Abstract

Sugar-based polymers have been extensively explored as a means to increase drug delivery systems' biocompatibility and biodegradation. Here, we review the use of sugar-based polymers for drug delivery applications, with a particular focus on the utility of the sugar component(s) to provide benefits for drug targeting and stimuli-responsive systems. Specifically, numerous synthetic methods have been developed to reliably modify naturally-occurring polysaccharides, conjugate sugar moieties to synthetic polymer scaffolds to generate glycopolymers, and utilize sugars as a multifunctional building block to develop sugar-linked polymers. The design of sugar-based polymer systems has tremendous implications on both the physiological and biological properties imparted by the saccharide units and are unique from synthetic polymers. These features include the ability of glycopolymers to preferentially target various cell types and tissues through receptor interactions, exhibit bioadhesion for prolonged residence time, and be rapidly recognized and internalized by cancer cells. Also discussed are the distinct stimuli-sensitive properties of saccharide-modified polymers to mediate drug release under desired conditions. Saccharide-based systems with inherent pH- and temperature-sensitive properties, as well as enzyme-cleavable polysaccharides for targeted bioactive delivery, are covered. Overall, this work emphasizes inherent benefits of sugar-containing polymer systems for bioactive delivery.

1. Introduction

Great advancements in polymer synthetic methods in the past few decades have led to a new generation of sugar-based polymers with complex architectures, compositions, and well-defined molecular weights. All of these characteristics greatly enrich polymer diversity and enable a range of functions in biomaterials and biomedicine [1]. Compared with other synthetic polymers, sugar-based biomaterials have the advantages of being biocompatible, biodegradable, and non-immunogenic, making them particularly suitable for *in vivo* therapeutic applications. Sugar-based polymers have attracted substantial interest for biomedical applications, including drug, gene, protein, and antigen delivery, as well as diagnostic devices. As such, they represent one of most promising delivery vehicles and can be easily fabricated into different formulations, such as nanoparticles, micelles, and hydrogels, to encapsulate bioactive agents with varying hydrophobicity [2].

Sugars, as an essential component of the human body, are integral in several biological processes. Rapidly-growing interdisciplinary research provides insight into incorporating sugars, such as mannose, lactose, or galactose, into polymers as targeting ligands due to the high specificity of sugar-protein interactions [3]. Sugar-based conjugates have shown success as multifaceted carriers by exhibiting inherent bioactivity through competitive receptor inhibition in addition to mediating delivery of bioactive agents [4]. While various strategies such as introducing pH-sensitive bonds into polymers have been well-documented elsewhere, the use of sugar-based polymers (e.g., polysaccharides) with intrinsic stimuli-responsiveness is highlighted herein.

This review presents the preparation and development of tunable and versatile sugar-based polymers as targeted carriers and stimuli-responsive controlled release systems for bioactives over the past decade, highlighting the benefits of using sugar-based polymers over other synthetic polymers. It describes the design and functionalization strategies of sugar-based systems to improve carrier targeting specificity and stimuli-triggered localized drug release.

2. Benefits of sugar-based polymeric delivery systems

In recent years, sugars (i.e., saccharides) have attracted increased interest in the field of drug delivery due to their inherent biocompatible, biodegradable, and bioadhesive merits [5]. Furthermore, they are derived from abundant natural resources, exist in various repeat units (i.e., monosaccharides, oligosaccharides, and polysaccharides), and possess functional groups amenable to a wide range of chemical modifications. These features make them especially suitable structural building blocks for bioactive carriers. Sugars also play essential roles in many biological processes, such as molecular recognition, adhesion, and inflammation [6], motivating the development of sugar-comprised delivery systems to mimic natural biological processes. Sugar conjugation and modification also enable numerous desirable properties, such as reducing toxicity and immunogenicity [7, 8], improving serum stability, depressing freezing point [9], and promoting bioadhesion [10].

Sugars, such as chitosan or starch, are rich in hydrophilic functional groups, which allow for interactions with biological tissues. Carriers made of sugars have prolonged residence time in certain tissues, thus increasing absorbance of loaded drugs [11]. While synthetic polymers such as poly(ethylene glycol) (PEG) effectively shield carriers from uptake by the reticuloendothelial system, and thus extend half-life, they also retard cellular internalization due to decreased interactions between carriers and cellular membranes. Alternatively, sugar functionalization can camouflage delivery systems, increasing circulation time in the bloodstream, while also enabling cellular entry, which is highly desirable for delivery applications [12]. Polymeric delivery systems bearing pendant sugars with appropriate spatial arrangements can induce remarkable binding affinity enhancement for proteins due to multivalent interactions, known as cluster glycoside effects [1], which is one of the underlying merits of sugars as active targeting ligands (see Section 4 for more detailed discussion).

Recent innovation in synthetic approaches to generate sugar-based polymeric delivery systems [13] enables their construction in a controlled manner and assists the understanding of structure-activity relationships in extensive detail [14, 15]. These well-defined polymers are highly tunable and can be manipulated into different formulations (e.g., micelles, nanoparticles, vesicles, hydrogels), presenting a versatile platform for bioactive delivery. As such, sugar-based polymers have become increasingly prevalent in the broad portfolio of biomedicine and biomaterial applications [16].

3. Sugar-based polymers

Synthesis of polymeric materials has attracted tremendous interest over past few decades due to the precise control over architecture, stereochemistry, and composition. Compared to synthetic building blocks, sugar units have inherent tunability, chirality, and unique degradation properties *in vivo*. Linear sugars have varying numbers of hydroxyl groups, which can be used as conjugation sites for polymer decoration, and the differences in relative orientation of hydroxyl groups (i.e., stereochemistry) renders specific 3D configuration and spatial arrangement of conjugated moieties. More interestingly, as the human body can only metabolize the dextrorotary (D) form of sugars, the ratio of D and

levorotary (L) sugar enantiomers sugars can be altered to tune the polymer degradation profile.

3.1 Synthetic approaches for sugar-based polymers

Sugar-based polymeric delivery systems can be categorized into three major types according to the roles of the sugar entities: (i) polysaccharide derivatives, where the sugar is the bulk polymer composition; (ii) sugar-functionalized polymers (i.e., glycopolymers), where sugar moieties are conjugated as pendent groups, and (iii) sugar-linked polymers, where a sugar is used as a branch site or backbone (Fig. 1).

Natural polysaccharides can be easily modified due to their various functional groups, such as hydroxyl, carboxyl, and amino groups. Liu *et al.* have written an excellent review on polysaccharide derivatives in 2008 [5]. Various conjugation methods have been well-established to accommodate different reactive groups, such as carbodiimide-mediated and alkoxychloro 1,3,5-triazine-mediated coupling for ester and amide formation respectively [17, 18], leading to comprehensive libraries of hydrophobically- and hydrophilically-modified polysaccharides. One example of a synthetic approach particularly amenable to sugar-based polymers is the use of 4-(4,6-dimethoxy-1,3,5-triazin-2-yl)-4-methylmorpholinium chloride as a coupling reagent for polysaccharide modification, due to its ability to selectively promote amide formation in the presence of unprotected hydroxyl groups [19]. When necessary, linker molecules are used to enable conjugation and present alternative functional groups, such as a succinic [20] or less frequently used formaldehyde linker [21].

