*control criteria.*

The call rate threshold for samples was  $\geq 90\%$ . We have added a statement to this effect in the Methods.

4. *No rationale provided for selection of individuals for sequencing. For example, why were all individuals in Family 1 sequenced but only the offspring in family 3?*

We selected the individuals within each family that were likely to be the most informative in sequencing studies. For example, the phenotypes of the parents in family 3 are unknown, sequencing data is unlikely to be of additional benefit, as we would be unable to determine whether variants of interest co-segregate with the phenotype. We have added a section in the Methods outlining these choices.

5. *“...several [of the coding variants] were associated with the major haplotype of interest in one of the three families”. It would be helpful to know how many variants were associated with the haplotype of interest, without having to go to the Supplemental Table.*

We have added this information in the text of the Results section and have highlighted these variants in grey in Supplemental Table 3.

We hope that these revisions are satisfactory, and submit the revised manuscript for your consideration for publication.

Thank you very much,

Carol A. Mathews, MD

## ABSTRACT

Obsessive compulsive disorder (OCD) has a complex etiology that encompasses both genetic and environmental factors. However, to date, despite the identification of several promising candidate genes and linkage regions, the genetic causes of OCD are largely unknown. The objective of this study was to conduct linkage studies of childhood-onset OCD, which is thought to have the strongest genetic etiology, in several OCD-affected families from the genetically isolated population of the Central Valley of Costa Rica (CVCR). The authors used parametric and non-parametric approaches to conduct genome-wide linkage analyses using 5786 single nucleotide repeat polymorphisms (SNPs) in three CVCR families with multiple childhood-onset OCD-affected individuals. We identified areas of suggestive linkage (LOD score  $\geq 2$ ) on chromosomes 1p21, 15q14, 16q24, and 17p12. The strongest evidence for linkage was on chromosome 15q14 (LOD=3.13), identified using parametric linkage analysis with a recessive model, and overlapping a region identified in a prior linkage study using a Caucasian population. Each CVCR family had a haplotype that co-segregated with OCD across a ~7Mbp interval within this region, which contains 18 identified brain expressed genes, several of which are potentially relevant to OCD. Exonic sequencing of the strongest candidate gene in this region, the ryanodine receptor 3 (RYR3), identified several genetic variants of potential interest, although none cosegregated with OCD in all three families. These findings provide evidence that chromosome 15q14 is linked to OCD in families from the CVCR, and supports previous findings to suggest that this region may contain one or more OCD susceptibility loci.

## INTRODUCTION

Although multiple etiologic factors are important in the development of obsessive-compulsive disorder (OCD), there is strong evidence for a genetic contribution, particularly when symptoms begin in childhood (Pauls 2008). Several promising candidate genes have been identified for OCD, including SLC1A1 (Dickel et al. 2006; Arnold et al. 2006). However, these genes, if confirmed, will only account for a small proportion of the genetic variance of this complex disorder. Large-scale genome-wide association studies (GWAS) are currently underway for OCD; however, such studies will most likely account for only a proportion of the total disease variation (Yang et al. 2011; Manolio et al. 2009). For example, the estimated proportion of the variance explained by all currently reported genetic loci identified by GWAS for height, a complex trait with a heritability of 80-90%, is approximately 10%; this number increases to 45% with recently developed genomic partitioning approaches, but still does not approach 100%. Similar results are seen with categorical traits such as type 2 diabetes and Crohn's disease, where published susceptibility loci account for 6% and 20% of the total variance, respectively (Manolio et al. 2009). Linkage studies represent a complementary approach to candidate gene studies and GWAS. Where GWAS are useful for the identification of common variants with relatively small effect sizes, linkage studies are useful for the identification of rare variants with larger effect sizes that are increasingly believed to underlie a substantial proportion of the risk for complex disorders (Cirulli and Goldstein 2010).

To date, three primary linkage studies for OCD have been published, along with two secondary analyses and one targeted replication; these studies have identified several genomic candidate regions for OCD (Supplemental Table 1) (Wang et al. 2009; Samuels et al. 2007; Hanna et al. 2007; Shugart et al. 2006; Hanna et al. 2002; Willour et al. 2004). None of the

1  
2  
3 studies using OCD as the primary phenotype identified regions meeting genome-wide  
4 significance criteria for linkage, although two re-analyses of a large OCD affected-sib pair  
5 sample using alternate phenotypes or sample selection did identify significant linkage  
6 regions(Samuels et al. 2007; Wang et al. 2009). The first re-analysis included only families with  
7 two or more members affected with compulsive hoarding, and identified a region on  
8 chromosome 14q with a LOD score of 3.7, and the second focused on families with male  
9 probands only, and identified a region on chromosome 11p with an initial LOD score of 2.92 and  
10 a subsequent LOD score of 5.08 following fine mapping with additional markers(Samuels et al.  
11 2007; Wang et al. 2009).

