21 Southern Great Plains, wheat

1 Abstract

2 Climate, vegetation cover, and management create fine-scale heterogeneity in unirrigated
3 agricultural regions, with important but not well-quantified consequences for spatial and
4 temporal variations in surface CO₂, water, and heat fluxes. We measured eddy covariance fluxes
5 in seven agricultural fields— comprising winter wheat, pasture, and sorghum —in the U.S.
6 Southern Great Plains (SGP) during the 2001–2003 growing seasons. Land-cover was the
7 dominant source of variation in surface fluxes, with 50–100% differences between fields planted
8 in winter-spring versus fields planted in summer. Interannual variation was driven mainly by
9 precipitation, which varied more than two-fold between years. Peak aboveground biomass and
10 growing-season net ecosystem exchange (NEE) of CO₂ increased in rough proportion to
11 precipitation. Based on a partitioning of gross fluxes with a regression model, ecosystem
12 respiration increased linearly with gross primary production, but with an offset that increased
13 near the time of seed production. Because the regression model was designed for well-watered
14 periods, it successfully retrieved NEE and ecosystem parameters during the peak growing
15 season, and identified periods of moisture limitation during the summer. In summary, the effects
16 of crop type, land management, and water limitation on carbon, water, and energy fluxes were
17 large. Capturing the controlling factors in landscape scale models will be necessary to estimate
18 the ecological feedbacks to climate and other environmental impacts associated with changing
19 human needs for agricultural production of food, fiber, and energy.

21

1 **1. Introduction**

2 Land-surface exchanges of energy, water, and CO₂ are the dominant factors affecting near-
3 surface air temperatures, boundary-layer CO₂ concentrations, boundary-layer development and
4 structure, cloud development, and precipitation. In the case of energy budgets and surface
5 climate, previous work has shown that spatial complexity and temporal variations in land cover
6 generate variations in climate at the regional scale (Song et al. 1997; Doran et al. 1998; Cooley et
7 al. 2005). Accurately capturing these processes over large scales in agricultural systems is
8 difficult because of spatial heterogeneities driven by land management and large temporal
9 variations (often driven by available moisture). Similar problems exist in capturing variations in
10 the carbon cycle.

11
12 Early work focused on quantifying the seasonal variations in surface exchange during growing
13 seasons for individual crop systems (Anderson and Verma, 1986; Baldocchi 1994), whereas later
14 studies explored within-season and interannual variations in sensible heat (H), latent heat (LE),
15 and net ecosystem CO₂ exchange (NEE) in tall-grass prairies, pasture sites, and crop fields
16 (Dugas et al. 1999; Meyers 2001; Suyker and Verma, 2001; Suyker et al. 2003). Recent studies
17 have explored the spatial variations between nearby fields. Initial results from a detailed study of
18 the carbon cycle response to different management strategies demonstrated the large increase in
19 maize production that might be expected under irrigated versus dry-land farming (Suyker et al.
20 2004). In a two-year study in New South Wales, Australia, flux measurements were made in
21 three sets of paired crop and pasture fields, with the pairs organized along a moisture gradient
22 transect (Leuning et al. 2004). Here, the variations along the moisture gradient and between wet
23 and dry years were all much greater than the differences between the paired crop and pasture

1 fields. However, capturing the effect of moisture in predictive models remains a stubborn
2 problem (Gilmanov et al. 2003; Riley et al. 2003; Hanan et al. 2005, Lai et al. 2006; Inoue and
3 Oliosio 2006).

4
5 The Southern Great Plains (SGP) region of the United States presents a challenging environment
6 for predicting surface exchanges, because of the frequent chronic and often severe moisture
7 limitations of the region. In the SGP, 80% of the area is managed for agriculture and grazing in a
8 variety of land cover types. Of the agricultural land, about 40% is planted in winter wheat, a C₃
9 species growing from November to June followed by fallow; 40% is (mostly lightly grazed)
10 pasture containing mixes of C₃ and C₄ grasses that grow from March to October; and the
11 remaining 20% is planted with a mix of C₃ and C₄ crops (e.g., soy beans, grain sorghum, corn)
12 that grow from April through August (Cooley et al. 2005).

