SUMMARY

New techniques for improving both the computational and imaging performance of the three-dimensional (3D) electromagnetic inverse problem are presented. A non-linear conjugate gradient algorithm is the framework of the inversion scheme. Full wave equation modelling for controlled sources is utilized for data simulation along with an efficient gradient computation approach for the model update. Improving the modelling efficiency of the 3D finite difference method involves the separation of the potentially large modelling mesh, defining the set of model parameters, from the computational finite difference meshes used for field simulation. Grid spacings and thus overall grid sizes can be reduced and optimized according to source frequencies and source-receiver offsets of a given input data set. Further computational efficiency is obtained by combining different levels of parallelization. While the parallel scheme allows for an arbitrarily large number of parallel tasks, the relative amount of message passing is kept constant. Image enhancement is achieved by model parameter transformation functions, which enforce bounded conductivity parameters and thus prevent parameter overshoots. Further, a remedy for treating distorted data within the inversion process is presented. Data distortions simulated here include positioning errors and a highly conductive overburden, hiding the desired target signal. The methods are demonstrated using both synthetic and field data.

1 **1 INTRODUCTION**

2 Controlled source electromagnetic (CSEM) techniques use the electromagnetic energy of an ar-
3 tificial transmitter for detecting contrasts in the subsurface electrical conductivity. The bulk con-
4 ductivity of rocks is dominated by the content of pore fluids, owing to the typically strong contrast
5 between the highly resistive minerals and nonmineral substances, such as water, brine, or hydro-
6 carbons. Even pore fluid substances can exhibit conductivity contrasts which are easily detectable
7 by CSEM methods. While saline formation water has a typical resistivity range between 0.5 and
8 $2 \Omega \cdot \text{m}$, the resistivity of hydrocarbon filled rocks can be up to two orders of magnitude larger
9 (Schlumberger 1987). This has recently made the marine CSEM technique emerge with consider-
10 able potential of providing valuable complementary data to seismic hydrocarbon mapping. Seismic
11 methods have a long and established history in hydrocarbon exploration, because they are proven
12 to be very effective in mapping geological horizons with contrasting acoustic properties. CSEM
13 methods, on the other hand, may delineate the different types of fluids within the horizon. With the
14 marine CSEM method, a deep-towed electric bipole transmitter is used to excite a low-frequency
15 (typically 0.1 to 10 Hz) electromagnetic signal that is measured on the sea floor over electric and
16 magnetic field detectors, where larger transmitter-detector offsets can exceed 15 km (MacGregor
17 & Sinha 2000; Eidesmo et al. 2002; Ellingsrud et al. 2002). With the current technology, typical
18 depths of investigation range from 1 to 4 km for offshore prospects. This results in a tradeoff;
19 achievement of greater depths of penetration is accompanied by a loss of resolution.

20 Large-scale CSEM three-dimensional (3D) geophysical imaging is now receiving consider-
21 able attention (Carazzone et al. 2005). While one-dimensional (1D) modelling is relatively easy
22 and trial and error 3D forward modelling straight forward (Weiss & Constable 2006), the need for
23 3D imaging is necessary as the search for hydrocarbons now increasingly occurs in highly com-
24 plex and subtle offshore geological environments. This also further emphasizes the importance of
25 combining the information obtained by CSEM surveys with existing 3D seismic depth migration
26 technologies (Hoversten et al. 2000). Faster 2D CSEM imaging has some relevance to this prob-
27 lem. However, because of its assumption of 2D geology, it cannot always be relied upon for a

1 consistent treatment of the real environment, especially when measurements are made on survey
2 grids specifically designed for 3D imaging experiments (Carazzone et al. 2005).

3 In this study, we present techniques which further advance the 3D CSEM inversion tech-
4 nique. Its inherently high computational requirements are a main obstacle to industrial applica-
5 tions. Whether finite volume, finite element, or finite difference techniques are used for simulating
6 measurements in three dimensions, the modelling grids designed for approximating complex ge-
7 ology on a large scale usually become too computationally expensive for carrying out fast forward
8 simulations. On the other hand, industrial large-scale 3D surveys with vast data volumes require
9 both large modelling grids as well as many forward simulations; each CSEM transmitter loca-
10 tion requires a separate forward calculation for simulating its response. To mitigate this problem,
11 we present a method where the computational simulation grids are decoupled from an underlying
12 common modelling grid. The latter represents the conductivity variation within the survey area. A
13 simulation grid can then be adapted and thus optimized specifically to the geometries and offsets
14 of a given transmitter and its detectors.

15 Since CSEM inversion is an ill-posed problem, implementation of constraints is important in
16 reducing the solution ambiguity. We present new types of constraints, realized by model parameter
17 transformation functions, to address this issue. Thereby, the electrical conductivity updates during
18 the inversion process are restricted such that non-realistic results are suppressed.

19 A further technique outlined in this paper aims at efficiently using computing resources for
20 the case of very large data sets. It is realized by the combination of two different levels of paral-
21 lelization. On the first level, the solution of the forward simulation problem is distributed among a
22 bank of processors. This solution parallelization scales linearly up to a point where the necessary
23 message passing required for completing matrix-vector multiplications in the iterative solution
24 becomes dominant. To maintain the ability to use an arbitrarily large number of processors with-
25 out a prohibitive message passing overhead, the solution of multiple forward problems is further
26 distributed among groups of processor banks.

27 Furthermore, we have experimented with the source signature estimation applied to the CSEM
28 inversion problem. While the source signature estimation problem is common in seismic waveform

1 inversion, it also promises to alleviate data distortions in both amplitude and phase which might
 2 otherwise have negative effects on CSEM inverse modelling.

3 After introducing the theory for both the CSEM inverse and forward problem, the grid separa-
 4 tion technique is outlined. Key to this approach is a proper material averaging scheme to map
 5 the conductivity parameters of the geological model to the computational grids used for the field
 6 solution in the forward problem. Consequently, the inverse problem requires an inverse mapping
 7 scheme to update the model parameters from the field solutions obtained on the computational sim-
 8 ulation grids. We have made experience with the material averaging scheme used in this study. In
 9 an earlier work (Commer & Newman 2005), we applied multi-grid concepts to a finite-difference
 10 time-domain modelling scheme. This involved the averaging of material properties on a sequence
 11 of coarser simulation grids.

12 We next present various marine CSEM imaging scenarios using synthetic data to demonstrate
 13 the highly improved efficiency achieved by optimizing the simulation grids. This also includes
 14 inversion examples where the source signature estimation problem is solved within the inversion
 15 framework in order to correct for highly distorted data. At last, the inversion of real field data is
 16 presented, where the grid separation method is also further demonstrated. We use a data set of the
 17 Troll West Gas Province, located offshore Norway (Gray 1987). These measurements have been
 18 used for calibration purposes and modelling studies, since the data is known to contain strong
 19 signals caused by a large hydrocarbon reservoir (Johansen et al. 2005; Hoversten et al. 2006).

20 **2 PROBLEM FORMULATION**

21 We give a brief introduction of both the inverse and forward simulation problem. This shall provide
 22 the necessary framework for the later outlined concept of separating the model parameter grid from
 23 the computational simulation grids. A more detailed formulation of the EM inverse problem can
 24 be found in the works of Newman & Alumbaugh (1997; 2000) and Newman & Hoversten (2000).