24  
25  
26 As linkage and segregation studies suggest, the identification of susceptibility genes in OCD  
27 is likely confounded by a complex oligogenetic architecture, as well as genetic and environmental  
28 heterogeneity across populations(Cavallini et al. 1999; Geller et al. 2007; Eapen et al. 2006;  
29 Hanna et al. 2005; Nestadt et al. 2000). One approach to reducing genetic and environmental  
30 heterogeneity in such complex traits is to conduct studies using multiply-affected families in  
31 genetically isolated founder populations(Mathews et al. 2004; Hovatta et al. 1999). Studies in  
32 these populations benefit from decreased genetic heterogeneity due to decreased migration and,  
33 in some cases, increased inbreeding over a defined period of time(Mathews et al. 2004).  
34 Additional potential advantages include the possibility for decreased environmental  
35 heterogeneity due to the isolation of the population, and for decreased phenotypic heterogeneity  
36 due to cultural variations in symptom expression, interpretation, or reporting.

## 8 **MATERIALS AND METHODS**

### 9 **Families and Subjects**

10  
11  
12 As a part of ongoing genetic studies of OCD in Costa Rica, we identified three families with two  
13  
14 or more OCD-affected individuals and CVCR ancestry for whom DNA was available from  
15  
16 individuals in at least two generations (Figure 1). Families were originally ascertained via  
17  
18 probands with DSM-IV OCD whose obsessive-compulsive symptoms began before age 18, who  
19  
20 did not have Tourette Syndrome (TS), a pervasive developmental disorder, bipolar disorder,  
21  
22 schizophrenia, or a primary psychotic disorder. The study was approved by the Institutional  
23  
24 Review Boards of the University of California, San Francisco, the University of California, San  
25  
26 Diego, and the Hospital Nacional de Niños in San José, Costa Rica. After complete discussion of  
27  
28 the study with the participants, written informed consent or assent was obtained; parental  
29  
30 permission was also obtained for participants under age 18.  
31  
32  
33  
34  
35

36  
37 Clinical assessments were conducted in Spanish by psychiatrists and psychologists  
38  
39 specializing in OCD and trained in the research instruments (CAM, HG, and MB). Primary  
40  
41 assessment instruments included the Yale Brown Obsessive Compulsive Scale (YBOCS), the  
42  
43 Diagnostic Interview for Genetics Studies (DIGS) for adults, and the Kiddie Schedule for  
44  
45 Affective Disorders and Schizophrenia (KSADS) for children under 18. Additional clinical  
46  
47 assessments included the Leyton Obsessional Inventory, childhood version (LOI-CV), the  
48  
49 Structured Clinical Interview for DSM-IV Axis II diagnoses (SCID II), and a semi-structured  
50  
51 interview that assessed time course and impact of symptoms, presence and severity of related  
52  
53 symptoms (including tics), and developmental, school, social, and family history. Diagnoses  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 were assigned using a best estimate consensus approach using all available clinical data by two  
4  
5 research clinicians (DC, MG) who were blinded to the presumed clinical diagnosis, family  
6  
7 history, or relationship within the pedigree (Leckman et al. 1982; Chavira et al. 2007). Two OCD  
8  
9 diagnoses were assigned: narrow and broad OCD. A diagnosis of narrow OCD was given if the  
10  
11 individual met all of the DSM-IV criteria for OCD. A diagnosis of broad OCD encompassed  
12  
13 both DSM-IV OCD and subclinical OCD, which was considered present if the individual had  
14  
15 five or more obsessive-compulsive symptoms that were persistent, took less than an hour, and  
16  
17 caused some distress and/or impairment (even if mild), or if the symptoms took an hour or more  
18  
19 but were associated with minimal distress or impairment. The broad definition was designed to  
20  
21 capture a robust phenotype that is likely to be etiologically related to OCD, but was not severe  
22  
23 enough to meet strict DSM-IV criteria for OCD. We required the presence of at least five  
24  
25 obsessive-compulsive symptoms to ensure that isolated (usually ego-syntonic) symptoms (for  
26  
27 example, a cluster of two or three related cleaning behaviors causing little to no distress or  
28  
29 impairment), which occur frequently in the population, but may not be etiologically related to  
30  
31 OCD, were not included in the phenotype definitions, to avoid the introduction of phenocopies.  
32  
33 Consistent with this aim, individuals with one to four obsessive-compulsive symptoms were  
34  
35 coded as phenotype unknown. Age of onset of obsessive-compulsive symptoms was assessed in  
36  
37 all individuals. The average age of onset was 10.9, and all individuals had childhood-onset of  
38  
39 symptoms (range 3-18).  
40  
41  
42  
43  
44  
45  
46  
47  
48