Synthetic glycopolymers can be synthesized either by polymerization of glycosylated monomers or by post-functionalization of pre-synthesized polymer scaffolds. Considerable efforts have focused on the controlled synthesis of well-defined glycopolymers [22] by controlled/living radical polymerization, such as nitroxide mediated polymerization (NMP) [23], atom transfer radical polymerization (ATRP) [24], and reversible addition fragmentation chain transfer (RAFT) [15] polymerization. These synthetic methods enable facile preparation of polymers with low polydispersity indices and well-controlled molecular weights and monomer sequences, giving rise to precisely prepared bioactive carriers. Conventional free radical polymerizations, (e.g., ring-opening polymerization (ROP) [14]) commonly require protected sugar-containing monomers. This necessity limits the applicability of ROP, as sequential deprotection of the sugars involves the use of strong alkaline or acidic conditions that may not be compatible with the existing polymer backbone. Combination of multiple polymerization methods is a robust approach to prepare hybrid polymers, such as ROP/ATRP [25]. A less common, but still effective method, is the use of enzyme-mediated polymerization, which is also under investigation as an environmentally-friendly alternative to conventional polymerizations [24]. Another complementary strategy that has also been widely used is post-functionalization of polymeric scaffolds for ease of purification and presentation of protruding sugar moieties, including free-standing polymers or preformed formulation surfaces [26, 27]. The latter approach ensures the presence of sugar moieties on the formulation (e.g., nanoparticles) surface to enable cellular interaction, making it especially suitable for targeted delivery.

Glycosylation can be chemically achieved through reductive amination [12], click chemistry for alkyne bearing polymers [28, 29], coupling reactions for conjugation via ester or amide [26, 30], and enzymatic transglycosylation [12]. Click chemistry is beneficial for quantitative carrier glycosylation [29], as it allows for precise control over the degree of glycosylation.

Sugar linked-polymers usually use the multiple hydroxyl groups of sugars as attachment sites. Uhrich *et al.* developed several series of sugar-based amphiphilic polymers (SBAPs) by acylating or alkylating different sugar acids (e.g., mucic acid, galacturonic acid) to form a branched hydrophobic domain, followed by conjugation to a hydrophilic PEG tail [31–33]. The branched domain could be further functionalized with various ethyleneimines to prepare gene delivery vehicles [34]. Similarly, Synatschke *et al.* used a core-first approach with functionalized sugars with multiple initiating sites for sequential polymerization by ATRP [35].

3.2. Sugar-based polymers design criteria and strategies

3.2.1. Polysaccharide derivatives—Numerous polysaccharide derivatives have been synthesized to investigate the influence of polymer structure variations on materials effectiveness, such as degree of substitution (DS), substitution linkage types, grafting density, etc. The polysaccharide DS has been well explored to modulate drug loading, encapsulation efficiency, and release profiles [17, 36]. Higher degree of hydrophobic substitution is generally associated with more compact particles, leading to higher drug loading and encapsulation efficiency, along with extended and sustained cargo release [37]. This effect is likely due to stronger intra- and/or intermolecular hydrophobic interactions under aqueous conditions. It should be noted that excessive substitution may lead to limited polymer solubility in water, compromising translational capabilities as drug carriers [36].

Substitution linkage types also play a critical role in adjusting physicochemical properties of delivery systems. Vallée *et al.* showed that amide derivatives of alginate hydrogels had strongly reduced solubility and better degradation stability compared to ester counterparts [38]. In addition, grafting density is a robust tool to fine-tune hydrogel properties. Mundargi *et al.* reported that by increasing the acrylamide grafting ratio onto xanthangum, prolonged drug release and reduced swelling were achieved [39].

Tailoring the molecular weight and DS can modulate polymer-nucleic acid complex stability, unpacking, and transfection efficacy for nucleic acid delivery systems. A proper molecular weight and/or DS are required for efficient nucleic acid delivery due to the subtle balance between formulation stability and nucleic acid release. By fine-tuning the molecular weight of cationic chitosan and molar ratio of uncharged oligosaccharide, Strand *et al.* successfully identified the optimal chain length and substitution degree of glycosylated chitosan that would provide sufficient DNA protection and balanced electrostatic interactions with DNA to facilitate release upon cellular uptake [40].

3.2.2 Glycopolymers—Glycopolymers with different architectures (e.g., star-shaped, linear, and dendritic) have been extensively explored and characterized, providing insight into the rational design of sugar-functionalized delivery vehicles. Aggregates assembled

from star-shaped polymers typically demonstrate better thermodynamic stability compared to linear counterparts. Dai *et al.* reported the synthesis of star-shaped poly(ϵ -caprolactone)-*b*-glycopolymers from the controlled ROP of a ϵ -caprolactone monomer, followed by direct ATRP of unprotected glycomonomer [25, 41]. Through systematic investigation, the star macromolecular architecture was shown to be critical in improving the thermodynamic stability of aggregates. In fact, dendritic copolymers had an order of magnitude lower critical aggregation concentration compared to linear analogues. In addition, by adjusting the weight fraction of hydrophilic glucose-bearing segments, the self-assembly properties and aggregate morphologies of amphiphilic copolymers in aqueous solutions were significantly changed, which can be attributed to the hydrophilic-lipophilic balance (HLB). Morphologies including micelles, vesicles, and large compound aggregates can be fabricated from sugar-decorated polymers with varying HLB, presenting a range of sugar densities and spatial arrangements [42]. For example, giant polymersomes (i.e., vesicles) with 20–25 μm diameters were prepared with glycosylated polyethylene-*block*-poly(ethylene glycol) (PE-*b*-PEG) with appropriate HLB values, capable of hydrophobic dye encapsulation [43].

To better understand the influence of architecture on cationic nucleic acid delivery vectors, Ahmed *et al.* synthesized a library of cationic glycopolymers containing pendant sugars of different architectures (block vs. random) via RAFT [15]. Interestingly, the random copolymers demonstrated greater cell viability and higher transfection efficiency in both serum-free and serum-containing conditions in comparison with corresponding diblock copolymers. These results indicate that the sugar residues were less able to mask the toxicity of the cationic segment in the block configuration. It was likely that block glycopolymers form core-shell structures with a sugar-modified corona, as opposed to random copolymers with a more accessible surface charge (Fig. 2). However, polyplex aggregation induced by serum proteins was considered a major drawback as compared to block copolymers for *in vivo* applications [15]. Built upon aforementioned findings, Ahmed *et al.* further developed cationic “block-random” copolymers. To prepare these cationic vectors with block-random configurations, homopolymers of glycomonomer were first synthesized using RAFT polymerization and sequentially used as macro chain transfer agents for copolymerization with the cationic monomer. In contrast to statistical analogues, sugar-based block-random copolymers showed higher gene expression and lower toxicity, in addition to improved stability in physiological conditions [44].