13
14 In this paper, we describe measurements and analyses that examine the spatial heterogeneity
15 within and across cover types, as well as the interannual variations in growing-season ecosystem-
16 atmosphere exchange for unirrigated agriculture. Within seven unirrigated SGP fields planted
17 with three different crop types, we measured NEE and latent heat, as well as sensible heat
18 exchanges, aboveground biomass, and associated surface meteorological and soil variables.
19 These measurements were made from July 2001 through summer 2003, as part of research
20 conducted by the U.S. Department of Energy Atmospheric Radiation Measurement Program
21 (ARM).

22

1 **2. Methods**

2 2.1. Site Description

3 The measurements were performed within 5 km of the ARM central facility (CF), near Billings,
4 North Central Oklahoma (36.61 N, 97.49 W), between July 2001 and August 2003 (Figure 1).

5 We studied three wheat fields (f8, f14, f21), two pastures (f9, f21), two sorghum fields (fP,
6 f101). We note that the field numbers were defined by a preexisting map of the area provided by
7 staff at the ARM site. All fields were level (slopes $< 3^\circ$) and large enough to provide at least 200
8 m fetch in the smallest dimension (east or west or north), approximately 400 m fetch in the
9 southern (predominant wind) direction, and at least 200 m fetch in all other directions.

10

11 Soils in the area are well drained Kirkland (silt loam; fine mixed thermic Udertic Paleustolls),
12 Renfrow (silty clay loam; a fine mixed thermic Udertic Paleustolls), and Vernon (clay loam; a
13 clayey, mixed, thermic, shallow Typic Ustochrepts) associations. Replicate (n=4) soil cores were
14 collected at 10 and 30 cm depths in fields f8, f21, fP, and fS (see Figure 1) and used to determine
15 soil texture and water retention curves (Carter 1993). The sand:silt:clay ratio was consistent
16 across these fields in proportions 33:22:45 (± 3 on any percentage across fields).

17

18 Management of each field was determined by farmers. Table 1 lists the crops planted and
19 nitrogen applications for the fields on which we were able to obtain information; information
20 was unavailable for some fields. Nitrogen was applied as either dry ammonium nitrate or liquid
21 urea. All of the wheat planted was hard-red winter wheat (predominantly KSU Jaeger). Neither
22 of the pastures was fertilized, grazed, or burned during observations or in the three years
23 preceding observations.

1 2.2. Ecological Measurements

2 Total (green plus brown) leaf area index (LAI) was measured optically at one time point in each
3 field in July 2001 and at one time point (shortly before harvest) in spring 2002 using a Licor
4 LAI-2000 Plant Canopy Analyzer (LiCor Biosciences; Welles and Norma, 1991). Aboveground
5 plant biomass (AGB) was measured destructively at the same times. In spring 2003, total LAI
6 was measured biweekly and aboveground biomass was measured shortly before harvest. For
7 each date and field, LAI was measured in ten 1 m² squares that were placed at approximately 40
8 m intervals on transects centered on the flux towers. Total AGB was estimated by harvesting
9 biomass within the 10 sampling squares, drying for 24–48 hr at 60°C, and weighing. The carbon
10 content (which varied from 43 to 46 % by mass) and nitrogen content (which varied from 1% to
11 4% by mass) of the vegetation was determined from subsamples of whole plant vegetation using
12 a Carlo Erba C&N analyzer. Individual results from the measurements of chemical composition
13 are not reported in this paper.

