early system as a driver flowing against a uniform magnetized background plasma. In Fig. 3 b1), we observe that this interaction creates a region of compressed magnetic field in the downstream region, where the background plasma is located, and expels the magnetic field in the region of the driver, leading to a magnetic cavity in the upstream region with approximately null magnetic field[20].

In Figs. 3 a2) and b2), we start to observe the effects of the dipolar magnetic field for a later time ($t\omega_{ci} = 3.0$).

As the magnetic pressure exerted against the plasmas increases, a region of compressed background plasma forms in front of the dipole, as Fig. 3 a2) shows. After the interaction between the background and the dipole, the magnetic field pressure becomes large enough to counterbalance the kinetic pressure of the driver, reflecting it upstream. This can be seen in Fig. 3 a3) for a subsequent time ($t\omega_{ci} = 4.5$). After the reflection, there is no longer a plasma flow pushing the magnetic compression forward or holding the decompression by the left side of the background region, and as a result, the region near the dipole quickly decompresses — see Fig. 3 b3).

To compare the numerical results with the experimental data shown in Fig. 1, synthetic diagnostics were obtained from the simulations. In Fig. 4, the variation of the magnetic field ΔB_z and the current density J_x measured at the axis of symmetry $x = 0$ and as a function of time are plotted for simulation B. These diagnostics are important to comprehend the system dynamics, due to the importance of the z direction of the magnetic field in the motion of the particles.

The main features of Fig. 4 are consistent with the experimental results. In the magnetic field plot of Fig. 4 a), both the upstream magnetic cavity and the downstream magnetic compression are present. Between $t\omega_{ci} = 0$ and $t\omega_{ci} \approx 1.5$, the system behaves approximately as a driver piston moving against a uniform magnetized plasma. As the driver pushes the background plasma and magnetic field, the discontinuity that separates these two media travels at constant coupling velocity $v_c < v_0$, measured as $v_c \approx 0.49\ v_0$ for this simulation. The leading edge of the compression of the magnetic field travels with a velocity close to v_0 for the runs considered.

The driver experiences increasingly higher magnetic fields until the magnetic pressure is enough to reflect the driver near the expected standoff $y_0 = -L_0$, at $t\omega_{ci} \approx 3$. The magnetic cavity and magnetic compression are also reflected, and the boundary between these two regions travels with a velocity v_r after reflection. The background magnetic decompression is seen after $t\omega_{ci} = 5$.

TABLE II. Typical parameters associated with lunar mini-magnetospheres[4,6,11,42], the range of parameters of LAPD[39] and the canonical simulation B. The parameters are written in both physical and normalized units to facilitate the comparison between the space, the laboratory environments and the PIC simulations. The experimental parameters are presented in ranges of values computed with the possible LAPD values for the flow velocity v_0, the density n_0 and the electron and ion temperatures $T_{e,0}$ and $T_{i,0}$, respectfully, of the background plasma. The plasma parameters shown for lunar mini-magnetospheres are relative to the solar wind, while for the experiments and the simulations, they are relative to the background plasma. The ion data shown corresponds to only the hydrogen ions. The ion and electron gyroradii and gyroperiods for the experiments and simulations are estimated with the driver velocity v_0 and the magnetic field B_0. The magnetic field B_{std} is calculated at the standoff position, i.e., at a distance L_0 from the center of the obstacle. Some driver parameters for the experiments are not represented because their values are not well known. However, we have an idea for the order of magnitude for some of these parameters[43].

In the current density plot of Fig. 4 b), we can observe the diamagnetic current that supports the magnetic field gradient between the driver and background plasmas and that identifies the leading edge of the magnetic cavity. During the driver reflection, this current branches into multiple components due to the multi-stream velocity distributions developed in the driver and background plasmas. We can also verify that this structure is reflected near the expected standoff $y_0 = -L_0$. Between $t\omega_{ci} \approx 2$ and $t\omega_{ci} \approx 3$, a second current structure is present in the background region. It is associated with the magnetopause of the system and the small decompressed field region that we see in Fig. 4 a), and it arises

from the interaction of the accelerated background ions with the dipole, as we show in Sec. III E. The presence of these two current structures is consistent with the experimental results.

In Fig. 4 b) we can also see the formation of waves in the background plasma, near the dipole region. These waves are excited in regions of highly non-uniform density and magnetic field, and have periods and wavelengths between the ion and electron kinetic scales. We have verified that their properties change significantly for different ion thermal velocities. In particular, we have found these waves to be more clearly excited for lower ion temperatures. A detailed characterization of these waves and the

FIG. 3. Spatiotemporal evolution of a) the total ion density and b) the variation of the z component of the magnetic field in simulation B (see Table I for a list of parameters). Columns 1-3 correspond to three different times in the simulation. The vertical and circular dashed lines mark the initial border between the driver and background plasma and the dipolar magnetic obstacle with radius L_0, respectively.

conditions for their formation is out of the scope of this paper, and shall be addressed in a future work.