Molecular weight is a major factor in cytotoxicity and gene transfection efficiency, which is consistent with trends observed for a broad range of nucleic acid delivery vehicles [45]. High molecular weight cationic glycopolymers (Fig. 2) were found to show comparable gene expression to the poly(ethyleneimine) (PEI) control with significantly lower toxicity [15].

Variations in hydrophobicity and saccharide length should also be considered when optimizing delivery properties. For example, Bhatia *et al.* developed biocompatible sugar-PEG-based drug carriers by lipase-mediated copolymerization of PEG dimethyl ester and hydrophobically modified sugar monomers. The hydrophobicity of the monomers was modulated to promote aggregation and achieve higher micellar drug loading [24]. Höbel *et al.* varied the length of oligosaccharides used for preparing grafted PEI from maltose,

maltotriose, to maltoheptaose and established the influence of sugar length on physicochemical and biological properties of corresponding nucleic acid complexes. The longer oligomaltose further shielded the surface charge after complexation with siRNA as compared to shorter oligomaltoses, resulting in altered uptake and biodistribution [7].

Sugar-functionalized polymers prepared by post-functionalization from a pre-formed polymer scaffold typically include optimizing sugar conjugation location sites. Kim *et al.* modified branched PEI (25 kDa) with PEG and mannose as siRNA delivery systems. To characterize the effect of mannose ligand location on cellular uptake and gene silencing efficiency, the mannosylated PEGylated PEI delivery systems targeting macrophages were constructed by either directly conjugating mannose and PEG to the PEI backbone (Man-PEI-PEG) or conjugating mannose to PEI via a PEG spacer (PEI-PEG-Man). The PEI-PEG-Man/siRNA polyplexes, which had mannose moieties exposed on the surface, exhibited faster endocytosis and higher knockdown efficiency than Man-PEI-PEG [46]. The study implies that sugar moieties should be incorporated onto carrier surfaces so that they are available for sugar-cell interactions.

3.2.3 Sugar-linked polymers—Although sugars used as backbones or branch points are less exploited, a few research groups have explored the structure-activity relationship of sugar-linked polymers for bioactive delivery. Particularly, Uhrich *et al.* developed a series of SBAPs with extremely low critical micelle concentrations (CMCs) (10^{-7} – 10^{-4} M) as stabilized micellar delivery systems [31, 47, 48]. Unlike conventional diblock copolymers, SBAPs have a branched hydrophobic domain, where the degree of branching [31, 49], linkage type [32], and stereochemistry [50] of the hydrophobic domain were systematically analyzed to determine structure-property relationships. By changing the sugar acid backbone (e.g., tartaric acid vs. mucic acid), the degree of branching, and thus the size of the hydrophobic domain, the structure was conveniently tuned for the desired applications [47, 49]. Interestingly, the conjugation chemistry (e.g., ester linkage versus ether linkage) between alkyl arms and sugar backbone appeared to contribute significantly to solution properties of polymeric micelles. Ether-linked SBAPs had CMC values one or two orders of magnitude lower than corresponding ester-linked SBAPs, correlating well with molecular modeling observations. Better alignment and packing within the hydrophobic domain could be achieved by replacing the relatively rigid ester bond with more flexible ether bond (Fig. 3), leading to more compact aggregates and enhanced colloidal stability [33].

Evidence has accumulated that non-viral gene delivery systems with nonlinear architecture (e.g., star-shaped polycations) manifest better transfection efficacy than linear polycations [51]. By polymerizing poly(2-(dimethylamino)ethyl methacrylate) (PDMAEMA) from functionalized sugars (glucose and saccharose) with multiple initiating sites as the central core, Synatschke *et al.* generated two star-shaped PDMAEMA polymers containing 3-arm stars and 5-arm stars via ATRP. Despite the high general toxicity of polycations, 5-arm stars afforded lower cytotoxicity compared to 3-arm stars with a similar molecular weight, suggesting that cytotoxicity decreased with increased branching degree [35]. While the potential mechanism remains unclear, it was hypothesized that the internal positively charged nitrogens of the star polymers were sterically hindered from interacting with cell membranes, improving cytocompatibility.

4. Sugar-based carriers for targeted drug delivery

Key concerns in the field of drug delivery include systemic toxicity, low drug bioavailability, and rapid drug clearance. Recently, targeted drug delivery systems have gained interest as a way to increase therapeutic efficacy and address these issues by delivering bioactive agents to specific areas of the body. Of the potential targeting strategies, glycosylation targets specific locations in the body, while improving carrier biocompatibility and circulation time [2]. In addition, the bioadhesive properties of glycosylated delivery systems allows for alternative, non-invasive administration routes [52]. Sugar-based polymers can act as carriers for both active and passive targeting. Active targeting provides specific delivery to sugar receptors and reaches the target site with high efficacy, while passive targeting relies on the carrier's physicochemical properties for localized drug accumulation. This section highlights recent advances in sugar-based drug targeting technologies, focusing on their unique ability to provide cell- and tissue-specific interactions, adhere to and absorb through biological tissues, and be selectively metabolized by cancer cells.

4.1 Passive targeting with sugar-based carriers

Passive targeting with glycosylated nanoassemblies is a common approach, especially for tumors [53]. In cancer progression, partial angiogenesis leads to leaky vasculature and enlarged gap junctions (100 nm to 2 μ m), allowing macromolecular carriers to enter the tumor interstitial space and remain for extended time periods by the enhanced permeability and retention effect (EPR) [54].

A number of groups have used sugar-based polymers to locally deliver drugs by mimicking proteins' physicochemical properties (e.g., surface charge) involved with biological processes at target sites [4, 55]. Additionally, these systems are found to exhibit inherent bioactivity by competitively inhibiting ligands from binding to their receptors and interrupting the normal ligand-activated pathways, such as intracellular signaling, immune response, and other disease cascades. For example, several research groups have exploited the ability of ionic micelles, liposomes, or nanoparticles to preferentially accumulate in macrophages and repress atherosclerosis [55–59]. Cardiovascular research by Moghe and Urich *et al.* has demonstrated that by tailoring polymer charge, anionic nanoparticles comprised of SBAPs with a sugar-based backbone and PEG tail target the lesion sites and competitively bind macrophage and smooth muscle cell scavenger receptors to limit cholesterol accumulation in atherosclerosis and neointima hyperplasia in restenosis, respectively [57]. Another example of passive targeting is the use of sulfated ester nanoparticles with a lactose core, which demonstrate high selectin binding efficacy on leukocytes and platelets in blood. For instance, dendritic β -lactose-PEG glycopolymers with terminal sulfate moieties competitively bind leukocyte-selectin receptors to block chemokines from binding to the epithelium, thereby providing anti-inflammatory effects. The authors suggested this effect was likely due to multivalent properties of the glycopolymers, where multiple sulfate moieties associated with leukocyte- and platelet-selectins through electrostatic interactions [60, 61]. Sulfated esters also bind to other selectins, such as glyCAM-1 on endothelial cells, despite the fact that the polymers lack the

typical fucose and sialic acid residues required for ligand-receptor binding [62, 63]. While great advancements continue to be made in passive targeting research, the remainder of this section will highlight current strategies for designing particles that promote active targeting specificity.