25 The inverse problem is formulated by the minimization of the error functional,

$$26 \Phi = \frac{1}{2}[\mathbf{D}(\mathbf{d}^o - \mathbf{d}^p)^{T*} \mathbf{D}(\mathbf{d}^o - \mathbf{d}^p) + \frac{1}{2}\lambda(\mathbf{W}\mathbf{m})^{T*}(\mathbf{W}\mathbf{m})], \quad (1)$$

1 where T^* denotes the transpose-conjugation operator. In the above expression, the predicted and
 2 observed data vectors are denoted by \mathbf{d}^p and \mathbf{d}^o , respectively, where each has N_d complex values.
 3 These vectors consist of electric or magnetic field values specified at the measurement points.
 4 The predicted data are determined through solution of the forward modelling problem, discussed
 5 below. We have also introduced a diagonal weighting matrix, $\mathbf{D}_{N_d \times N_d}$, into the error functional to
 6 compensate for noisy measurements; it is typically based on the inverse of the standard deviations
 7 of the measurements.

8 In eq. (1), the properties of the model space are given by the vector \mathbf{m} . In our finite difference
 9 (FD) formulation, the model space consists of a 3D mesh of rectangular cells, where the inversion
 10 domain can be represented by the whole model space or a subset of it. Each cell has electrical con-
 11 ductivities, dielectric and magnetic permeability properties assigned to it. Here, we only consider
 12 varying electrical conductivities σ as unknowns in the inverse problem.

13 To stabilize the minimization of equation (1), we are required to add a regularization term,
 14 acting on the parameter unknowns. Many choices are available. In our past work we have focused
 15 on a class of conductivity models using Tikhonov regularization that exhibit smoothly varying
 16 properties. Thus we introduce a matrix \mathbf{W} , based upon a FD approximation to the Laplacian (∇^2)
 17 operator applied in Cartesian coordinates, to reduce model curvature in three dimensions. The
 18 influence of the smoothing constraint is controlled by the parameter λ . A common recipe for its
 19 selection is based upon a cooling approach (Haber & Oldenburg 1997). One carries out multiple
 20 solutions to the inverse problem starting with a large fixed value for λ . As λ is reduced, the data
 21 error, represented by the first term in equation (1), will decrease. The process of reducing λ can
 22 then be repeated until the data error agrees with a target misfit based upon the assumed noise
 23 content of the data.

24 **2.1 Non-Linear conjugate gradient minimization**

25 In large-scale nonlinear problems, as considered here, we shall minimize (1) using gradient based
 26 optimization techniques because of their minimal storage and computational requirements. We
 27 characterize these methods as gradient based techniques because they employ only first deriva-

1 tive information of the error functional in the minimization process. Gradient based methods in-
 2 clude steepest descent, nonlinear conjugate gradient (NLCG) and limited memory quasi-Newton
 3 schemes. Newman and Boggs (2004) provide detail derivation of the gradients and an efficient
 4 scheme for their computation. Here, the focus is on a NLCG minimization approach because our
 5 past experiences have shown it to be the most efficient. The preconditioned NLCG algorithm we
 6 use in the minimization of eq.(1) is written as follows:

7 NLCG Algorithm

- 8 (1) set $i=1$, choose initial model \mathbf{m}_i and compute $\mathbf{r}_i = -\nabla\Phi(\mathbf{m}_i)$
- 9 (2) set $\mathbf{u}_i = \mathbf{M}_i^{-1}\mathbf{r}_i$
- 10 (3) perform line search to find α_i that minimizes $\Phi(\mathbf{m}_i + \alpha_i\mathbf{u}_i)$
- 11 (4) set $\mathbf{m}_{i+1} = \mathbf{m}_i + \alpha_i\mathbf{u}_i$ and compute $\mathbf{r}_{i+1} = -\nabla\Phi(\mathbf{m}_{i+1})$
- 12 (5) stop when $|\mathbf{r}_{i+1}| < \epsilon$, otherwise go to step 6
- 13 (6) set $\beta_{i+1} = (\mathbf{r}_{i+1}^T\mathbf{M}_{i+1}^{-1}\mathbf{r}_{i+1} - \mathbf{r}_i^T\mathbf{M}_i^{-1}\mathbf{r}_i)/\mathbf{r}_i^T\mathbf{M}_i^{-1}\mathbf{r}_i$
- 14 (7) set $\mathbf{u}_{i+1} = \mathbf{M}_{i+1}^{-1}\mathbf{r}_{i+1} + \beta_{i+1}\mathbf{u}_i$
- 15 (8) set $i=i+1$ and go to step 3

16 The matrix operator \mathbf{M}_{i-1} in the algorithm is a preconditioner, which steers and scales the
 17 conjugate search direction \mathbf{u}_i such that it more closely approximates the Newton direction. A prop-
 18 erly chosen preconditioner has a tremendous impact in accelerating the algorithm's convergence
 19 (Newman & Boggs 2004), however at a higher computational expense. To use the NLCG algo-
 20 rithm sensibly also requires efficient computation of the gradient \mathbf{r} . Sometimes, implementations
 21 of NLCG include a very accurate line search to ensure conjugacy. However, for the 3D problems
 22 this is not practical because the evaluation of the error functional is very expensive. Moreover, con-
 23 jugacy has little meaning in the nonlinear and nonquadratic context. Instead, we have developed
 24 a procedure that gives an acceptable decrease of the functional with a minimal number of evalu-
 25 ations. Newman and Alumbaugh (2000) discuss the issue and show that it is possible to achieve
 26 acceptable decreases in the error functional using a line search based upon quadratic interpolation,
 27 safeguarded with back tracking. Usually, an additional forward modelling application per source,

1 defined by a transmitter operating at a specific frequency, is all that is needed for the line search.
 2 This yields three forward modelling applications per source and per inversion iteration.

3 **2.2 The forward problem**

4 Minimization of eq. (1) involves the error functional gradient $\nabla\Phi$, i.e. the derivative of Φ with
 5 respect to the model parameters in the vector \mathbf{m} . The data part of Φ and the predicted data \mathbf{d}^p
 6 are linked directly through the forward problem. It is described by the time harmonic Maxwell
 7 equations in the diffusive approximation,

$$\sigma\mathbf{E} - \nabla\mathbf{H} = -\mathbf{J} \quad (2)$$

$$\nabla\mathbf{E} + i\omega\mu_0\mathbf{H} = -\mathbf{M}, \quad (3)$$

8 where a time dependence of $e^{i\omega t}$ is assumed ($i = \sqrt{-1}$). For CSEM applications, the typical range
 9 of the angular frequency ω allows us to neglect displacement currents.

10 Applied currents generate the electric and magnetic fields, \mathbf{E} and \mathbf{H} , and are denoted by \mathbf{J}
 11 and \mathbf{M} for electric and magnetic sources, respectively. The Earth's electrical conductivity σ is a
 12 function of position that is allowed to vary in three dimensions. On the other hand, we set the
 13 magnetic permeability μ to its free space value μ_0 . Variations in the magnetic permeability are
 14 rare, and are usually confined to magnetic ores and some volcanic soils.