To better understand the particle motion during the events described, we show in Fig. 5 the phase spaces of ions and electrons located near $x = 0$. For the ions, the y component of the velocity of the particles is presented, to illustrate their reflection and accumulation, while for the electrons, the x component is shown instead, to show

the formation of the currents. The magnetic field B_z, the current density J_x, and the electric field E_y profiles for $x = 0$ are also represented. Once again, we used the parameter set B of Table I.

Fig. 5 a1) shows the v_y velocity of the ions when the dipole field is still negligible. The ions initially move upstream with velocity v_0 until they interact with the background field. After reaching the background, they
FIG. 4. Temporal evolution of a) the variation of the magnetic field B_z and b) current density J_x at $x = 0$ for the simulation B. The driver has a 2 d_i length and a density $n_d = 2\,n_0$. The dashed lines have slopes that match the flow velocity v_0, the coupling velocity v_c and the reflection velocity v_r. The measured values for these velocities are $v_c/v_0 \approx 0.49$ and $v_r/v_0 \approx -0.58$, with $v_0 = 0.1\,c$.

are mostly decelerated and reflected by electric field E_y in the interface between the plasmas[20], visible in Fig. 5 c1) and end up with a flow velocity that is close to zero for the simulation considered. The reflection occurs near the boundary of the magnetic cavity, which moves with velocity v_c through the background, as mentioned above. During this stage, the background ions accelerate from rest to velocities of average close to v_c.

The driver and the accelerated background ions continue to approach the dipole until they are reflected. This can be seen in Fig. 5 a2). During this interaction, two main current structures are visible in the J_x profile in Fig. 5 c2). The first one (from the left) corresponds to the typical diamagnetic current, while the second one corresponds to the magnetopause. To the right of these two main current structures, we can see the background waves observed in Fig. 4 b). In Fig. 5 a3), the driver ions are totally reflected. The ions reflected by the dipole obtain a velocity close to $-v_0$, while the magnetic cavity moves back with velocity v_r.

Because the simulation considers a cold plasma approximation, the ion thermal velocities remain small most of the time, except for the boundary between the two plasmas, where the velocity of the ions changes abruptly. The same does not occur for the electrons. We can see in the v_y velocity of the electrons, represented in Figs. 5 b1) to b3) that, although the electron thermal velocities are initially small, they rapidly increase considerably. At the boundary, the electrons can reach thermal velocities of 6 v_0, much higher than the ion velocities. Because the electron and ion density profiles are

very similar during the entire evolution of the system, the current density $J_x = e(n_i v_{ix} - n_e v_{ex})$ is then mainly transported by the electrons, where n_j is the density and v_{jx} the x component of the velocity of the ions and electrons ($j = i, e$, respectively). This is also consistent with the observed spatial distribution of electrons during the reflection, which shows an excess of fast electrons around the standoff position.

In this section, we used a driver with a density of 2 n_0 and a length of 2 d_i. In the experiments, however, the density, length and other parameters of the driver are not well known. The parameters used here were obtained after performing the multiple parameter scans of the following sections to identify what driver parameters best replicate the experimental results.

C. Driver length

To choose a driver length that best reproduces the experimental results shown in Fig. 1 and to understand its role on the magnetic field and current density structures, we performed simulations C1 to C3 (see Table I) with varying driver length L_y. In Fig. 6, we show ΔB_z and J_x at $x = 0$ for $L_y = 1\,d_i$ (C1), $L_y = 4\,d_i$ (C2) and for an infinite driver (C3). For these simulations, the properties of the background plasma and the width of the driver L_x were kept unchanged. The density of the driver was $n_d = 2\,n_0$.

In Figs. 6 a1) and b1), we see the magnetic field and current density plots for the short driver length $L_y = 1\,d_i$. We observe most of the features of Fig. 4, namely the reflection of the compressed magnetic field in a1) and the diamagnetic and magnetopause currents in b1). For this length, however, the driver never fully interacts with the dipole. The closest that the diamagnetic current structure gets to the dipole is $y_r \approx -3.0\,d_i$, i.e., much farther than the expected standoff $y_0 = -L_0 = -1.8\,d_i$. To replicate the experimental results and ensure that the driver can reach the dipole, we should thus use a sufficiently long driver such that $y_r > y_0$. Additionally, short drivers risk entering in a decoupling regime between the two plasmas[44], which can compromise the observation of a magnetopause. The coupling effects on the results are discussed in detail in Sec. III D.

The position where the driver is fully reflected by the background can be estimated as $y_r \approx y_B + L_y v_c/(v_0 - v_c)$, where y_B is the initial boundary position between the two plasmas. This estimate is obtained by computing the volume of the background plasma required for the driver plasma to deposit its kinetic energy, i.e. $y_r - y_B$ corresponds to the magnetic stopping radius of the system[45].