4.2 Active targeting with sugar-based carriers

Active targeting has gained significant attention as a method to deliver bioactives to specific cell or tissue types and with minimal effects to other areas of the body. In contrast to passive targeting, where sugars are usually present in the macromolecular backbone, active targeting requires the bioactive (e.g., sugar, antibody, etc.) to be displayed on the outside of the nanoassemblies to promote receptor binding.

Carbohydrate receptor-mediated delivery systems are favorable since they are easy, cost-effective, and have well-established synthetic, fabrication, and characterization methods. Specific sugar molecules, such as galactose and mannose, are recognized by carbohydrate-binding proteins (i.e., lectins) present on a variety of cell surfaces [64]. These interactions can be utilized for sugar-mediated targeting by decorating the carrier surface with sugars, known as glycosylation. Once glycosylated particles are bound to the lectins or vice versa, receptor-mediated endocytosis occurs, where the particles are internalized by the cell [64]. The process of endocytosis begins with invagination of the cellular membrane which results in particle uptake, internal vesicle (i.e., endosome) formation, and internalization of extracellular particles.

Alternative common targeting ligands to sugars include small molecules (e.g., folic acid, biotin, etc.), peptides/proteins, nucleic acids, aptamers, and antibodies [65]. Small targeting molecules are favorable due to their efficacy in targeting cancer cell receptors [66], facile preparation, and inexpensive particle conjugation with good efficacy [65]. However, many normal cell types, such as the placenta and kidneys, express the same receptors, so high specificity is often difficult to achieve [67]. Peptide ligands have good targeting specificity [68], small size, high stability, and relative scalability for large-scale synthesis. Nucleic acid aptamers can recognize proteins, phospholipids, sugars, and nucleic acids with high affinity and specificity, and have cost-effective production with good reproducibility and lower immunogenicity and smaller size than antibodies to allow for specific receptor-target interactions [65]. While antibodies provide high specificity and a range of binding affinities, the associated immunogenicity and the logistical and cost challenges of biologic therapeutics has limited its clinical success.

As a result, hybrid technologies have emerged, such as the development of antibodies glycosylated with oligosaccharides to target sugar receptor-bearing cells [69]. Although these antibody therapies were designed to have reduced immunogenicity and improved physiological retention time, studies have demonstrated mixed results. As some glycosylated antibodies have a comparable or shorter half-life than the natural glycoforms of IgG Fc, additional research is needed to provide a therapeutic benefit [70, 71].

4.2.1 Sugar receptor-mediated active targeting—Numerous glycosylated polymeric delivery systems take advantage of active targeting via sugar receptors. A critical aspect of

glycopolymer development is the selection of an appropriate targeting ligand, where the ligand physicochemical properties, biocompatibility, cell specificity, binding affinity, and ease of conjugation and processing affect ligand suitability for a particular application [72]. As targeting ability is primarily dependent on the interactions between glycosylated material and lectin, much research has focused on understanding protein-polymer interactions. Additionally, some receptors, such as the mannose receptor, are present on multiple types of cells or tissues. Several types of intermolecular forces exist between the lectin receptor and the glycosylated polymer, and are specific to the structural conformations of each entity. Sugars primarily interact with receptors through H-bonding between sugar hydroxyls and amides or acid groups of the receptor's amino acids and the protein hydration shell [73]. If the hydroxyl is not available to hydrogen bond with amino acids, such as upon ester or amide formation during sugar modification, the binding affinity will be reduced, resulting in a relatively high ligand concentration required to achieve the maximum physiological response. C-H- π stacking also exists, where aliphatic C-H groups interact with aromatic residues in the binding pocket, giving rise to van der Waals forces [74]. While significant progress has been made to understand these interactions using computational and/or experimental methods, sugar structure diversity and the wide range of lectins makes it difficult to precisely elucidate structure-activity relationships.

A vast array of cellular lectins have been identified (Fig. 4). A prevalent family of receptors, C-type lectin receptors, facilitate a range of cellular functions, such as cell-cell adhesion, immune response to pathogens, and apoptosis [75]. The most common C-type receptors are the mannose receptor, asialoglycoprotein, liver- and dendritic cell-specific intercellular adhesion molecule-3 grabbing non-integrin (DC-SIGN), and selectins [76]. More information on sugar receptors and their targeting ligands can be found in Table 1.

Various research groups evaluated the influence of conjugation variables, including sugar type, degree of glycosylation, and the number of sugar repeat units on lectin binding. For enhanced binding, some groups evaluated the targeting ligand density by grafting multiple sugars to one grafting site for cooperative multivalent interactions [77, 78]. A fundamental study evaluating the role of sugar type (i.e., galactose and lactose) and sugar valency in the recognition of hydroxypropyl methacrylamide copolymers by colon adenocarcinoma cells demonstrated that binding was dependent on the number of sugar residues at a single grafting site [77]. In many cases, multiple sugars at one grafting site increases the binding affinity and leads to increased targeting efficacy via the glycoside cluster effect [77, 78]. To overcome weak binding affinity, multiple sugars can be conjugated to the polymer surface to enhance lectin interactions [67, 78].

The impact of polymer molecular weight and DS on tumor targeting characteristics of nanosized drug delivery systems was investigated by Kwon *et al.* [79, 80]. They prepared nanoparticles from hydrophobically modified glycol chitosan with different molecular weights (20 kDa, 100 kDa, and 250 kDa), yet a similar degree of hydrophobic substitution. Despite different molecular weights, all three glycol chitosan nanoparticles exhibited similar particle size, surface charge, and *in vitro* stability. *In vivo* tissue distribution and tumor accumulation revealed that high molecular weight glycol chitosan nanoparticles displayed prolonged blood circulation time and enhanced tumor accumulation. They also identified

that the hydrophobic DS greatly influenced stability and deformability of resulting nanoparticles, thus affecting tumor targeting efficiency *in vivo* [80]. A proper DS was required to balance stability and deformability to reach optimal blood circulation time and tumor-targeting efficiency through the EPR effect [81].

In addition to monosaccharide conjugation, oligosaccharides have been used to decorate the nanoassembly exterior. For example, trimethylated chitosan-conjugated poly(lactic-co-glycolic acid) nanoparticles demonstrated successful coumarin delivery to the brain by targeting extracellular lectins and negatively charged membranes [91]. Another example of oligosaccharide ligands is the use of hyaluronan technologies to target CD44 receptors overexpressed on several tumor cell surfaces and provide delivery of cancer therapeutics [92, 93].