15 Our solution method for the forward modelling problem is based upon the consideration that
 16 the number of model parameters, required to simulate realistic 3D geology, can typically exceed
 17 10^7 . Finite difference modelling schemes are ideally suited for this task, because they can be
 18 parallelized to handle large-scale problems that cannot be easily treated otherwise (Alumbaugh et
 19 al. 1996). After approximating the Maxwell equations on a staggered grid (Yee 1966) at a specific
 20 angular frequency, using finite differencing and eliminating the magnetic field (Alumbaugh et al.
 21 1996), we obtain a linear system for the electric field,

$$22 \mathbf{KE} = \mathbf{S} \quad (4)$$

23 where \mathbf{K} is a sparse complex symmetric matrix with 13 non-zero entries per row. The dimension
 24 of \mathbf{K} is $N_e \times N_e$, where N_e is the FD grid's total number of edges. Its diagonal entries depend

explicitly on the electrical conductivity, σ . The conductivity distribution throughout the model space is to be estimated by the inversion process. Since the electric field, \mathbf{E} , also depends upon the conductivity, implicitly, this gives rise to the nonlinearity of the inverse problem. The fields are sourced with a grounded wire or loop embedded within the modelling domain. The corresponding discrete source vector \mathbf{S} includes Dirichlet boundary conditions imposed upon the problem. To avoid excessive meshing near the source, we favor a scattered-field formulation to the forward problem. In this instance, \mathbf{E} is replaced with \mathbf{E}_s in eq. (4). The source term, for a given transmitter, will now depend upon the difference between the 3D conductivity model and a simple background model, weighted by the background electric field, \mathbf{E}_b , where $\mathbf{E} = \mathbf{E}_b + \mathbf{E}_s$. We favor simple background models, such as whole space or layered half-space models that can be easily and rapidly simulated. Given the solution of the electric field in eq. (4), the magnetic field can be easily determined from a numerical implementation of Faraday's law,

$$\mathbf{H} = \frac{1}{-i\omega\mu_0} \nabla \times \mathbf{E}. \quad (5)$$

For realistic earth imaging, involving a large amount of data and hence many sources, a large number of solutions to eq. (4) follows. Consequently, an efficient solution process is paramount. We solve the forward problem to a predetermined error level using iterative Krylov subspace methods, using either a biconjugate gradient (BICG) or quasi-minimum residual (QMR) scheme with preconditioning (Alumbaugh et al. 1996). In general we employ the QMR method with a Jacobi preconditioner for marine CSEM type problems. More elaborate preconditioners have been tested and shown to be not that effective for this problem. These include simple Neumann and Least Squares polynomials, incomplete Cholesky factorization, and algebraic multi-grid (AMG) (Newman et al., 2004). The AMG scheme is most elaborate of the preconditioners tested, and attempts to preserve the null space of the Maxwell operator through properly designed grid transfer operators. While this scheme can produce very fast solutions to the forward problem, it is also highly unstable and unreliable for use within a non-linear inversion framework.

3 OPTIMIZATION OF THE SIMULATION MESH

We assign a conductivity parameter, σ_k , $k = 1, \dots, M$, to each cell of the model domain, where M equals the total number of model cells. In the following, the model grid is denoted by Ω_M . The subset $\Omega_m \subseteq \Omega_M$ shall represent the inversion domain, with m model unknowns. The parameter σ_k is real valued and collectively stored in the model vector $\mathbf{m} = \Sigma_M$, which is piecewise constant. Further, the finite-difference simulation grid Ω_S of size N_c , where N_c equals the number of FD mesh cells, is introduced. Both grids are Cartesian with conformal grid axes along the x , y , and z -directions. Usually, one has $\Omega_M = \Omega_S$ ($M = N_c$).

The solution of the forward problem requires a conductivity mapping from Ω_M to Ω_S , i.e. the computation of an effective conductivity on the edges of the FD mesh, where the electric fields \mathbf{E} are sampled. For a given 3D mesh Ω_S we define the vector of directional edge conductivities,

$$\Sigma_S = (\sigma_1^x, \sigma_1^y, \sigma_1^z, \dots, \sigma_{i_c}^x, \sigma_{i_c}^y, \sigma_{i_c}^z, \dots, \sigma_{N_c}^x, \sigma_{N_c}^y, \sigma_{N_c}^z)^T = (\sigma_1^e, \dots, \sigma_{i_e}^e, \dots, \sigma_{N_e}^e)^T,$$

for building the $N_e \times N_e$ FD stiffness matrix \mathbf{K} of the linear system (4). Note that N_c and N_e denote the total number of grid cells and edges, respectively, belonging to the grid Ω_S . To compute the edge conductivities, we introduce a linear mapping operator $\mathcal{M}_{N_e \times M}$,

$$\mathcal{M}(\Sigma_M) = \Sigma_S, \quad (\mathcal{M} : \Omega_M \rightarrow \Omega_S).$$

Consider a given edge i_e , belonging to the cell i_c of the FD mesh Ω_S , for the example of an edge along the x -axis. In the case $\Omega_M = \Omega_S$, the corresponding element of Σ_S is computed from

$$\sigma_{i_e}^e = \sigma_{i_c}^x = \sum_{i=1}^4 \sigma_i w_i, \quad w_i = \frac{dV_i}{\sum_{j=1}^4 dV_j}, \quad (6)$$

where w_i are weights determined by volume fractions. Fig. 1a shows that the four cell conductivities σ_i are given by the four model cells connected by the edge where $\sigma_{i_c}^x$ (red arrow) is sampled. These four adjoining cells describe a parallel circuit. Hence, each line of the matrix operator $\mathcal{M}_{N_e \times M}$ represents an arithmetic average of the form as in eq. 6. For the equal-grid case, its corresponding edge i_e thus has four non-zero entries $w_i = \frac{1}{4}$.

In the case $\Omega_M \neq \Omega_S$, we employ a material averaging scheme based on an integro-interpolation method mentioned by Moskow et al. (1999). In principle, the method allows to compute edge conductivities on the grid Ω_S from a series of parallel circuits on Ω_M . Moreover, there may exist an

1 arbitrary translation, assuming conformal grid axes, between Ω_M and Ω_S . It can be seen that the
 2 example of eq. (6) represents a special case of the more general formulation

$$3 \sigma_{i_e}^e = \sigma_{i_c}^x = \left[\sum_{j=1}^J \left(\frac{1}{V_j} \sum_{i=1}^{I_j} \sigma_i dV_i \right)^{-1} \Delta x_j \right]^{-1} \Delta X_{i_c}, \quad (7)$$

4 where

- 5 • ΔX_{i_c} =length of the edge i_e (here along the x-axis),
- 6 • J =number of discrete parallel circuits P_j along ΔX_{i_c} ,
- 7 • V_j =total volume of a discrete parallel circuit P_j ,
- 8 • I_j =number of model mesh cells included in the volume V_j or overlapped by V_j ,
- 9 • dV_i =volume fraction of σ_i contributing to a parallel circuit P_j , ($\sum_{i=1}^{I_j} dV_i = V_j$).
- 10 • Δx_j =segment length of the parallel circuit P_j (here along the x-axis), ($\sum_{j=1}^J \Delta x_j = \Delta X_{i_c}$).

11 In eq. (7), the inner arithmetic average produces the effective conductivity owing to a parallel
 12 circuit of the conductors σ_i . Further, the outer sum represents a serial integration of the parallel
 13 circuits along the total edge length ΔX_{i_c} . The averaging scheme is best illustrated in two dimen-
 14 sions. In Fig. 1b, Ω_M and Ω_S are indicated by the black and red grid lines, respectively. For this
 15 case one has $J = 4$, $I_j = 2$ for all j , and the dependencies of P_j on the overlapped cells of Ω_M
 16 are: $P_1(\sigma_1, \sigma_4), P_2(\sigma_2, \sigma_4), P_3(\sigma_3, \sigma_4), P_4(\sigma_3, \sigma_5)$. The volumes dV_i are given by the overlap of the
 17 integration area assigned to the edge $\sigma_{i_c}^x$ (shown in pink) with the volume of the model cell σ_i .
 18 Obviously, to obtain $\sigma_{i_c}^y$ and $\sigma_{i_c}^z$ for the 3D case, this serial/parallel circuit integration is carried out
 19 along the y and z edges of the simulation grid cell i_c , respectively.