In the simulation with $L_y = 4\,d_i$, represented in Figs. 6 a2) and b2), we observe once more the main features identified in Fig. 4, but unlike the $L_y = 1\,d_i$ case, the driver is long enough and ends up reflected by the dipole. We observe that the diamagnetic current reaches the ex-

plots/phase-scan-standard.pdf

FIG. 5.   Ion (a) and electron (b) phase spaces, and magnetic field B_z, current density J_x, and electric field E_y profiles at $x = 0$, for simulation B and for three different times (1-3). The particles shown were randomly selected in the region $-0.2\ d_i < x < 0.2\ d_i$. The frames labeled a1) to a3) show the v_y velocity of the ions, while the frames labeled b1) to b3) show the v_x velocity of the electrons. Blue/orange markers correspond to background/driver plasma particles. The frames c1) to c3) show the magnetic field B_z with a green line, the current density J_x with purple, and the electric field E_y with orange. The electric field E_x is not show here, but in the driver region it is approximately zero, and in the background region it is $\simeq -\mathbf{v} \times \mathbf{B}$. The other electric and magnetic field components are negligible.. The left dashed line marks the initial border between the driver and the background plasmas, and the right dashed line marks the expected standoff $y_0 = -L_0$.

pected standoff and has enough plasma to maintain it near the dipole for a time period ($t\omega_{ci} \approx 3$ to $t\omega_{ci} \approx 5$) longer than the 2 d_i case shown in Fig. 4. As a result, the magnetic decompression in the background region is delayed for longer drivers. However, because the full driver reflection also occurs later, longer drivers will result in

short-lived reflections of the compression of the magnetic field.

In Figs. 6 a3) and b3), we show the results for a driver with infinite length ($L_y = +\infty$). In this simulation, the driver plasma is only partially initialized inside the simulation domain, and a flow is continuously injected from

the lower y boundary. An infinite driver configuration allows us to understand the dynamics of the system in an asymptotic regime in which the driver plasma stays close to the dipole. As expected, until $t\omega_{ci} = 3$, the features observed are very similar to $L_y = 2\ d_i$ and $L_y = 4\ d_i$. After this time, the magnetic and the driver kinetic pressures balance each other near y_0, so the diamagnetic current remains stationary. Because the driver can hold for longer near the dipole, the decompression in the background region is much slower and is not visible for the time range of the plot. We can also observe that the background waves are only visible during a transient.

In all the three simulations, the coupling velocity measured was always $v_c \approx 0.49\ v_0$. Given the results shown in Fig. 6, we chose a driver length of $2\ d_i$ to reproduce the experimental results. This driven length is large enough to ensure that the driver arrives at the dipole and small enough to observe a significant reflection of the compression of the magnetic field as we see in the experiments.

D. Plasma coupling with density ratio

As expected from previous works, increasing the ratio between the driver and background plasma densities should improve the coupling between the two plasmas[20,44], meaning that, for denser drivers, the transfer of momentum and energy from the driver to the background plasma is more efficient. To better understand the role of the coupling mechanism, we performed simulations with different values of the driver density, namely $n_d = n_0$ (D1), $n_d = 2\ n_0$ (D2) and $n_d = 4\ n_0$ (D3), while keeping a constant background density n_0 and a driver length $L_y = 2\ d_i$. For each run, the magnetic moment was chosen such that the expected standoff obtained from Eq. (1) was always $L_0 = 1.8\ d_i$. The synthetic magnetic field and current density diagnostics were obtained for these simulations and are shown in Fig. 7.

In Figs. 7 a1) and b1) we can see ΔB_z and J_x for the lowest driver density considered, $n_d = n_0$ (i.e., background and driver with the same initial density). In this regime, the coupling is less efficient and, as a result, the coupling velocity $v_c \approx 0.38\ v_0$ is lower than obtained in the higher densities cases represented in Fig. 7. Due to the low coupling velocity, the driver plasma is reflected more quickly by the background than for denser drivers, and the expected position y_r for the total reflection on the background is farther from the dipole than the expected standoff y_0, meaning $y_r < y_0$. As a result, Figs. 7 a1) and b1) show similarities with the short driver length represented in Figs. 6 a1) and b1), because, in both simulations, the driver parameters do not ensure that the driver arrives near the dipole.

In Figs. 7 a2) and b2), we show the results for $n_d = 2\ n_0$, which is the same run represented in Fig. 4. For this density, the coupling velocity, measured as $v_c \approx 0.49\ v_0$, is high enough to secure a reflection of the driver by the dipole, as we observe at $t\omega_{ci} \approx 3$. In Figs. 7 a3)

and b3) we show the case with the highest driver density $n_d = 4\ n_0$, which is similar to the $n_d = 2\ n_0$ case, because the measured coupling velocity for Figs. 7 a3) and b3) was $v_c \approx 0.56\ v_0$, i.e., only slightly larger than the v_c measured for Figs. 7 a2) and b2). In the high density case, we also see that the current density structures during the plasma reflection are filamented, due to analogous multi-stream velocity distributions discussed for Fig. 6 b2).