4.2.2. Active targeting by bioadhesion—Due to their tissue adhesive nature, glycosylated polymers can enable alternative dosage forms by adhering to tissues to prolong localized delivery [52]. Sugar-mediated mucoadhesion and cytoadhesion allows for enhanced bioavailability, local retention, and efficacy, and alternative administration routes, such as nasal or pulmonary delivery [52]. Delivery to the oral, nasal, or pulmonary mucosa is common, because they have relatively permeable membrane structures. The oral mucosa is frequently targeted due to the ability to bypass significant liver metabolism to increase drug bioavailability, unidirectional drug flux, and ease of accessibility and patient compliance. Moreover, many oral drugs are designed to be absorbed by the gastrointestinal (GI) system, but have limitations including high liver metabolism, enzymatic drug degradation during absorption, and high mucus turnover. Bioadhesive carriers are particularly useful in applications where fast clearance by EPR is an issue. Some notable examples of bioadhesive carriers include inhalable mannosylated liposomes for lung infections [83] and bioadhesive mannosylated NPs for oral retention [87].

For mucosal peptide or protein delivery, a number of chitosan-based carriers have been developed to deliver insulin [94, 95], plasmid DNA [96], or siRNA [97] by encapsulation [94–96] or self-assembly [98]. A common mucoadhesive moiety, chitosan, is a biocompatible, biodegradable, and cationic polysaccharide, which are favorable properties for mucoadhesion [99]. While chitosan alone can be used to form mucoadhesive carrier systems, co-incorporation of high charge density anionic polymers, such as dextran-sulfate or alginate in an ionic gelation processes can produce nanospheres capable of high insulin encapsulation efficiency (~49–96%) and controlled drug release [95, 100]. Mucoadhesive systems release insulin by dissociation as the pH changes. In these cases, mucoadhesion allows for a highly specific targeted and localized release. Another notable application is to improve the gene transfection efficiency of polylactic acid (PLA), a biocompatible and biodegradable non-viral gene delivery vector, by copolymerizing methoxypoly(ethylene glycol)-PLA and chitosan [101]. The *in vivo* results in mice demonstrated that localized polymer retention led to higher gene expression in the stomach and intestine compared to co-blended PLA-chitosan/DNA and lipofectamine/DNA complexes. To improve chitosan carriers, trimethyl chitosan-cysteine (TMC) conjugates were evaluated. Contrary to the low permeability of insoluble chitosan, TMC is a quaternized cationic derivative with good solubility and enhanced permeation. Combining TMC with thiolated polymers imparted

increased mucoadhesion compared to non-thiolated nanoparticles and resulted in up to a 12-fold increase in insulin transport through rat intestines and 13-fold increase in Caco-2 cell internalization [98].

Targeting mucous layers is of particular interest for drugs that cannot be orally delivered due to acidic degradation or significant liver metabolism. Many absorptive epithelial mucosa, such as those found in the intestines, oral cavity, and airway epithelium, are covered with a highly glycosylated mucin-based layer that is anionically charged [102]. Under the mucosal layer is the glycocalyx, comprised of proteoglycans, glycoproteins, and glycolipids in the cell membrane. An alternative strategy of using sugars to target the mucosal surfaces is to decorate the delivery system exterior with lectins to interact with glycosylated surfaces, such as mucosal surfaces [103]. Studies have evaluated lectinized liposomes in binding to alveolar type II epithelial cells [104] or to intestinal mucosa for oral delivery [105].

4.2.3. Active targeting via sugar recognition by cancer cells—The Warburg effect, where malignant cells have an accelerated metabolism and high glucose requirements compared to non-malignant cells, has been well-established in cancer pathology [106]. Glucose and other glucose transporter substrate sugars are internalized by the tumor cells via the glucose transporter protein GLUT, which is overexpressed on human cancer cells [107, 108]. GLUT is correlated to poor cancer prognosis [109, 110], and glucose is utilized as a nutrient source to increase cell proliferation, leading to rapid tumor growth [111]. Thus, sugar-based therapeutics have been investigated for higher uptake rates by tumor cells compared to normal basal cells. Much of this work was inspired by early research where Som and coworkers successfully employed fluorescently-labeled glucose analogues to deliver the fluorescent dye to tumor cells for subsequent imaging with positron emission tomography [112]. More recently, fluorescently-labeled glucose carriers have been applied to deliver and track the anti-cancer therapeutic cisplatin [113].

A number of glucose-based drug delivery technologies provide enhanced solubility of hydrophobic actives and target lung, breast, colorectal, endometrial carcinomas, bone and soft-tissue sarcomas, and a number of lymphomas [106]. A common strategy is the use of glycan-conjugated prodrugs, which target cancer cell uptake via the GLUT transporter and release the active compound upon hydrolysis [114]. As cancer cells rapidly internalize glucose, the glucosylated carriers promote malignant cell apoptosis by upregulating GLUT in a positive feedback mechanism, causing an increased uptake of the glycan-prodrug polymer [115]. For example, glucosylated paclitaxel demonstrated high aqueous solubility and cytotoxicity against cancer cells, but limited toxicity towards normal cell lines or cells with low GLUT receptors levels [114]. Another glucose analogue, 2-deoxy-D-glucose (2-DG), has met great success in inhibiting glucose metabolism. 2-DG is recognized and internalized by tumor cells, in a similar manner to glucose, but cannot be converted to adenosine triphosphate to provide energy for cells [115]. When 2-DG is conjugated to anti-cancer therapeutics, the glycosylated shell enhances drug solubility, promotes cellular internalization of the prodrug, and upregulates GLUT expression. After the drug is internalized by the cell, hydrolysis of the anti-cancer prodrug leads to apoptosis, quickly killing tumor cells (Fig. 4) [114]. One example is to conjugate monosaccharides to DNA alkylators, which are used in chemotherapy to damage the DNA of cancer cells [116, 117].

Reux *et al.* demonstrated high specificity of 2-fluorodeoxyglucose-conjugated chlorambucil towards cancer cells in a mouse leukemia model. The glycoconjugated anti-cancer drug demonstrated increased cytotoxicity *in vivo* compared to the unacetylated sugar analog and the unconjugated chlorambucil in human cancer cell lines [116]. For targeted brain delivery, 2-DG-modified PEG-poly(trimethylene carbonate) nanoparticles were used as a dual-delivery system to enhance the blood-brain barrier penetration and glial drug accumulation by GLUT-mediated transcytosis and endocytosis, respectively [118]. Fluorescent images demonstrated high specificity and efficiency of these particles in an *in vivo* intracranial tumor mouse model with no acute toxicity to other organs after one week, representing a promising technology for brain glioma.

5. Stimuli-responsive sugar-based polymers

Stimuli-responsive delivery systems are designed to release bioactive agents at a desired location in response to physical or chemical changes. The stimuli can be biological or applied from an external source, and includes changes in pH or ionic strength in different tissues or cellular compartments [119, 120], the presence of tissue-specific enzymes [121], or external heat, ultrasound, or infrared irradiation application. Upon exposure to stimuli, a change in the polymer system occurs, resulting in bioactive release. This response can occur via chemical composition changes of the polymer [122, 123] or alterations in the polymer's physical or conformational properties (Fig. 5) [123]. Some notable examples are that changes in chemical composition may be induced by conjugating the polymer to a bioactive, similar to a prodrug, by a stimuli-cleavable bond for local release of the free drug upon stimuli exposure. This stimulus-induced change can include cleavage via enzymes or pH changes [124, 125]. Physical changes include stimuli-triggered changes in hydrogel swelling properties [122], polymer folding conformation [126], or aggregate assembly morphology.