20 Since the inversion unknowns σ_k belong to Ω_m , a mapping from Ω_S to Ω_M is required for
 21 computation of the gradient vector \mathbf{r} in the NLCG algorithm. Consider the data component, $\nabla \Phi_d$,
 22 of the gradient, that is the term $-\nabla \Phi(\mathbf{m})$ involving only the first term of the right-hand side of
 23 eq. (1),

$$24 \nabla \Phi_d = -\text{Re} \left(\{\mathbf{D}\mathbf{J}\}^T \{\mathbf{D}(\mathbf{d}^o - \mathbf{d}^p)\}^* \right).$$

25 Computing $\nabla \Phi_d$ implicitly requires the Jacobian, \mathbf{J} . Note, however, that we never form \mathbf{J} explic-
 26 itly. Its elements are

$$J_{jk} = \frac{\partial d_j^p}{\partial \sigma_k}, \quad j = 1, \dots, N_d; \quad k = 1, \dots, M,$$

In terms of the electric field, a Jacobian element is defined by

$$J_{jk} = \mathbf{q}_j^T \frac{\partial \mathbf{E}}{\partial \sigma_k},$$

where \mathbf{q}_j is the j th column vector of a $N_d \times N_e$ ($N_d = \text{size of } \mathbf{d}^\circ$) interpolation operator, which maps the electric field solution \mathbf{E} from Ω_S onto the N_d detector locations defined on Ω_M . The data sensitivities $\frac{\partial \mathbf{E}}{\partial \sigma_k}$ follow from differentiating eq. (4) with respect to the model unknowns σ_k (Newman & Hoversten 2000),

$$\frac{\partial \mathbf{E}}{\partial \sigma_k} = \mathbf{K}^{-1} \left(\frac{\partial \mathbf{S}}{\partial \sigma_k} - \frac{\partial \mathbf{K}}{\partial \sigma_k} \mathbf{E} \right). \quad (8)$$

Note that the term $\frac{\partial \mathbf{S}}{\partial \sigma_k}$ is non-zero/zero for a scattered/total field solution. The data sensitivity for the k th model parameter has non-zero entries for these edges i_e that have a contribution from σ_k through the average (7). In the case $\Omega_M = \Omega_S$, this amounts to 12 edge contributions, arising from the edges that define the boundaries of the model cell σ_k . In other words, as illustrated by the additional arrows in Fig. 1a, there are four edge conductivities for each Cartesian direction, which depend on σ_k through their corresponding average exemplified by eq. (6). In the general case, we denote the number of edge contributions by $N_e(k)$. Then it follows from the chain rule

$$\frac{\partial \mathbf{K}}{\partial \sigma_k} = \sum_{n=1}^{N_e(k)} \frac{\partial \mathbf{K}}{\partial \sigma_n^e} \frac{\partial \sigma_n^e}{\partial \sigma_k}, \quad (9)$$

and a similar expression for $\frac{\partial \mathbf{S}}{\partial \sigma_k}$. The inner derivatives, $\frac{\partial \sigma_n^e}{\partial \sigma_k}$, of (9) are obtained from the derivative of eq. (7),

$$\frac{\partial \sigma_n^e}{\partial \sigma_k} = \frac{\sigma_n^e{}^2}{\Delta X_{i_c}} \sum_{j'=1}^{J'} \Delta x_{j'} \left(\frac{1}{V_{j'}} \sum_{i=1}^{I_{j'}} \sigma_i dV_i \right)^{-2} \frac{dV_k}{V_{j'}}. \quad (10)$$

Here, $J' \leq J$ is the number of segments (parallel circuits $P_{j'}$) with a non-zero contribution from σ_k . For $\Omega_M = \Omega_S$, one has $J' = 1$, $\Delta x_{j'} = \Delta X_{i_c}$, and hence $\frac{\partial \sigma_n^e}{\partial \sigma_k} = w_k$, which are the corresponding weighting coefficients of the simple average (eq. 6). The general case is again illustrated in two dimensions in Fig. 1b. For this example, the model cell σ_4 (yellow rectangle) shall also correspond to the fourth model unknown ($k = 4$). Then eq. (10) becomes

$$\frac{\partial \sigma_{i_c}^x}{\partial \sigma_4} = \frac{\sigma_{i_c}^x{}^2}{\Delta X_{i_c}} \sum_{j'=1}^3 \Delta x_{j'} \left(\frac{1}{V_{j'}} \sum_{i=1}^2 \sigma_i dV_i \right)^{-2} \frac{dV_4}{V_{j'}}.$$

1 Here, $J' = 3$, because σ_4 contributes to the three parallel circuits $P_1(\sigma_1, \sigma_4), P_2(\sigma_2, \sigma_4), P_3(\sigma_3, \sigma_4)$.

2

3 **4 IMPLEMENTATION OF CONSTRAINTS**

4 Implementation of constraints is helpful in reducing solution ambiguity in the imaging process and
 5 avoiding nonphysical conductivity estimates, i.e. negative or unrealistically high conductivity esti-
 6 mates. Here, we consider box constraints to restrict the electrical conductivity within the imaging
 7 volume to be bounded. Specifically, one requires

$$8 \quad a_k < m_k < b_k,$$

9 for the k th model parameter. Two schemes have been implemented in the NLCG inversion itera-
 10 tion to enforce the box constraints. An active set method requires the model update to be strictly
 11 feasible. When components of the current model are on the bounds, the method checks the steepest
 12 descent direction to determine if the corresponding components of the pending model update will
 13 be no longer feasible. If this is the case, we deflate to zero those corresponding components in the
 14 search direction that will be used in the line search process to update the model. Hence, there will
 15 be no changes in these model components on the bounds during and after the update. On the other
 16 hand, if during the line search, a trial step shows that a bound would be violated, backtracking
 17 along the deflated search direction keeps the updated model strictly feasible. Implementation of
 18 an active set scheme to enforce bound constraints is straight forward, but may cause convergence
 19 degradation of the NLCG algorithm.

20 An alternative involves usage of transformation functions that map the bounded conductiv-
 21 ity parameters to an unbounded domain in the transform space. Our inversion scheme allows to
 22 choose between two such transformations. The first is an inverse hyperbolic tangent transforma-
 23 tion and the second is based on log parameters. In effect, both schemes transform a constrained in-
 24 verse problem to an unconstrained type. Similar types of transformations within multi-dimensional
 25 frequency- and time-domain inversion frameworks, based on logarithmic parameters, have been

1 quite effective in insuring that the electrical conductivity is strictly positive (Newman & Alum-
2 baugh 2000; Commer et al. 2006).