To guarantee that the driver reaches the expected standoff, we thus require that $y_r > y_0$. In fact, the position where the driver is reflected y_r, for no dipole cases, increases with the driver length L_y and the velocity ratio v_c/v_0, and thus, both quantities must be large enough to guarantee that $y_r > y_0$. In turn, the ratio v_c/v_0 increases with increasing driver density ratio n_d/n_0, and so, the driver should be sufficiently long and dense to effectively couple to the background plasma. Our results (in particular Sec. III B) show that a driver with $L_y = 2\ d_i$ and $n_d = 2\ n_0$ qualitatively reproduces the experimental results.

A separate study was also performed to analytically determine the properties of the driver-background plasma coupling. The results of this study will be presented in a future paper.

E. Dependency of the magnetopause position with the magnetic moment

To confirm that the features previously associated with the magnetopause location change according with its expected position, we performed simulations with a $2\ d_i$ long driver with density $n_d = 2\ n_0$ for three different magnetic moments. Considering the magnetic moment that results in the expected standoff $L_0 = 1.8\ d_i$ as M_0 (simulation B/E2 on Table I), simulations with the magnetic moments $2\ M_0$ (E1) and $M_0/2$ (E3) were also performed, corresponding respectively to the expected standoffs $L_0 \approx 2.3\ d_i$ and $L_0 \approx 1.4\ d_i$. Fig. 8 shows the ΔB_z and J_x synthetic diagnostics at $x = 0$ for the three simulations.

Figs. 8 a1) and b1) show the results for the highest magnetic moment $M = 2\ M_0$. We see that the current structures associated with the magnetopause and the background waves are less evident than for the lower magnetic moments, as they are formed farther from the dipole. Figs. 8 a2) and b2) correspond to the magnetic moment M_0 that leads to $L_0 = 1.8\ d_i$ and are the same results shown in Fig. 4. As previously mentioned, there are two main observable current structure standoffs. The first one is associated to the diamagnetic current, which is reflected around $t\omega_{ci} \approx 3$ near the expected value $y_0 = -L_0 = -1.8\ d_i$. This standoff is related to the interaction between the driver ions and the dipole. The second standoff occurs between $t\omega_{ci} \approx 2$ and $t\omega_{ci} \approx 3$ and it is located in the background plasma region. This standoff also occurs near $y = -1.8\ d_i$.

FIG. 6. Temporal evolution of the variations of a) the magnetic field ΔB_z and b) current density J_x at $x = 0$, for driver lengths of 1) 1 d_i, 2) 4 d_i and for 3) an infinite driver length (see Table I for a full list of the parameters). The horizontal dashed lines represent the expected standoffs $y_0 = -L_0 = -1.8\ d_i$. The other dashed lines represent the slopes of the flow velocity v_0, the coupling velocity v_c, and the reflection velocity v_r. The measured values for these velocities are for 1) $v_c/v_0 \approx 0.48$ and $v_r/v_0 \approx -0.64$, 2) $v_c/v_0 \approx 0.50$ and $v_r/v_0 \approx -0.53$, and 3) $v_c/v_0 \approx 0.49$, with $v_0 = 0.1\ c$.

In Figs. 8 a3) and b3), we show the results obtained for the half magnetic moment $M = M_0/2$. In this case, the magnetic pressure exerted by the dipole is lower, leading to a smaller L_0, and consequently, the diamagnetic current feature visible in b3) is closer to the dipole than in Figs. 8 b1) and b2). The main changes, however, occur in the magnetopause current. Unlike what we observe for the other magnetic moments, the magnetopause current, pinpointed in the current density plot, lasts for a longer time (until $t\omega_{ci} \approx 4$). This current is also more separated from the diamagnetic current standoff and is easier to identify. This is consistent with the experimen-

FIG. 7. Temporal evolution of the variations of a) the magnetic field ΔB_z and b) current density J_x at $x = 0$, for different ratios between the driver and background densities n_d/n_0. The magnetic moment was chosen so that the expected standoff distance L_0, calculated from Eq. (1), was kept as 1.8 d_i for all the simulations. Panels 1-3) show results for $n_d = n_0$, $n_d = 2\,n_0$ and $n_d = 4\,n_0$, respectively. The measured values for the slopes of the dashed lines are for 1) $v_c/v_0 \approx 0.38$ and $v_r/v_0 \approx -0.50$, 2) $v_c/v_0 \approx 0.49$ and $v_r/v_0 \approx -0.58$, and 3) $v_c/v_0 \approx 0.56$ and $v_r/v_0 \approx -0.94$, with $v_0 = 0.1\,c$.

tal observations.