## 49 **Genotyping**

50  
51 DNA extraction was performed from blood or immortalized lymphoblastoid cell lines according  
52  
53 to standard procedures. Genotyping was performed on approximately two-thirds of the sample at  
54  
55 the Southern California Genotyping Consortium (SCGC) using the Illumina linkage panel IVa;  
56  
57  
58  
59  
60

1  
2  
3 the remaining sample was genotyped at the UCSF Genome Core Facility (UCSF GCF) using the  
4  
5 Illumina linkage panel IVb. Only markers that were present in both linkage panels were retained  
6  
7 (N=5858). Data for each sample were analyzed for quality control and Mendel errors using  
8  
9 GenomeStudio Data Analysis software (Illumina). The average call rate for the 5858 SNPs was  
10  
11 0.99. After initial data cleaning on each sample, data from the two sample sets were merged, and  
12  
13 additional data cleaning and quality control procedures were performed. Error checking was  
14  
15 completed using Illumina GenomeStudio, Progeny and Pedcheck(Lab ; O'Connell and Weeks  
16  
17 1998). Markers that showed Mendelian inconsistency, those that were not in Hardy-Weinberg  
18  
19 equilibrium (HWE) (exclusion threshold  $p < 0.0001$ ), and those with  $< 95\%$  call rates were  
20  
21 removed from the marker set, resulting in a final total of 5786 SNPs (98.8%) retained for  
22  
23 analysis. The threshold for exclusion of individual samples was set at genotyping call rates  
24  
25  $< 90\%$ . However, all genotyped individuals passed this threshold and therefore, none were  
26  
27 excluded.  
28  
29  
30  
31  
32

### 33 34 35 36 **Statistical analysis**

37  
38 To maximize the power of this small sample, the primary analysis was a multipoint parametric  
39  
40 linkage analysis. We chose to examine a model-based approach (dominant and recessive models)  
41  
42 as our primary analysis, in addition to the secondary non-parametric (model-free) analysis, to  
43  
44 maximize the power of this small sample, and because examination of the pedigrees suggested  
45  
46 that either a dominant or a recessive mode of inheritance was possible (Figure 1). Simulation  
47  
48 studies have shown that formulating a genetic model that approximates the true inheritance may  
49  
50 have more power than nonparametric analyses(Greenberg et al. 1998). Pedigree relationships  
51  
52 were confirmed prior to analysis using PREST and PLINK. Parametric linkage analyses were  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 conducted using MORGAN version 3.0 and Merlin(Wijsman et al. 2006; Abecasis et al. 2002).  
4  
5 MORGAN uses genetic and phenotypic information from all available family members. Prior to  
6  
7 performing the linkage analysis, the linkage panel was pruned so that only SNPs with a pairwise  
8  
9  $r^2 \leq 0.5$  were analyzed (N=2526), to avoid an increase in false positives that may occur when  
10  
11 linkage disequilibrium (LD) between SNPs is not taken into account. In contrast, MERLIN has  
12  
13 the capacity to analyze all SNPs, accounting for LD, but is not able to use all individuals due to  
14  
15 the size and complexity of the largest family. For the MERLIN analysis, PedShrink was used to  
16  
17 trim the pedigrees as needed, with priority on trimming uninformative individuals(Schaid 2009).  
18  
19 For the dominant model, we assumed a disease allele frequency of 0.01, a penetrance of 0.01 for  
20  
21 the wildtype genotype (dd), a penetrance of 0.6 for the heterozygote (Dd) and homozygote  
22  
23 genotypes (DD), where D is the disease-causing allele and d is the wildtype allele, resulting in a  
24  
25 phenocopy rate of 45%. For the recessive model we assumed a disease allele frequency of 0.10, a  
26  
27 penetrance of 0.01 for the wildtype and heterozygote genotypes, and a penetrance of 0.6 for the  
28  
29 homozygote genotype, resulting in a phenocopy rate of 50%. These parameters were chosen to  
30  
31 model a relatively rare locus with a large effect size, as might be expected to occur in families  
32  
33 with multiple affected individuals collected from a genetically isolated population. We used two  
34  
35 phenotypes, narrow and broad OCD, as described above. Individuals with subclinical OCD, who  
36  
37 were coded as affected for the broad analyses, were coded as unknown in the narrow analyses.  
38  
39 Nonparametric linkage analyses (NPL) were conducted using Simwalk2snp, using the LD-  
40  
41 pruned SNP panel(Sobel et al. 2001). The primary parameters examined were the NPL-pairs  
42  
43 statistic, which is a measure of allele sharing among affected relative-pairs (roughly equal to the  
44  
45 sum of the conditional kinship coefficient for all affected relative-pairs), and the NPL-all  
46  
47 statistic, which is a measure of whether a few founder alleles are overly represented in the  
48  
49  
50  
51  
52