3 Details of the transform method for enforcing upper and lower bounding constraints are as
4 follows. Consider the first transformation where

$$5 \quad m_k = \left(\frac{b_k - a_k}{2} \right) \tanh(x_k) + \left(\frac{b_k + a_k}{2} \right); \quad -\infty < x_k < \infty. \quad (11)$$

6 Here, x_k is the representation of the model component in the transform space, and $m_k = \sigma_k$.

7 Further, the transformed parameter is related to the original model parameter by the expression

$$8 \quad x_k = \tanh^{-1} \left(\frac{2m_k - b_k - a_k}{b_k - a_k} \right); \quad a_k < m_k < b_k. \quad (12)$$

9 Differentiating eq. (11) with respect to x_k , utilizing eq. (12), yields

$$10 \quad \frac{\partial m_k}{\partial x_k} = \left(\frac{b_k - a_k}{2} \right) \operatorname{sech}^2 \left[\tanh^{-1} \left(\frac{2m_k - b_k - a_k}{b_k - a_k} \right) \right]. \quad (13)$$

11 The hyperbolic secant function in eq. (13) is always positive and bounded and when squared is
12 similar to a normal Gaussian distribution. It achieves its maximum value of $(b_k - a_k)/2$ when

$$13 \quad m_k = (b_k + a_k)/2.$$

14 For the second option of logarithmic parameters one has for the equivalent of eqs (11)-(13)

$$15 \quad m_k = \frac{a_k + b_k \exp(x_k)}{1 + \exp(x_k)}; \quad -\infty < x_k < \infty. \quad (14)$$

$$16 \quad x_k = \log(m_k - a_k) - \log(b_k - m_k); \quad a_k < m_k < b_k. \quad (15)$$

$$17 \quad \frac{\partial m_k}{\partial x_k} = \frac{(b_k - a_k) \exp(x)}{(1 + \exp(x_k))^2} \quad (16)$$

18 Using eq. (13) or (16), it is a simple matter to recast the cost functional gradient in terms of
19 the transformed variable, where component wise we have

$$20 \quad \frac{\partial \Phi}{\partial x_k} = \frac{\partial \Phi}{\partial m_k} \frac{\partial m_k}{\partial x_k} \quad (17)$$

21 Another advantage of this type of transformation is that it may produce sharper image rendering if
22 tight bounds are selected from a priori information, as will be demonstrated in a synthetic example
23 below. However, if the bounds are too restrictive, then it is possible that unacceptable data fits will
24 result. With the transformed expression for the gradient in eq. (17), one can apply the NLCG al-
25 gorithm directly to the transformed problem, which implicitly enforces the bound constraints. It is

1 also understood that the regularization operator now applies directly to the transformed unknowns,
 2 x_k ($k = 1, \dots, m$), in the minimization procedure.

3 **5 EXPLOITATION OF SOLUTION PARALLELISM**

4 In a real industrial-sized data application, up to hundreds of transmitters might have to be em-
 5 ployed, in order to image the subsurface at a sufficient level of spatial resolution and detail for
 6 mapping reservoirs (Carazzone et al. 2005). This can lead to tens of thousands of solutions to the
 7 forward modelling problem for a single imaging experiment. Hence, the computational demands
 8 for solving the 3D inverse problem are enormous and non-trivial. To cope with this problem, our
 9 algorithm utilizes two levels of parallelization, one over the modelling domain, and the other over
 10 the data volume. All processor communication is carried out using the Message Passing Inter-
 11 face (MPI) software library. In solving the forward problem on a distributed environment, we first
 12 split up the FD modelling domain, not the matrix, into a Cartesian topology. The details of this
 13 scheme are outlined by Alumbaugh & Newman (1996). Thus a forward modelling problem is
 14 solved amongst a number of $N_{xyz} = n_x \times n_y \times n_z$ processors. As the linear system is relaxed,
 15 which involves matrix-vector products on each of the N_{xyz} processors, values of the solution vector
 16 at the current Krylov iteration, that are not stored on the processor, must be passed by neighboring
 17 processors to complete the product. In addition to this message passing between neighboring pro-
 18 cessors, several global communications are carried out to complete the dot products needed for the
 19 Krylov relaxation iterations. The solution time's rate of decrease using this kind of parallelization
 20 flattens with increasing N_{xyz} , since the overhead due to message passing becomes more and more
 21 dominating.

22 To avoid a message passing overhead, a second level of parallelization is realized by distribut-
 23 ing the data, i.e. the transmitters of a data set, over groups of processors. With a number N_{data} of
 24 such processor or data groups, one has thus a total number of tasks $N_{total} = N_{xyz} \times N_{data}$. This
 25 allows to keep a balanced ratio between N_{xyz} and the size of the forward problem, which is dic-
 26 tated by the size of its corresponding FD mesh Ω_S . At the same time, an arbitrarily large number
 27 of CPUs can be employed, as the number of data groups, N_{data} , can be increased linearly with the

1 total number of transmitters employed in the imaging experiment. One is interested in achieving
 2 maximum load balancing among the processor groups assigned to each data group, because global
 3 communication to compute dot products needs to be done several times per inversion iteration.
 4 Consider a group of transmitters where source-receiver configurations and source excitation fre-
 5 quency vary for each transmitter. Optimized FD meshes within the group may vary considerably
 6 in size. To keep the workload balanced, we keep N_{xyz} constant for each data group and distribute
 7 the transmitters among the data groups such that each group has a similar workload in terms of
 8 grid sizes.

9 This data decomposition is highly parallel. The main computational burden occurs with the
 10 forward FD solves. We have achieved nearly perfect scaling with this scheme. Provided sufficient
 11 computational capacity, it allows for realistic data sizes and 3D imaging volumes to be analyzed
 12 on time scales acceptable to the exploration process.

13 6 SYNTHETIC MARINE CSEM SURVEY EXAMPLES

14 Synthetic inversion examples using data from a simulated marine environment are presented. The
 15 model consists of a resistive reservoir ($\sigma = 0.02$ S/m) of size $3 \text{ km} \times 3 \text{ km} \times 0.3 \text{ km}$ along the
 16 x , y and z coordinates, respectively. The target is embedded into a homogeneous and conductive
 17 background ($\sigma = 1.4$ S/m) and its upper boundary lies at a depth of $z = 1200$ m below the seafloor
 18 ($z = 0$ m). Inversion results of different transmitter-receiver configurations will be shown below.
 19 Synthetic electric field data for the frequencies 0.25, 0.75, and 1.25 Hz were generated. Normally
 20 distributive Gaussian noise was added to the data, based upon three percent of the measurement
 21 amplitude. In addition, any data below an assumed noise floor of $1 \cdot 10^{-13}$ V/m were discarded
 22 from the analysis.

23 For this scenario, we design a rather conservative model grid Ω_M with a uniform node spacing
 24 of $\Delta = 75$ m and a size of $N_c = 134 \times 134 \times 134$ cells. This spacing fulfills a typical spatial
 25 sampling requirement of 5 grid nodes per skin depth δ , where

$$26 \delta \approx 503 \sqrt{\frac{1}{\sigma_b f}} \quad (18)$$

Table 1. List of model and simulation grids for synthetic data generation and inversion

Grid	Number of cells	spacing Δ (m)	f (Hz)
Ω_M^0	$200 \times 200 \times 200$	50	
Ω_M	$134 \times 134 \times 134$	75	
Ω_S^1	$50 \times 50 \times 50$	200	0.25
Ω_S^2	$80 \times 80 \times 80$	125	0.75
Ω_S^3	$100 \times 100 \times 100$	100	1.25

1 is estimated using the seafloor background conductivity ($\sigma_b = 1.4$ S/m) and the highest employed
 2 frequency, $f_3 = 1.25$ Hz.

3 The inversion domain Ω_m covers 90 % of the model space below the seafloor. Because the
 4 CSEM data are generated from the same forward solution used in the inversion, we have taken
 5 steps to insure that the simulated data have some degree of independence from Ω_m . Specifically, a
 6 finer mesh, Ω_M^0 , with a node spacing $\Delta = 50$ m, and thus a size of $N_c = 200 \times 200 \times 200$ cells,
 7 was used as FD simulation grid for data generation. The three simulation grids Ω_S employed in
 8 the inversions each have a uniform grid node spacing, which is adapted to the source frequency
 9 using eq. (18). For each grid, the grid spacing Δ is chosen to meet a spatial sampling requirement
 10 of 4 nodes per skin depth δ . Table 1 summarizes the details of all grids. The main purpose of
 11 the synthetic data inversions presented here is a feasibility study for adaptive simulation meshes.
 12 Therefore, we choose a rather ideal starting model with the true background conductivity for all
 13 inversions.