To identify the pressure balances associated with the two observed standoffs, and because the magnetic and kinetic pressures vary over time, we studied the temporal evolution of the different plasma and magnetic pressure components of the system. In particular, we calculated the spatial profiles of the magnetic pressure $B^2/8\pi$, the ram pressure $n_j m_j v_{flj}^2$ and the thermal pressure $n_j m_j v_{thj}^2$ as a function of time for $x = 0$. In these expressions, n_j, m_j, v_{flj} and v_{thj} refer to the density, mass and flow and thermal velocities, respectively, of the ions $(j = i)$ and electrons $(j = e)$. The magnetic pressure

plots/different-momentums-plot.pdf

FIG. 8. Temporal evolution of the variation of a) the magnetic field ΔB_z and b) current density J_x at $x = 0$, for three different magnetic moments. The magnetic moments M considered were 1) $M = 2\ M_0$, 2) $M = M_0$ and 3) $M = M_0/2$, where M_0 represents the magnetic moment that corresponds to a standoff $L_0 = 1.8\ d_i$ for a driver density $n_d = 2\ n_0$. The corresponding standoffs for these simulations is $y_0 = -L_0$ with 1) $L_0 \approx 2.3\ d_i$, 2) $L_0 = 1.8\ d_i$ and 3) $L_0 \approx 1.4\ d_i$ (represented by the horizontal dashed lines).The measured values for the slopes of the other dashed lines are for 1) $v_c/v_0 \approx 0.46$ and $v_r/v_0 \approx -0.55$, 2) $v_c/v_0 \approx 0.49$ and $v_r/v_0 \approx -0.58$, and 3) $v_c/v_0 \approx 0.53$ and $v_r/v_0 \approx -0.52$, with $v_0 = 0.1\ c$.

was calculated from the magnetic field measured in each PIC grid cell located at $x = 0$. The flow and thermal pressures, were calculated from averaged particle data. To ensure that the calculation of each kinetic pressure considered a sufficiently large number of particles, all the particles between $-0.1\ d_i < x < 0.1\ d_i$ were binned into equal-sized bins of width $0.05\ d_i$ over the y direction. For each bin we computed: i) the average density of each species, ii) the flow velocity, corresponding to the average of the velocity of the particles, and iii) the thermal

velocity, corresponding to the standard deviation of the velocity of the particles[46]. With these averaged quantities, the ram and thermal pressures were calculated in each bin for each species of ions and electrons and each component of the velocity x, y, and z. The x and z components of the pressures, however, are negligible.

These pressure profiles were obtained for simulation E3 with magnetic moment $M = M_0/2$ and are plotted in Fig. 9 for times where a) the magnetopause and b) the diamagnetic current standoff can be observed. The kinetic pressures represented were calculated by adding all the components of the ram and thermal pressures of the ions and electrons for the background (P_0) and the driver (P_d) plasmas. The magnetic pressures represented were calculated by considering the total and the relative magnetic field pressures ($P_{mag} = B_z^2/8\pi$ and $P_{rel} = P_{mag} - B_0^2/8\pi$, respectively). The pressures were normalized to the initial ram pressure of the driver ions.

Fig. 9 a) shows the magnetic and kinetic pressures at time $t\omega_{ci} \approx 2.33$ where we observed the magnetopause in Fig. 8 b3). When the driver starts pushing the background, the pressure of the driver at the interface between the plasmas increases because the driver density and ion and electron thermal velocities also increase. During the flow, the driver transfers energy and momentum to the background plasma, and as a result, the background develops a strong kinetic pressure. At the time represented in Fig. 9 a), the background plasma pressure equals the total and the dipolar magnetic pressures in $y \approx -1.4\ d_i$, near the location of the magnetopause current of Fig. 8 b3). This observation supports the hypothesis that this current emerges from the standoff between the background and magnetic pressures. Fig. 9 b) shows the pressures for $t\omega_{ci} = 3$ where we see the beginning of the reflection of the driver. The driver pressure equals the magnetic and dipolar pressures near $y_0 = -L_0 \approx -1.4\ d_i$. After this time, the driver is incapable of moving any further into the background because the magnetic pressure exceeds its kinetic pressure.

The energy variations integrated over the entire simulation domain can also help us understand the system dynamics. Fig. 9 c) shows the variation of the total driver and background kinetic energies, $\Delta W_{kin,d}$ and $\Delta W_{kin,0}$, respectively, as well as the variation of the magnetic energy ΔW_{mag}, and of the total energy ΔW_{tot}. The kinetic energies of the background and driver plasmas consider all ions and electrons. In early times $t\omega_{ci} < 3$, as the driver and background plasmas interact, the driver transfers its energy to the background plasma and the magnetic field. The total energy, given by the sum of the electromagnetic energy and the kinetic energies, remains constant during this period. After the driver is fully reflected by the dipole for $t\omega_{ci} > 3$, the magnetic field loses most of its energy to the background and driver plasmas leading to a drop of the magnetic energy. After $t\omega_{ci} \approx 4$, the background ions start to leave the simulation box, and the total energy is no longer conserved. The background kinetic energy remains approximately constant

because the background plasma loses energy to the sink at the right boundary of the simulation but gains energy from the magnetic field. For both driver and background plasma, the ions carry most of the energy.