10  
11

### 12 13 14 15 **Haplotype analysis and candidate gene selection**

16  
17 Chromosomal regions that had >5 consecutive SNPs with LOD or NPL scores (either NPL-pairs  
18 or NPL-all)  $\geq 2.0$  were identified as being of interest for further investigation, and were  
19 prioritized according to the following criteria: 1) the magnitude of the LOD score; 2) the number  
20 of consecutive markers with LOD scores  $\geq 2$ ; 3) identification as a region of interest for OCD in  
21 previous linkage analyses, or known to contain candidate genes for OCD; and 4) presence of a  
22 haplotype that co-segregated with the OCD phenotype.  
23  
24  
25  
26  
27  
28  
29  
30

31  
32 Estimated haplotypes were generated for each pedigree using the “haplotype analysis”  
33 command in Simwalk2snp. The haplotypes were then visualized using HaploPainter(Thiele and  
34 Nurnberg 2005). As a further check, haplotypes were also constructed by hand (blind to the  
35 results generated by Simwalk2snp) for the most significant regions of interest and compared to  
36 the results of the haplotype analysis for discrepancies. Haplotypes that were inherited identical  
37 by descent and co-segregated with the OCD phenotype were assessed within each family. The  
38 families were then assessed to identify haplotypes or portions of the haplotypes that were shared  
39 across families. After the genomic region of highest interest was determined, candidate genes  
40 within the region were identified for further exploration. Initially, all genes and transcripts were  
41 identified using the UCSC genome browser, assembly GRCh37 (<http://genome.ucsc.edu/>). Only  
42 those genes that were identified as brain expressed in the UCSC genome browser were examined  
43  
44  
45  
46  
47  
48  
49  
50  
51

55  
56  
57  
58  
59  
60

1  
2  
3 further. Candidate genes were then ranked according to 1) whether they had been previously  
4 associated with OCD; 2) where in the brain they were expressed, with priority given to those  
5 expressed in regions that have been associated with OCD (i.e., striatum, orbitofrontal cortex,  
6 thalamus, hippocampus, cingulate); and 3) where they fell under the linkage peak, with priority  
7 given to those with the strongest evidence for linkage (Menzies et al. 2008). The top ranking  
8 candidate gene was then sequenced as described below.

### 18 **Sequencing**

19  
20 Sequencing of the top candidate gene was conducted in selected OCD-affected individuals from  
21 each family. Individuals for sequencing were chosen from within each family so as to maximize  
22 the information and minimize the number of total individuals sequenced. In family 2, three  
23 individuals who carried the haplotype in the area of interest (one from each living generation;  
24 individuals 1, 13, and 23), and two OCD-affected individuals who did not carry the haplotype  
25 (individuals 7 and 16) were sequenced. In family 1, where phenotypes were known for all family  
26 members, all individuals were sequenced, and in family 3, the two OCD-affected siblings were  
27 sequenced, while the parents, who had unknown phenotypes and were therefore not informative,  
28 were not. Note that the mother in family 1 endorsed OCS that did not meet the threshold for  
29 subclinical OCD; therefore, she was coded as unknown in the genetic analyses. The exons and  
30 150bp on either side of the exon were sequenced. Sequence data were viewed and analyzed with  
31 the Sequencher program (GeneCodes), and sequence variants were identified by comparison  
32 with the reference human genome. Sequence variants were confirmed by sequencing the  
33 opposite strand using the Sanger sequencing method. All sequence variants that were present in  
34 the OCD-affected individuals, both those carrying the haplotype of interest and those who did  
35 not carry the haplotype, were investigated further. We examined both non-synonymous and

## 20 **RESULTS:**

### 21 **Parametric linkage analysis**

22  
23  
24  
25  
26 We carried out parametric linkage analysis on the three families shown in Figure 1 for the  
27  
28 narrow and broad phenotypes under both autosomal dominant and autosomal recessive models.  
29  
30 We identified eleven chromosomal regions with LOD scores  $\geq 1.5$ , a threshold commonly used to  
31  
32 identify areas of interest in linkage studies, and four with LOD scores  $\geq 2$  (Table 1). Three of  
33  
34 these regions met our criteria for further investigation. The first was on chromosome 15q14, with  
35  
36 a maximum LOD score of 3.13 under the recessive model using the broad phenotype, the second  
37  
38 was on chromosome 1p21, which had a LOD score of 2.16 under recessive model using the  
39  
40 narrow phenotype, and the third was on chromosome 16q24, and had a LOD score of 2.15 under  
41  
42 the dominant model using the narrow phenotype. The heterogeneity alpha for the region on  
43  
44 chromosome 15 was 1.0, suggesting that all three families contributed to the LOD score in this  
45  
46 region. The peak individual family LOD scores in this region were: 0.7813 (family 1), 1.8758  
47  
48 (family 2), and 0.474 (family 3). Figure 2 shows the LOD scores for chromosomes 1, 15, and 16;  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60  
LOD scores for the other chromosomes are in Supplemental Figure 1. The LOD scores for