14 In the following, each imaging experiment shall be numbered consecutively. The configura-
 15 tion of the first synthetic imaging study, referred to as inversion 1, is shown in Fig. 2. A single
 16 profile with 7 inline horizontal electric dipole transmitters runs across the target's center, where
 17 each source has a length of 200 m and is located at $z = 0$ m. Note that we have applied the
 18 reciprocity principle to the synthetic data. The positions of the real CSEM transmitter along the
 19 sail line become the computational receiver positions, and the real CSEM detectors on the seafloor
 20 become computational sources. Therefore, the expressions sources and receivers refer to the (com-
 21 putational) sources and receivers as they are defined in the simulations. The electric point dipole
 22 receivers are located at $z = -50$ m and are separated by a distance of 100 m. Only inline electric

Table 2. Computational times and resources employed for the shown inversion results. Hardware specifications: Intel(R) Xeon(TM) CPU 3.60 GHz.

Inversion number	Number of CPUs ($n_x \times n_y \times n_z \times n_d$)	Iterations	Computing time per iteration (min)	Total computing time (hrs)
1 (reference)	144 ($3 \times 4 \times 4 \times 3$)	87	32.5	47.1
1 (coarse-grid)	144 ($3 \times 4 \times 4 \times 3$)	97	5.1	8.2
2 (reference)	27 ($3 \times 3 \times 3 \times 1$)	80	50.2	66.9
2 (coarse-grid)	27 ($3 \times 3 \times 3 \times 1$)	75	1.3	1.6
3	100 ($5 \times 5 \times 4 \times 1$)	250	4.7	20.0
4	64 ($4 \times 4 \times 4 \times 1$)	150	0.63	1.6
5	128 ($4 \times 4 \times 4 \times 2$)	172	19.8	56.7

1 fields are inverted, these are the fields parallel to the transmitter orientation. Each source operates
 2 at the three frequencies $f_1 = 0.25$ Hz, $f_2 = 0.75$ Hz, and $f_3 = 1.25$ Hz. Hence, computation of the
 3 predicted data at each inversion iteration effectively requires 21 forward solutions. We refer to the
 4 inversions using the coarser simulation meshes as coarse-grid inversions. For a comparison, a ref-
 5 erence inversion result was also produced, where $\Omega_S^i = \Omega_M$ for all three frequencies f_i . Further,
 6 a logarithmic type of parameter transformation according to eq. (15) with constant lower/upper
 7 bounds of 0.005/1.5 S/m is employed.

8 Both the data and model part of the total error functional, computed from eq. (1), are depicted
 9 in Fig. 3. Data fits are exemplified for the frequency $f_1 = 0.25$ Hz in Fig. 4. The reference and
 10 coarse-grid inversions needed 87 and 97 iterations, respectively, to reach a final data misfit of one.
 11 Refer to Table 2 (Inversion number 1) for details about the computational resources used for this
 12 result. While the coarser meshes enable a computational speed-up factor of 5.5, the final image
 13 shows no significant deterioration, compared to the reference inversion, as can be seen in Fig. 5.

14 In a typical imaging experiment, one might want to start inverting a subset of the data in order
 15 to refine an image in a step-by-step fashion. In the next study (inversion 2), we demonstrate that
 16 for the kind of target chosen here, the data of the lowest frequency, $f_1 = 0.25$ Hz (7 sources),
 17 provides sufficient information for resolution of the conductor at depth. Error functional and final

1 model are shown in Figs 6 and 7. This inversion produces an image very similar to the previous
 2 one, however with a slightly less pronounced conductor.

3 Because both inversions 1 and 2 only employ a single sail line, one observes limited lateral
 4 sensitivity perpendicular to the sail line. While the resolution along the profile is satisfactory for
 5 this target, the lateral sensitivity to the target is limited to ± 1 km along the y direction. The bow-
 6 shaped lateral image (“migration smile”) also results from a lack of resolution. Obviously, the
 7 lateral geometry of the target that can be recovered will be highly dependent on the survey cov-
 8 erage. Hence, high resolution 3D imaging of marine CSEM measurements will require spatially
 9 exhaustive data volumes such as those generated by multiple sail lines over the target.

10 A third imaging study (inversion 3) uses data from six profiles in a radial configuration (Fig. 8).
 11 A similar survey layout with a larger number of transmitter sail lines, was used in an imaging
 12 experiment presented by Carazzone et al. (2005). Here, the profiles contain altogether 25 source
 13 locations, where each location has two horizontal source polarizations. In contrast to the previous
 14 inversions, the receiver dipoles have two endpoints and a length of 100 m. We invert only the
 15 data of the frequency $f_1 = 0.25$ Hz. In total, the data set contains 50 effective sources and 20020
 16 data points. The larger data set requires more inversion iterations in order to achieve the target
 17 misfit (Fig. 9). In a preliminary study, we observed very similar results between reference and
 18 coarse-grid inversions for such a profile layout. Here, only the coarse-grid result, using grid Ω_S^1 , is
 19 shown in Fig. 10. Comparing with the single-profile results, the image is highly improved laterally.
 20 Deviations from the true target are a slightly non-planar upper boundary and a concentration of
 21 decreased conductivities, with a minimum of $\sigma = 0.01$ S/m, towards the target’s center. Instead of
 22 running a (fine-grid) reference inversion for the same number of iterations, only the preliminary
 23 stage of the inversion was repeated using $\Omega_S = \Omega_M$; thereby we can estimate a computational
 24 speed-up factor of approximately 40 for this example.

25 For marine CSEM imaging experiments, thus far, the lower and upper bounding constraints
 26 promise to be very useful in alleviating conductivity overshoots (Gibbs phenomenon) near struc-
 27 tural boundaries. We have also made the experience that, in contrast to unbounded parameters,
 28 both types of parameterizations are more powerful in suppressing near-surface image artifacts due

1 to statics and positioning errors at the detectors. Though the shown synthetic studies demonstrate
 2 that acceptable models can be recovered, solution nonuniqueness remains a formidable problem.
 3 While employing both upper and lower bounding constraints can be highly beneficial, a conver-
 4 gence failure may result from too restrictive bounds. It is therefore imperative that prior infor-
 5 mation be incorporated in the imaging process to restrict the class of solutions to geologically
 6 meaningful ones.

7 SOURCE SIGNATURE CORRECTION

8 In an inversion scenario with real field data, it is likely that data distortions due to systematic
 9 measurement errors vary in the transmitter's frequency. Moreover, each distinct source may be
 10 affected differently by positioning errors or local inhomogeneities in its vicinity that are not ac-
 11 counted for in a starting model. In time-domain forward modelling, such transmitter-characteristic
 12 data distortions can be taken into account by convolution of the modelling time curve with the
 13 Earth's impulse response measured nearby the transmitter. In the frequency domain, this translates
 14 to multiplication of the right-hand-side of eq.(4) by a complex-valued scaling factor s ,

$$15 \quad \mathbf{KE} = s\mathbf{S}. \quad (19)$$

16 Following the findings of Pratt (1999) for seismic waveform inversion, we found that it may be
 17 beneficial to assign an unknown complex scaling factor to each CSEM source, thus taking into
 18 account data distortions in the form of both amplitude and phase shifts. In an inversion framework,
 19 this is realized by augmenting the inversion parameters with a set of scaling factors, where one
 20 factor can be assigned to each distinct source or to multiple sources. Hence, one solves a source
 21 signature estimation problem together with the imaging problem by also minimizing the data part
 22 of eq. (1) with respect to s , where s is embedded within \mathbf{d}^p , leading to

$$23 \quad s = \frac{\mathbf{d}^o{}^T \mathbf{d}^p{}^*}{\mathbf{d}^p{}^T \mathbf{d}^p{}^*}. \quad (20)$$

24 In practice, s is computed after each model update during an inversion iteration and applied to the
 25 modelling data \mathbf{d}^p afterwards.