From Fig. 9, we can identify the positions where multiple pressure balances occur, and therefore, develop an insight into the pressure equilibria that are behind the structures of the current density synthetic diagnostics. Using the previously calculated pressures, we obtained the equilibrium positions where certain pressure balances manifested and plotted them in Fig. 10 alongside J_x.

This analysis shows that the system has, in general, two magnetopause structures: one driven by the background, and one by the driver plasma. The former structure is defined by the balance $P_0 = P_{rel}$. For the latter structure to form, the driver needs to have almost enough energy to push the diamagnetic current up to the magnetopause, defined by Eq. 1. This is illustrated in Fig. 10, where we show the location of the pressure equilibrium between the driver kinetic pressure and the total magnetic pressure, $P_d = P_{mag}$.

As shown in Fig. 9, the current associated with the background magnetopause seems to overlap with the region of background and magnetic pressure balance. Unlike the driver, the background plasma is magnetized. If we neglect the compression of the magnetic field in the downstream region, the pressure balance that describes this magnetopause can then be estimated by the equilibrium of the kinetic pressure of the background plasma with the relative magnetic pressure, $P_0 = P_{rel}$. In Fig. 10, we show that this pressure balance, represented by the dotted line, describes well the position of the current feature identified as the magnetopause between times $t\omega_{ci} \approx 2$ and $t\omega_{ci} \approx 3$.

After $t\omega_{ci} \approx 3$, the magnetopause current is well described by the pressure balance $P_d = P_{rel}$, as illustrated by the dashed line in Fig. 10. In fact, after inspecting the phase spaces in Figs. 5 a3) and b3), we can observe that a combination of driver plasma particles (separated from the bulk distribution) and background ions pushes the dipolar field and sets the position of the magnetopause.

We stress that, although we are checking the profile intersections with kinetic resolution, we are investigating MHD pressures that should be considered asymptotically, and therefore, some caution must be taken to ensure that we are observing the equilibria between the correct pressures and not merely the location of magnetic and density gradients. To ensure that the pressure equilibria were correctly determined, we always carefully inspected the locations of equilibria with additional diagnostics, such as pressure and density profiles, and phase spaces.

F. Realistic parameters

Due to the need for more extensive scans (and thus using physically equivalent but computationally feasible parameters), the simulations shown so far considered re-

duced ion mass ratios, cold plasmas, and higher velocities than the ones used in the LAPD experiments - see Table II. To ensure that the main results presented in the previous sections are also valid with realistic parameters, we have performed a set of simulations with parameters similar to those expected experimentally.

Three simulations were performed, labeled as runs F1 to F3. Run F1 employs realistic mass ratios $m_{i,d}/m_e = m_{i,0}/m_e = 1836$. Additionally, run F2 also considers a ratio between the electron thermal and flow velocities close to the ones expected for the background plasma of the LAPD experiments, namely $v_{the,y}/v_0 = 2.5$ and $v_{thi,y}/v_0 = 0.033$, leading to higher ion and electron temperatures than in the previous simulations, and thus allowing possible thermal effects on the system. The same ratios are used for the background and the driver. Finally, run F3 considers the same electron thermal velocity ratios of F2 but the standard reduced mass ratios.

The ΔB_z and J_x plots for these simulations are shown in Fig. 11. Note that, due to changes in m_i/m_e, their spatial and temporal scales were recalculated for the new parameters. Once again, the magnetic dipole moment for the three simulations was adjusted to ensure that $L_0 = 1.8\ d_i$.

As expected, these simulations show the same main structures discussed in the previous sections. We observe the typical reflection of the compression of the magnetic field and the current structures of the magnetopause and diamagnetic cavity. However, some differences are also visible. In Figs. 11 a1) and b1), *i.e.* for the realistic mass ratios but cold plasmas simulation, we observe a stronger filamentation of the plasma flow reflected off the dipole and a thinner diamagnetic current. This is because d_e is the characteristic length scale of the current layer and we have lower d_e/d_i values for larger m_i/m_e. Figs. 11 a2) and b2), for the simulation with higher ion and electron temperatures, show no major differences with Figs. 11 a1) and b1), even though there is a significant increase in the thermal velocities.

In Figs. 11 a3) and b3), however, we observe significant differences for reduced mass ratios with realistic thermal velocity ratios. In particular, we observe in the current density plot smoother magnetic and current structures and less defined background waves between the magnetopause and the dipole. This is expected, since the characteristic plasma scales, *e.g.* the ion and electron gyroradii, change with the ion to electron thermal velocities and the mass ratios. We also observed for increased ion thermal velocities, for example, $v_{thi}/v_0 \approx 0.25$, that the background waves are no longer visible.