1  
2  
3 family 2, which contributed the most to the overall LOD score on chromosome 15q14, are shown  
4  
5 in Supplemental Figure 2.  
6  
7

8  
9 **Examination of haplotypes:** We examined the haplotypes generated by Simwalk2snp for the  
10 chromosome 15q14, chromosome 1p21, and chromosome 16q24 regions, with a primary focus  
11 on chromosome 15q. All three families contributed to the LOD score on chromosome 15q, which  
12 showed the strongest evidence of linkage, and had been identified in a previous linkage study of  
13 OCD as a region of interest (Shugart et al. 2006). In each of the families, we identified a  
14 conserved haplotype that co-segregates with OCD on 15q, encompassing the region with the  
15 highest genome-wide LOD scores. In family 1 (see Figure 1 for family structures), all four  
16 siblings carried a common haplotype inherited from the OCD-affected father; the three OCD-  
17 affected siblings also carried a smaller haplotype in this region inherited from the mother, who  
18 endorsed some obsessive compulsive symptoms but did not meet the full best estimate criteria  
19 for the broad phenotype and therefore was coded as phenotype unknown. In family 3, the two  
20 OCD-affected siblings carried a shared haplotype inherited from the mother and one inherited  
21 from the father; both parents' phenotypes are unknown. In family 2, the largest of the families, 9  
22 of 11 individuals with the narrow phenotype, and one individual who is an obligate carrier and  
23 has the broad phenotype (subclinical OCD) shared a haplotype, including the three affected  
24 siblings in the founding generation (Figure 3). Two individuals with the narrow phenotype (a  
25 mother and son pair) did not carry the shared haplotype. While there was haplotype sharing  
26 within each family, we did not identify a haplotype that was shared by all three families.

50

51  
52  
53 The region of chromosome 15q as defined by the conserved haplotype in family 2 covers  
54 approximately 15 Mbp and contains 18 brain-expressed genes (Supplemental Table 2). In  
55  
56  
57  
58  
59  
60

1  
2  
3 combining the information provided from recombinations that defined the haplotypes in each of  
4  
5 the families, we were able to narrow the region of interest on 15q from 15 Mbp to approximately  
6  
7 7 Mbp (bounded by SNPs rs1520942 and rs1003223).  
8  
9

10  
11 Although all brain-expressed genes in this region are potentially of interest as candidate  
12  
13 genes for OCD, the SNPs with the strongest evidence of linkage in all families (6 consecutive  
14  
15 SNPs) were located in the intronic region between exons 1 and 2 of the ryanodine 3 receptor  
16  
17 (RYR3). According to the Allen Brain Atlas, RYR3 is broadly expressed in human brain, with  
18  
19 high levels of expression in the cingulate gyrus, hippocampus, parahippocampal gyrus, occipital  
20  
21 and parietal lobes, temporal lobe, globus pallidus, striatum (including the caudate and putamen),  
22  
23 dorsal thalamus, pontine tegmentum, and myelencephalon(Allen Brain Atlas Resources 2009).  
24  
25 Functional and structural imaging studies have consistently implicated several of these regions in  
26  
27 OCD pathophysiology, particularly the cingulate gyrus, the hippocampus, the striatum, and the  
28  
29 thalamus(Takeshima et al. 1996; Rauch et al. 2001; Nakashima et al. 1997; Menzies et al. 2008).  
30  
31 For these reasons, we chose RYR3 as our top candidate for sequencing. RYR3 is a large gene,  
32  
33 with 103 exons, and encoding 4870 amino acids.  
34  
35  
36  
37  
38  
39

### 40 **Sequencing of RYR3**

41  
42 We identified 184 sequence variants in the exons and surrounding intronic regions that  
43  
44 differed between our sample and the reference human genome, 23 (12.5%) of which were novel.  
45  
46 The variants identified included 9 non-synonymous coding variants, two of which were novel,  
47  
48 and 16 synonymous coding variants, two of which were novel. However, none of the identified  
49  
50 coding variants were uniquely associated with OCD in all families, although six were associated  
51  
52 with the major haplotype of interest in one of the three families (highlighted in grey in  
53  
54 Supplemental Table 3).  
55  
56  
57  
58  
59  
60

1  
2  
3 We also identified 159 intronic variants; of these, 19 were novel. None of the variants  
4 segregated perfectly with the haplotype of interest in all three families, although 48 variants had  
5 allele frequencies of  $<0.5$  and were present on the haplotype of interest in at least one of the two  
6 larger families (Supplemental Table 3). The intronic variants included several that are predicted  
7 by programs such as FastSNP and F-SNP to have potential functional effects (to be involved in  
8 splice site regulation, for example) (Supplemental Table 3).