Stimuli-triggered release systems offer several advantages, including reduced toxicity associated with systemic exposure by releasing the bioactive at the desired location. This approach reduces the amount of drug required during administration to elicit a therapeutic effect, as the localized release mechanism causes a higher concentration at the target site. While a vast number of polymer systems exhibit stimuli-dependent differential release, several sugar-based polymers inherently enable stimuli-triggered release [127, 128]. This section will focus on sugar-based systems where stimuli-responsive properties are a direct result of the sugar components. For delivery systems that incorporate sugars, but where the stimuli-responsiveness is not necessarily attributed to the sugar, readers are referred to a few excellent reviews [122, 123].

5.1 pH-responsive sugar-based polymers

One of the most commonly used triggers is pH. When the desired drug release location is intracellular, the pH of cellular compartments associated with uptake mechanisms, such as endocytosis, is utilized. As endocytosis progresses, the endosome pH decreases, from pH 5–6 in the early endosome, to pH 4–5 when the endosome fuses with the lysosome [120]. Drug release prior to lysosomal fusion is favorable to avoid cargo degradation. Additionally, certain tissues differ in pH compared to circulation; cancerous tumors have a slightly more acidic extracellular pH (pH 6–7) than normal tissues [119]. This difference is primarily due

to the Warburg effect and increased glycolysis rate, which exports acidic molecules to the extracellular environment (Fig. 4C) [129]. Alternatively, the pathway taken by oral delivery systems experiences a gradual pH increase, culminating in the basic environment of the colon (pH 7.4–8.0).

As the pH of different cellular compartments varies, polymer systems with acid-labile bonds or protonatable functionalities can be utilized to facilitate endosomal drug release by increasing hydrolysis rates [130] or changing the polymer protonation [94]. Several sugars have pKa values close to physiological conditions, such as chitosan. This feature results in protonation differences under the different pH of intracellular vesicles and tumor tissues and leads to a change in biological or polymer conditions to release entrapped cargo. Ionic and/or reactive functional groups, such as those in chitosan and alginate, further allow for conjugation to other materials to impart pH sensitivity by chemical modification via pH-sensitive bonds [124, 130] or stimuli-responsive bulk polymer systems (e.g., poly(acrylic acid)) [131].

Many sugar-based polymers naturally exhibit pH sensitivity and can be utilized for controlled bioactive release in response to pH changes. Chitosan bears primary amines with a pKa of approximately 6.2 resulting in more protonated amines under acidic conditions, promoting endosomal escape of polysaccharide-drug complexes into the intracellular environment through the proton sponge effect [132]. An excellent review of chitosan-based hydrogel delivery systems has recently been reported [127]. An alternative approach to impart pH sensitivity into chitosan is to use the free carboxylates as crosslinking sites to generate sugar-based hydrogels [133]. The crosslinking agents can be naturally derived, such as genipin [134] and alginate [135], or the hydrogels can be blended with hydrophilic polymers, such as poly(vinyl alcohol) to increase swelling responses to pH changes [134]. Alternatively, negatively charged sugars such as alginate can be crosslinked with divalent cations to generate pH sensitive hydrogel systems for controlled release [136, 137]. Notably, Zhuo *et al.* designed Ca²⁺ crosslinked alginate, chitosan, and pectin composite beads that were subsequently released as microparticles for oral protein delivery [137]. Composite systems exhibited enhanced pH-sensitive protein release profiles under basic conditions, while protecting the protein from degradation in acidic conditions.

Systems have also been developed to release cargo under neutral or basic conditions for GI delivery. Wang *et al.* generated semi-interpenetrating network hydrogels of carboxymethyl chitosan crosslinked with alginate for pH-sensitive protein delivery to the colon and intestines. Under neutral and basic conditions, the hydrogels have decreased swelling volumes, resulting in bioactive release [135]. Similarly, chitosan particles designed to complex oligonucleotides, have been prepared by reverse microemulsion techniques and also demonstrated an increase in burst release under neutral and basic conditions compared to acidic conditions [138]. At elevated pH, the net cationic charge of chitosan is decreased, likely resulting in decreased oligonucleotide affinity. Alternative formulations, such as microcapsules [139] or nanoparticles [94] of chitosan-derived materials, also exhibit pH sensitivity and controlled release of encapsulated drugs and peptides. Of particular interest are chitosan-coated alginate nanoparticles designed by Kundu *et al.* to encapsulate insulin for oral delivery [140]. The alginate interior exhibits a collapsed structure under acidic

conditions, protecting insulin under simulated stomach acid conditions. Upon neutralization, mimicking entry into the GI tract, insulin release increases as the polymer returns to an un-collapsed state. The chitosan-coated alginate nanoparticles demonstrate promise in protecting insulin during oral delivery to aid intestinal adsorption.

Heparin, a highly sulfated glycosaminoglycan, interacts with tumor-related factors and reduces tumor growth and metastasis [141]. It can be utilized to elicit synergistic effects with tumor drugs for cancer treatment. Gu *et al.* conjugated doxorubicin to dendronized heparin via a pH-sensitive hydrazone bond for tumor-specific release, which led to a significantly reduced tumor volume in mice [142]. The numerous functional groups on different polysaccharides provide sites for direct drug conjugation via a variety of pH-sensitive linkages, such as oxime, hydrazone, imine, and acetal bonds [124]. Examples of linear sugar-based polymers conjugated to anti-cancer drugs or PEG through a hydrazone linkage exhibit enhanced drug loading in micellar aggregates and pH sensitivity [125, 130]. The Uhrich group utilized a hydrazone linkage to conjugate a hydrophobically modified sugar backbone to PEG to generate SBAPs that self-assemble into micelles under neutral and basic conditions [125]. At acidic pH, the labile hydrazone is cleaved, separating the hydrophilic and hydrophobic domains, resulting in aggregate assembly disruption and subsequent drug release.

5.2. Enzyme-specific cleavage of sugar-based polymers

A particularly unique feature of sugar-based polymers is their recognition as natural substrates by naturally-occurring human or bacterial enzymes, allowing for the use of polysaccharides for colon specific delivery [143]. Due to the differential enzyme expression, or habitable environments of naturally-occurring bacteria, drugs can be physically encapsulated in sugar-based polymer networks and controllably released at target locations upon glycoside linkage cleavage. A natural gradient exists in the number of bacterial colonies within the digestive system: the small intestine has 10^3 – 10^4 colony forming units (CFUs) while there are approximately 10^{11} – 10^{12} CFU/mL in the colon [121]. These naturally-occurring colonic microflora express enzymes that break down plant carbohydrates to facilitate digestion [144]. The specific recognition of particular polysaccharides by such enzymes facilitates greater specificity and localized release compared to analogous biodegradable polymer systems that rely on non-specific esterases or amidases for degradation-mediated release.