Additionally, other simulations were performed to look for possible changes with realistic parameters. A simulation with a lower flow velocity $v_0 = 0.01\ c$ and realistic thermal velocity ratios lead to no significant features observed, and the obtained synthetic diagnostics were very similar to the ones in Figs. 11 a3) and b3), meaning that the system scales well with v_0. Another simulation was performed to observe if the shape of the

initial density profiles of the plasmas would affect the main results. Namely, the constant density profiles used on both the driver and background plasmas were replaced by Gaussian density profiles with a typical gradient scale $\sigma = 1\ d_i$ on the edges of the plasmas. This simulation did not show meaningful differences, in agreement with previous plasma coupling works, which observed that the leading edge of the plasmas evolves similarly for different initial density profiles[47].

G. Finite transverse size

For simplicity, and because we were more interested in studying the system along the axis of symmetry $x = 0$, the previous simulations only considered a driver with infinite width L_x and a length of $L_y = 2\ d_i$. In the experiments, however, the drivers had a width comparable to their lengths and did not have the sharp boundaries used in the simulations. To investigate if and how our results are modified with a more complex-shaped driver, we performed a simulation with a finite width, semi-circular-shaped driver plasma. This driver is initially defined with the conditions $(y + 7.25\ d_i)^2 + x^2 < (3.25\ d_i)^2$ and $y > -6\ d_i$ and has length $L_y = 2\ d_i$ and width $L_x = 6\ d_i$. Fig. 12 shows the results of this simulation and includes the initial shape of the driver in Fig. 12 a).

Due to the finite width of the new driver and its particular shape, we should expect to see significant differences in the regions of the simulation plane far from $x = 0$. In the total ion density plot of Fig. 12 a) for a time $t\omega_{ci} = 3$, when there is a strong interaction of the driver with the dipolar magnetic field, we observe the propagation of waves at the lower and upper sides of the dipole caused by the finite width of the driver, that was not present for infinite width drivers.

In Figs. 12 b) and c), we see the usual magnetic and current density plots at $x = 0$ for this simulation. By shortening the driver plasma width, the background particles escape from the bottom and top regions of the simulation box, and the driver has more difficulty holding the magnetic decompression in the background region. The decompression, therefore, occurs quicker for finite drivers, as seen in Fig. 12 b), leading to short reflections of the magnetic compression.

Although this complex-shaped driver gets us closer to the experimental configuration, the simulations did not include all the properties of the experimental driver, as for example, the non-uniform density, velocity profiles of the plasmas and the flow divergence. Additionally, 3D effects should also be considered. Future simulations are planned to study the effect of these properties in the results. However, we expect that these features will not change the main results of the simulations.

IV. DISCUSSION AND CONCLUSIONS

In this work, we have performed PIC simulations of mini-magnetospheres in the interaction between a plasma flow and a magnetized background plasma, in a super-Alfvénic regime. In particular, we have successfully reproduced results from recent experiments performed at the LAPD, validating the experimental platform to study mini-magnetospheres in the laboratory. We have also explored an extensive parameter space defining the interaction, allowing us to i) determine how the main properties of the system change with the parameters and ii) identify the required conditions for the magnetospheric features observed the experiments.

Our simulations have shown that some system features are present across multiple regimes. The initial flow of the driver expels the magnetic field in the upstream region, leading to a magnetic cavity, and compresses the downstream magnetic field. The driver travels through the background until the magnetic field pressure is large enough to counterbalance the driver plasma pressure. A fast decompression of the background magnetic field then follows. If the background decompression occurs after the total reflection of the driver plasma, then we can observe the reflection of the compression of the magnetic field. To see this feature, the driver needs to be short enough to anticipate the driver reflection relative to the decompression but sufficiently long to ensure that it can get close to the dipole.

For the flows considered, the driver particles are reflected upstream during the interaction with the background plasma and the magnetic field. The coupling velocity (*i.e.*, the velocity at which the leading end of the driver travels through the background) is lower than the flow velocity and increases with the increase of the ratio between the driver and background densities. The coupling velocity and the length of the driver determine how far the driver can go through the background region without a dipole, for a uniform driver plasma.

The interaction of the plasmas with the dipole results in two magnetopauses. The first describes the balance between the kinetic pressure of the propelled background plasma plus the pressure of the plasma internal magnetic field and the total magnetic pressure. The seconds describes approximately the balance between the kinetic pressure of the driver plasma separated from the bulk distribution and the relative magnetic pressure. Using simulations with different dipole moments, we have shown that, for lower magnetic moments, the driver and background standoffs are closer to the center of the dipole, and the magnetopause current is more clearly identified than for higher magnetic moments. Furthermore, it is also easier to separate the magnetopause and diamagnetic currents for lower magnetic moments, consistent with experimental observations.