## 20 **DISCUSSION**

21  
22  
23 Our results provide evidence from linkage and haplotype studies that chromosome 15q14  
24 may harbor one or more susceptibility genes for OCD. This study specifically focused on OCD-  
25 affected families from the genetically isolated population of the CVCR, which has the potential  
26 advantage of increasing the power to detect linkage even in a relatively small number of families.  
27  
28 In fact, even with only three families, the linkage finding on chromosome 15 is the strongest that  
29 has yet been reported for a primary analysis of OCD, and is further strengthened by the  
30 identification of shared haplotypes within each family that co-segregate with the OCD  
31 phenotype. The utility of looking for individual or private mutations in relatively small numbers  
32 of families from specific populations such as the CVCR has been previously successful for  
33 complex traits such as Alzheimer disease, where linkage studies of a small number of Volga  
34 German families identified a linkage on chromosome 1 that eventually led to the identification of  
35 the PS-2 mutation, which was then subsequently identified in sporadic Alzheimer disease  
36 cases (St George-Hyslop and Petit 2005).

1  
2  
3 Chromosome 15q14-15 has been previously implicated as a region of interest for OCD in  
4 a linkage analysis using affected sib pair families(Shugart et al. 2006). The Shugart et al. study,  
5 which used a non-parametric analysis and comparable phenotype definitions to those used in this  
6 study, identified a Kong and Cox LOD score of 1.32 under the broad phenotype on chromosome  
7 15q13-15q35. Chromosome 15q14-15 has also been implicated in studies of compulsive  
8 behavior in mice, where linkage to compulsive wheel running was found on mouse  
9 chromosomes 2, 6, and 7; the linked region of the mouse chromosome 2 is homologous to the  
10 human chromosome 15q region identified previously and in our study(Kas et al. 2010). In  
11 addition, multiple SNPs in the 15q14 region have recently been found to be associated with both  
12 OCD and with Tourette Syndrome, a closely related neuropsychiatric disorder, in GWAS (p  
13 values of  $\sim 10^{-4}$ ) (J. Scharf and SE Stewart, personal communication, unpublished data).  
14 However, to date, no gene in this area has been extensively examined for evidence of a  
15 relationship to OCD.

32

33  
34  
35 Although there are multiple potential candidate genes of interest for OCD in this region,  
36 we chose to examine RYR3, which is of particular interest as a candidate gene for OCD not only  
37 because of the localization of the strongest linkage signal in our study to this gene, but also  
38 because of its brain expression patterns and its potential relationship to fear conditioning and  
39 synaptic plasticity (Rauch et al. 2001; Nakashima et al. 1997; Matsuo et al. 2009; Balschun et al.  
40 1999). We were unable to identify any sequence variants that were both associated with OCD in  
41 all three families and were predicted to have a clear functional effect, although we did identify  
42 SNPs that were associated with OCD in two of the three families, and were predicted by *in silico*  
43 methods to have a potential functional impact on the RYR3 protein.

1  
2  
3 The ryanodine receptors are calcium induced calcium release (CICR) channels primarily  
4 located in smooth and cardiac muscle(Takeshima et al. 1996). RYR3 is expressed in smooth  
5 muscle at low levels, but appears to be primarily expressed in brain; as noted previously, it is  
6 expressed at high levels in multiple areas implicated in OCD pathology(Rauch et al. 2001;  
7 Nakashima et al. 1997). Calcium influx via AMPA-type glutamate receptors has been shown to  
8 elicit CICR from ryanodine receptors in rat ganglion cells, suggesting a relationship between  
9 glutamate, which has been implicated in OCD pathophysiology, and ryanodine(Morton-Jones et  
10 al. 2008). Similarly, RYR3 interacts with BDNF to promote hippocampally-mediated spatial  
11 memory learning and memory consolidation(Adasme et al. 2011). Mutant mice lacking RYR3  
12 show impaired spatial learning, impaired hippocampal synaptic plasticity, and impairments in  
13 contextual fear conditioning and deficits in social interactions(Matsuo et al. 2009; Balschun et al.  
14 1999; Kouzu et al. 2000). RYR3's effect on fear conditioning appears to be modulated through  
15 its ability to activate Ca<sup>2+</sup>/calmodulin-dependent protein kinase II (CaMKII), which is one of the  
16 key synaptic molecules involved in long-term fear memory formation, and is highly expressed in  
17 the amygdala and hippocampus(Radwanska et al. 2010).