Konjac glucomannan (KGM) [128] and pectin [145] are two naturally-occurring polysaccharides that are cleaved by colonic bacterial enzymes, such as β -mannanase, β -D-glucosidase, β -D-galactosidase, etc., and are utilized to facilitate specific drug release in the colon for GI disorder treatment. These polysaccharides are commonly formulated into hydrogels [145, 146] and engineered as nano- or micro-particles [147–149] for drug encapsulation. Generally, higher degrees of crosslinking result in extended release by limiting the drugs' ability to diffuse out of the hydrogel, and lower crosslinking density results in burst release [148, 150].

As these polysaccharides can be naturally derived, their specific chemical properties, often based on their isolation source, influencing delivery properties [145]. Martínez-Pacheco *et*

al. explored the effect of varying acetylation degrees between KGM of different origins on particle size, swelling properties, and degradation rates in a mixed hydrogel. KGM and xanthan gum were formulated as thermoreversible gels for diltiazem delivery to the colon. Studies revealed that the drug was fully released in 24 h in the presence of β -mannanase for highly acetylated Japanese KGM, but only 60% released under identical conditions from American KGM-based hydrogels. These results highlight the potential tunability of combining various ratios of highly acetylated and deacetylated KGM in hydrogel formulations for colon specific delivery [151]. KGM has been incorporated into other formulations for colon-targeted delivery, such as a plug for a rapid dissolving capsule [147], and cationic KGM in combination with phytigel has been used for siRNA delivery against TNF- α for inflammatory bowel disease [146].

Pectin is a natural polysaccharide that can be enzymatically degraded by colonic microflora. Pectin varies by its esterification degree, and low-methoxyl pectin, with a higher degree of esterification is highly soluble in stomach and upper GI tract fluids, where drug delivery and adsorption are not beneficial, thus limiting use as an oral drug delivery matrix [152]. However, the carboxylates of pectin can be crosslinked by divalent cations, such as Zn^{2+} and Ca^{2+} , resulting in solubility characteristics amenable to oral delivery [145]. Organic molecules bearing cationic functionalities, such as chitosan, can also be used for cross linking [150]. Ng *et al.* developed Zn-pectin-chitosan composite nanoparticles that demonstrated colon-specific release *in vitro* following pre-exposure to acidic conditions, such as in the stomach, and *in vivo* in rats. They concluded that higher incorporation of chitosan increased the lag time preceding drug release, allowing the drugs to reach the intended site [150]. Previously described composite microparticles developed by Zhuo *et al.* further benefit from inclusion of pectin. In addition to the pH-sensitive release, enhanced specificity was demonstrated by the faster release profile of encapsulated protein with pectinase present [137].

Additionally, there are examples of sugar-based systems that do not use enzyme-susceptible polysaccharides as the bulk component. Rather, they utilize an oligosaccharide shell that is enzymatically degradable to promote drug release [153, 154]. Notably, Amorós *et al.* developed saccharide- (e.g., starch, lactose, etc.) capped silica nanoparticles, where the saccharide acts as shell and enzymatic cleavage, by enzymes such as pancreatin or β -D-galactosidase, release drugs by a gate-controlled mechanism at the target location (Fig. 6) [154].

5.3 Temperature-sensitive sugar-based polymers

Temperature-triggered release can be beneficial for localized therapeutic delivery by external heat. A few sugars inherently possess temperature sensitivity. Gellangum and xanthangum are two polysaccharides that exhibit conformational transitions from ordered helical structures to random coiled structures at elevated temperatures [155, 156]. In addition, several saccharide-containing polymers have a lower critical solution temperature (LCST), and sugar addition can modulate the LCST of synthetic polymers by altering the hydrophilicity or H-bonding capabilities of the polymer [157]. Above the LCST, the polymer adopts gel-like properties, allowing for small molecule encapsulation. Below the

LCST, these sugar-based polymers are free flowing solutions, allowing for ease of handling and injection for translational applications [123].

The majority of sugar-based systems with temperature-sensitive properties utilize polysaccharides as the bulk sugar components. For example, when crosslinked with aspartic acid, xanthan gum hydrogels exhibited reversible thermo-responsive swelling properties that are dependent on the sugar to amino acid ratio [158]. It is also noteworthy that the combination of these two naturally-occurring materials provided additional pH- and ionic strength-dependent swelling properties. Temperature-sensitive properties must be able to be fine-tuned, as highly elevated temperatures will cause irreparable cell damage. An example of a highly tunable system is pullulan-g-poly(L-lactide) nanogels developed by Na *et al.* that exhibited temperature sensitivity just above physiological conditions (37°C-42°C). This temperature range is amenable to external heat application but within the temperature range that will not significantly damage cells. A notable increase in drug release was observed at high temperatures, and the grafted L-lactide density had a strong influence on the temperature at which release occurred [159].

Alternatively, saccharides can be utilized as a cross-linking agent or additive to fine tune the temperature that a physical change in pre-synthesized polymers occurs. Although not inherently temperature-sensitive, addition of sodium alginate to semi-interpenetrating network hydrogels of PEG-co-poly(ϵ -caprolactone) macromer and N-isopropylacrylamide increased temperature sensitivity. The addition of alginate further contributed to increased mechanical properties and higher total protein release from the network [160]. Similarly, upon addition of dextran maleic anhydride to poly(N-isopropylacrylamide) (PNIPAm) hydrogels, the LCST of the synthetic polymer system could be fine-tuned from 35 to 39 °C, depending on the amount of incorporated dextran, and higher sugar content increased the LCST [161].

Semi-interpenetrating polymer networks of PNIPAm with gellan gum were developed by Aminabhavi *et al.* and formulated into microspheres for controlled delivery of atenolol. The formulations exhibited pulsatile release, with rapid release at 25°C and nearly no release at 37°C. The ratio of polymer to saccharide had a drastic influence on particle size, drug loading, and release profiles of atenolol [162]. This example has direct implications for delivery of highly toxic drugs that must only be released at the intended site.

The addition of non-conjugated saccharides to polymers with an LCST also influences phase transition, as sugars influence the solution hydrophilicity and compete with water molecules to interact with the polymer. Recently, Le Cerf *et al.* investigated the role of sugar length and structure on LCST decreases of a PEG and poly(propylene oxide) polymer using differential scanning calorimetry, nuclear magnetic resonance spectroscopy, and cloud point measurements [163]. As the length of the saccharide chain increased, the effect on LCST was less pronounced. For example, tri-saccharides exhibited minimal influence on LCST, whereas the same concentration of mono-saccharides significantly altered the phase transition temperature. They further identified structural parameters that influence the sugar's ability to interact with the polymer, particularly the hydroxyl at the C4-position and the linkage type between disaccharide monomers.

6. Conclusions and future perspectives

A variety of sugar-based systems have been explored for bioactive delivery. Among these systems, sugar-based polymers have drawn considerable attention due to high composition diversity, architecture, molecular weight, and functionalization offered by advanced synthetic approaches. The utilization of sugar-based polymeric delivery systems has provided pharmaceutical benefits including improved *in vivo* stability, prolonged circulation time, reduced toxicity of carriers, localized and sustained release, and improved pharmacokinetic profiles and superior tissue distribution since the advent of targeting and stimuli-responsiveness. Despite their clear promise, few examples exist of their translation to clinical practice and development. For instance, PK2, a galactosamine polymer doxorubicin conjugate, rapidly cleared from circulation in Phase I clinical trials despite encouraging results acquired in a rat model [3].