In the simulations performed, we also observed the formation of waves in the background plasma region, between the magnetopause and the center of the dipole, where the magnetic field gradient was significant. These waves result from the excitation that always followed the formation of the magnetopause and were only observed for background plasmas with relative low ion thermal velocities.

Most of the simulations presented in this work were performed in idealized configurations. In particular, we used reduced ion-to-electron mass ratios, unrealistically high flow velocities, a simple flat-top driver density profile, and neglected thermal effects. In Sec. III F and III G, we presented simulations that drop some of these simplifications. Replacing reduced ion mass ratios with realistic ones and considering high thermal velocities ratios close to the obtained in the experiments did not lead to significant changes in the results. The same occurred when considering smoothed density profiles. It was also possible to conclude that the main features of the system scaled as expected with the absolute value of the driver flow velocity. We also presented a simulation to study possible effects associated with the complexity of the experimental laser-ablated driver. A simple circular segment-shaped driver was considered and led to similar results in the axis of symmetry as the infinite width driver simulations. However, wave-like structures were observed on both the bottom and upper sides of the dipole. For future studies on the regions outside the axis of symmetry, the driver shape and complexity must be considered.

Additionally, we also performed other parameter scans related to the complexity of the driver. For instance, we performed simulations where the driver ions were heavier than the background ions to simulate the small role of the carbon ions in the experimental driver. These studies showed no significant differences to the lighter ions simulations.

In conclusion, the simulations were consistent with the LAPD experimental results, and the multiple parameter scans performed dictated the formation conditions of the main features of mini-magnetospheres. For future works, we intend to exploit the features present in the sides of the dipole, exploit anti-parallel magnetic field configurations, perform 3D simulations, and consider even more realistic properties of the driver.

plots/pressures_and_energy.pdf

FIG. 9. Pressures profiles calculated for simulation E3 with a magnetic moment $M = M_0/2$ (shown in Fig. 8 3)), during the occurrence of a) the magnetopause and b) the standoff of the diamagnetic current. The magnetic pressures are $P_{\mathrm{mag}} = B_z^2/8\pi$ and $P_{\mathrm{rel}} = P_{\mathrm{mag}} - B_0^2/8\pi$. The kinetic pressures P_{d} and P_0, corresponding to the driver and background plasmas, respectively, consider both the ions and electrons and the flow and thermal components of the velocity. c) Temporal evolution of the variation of the total kinetic energies of the driver $\Delta W_{\mathrm{kin,d}}$ and background $\Delta W_{\mathrm{kin,0}}$ plasmas, the magnetic energy ΔW_{mag}, and the total energy of the simulation box ΔW_{tot}. The total energy is calculated by adding all the kinetic energies and the electric and magnetic energies. Since the background plasma is magnetized, the electric energy term is many orders of magnitude smaller than the magnetic energy term. The energies were normalized to the initial total energy of the driver ions $W_{\mathrm{d,ini}}$. The loss of energy conservation near $t\omega_{ci} \approx 4$ is caused by the escape of background plasma particles and magnetic field through the right hand side of the simulation box.
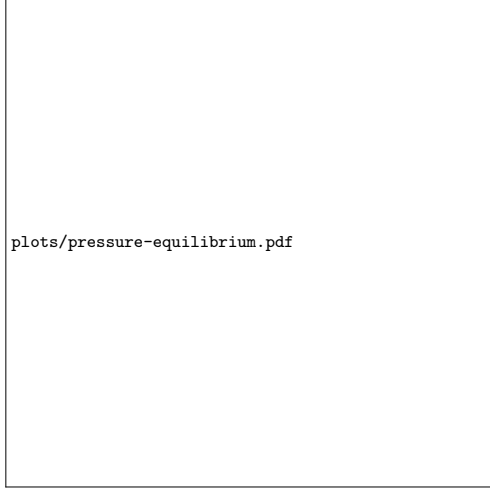

FIG. 10.   Temporal evolution of the current density J_x at $x = 0$, with the closest locations to the dipole of different pressure balances for multiple times. The represented locations of pressure balances are the equilibria between the driver kinetic pressure P_d with the total magnetic field pressure $P_\mathrm{mag} = B_z^2/8\pi$, represented by the solid line; the background kinetic pressure P_0 with the pressure exerted by the relative magnetic field $P_\mathrm{rel} = P_\mathrm{mag} - B_0^2/8\pi$, by the dotted line, and $P_\mathrm{d} = P_\mathrm{rel}$, by the dashed line. The results correspond to simulation E3 (see Table I).

plots/realistic.pdf

FIG. 11.   Temporal evolution of a) the variation of the magnetic field ΔB_z and b) the current density J_x at $x = 0$, for the simulations with similar parameters to the experiments. Run F1 considers realistic mass ratios for the driver and background plasmas and low ratios between the thermal and flow velocities; run F2 uses realistic mass ratios and ion and electron thermal velocity ratios close to the ones expected in the experiments; run F3 uses the realistic thermal velocity ratios but reduced mass ratios.