## 38 39 **Limitations**

40  
41  
42  
43 There are two main limitations to this study that potentially limit the generalizability. The  
44 first is that the sample size is relatively small, and although all three of the families studied  
45 contribute to the linkage signal on chromosome 15q14, the majority of the signal comes from  
46 family 2, the largest and most complex pedigree. The second limitation is that we used multiple  
47 analytic approaches and two phenotypic models, increasing the risk of identifying a false  
48 positive. Despite the multiple models tested, however, we believe that the linkage results, which  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 are consistent across multiple phenotypic and analytic models, are compelling, and as noted, are  
4  
5 congruent with findings from previous genetic studies of OCD and OCD-like behaviors. The  
6  
7 third limitation is that our sequencing studies did not provide clear and compelling evidence of a  
8  
9 causal sequence variant in the exonic regions of the primary candidate gene of interest, RYR3.  
10  
11 Given the phenotypic and genetic heterogeneity of OCD, our findings do not entirely rule out  
12  
13 RYR3 as a candidate gene, as future studies may identify functionally significant variants in the  
14  
15 intronic or regulatory regions. Further, as will likely be the case for many complex  
16  
17 neuropsychiatric disorders, genetic heterogeneity, the presence of phenocopies, and incomplete  
18  
19 penetrance within families may make the identification of specific causal variants in a given  
20  
21 linkage region difficult without complete targeted sequencing efforts followed by functional  
22  
23 studies of the identified associated variants.  
24  
25  
26  
27  
28  
29

### 30 **Summary**

31  
32  
33  
34 In summary, our results, in combination with previously reported OCD linkage studies,  
35  
36 recent genome-wide association studies, and mouse studies of the chromosome 15 homologous  
37  
38 region, provide multiple lines of evidence to implicate chromosome 15q14 in genetic  
39  
40 susceptibility for OCD, and suggest that RYR3, and potentially several other brain-expressed  
41  
42 genes under this linkage peak, the nicotinic receptor (CHRNA7) and the muscarinic cholinergic  
43  
44 receptor (CHRM5), for example, are worth investigating more fully as potential candidate genes.  
45  
46 Follow-up studies are needed to validate and extend these findings, including replication of the  
47  
48 linkage findings in additional families, both from the CVCR and other populations, sequencing  
49  
50 of the intronic and surrounding regions of the RYR3 gene, examination of the other brain-

**Table and Figure Legends and Footnotes:**

Table 1: Chromosomal regions with LOD scores  $\geq 1.5$ . \* = SNP(s) with highest LOD score. # SNPs = number of consecutive SNPs with LOD scores  $> 1.5$ . cM=centiMorgans

Figure 1: Pedigrees included in the linkage analysis. Full black symbols indicate DSM-IV OCD. Half black symbols indicate subclinical OCD. Grey symbols= affected or unknown phenotype. += individuals with genotype data. Circles indicate individuals with sequence data.

Figure 2: Plots of genome-wide LOD and NPL scores for chromosomes where LOD scores (MORGAN) or NPL scores  $\geq 2.0$ . Panel A: Chromosome 1. Panel B: Chromosome 15. Panel C: Chromosome 16. Plots of LOD and NPL scores for all other chromosomes can be found in the supplementary materials. Dominant=autosomal dominant model. Recessive=autosomal recessive model. Narrow=narrow OCD phenotype. Broad=broad OCD phenotype.

Figure 3: Haplotypes for family 2 in the region of interest on chromosome 15. Black symbols represent the narrow OCD phenotype. Major segregating haplotype is indicated by black line; minor segregating haplotype is indicated by grey line.