As such, increasing efforts have been devoted to designing formulations with optimized properties, such as batch-to-batch consistency, increased circulation half-lives, and improved tissue distribution [164]. Although still in their early stages, formulation technologies are rapidly emerging in targeted drug delivery and controlled drug release that incorporate multiple features to improve specific release of bioactives. For example, Kranning *et al.* generated glucopolymers that adopt a helical conformation under acidic conditions [126]. Under basic and neutral pH, the polymer transitions to a random coil conformation to present glucose functionalities and demonstrated enhanced selective binding to legume lectin, concanavalin, compared to non-glycosylated co-poly(L-glutamate)s. Two complimentary mechanisms, receptor targeting and stimuli-responsiveness, can be used to develop smart carrier systems for targeted drug release by combining active release features into the sugar-based polymer systems. Similar dual-targeting delivery approaches will create new opportunities for exciting, cutting-edge research on bioactive delivery to translate from the laboratory to clinical trials.

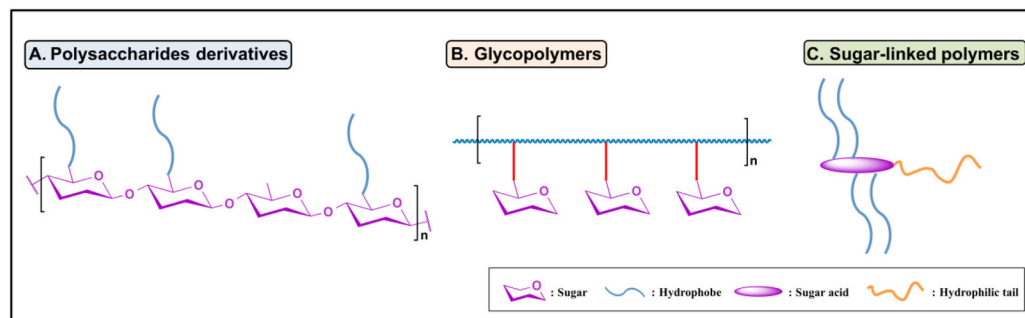

Fig. 1. Schematic representation and classification of sugar-based polymeric delivery systems.

Fig. 2. Schematic illustration of polyplexes prepared from diblock and random copolymers using plasmid DNA (adapted from [15] with permission).

Fig. 3. Equilibrium (low-energy) conformation of SBAPs with tartaric acid backbone (Left: Ether-linked, right: Ester-linked SBAP) in aqueous condition from dynamic simulation. Atoms are color-coded: C(gray), H(white), O(red). The blue arrows depict the orientation of alkyl arms (adapted from [33] with permission).

Fig. 4. Glycosylation enables a range of targeting strategies including glycosylated drug carriers for tissue- and cell-specific interactions (A), bioadhesion and/or mucoadhesion to tissues (B), and recognition as nutrients for cancer cell internalization (C).

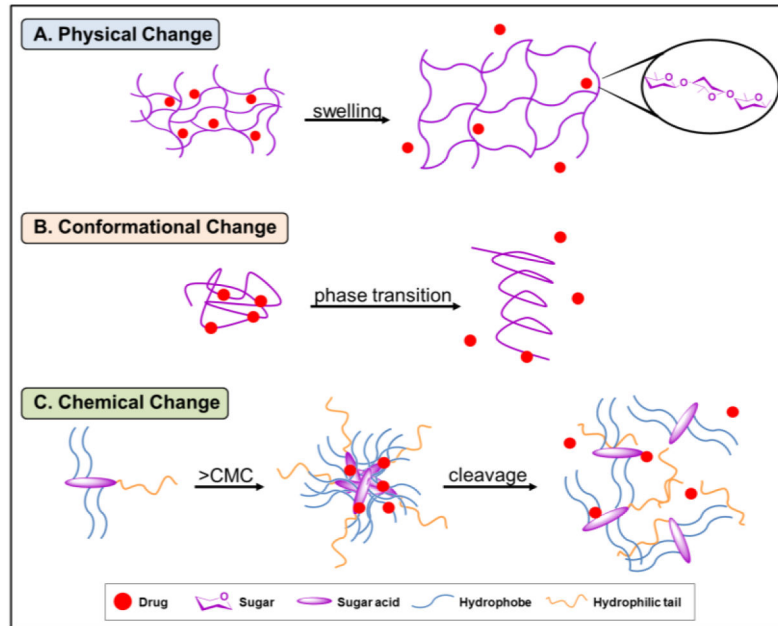

Fig. 5. Schematic representation of select examples of stimuli-triggered responses to mediate drug release

Fig. 6. Schematic representation of saccharide-capped silica nanoparticles that release drugs using a gate-controlled mechanism for enzyme-dependent release profiles (adapted from [153] with permission).

Table 1

Common receptors and corresponding ligands for a range of bio medical applications

Organ or Location	Cell Type	Receptor	Ligand(s)	Common Targeting Applications	Ref.
Liver	Hepatocytes, cancer cells	Asialoglyco-protein	Galactose Galactosamine Lactose	Cancer, Wilson's disease, hemochromatosis	[21, 82]
Liver	Endothelial cells and Kupffer cells	Mannose receptor (C-type lectin receptor)	Mannose	Bacterial infections, inflammation, cardiovascular disease, cancer, cerebral ischaemia/stroke, genetic metabolic diseases, Leishmaniasis	[83]
Liver	Hepatocytes Kupffer cells	Galactosyl receptor Fucose receptor, Lectin B	Galactose Fucose	Blood filtration Tissue binding, biofilm formation	[84]
Liver, spleen, brain, bone marrow, and lungs	Macrophages	Mannose receptor (C-type lectin receptor)	Mannose	Bacterial infections, inflammation, cardiovascular disease, cancer, cerebral ischaemia/stroke, genetic metabolic diseases, Leishmaniasis	[83]
Spleen, lymph nodes, blood, skin	Dendritic cells	Mannose receptor (C-type lectin receptor)	Mannose	Adaptive immune response/vaccination	[76, 85]
Tumor sites	Malignant cells	Lectin-like receptors (e.g., galectins)	Galactose, lactose, mannose, fucose, Sialic Lewis ^x glycosides	Anti-proliferation	[86]
Oral cavity	Buccal cells	Lectin receptors	Lactose and mannose	Bioadhesion	[87]
Eye	Corneal/ conjunctival cells	Lectin receptors	Glucose and galactose, chitosan	Conjunctivitis	[88]
Colon	Epithelial cells	Galectin	Galactose	Cancer, bioadhesion	[89]
Lung	Pulmonary cells	Lectin receptors	Galactose	Cystic fibrosis, lung cancer, and pulmonary tuberculosis	[90]
Brain	Neurons	Anionic membranes and lectins	Trimethylated chitosan	Crossing the blood brain barrier, memory impairment	[91]