Table 3. Inversion 4: Endpoint positions (x, y, z) of transmitter dipole in Meters for imaging study with source signature correction.

True (displaced) positions		Assumed positions	
Endpoint 1	Endpoint 2	Endpoint 1	Endpoint 2
-3100,0,0	-2900,-50,-50	-3100,0,0	-2900,0,0
-2100,0,-30	-1900,-20,0	-2100,0,0	-1900,0,0
-1100,-100,0	-900,-100,0	-1100,0,0	-900,0,0
0,0,0	200,0,0	-100,0,0	100,0,0
900,100,0	1100,0,-60	900,0,0	1100,0,0
1900,0,0	2000,0,-20	1900,0,0	2100,0,0
2900,-50,-20	3100,30,-70	2900,0,0	3100,0,0

1 For the following inversion study (inversion 4), we simulate a case where the measured po-
 2 sitions of the real detectors on the seafloor would have errors. We use the same data-generating
 3 model as in the previous examples, and a source-receiver configuration similar to that of inver-
 4 sion 2, with 7 sources and a transmitter frequency of $f_1 = 0.25$ Hz. For creation of the distorted
 5 input data, the endpoint positions of the computational sources are modified according to Table 3.
 6 The two left columns list the true endpoints used for the synthetic data generation, and the two
 7 right columns are the (erroneous) positions as assumed for the inverted data. Two inversions were
 8 carried out, one without activating the source signature factor, another one with a separate factor
 9 s for each of the 7 sources. Figs 11 and 12 show the error functional and the resulting images for
 10 both inversions. Comparing the results, it can be observed that there is significant improvement
 11 achieved by enabling the source scaling. While both model images exhibit the resistive target,
 12 additional artefacts, with the largest one nearly as large in size as the target, result from the inver-
 13 sion without scaling. The occurrence of artefacts is strongly suppressed when enabling the scaling
 14 factor. However, the convergence of the error functional towards a value of 27 indicates that the
 15 relatively large distortion imposed on the data can only be mitigated to a limited degree by the
 16 complex scaling factor.

17 In the next example, it is demonstrated for a different kind of data distortion, how the source
 18 signature correction (SSC) factor may improve the inversion result. To generate strong data dis-

1 tortions, a layer with randomly distributed conductivities between 4 and 10 S/m was added to the
2 true model used for our synthetic data. The layer starts below the sea bottom and has a thickness
3 of 200 m. As a starting model, a homogeneous background is assumed, again with the true con-
4 ductivity. Here, we use the same survey layout, number of sources and frequencies, and (coarse)
5 grids as for inversion 1. To see the effect of the SSC, two inversions without its activation are first
6 carried out. The difference between these two inversions is that the second one uses a solution pre-
7 conditioner (PC). Key to this enhanced solution approach is an adjoint method that allows for an
8 economical approximation of the Hessian used as the preconditioner \mathbf{M} for the NLCG algorithm
9 (see Section 2.1). The matrix operation \mathbf{M}_i^{-1} in the algorithm is a PC, that changes the conjugate
10 search direction \mathbf{u}_i such that it steers more toward the Newton direction. The effect of using the
11 PC is that it scales the search direction, causing the activation of deeper regions in the model,
12 i.e. the inversion tends to put more weight on the updates of the corresponding model components
13 σ_k , compared to more shallow model regions. For more details about this type of PC the reader is
14 referred to the work of Newman & Boggs (2004).

15 In addition to the two inversion without SSC, two more were carried out. The third one has the
16 SSC activated, and the fourth one has both the SSC and PC activated. The error functional curves
17 of all four attempts are shown in Fig. 13. Only the two inversions with SSC achieve a significant
18 misfit decrease, where the preconditioned one reaches a final misfit which is by a factor of 1.3
19 smaller. This also reflects in the final images shown in Fig. 14. The upper figure (a) shows the true
20 model with the upper conductive seabed. Below (figure b) is the result obtained without using the
21 SSC, where both the non-preconditioned and preconditioned inversions produce similar images.
22 No resistive target appears in these images. Using the scaling factor (c), the resistor appears very
23 faintly a few hundred meters above the true target. A strong yet distorted image of the reservoir is
24 obtained when using both SSC and PC.

25 Although great solution improvement is achieved by using the SSC in a preconditioned inver-
26 sion, one would have to exercise caution when interpreting the image. First, it has to be repeated
27 that the strong data distortions simulated here can only be represented partly by the source signa-
28 ture. Second, the activation of deeper model regions by the PC may be stronger than desired. We

1 note that the shown results using the SSC is a rather exploratory study, demonstrating its potential
2 of solution improvement. Further studies with different types of systematic data errors, which are
3 typical in CSEM surveys, are to be carried out to gain further understanding about usage of EM
4 source signatures in inversions.

5 **8 FIELD DATA EXAMPLE**

6 We present a field example using seabed logging data from the Troll West Gas Province (TWGP).
7 This hydrocarbon reservoir is part of the large Troll Field complex, located offshore Norway.
8 Details about the exploration site are given by Gray (1987), and the CSEM survey is outlined in
9 detail by Johansen et al. (2005). Here, we give a summary about both the survey and the reservoir
10 characteristics. The survey layout is further illustrated in Fig. 15 (a and b).

- 11 • The survey was designed with 24 CSEM detectors on a single profile, covering a profile
12 length of approximately 12 km.
- 13 • The transmitter antenna is a horizontal electric dipole of length 230 m. It was towed along an
14 overflight profile, at an average of 25 m above the detectors, covering a profile length of more than
15 25 km across TWGP.
- 16 • Sea water depth varies between 300-360 m in the Troll Field complex.
- 17 • The reservoir is embedded within Jurassic sandstones.
- 18 • Water bearing sands and overburden sediments have conductivities between 0.5 and 2 S/m.
- 19 • Resistivity measurements in an exploration well showed an average of 200-500 $\Omega \cdot \text{m}$ within
20 the hydrocarbon bearing layer, and a maximum reservoir thickness of 160 m.
- 21 • The upper reservoir boundary's depth is about 1400 m below sea surface.
- 22 • The reservoir is relatively large with a horizontal extension of approximately 8 km along the
23 survey profile.

24 In the following, the reciprocity principle is used again by changing the tow line of the real
25 CSEM transmitter to the computational receiver profile, and the real detector positions to the com-
26 putational sources. The inverted data set includes a total of 48 computational sources, operating at

1 the two frequencies $f_1 = 0.25$ Hz and $f_2 = 0.75$ Hz, with 24 sources per frequency. The measure-
2 ments consist of inline, i.e. parallel to the source orientation, electric fields, these are 1192 data
3 points in total. The survey also included measurements at a transmitter frequency of 1.25 Hz. The
4 noise content of the data increases with the transmitter frequency. Inverting only the data belong-
5 ing to the frequency f_1 , we were able to reach a final misfit of $\Phi = 1$. Adding data of the higher
6 frequencies, the misfit converges towards a higher value. Compared to the two lower frequencies,
7 the noise content of the data belonging to the frequency 1.25 Hz is relatively high. Hence, we
8 decided to exclude this data from the inverted data set.