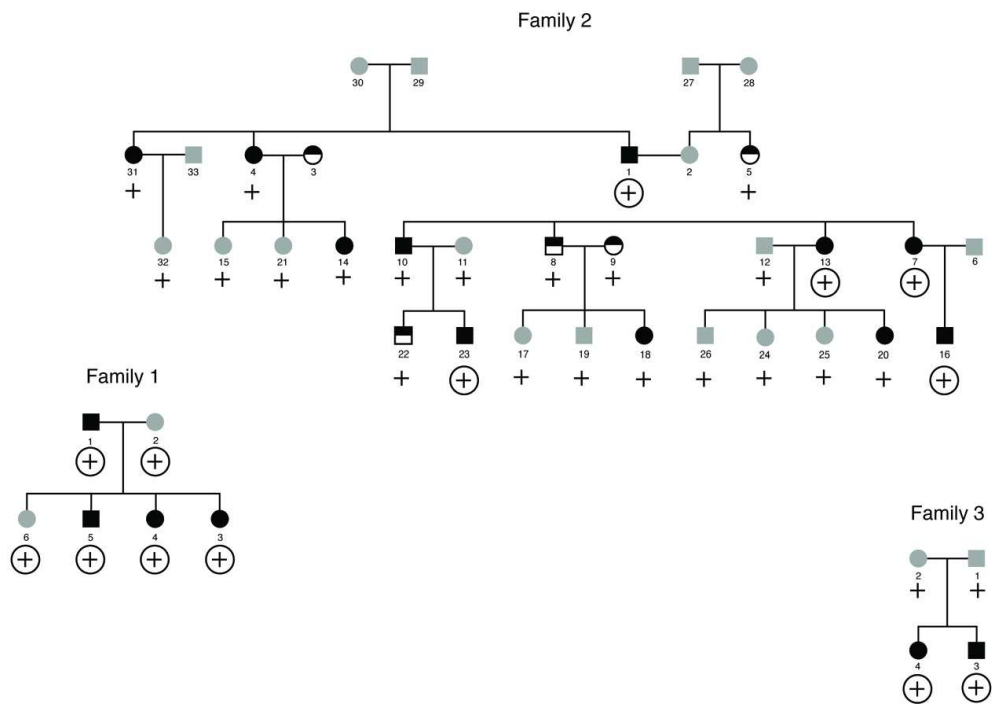

Chrom	SNP*	LOD score	# SNPs	Analysis	Model	Phenotype	Location (cM)
1	rs1445225 rs716581 rs977155	2.17	50	MORGAN	Recessive	Narrow	131
2	rs925229	1.81	13	MORGAN	Dominant	Broad	46

19q	NPL	OCD (DSM-III-R)	89	1.73	Hanna et al. 2002

Supplemental Table 1: Top linkage results from published OCD linkage studies.

NPL=non-parametric linkage. NPL studies reported Kong and Cox LOD scores, except for the Hanna et al study. \*=re-analysis of the Shugart et al. sample using only families with two or more members affected with compulsive hoarding.

Abbreviation	Gene name
TJP1	Tight junction protein 1
CHRFAM7A	CHRNA7/FAM7A fusion protein
MTMR15	Myotubularin related protein 15
TRPM1	Transient receptor potential cation channel, subfamily M, member 1
KLF13	Kruppel-like factor 13
OTUD7A	OTU domain containing protein 7A
CHRNA7	Cholinergic receptor, neural nicotinic, alpha polypeptide 7
ARHGAP11A	RHO-GTPase activating protein 11A
SCG5	Secretogranin V
GREM1	Gremlin homolog, cysteinesuperknot family
FMN1	Formin 1
RYR3	Ryanodine receptor 3
CHRM5	Cholinergic receptor, muscarinic 5
LPCAT4	Lysophosphatidylcholineacetyltransferase 4
GOLGA8A	Golgin subfamily A member 8B
NOP10	Nucleolar protein family A member 3
ZNF770	Zinc finger protein 770

Supplemental Table 3. Sequence variants in the RYR3 gene carried by OCD- affected individuals in at least one of the three CVCR OCD pedigrees. Grey rows indicate identified coding variants that are carried on the haplotype of interest in at least one family. Maj=carried on the major haplotype for that family. Min=carried on the minor haplotype for that family. All=carried by all OCD-affected individuals in that family. Unless otherwise indicated, all variants occur only in family members who carry the major haplotype co-segregating with OCD within that family. For family 1, the major haplotype is considered to be the maternal haplotype. \*indicates that the variant is carried by an unaffected sibling. †indicates that the variant is carried by the founder and the OCD-affected individuals who do not carry the major co-segregating haplotype. #carried by all OCD-affected individuals in family 2. N/A=information not available. CEU= allele frequency in the CEPH HapMap sample. MEX= allele frequency in the Mexican HapMap sample. ESE= exonic splice enhancer 1=ESE Finder, 2= RESCUE\_ESE, 3=ESRS Search, 4= PESX, 5=Ensembl

Supplemental Figure 1: Plots of genome-wide LOD and NPL scores for all chromosomes except chromosome 1, 15, and 16, which are found in the main text. Dominant=autosomal dominant model. Recessive=autosomal recessive model. Narrow=narrow OCD phenotype. Broad=broad OCD phenotype.

25 Supplemental Figure 2: Plots of LOD scores for family 2 in the region of strongest linkage  
26 on chromosome 15q14. Recessive=autosomal recessive model. Narrow=narrow OCD  
27 Broad=broad OCD phenotype.