9 In a preliminary modelling study, similar to the one outlined by Johansen et al. (2005), we
10 found that bathymetry effects are negligible compared to the relatively large reservoir response.
11 The maximum vertical difference between the source positions is 4 m over a source profile of more
12 than 12 km. Therefore, our starting model contains a flat seabed with an averaged water depth of
13 323 m. All sources are placed on the seabed at $z=323$ m, while the original receiver positions
14 with respect to the sources are kept. We use a starting model with a homogeneous background
15 of 0.3 S/m below the sea bottom. No further a priori information is utilized during the inversion.
16 Uniform model smoothing is applied within the whole inversion domain, using a regularization
17 parameter of $\lambda = 0.1$. Because of the large target size, no bathymetry, and a rather moderate
18 background conductivity variation within the model, a rather coarse modelling mesh can be used.
19 We believe that, expressed in terms of the principle of Occam's razor, it is favorable to limit the
20 number of model unknowns, thus countering to some degree the solution non-uniqueness of the
21 ill-posed inverse problem.

22 Again, the design of a proper modelling mesh and simulation meshes for both employed fre-
23 quencies is based on skin depth estimations, as outlined in section 6. All mesh details are sum-
24 marized in Table 4. While the simulation grid stretching, with the minimum and maximum cell
25 sizes also given in Table 4, is constant for all sources of the same frequency, a separate simulation
26 mesh is assigned to each source in practice. Each simulation grid's node positions can thus be
27 adapted to the source and receiver positions and their corresponding offsets. This is illustrated in
28 Fig. 15c for the sources R1/R24 located on the left/right end of the source profile. The simula-

Table 4. List of model and simulation grids for TWGP data inversion

Grid	Number of cells	Δ_x	Δ_y	Δ_z	
Ω_M	$125 \times 41 \times 59$	250	250	100	
		$\Delta_x^{min}/\Delta_x^{max}$	$\Delta_y^{min}/\Delta_y^{max}$	$\Delta_z^{min}/\Delta_z^{max}$	f (Hz)
Ω_S^1	$85 \times 41 \times 85$	125/250	250/250	25/200	0.25 (f_1)
Ω_S^2	$110 \times 43 \times 85$	75/125	125/250	25/200	0.75 (f_2)

1 tion grids assigned to these sources cover a different subset of the modelling mesh. Because of
 2 different skin depth criteria, the grids Ω_S^2 ($f_2 = 0.75$ Hz) cover a slightly smaller volume than
 3 Ω_S^1 ($f_1 = 0.25$ Hz).

4 We stopped the inversion (given number 5 in Table 2) after 172 iterations, when no more
 5 significant progress was made in the misfit decrease, shown in Fig. 16. The final data fits for
 6 both the real and imaginary parts of the electric field are shown in Fig. 17 for the frequency
 7 $f_1 = 0.25$ Hz and in Fig. 18 for $f_2 = 0.75$ Hz. Fig. 19 shows both xz and yz sections of the final
 8 image. The inversion reaches a satisfactory data fit, produced from a model with a clear image of
 9 the resistive target.

10 A common way of incorporating prior information would be the removal of the smoothing
 11 constraints, given by the second term in eq. (1), along surfaces identified as seismic horizons (Hov-
 12 ersten et al. 2006). This is based on the assumption that sharp changes in the acoustic impedance
 13 across reflection horizons also constitute layer boundaries with contrasting electrical conductivi-
 14 ties. Although we did not incorporate such sharp boundaries into the smoothing constraints, both
 15 the depth and location of the reservoir is well within the boundaries defined by two seismic hori-
 16 zons, which were available as prior information (Hoversten, 2006, pers. comm.), shown by the
 17 black lines in the middle Fig. 19. Below the reservoir, it is assumed that the high porosity sands
 18 are filled with brine. The presence of such a brine layer is clearly indicated in the model by in-
 19 creased conductivities below a depth of 2000 m. Similar to the observations in the model result of
 20 inversions 1 and 2, the lateral resolution is limited along the single survey profile. However, the
 21 yz sections of the image (Fig. 19) also support the large reservoir widths of 3.5-5 km assumed by
 22 Johansen et al. (2005).

1 This section is concluded with a comparison of the inversion result with a simplified geological
2 model by Johansen et al. (2005), shown in Fig. 20. The geological section in the upper figure
3 was based on 3D FD forward modelling, and the incorporation of seismic reflection data and
4 borehole EM measurements. A good match is achieved for the vertical reservoir position, while
5 the inversion result reveals a larger reservoir thickness than indicated by the exploration well data.
6 Note, however, that no further constraints in the form of sharp-boundary horizons were enforced.
7 Although rather speculative, it shall also be noted that the image may reveal a wider reservoir
8 extension than assumed in the geological section. This may be indicated by the left end of the
9 reservoir image, at profile positions $x = 3000 - 5000$ m in the lower Fig. 20. Here, the resistor
10 shows a clear agreement in shape with the sedimentary boundaries below $z = 1600$ m (indicated
11 by a red question mark in the section).

12 9 CONCLUSIONS

13 We have made significant progress in further reducing the computationally high demands of large-
14 scale CSEM inverse problems. Being able to separate the simulation space from the model space,
15 in terms of FD grid design, opens a range of possibilities. As demonstrated, a simulation mesh
16 can be adapted to the source excitation frequency, source-receiver offsets, and its corresponding
17 largest distances, and thus be optimized computationally. Depending on the location of a source
18 in the model and its coverage of the inversion domain, given by the source-receiver geometry, the
19 simulation mesh position can be optimized individually for each different source. As shown in
20 the field data example, one can thus let the simulation grids assigned to a survey profile “slide”
21 along the profile, where they only have the minimum required grid sizes. Such a capability is
22 essential for treatment of industrial field data sets, where survey profiles cover areas which may
23 easily exceed sizes of 100 km^2 . The computation times achieved with the grid separation scheme
24 show that 3D CSEM inversion is now feasible within reasonable times, using mid-sized, parallel
25 cluster computers.

26 The efficient usage of computer resources by combining two different levels of parallelization
27 is further essential for treatment of data sets of arbitrarily large sizes.

1 Both the synthetic results and field data inversion examples show relatively sharp images of
2 the known resistive targets. Here, using proper parameter constraints has proven to be extremely
3 valuable in avoiding conductivity overshoots, which are prone to happen in unbounded inversions,
4 particularly in the case of noisy data.

5 Including the source signature estimation problem, as shown in the synthetic studies, indicates
6 significant potential for correcting for unwanted data distortions directly within the imaging pro-
7 cess. Although a potentially very useful additional tool, it has to be emphasized that a careful data
8 preprocessing still remains very important to ensure maximum data integrity.

9 **10 ACKNOWLEDGMENTS**

10 This work was carried out at Lawrence Berkeley National Laboratory, with base funding provided
11 by the ExxonMobil Corporation and the United States Department of Energy, Office of Basic En-
12 ergy Sciences, under contract DE-AC02-05CH11231. We wish to thank the German Alexander-
13 von-Humboldt Foundation for support of MC through a Feodor-Lynen Research Fellowship. The
14 authors also express their gratitude to Statoil for access to the Troll field data set and the per-
15 mission to publish the Troll imaging results. We also acknowledge Erika Gasperikova of LBNL
16 for additional processing of the Troll field data, and Dmitriy A. Pavlov of ExxonMobil for many
17 fruitful discussions.