14 2.3. Micro-Meteorological Measurements

15 Surface flux measurements were made with three portable eddy covariance systems. The systems
16 were developed for rapid deployment in agricultural systems (Billesbach et al. 2004). Briefly,
17 each system comprised a sonic anemometer (Gill-Solent WindMaster Pro), an open-path infrared
18 gas analyzer (IRGA LiCor LI-7500), and a set of meteorological and soil sensors that monitor
19 net and photosynthetically active radiation, air temperature, relative humidity, precipitation, soil
20 heat flux, and profiles of soil moisture and temperature. The anemometer and IRGA were located
21 4 m above the ground, allowing a minimum of ~3 m between the top of the canopy and the
22 instruments for all crops included in this study. During 2002 and 2003, one system was

1 permanently located year round in a winter wheat field (f8), while the other two systems were
2 deployed for shorter periods in combinations (depending on the year) of winter wheat, pasture,
3 and sorghum. Calibrations of the IRGAs were performed prior to and at the completion of each
4 deployment and every six to twelve months in f8.

5
6 Turbulent vertical fluxes of CO₂, water, and heat were calculated every 30 minutes using
7 algorithms performing spike removal, coordinate rotation to zero mean vertical wind speed, and
8 block averaging of scalar quantities (Billesbach et al. 2004). Density corrections were applied to
9 the covariances of vertical wind, using CO₂ and H₂O densities obtained with the open-path
10 IRGA (Webb et al. 1980). Multiplicative spectral corrections caused by sensor separation and
11 other factors (Moore 1986) were estimated after confirming that the measured co-spectra were
12 consistent with similarity theory, as expected for the systems under study. In general, the
13 corrections were small (<10%) and consistent across the different field sites. Hence, we did not
14 apply the corrections, since they would not affect the primary conclusions of this study
15 concerning cross-site comparisons. Similarly, storage corrections to vertical fluxes from changes
16 in CO₂ concentration below the 4 m measurement height were estimated and found to be
17 negligible compared with turbulent fluxes (except for a small fraction of the measurements in
18 which the friction velocity u^* was less than 0.1 m s⁻¹, which were discarded). Hence, NEE was
19 directly estimated as the turbulent flux of CO₂.

20
21 The accuracy and precision of the portable systems have been verified through intercomparison
22 experiments. The first portable system produced was compared with existing systems at
23 Ameriflux sites near Shidler and Ponca City, Oklahoma, and to the Ameriflux Closed-Path

1 Intercomparison system (Billesbach et al. 2004). To verify the other two portable systems, we
 2 performed side-by-side measurements with all three in a sorghum field in July 2001, using large
 3 daytime CO_2 ($\text{NEE} \sim -30 \mu\text{mol C m}^{-2} \text{s}^{-1}$), sensible heat ($H \sim 250 \text{ W m}^{-2}$), and latent heat ($\text{LE} \sim$
 4 300 W m^{-2}) fluxes. Comparison of NEE, H, and LE measured by each of the three systems
 5 showed no significant differences with RMS deviations of $1.8 \mu\text{mol C m}^{-2} \text{s}^{-1}$, 12 W m^{-2} , and 11
 6 W m^{-2} respectively. These tests provide sufficiently tight constraints such that the fluxes obtained
 7 from the different fields and years of this experiment can be compared confidently.

8 2.4. Estimation of Gross Uptake and Respiration

9 We estimated gross primary production (GPP , $\mu\text{mol C m}^{-2} \text{s}^{-1}$) and ecosystem respiration (R_{eco} ,
 10 $\mu\text{mol C m}^{-2} \text{s}^{-1}$) from measured net ecosystem carbon exchange by decomposing NEE as

$$11 \quad \text{NEE} = R_{eco} - GPP, \quad (1)$$

12 (Note that negative fluxes imply energy or mass transfer toward the surface, and positive values
 13 imply transfer away from the surface.) We estimated R_{eco} from measured nighttime NEE, NEE_n ,
 14 using an exponential temperature relation:

$$16 \quad R_{eco}(T_s) = \text{NEE}_n = R_0 \exp(\beta T_s), \quad (2)$$

17
 18 where R_0 ($\mu\text{mol C m}^{-2} \text{s}^{-1}$) is the soil respiration scaled to a soil temperature of 0°C , and β ($^\circ\text{C}^{-1}$)
 19 is a constant related to Q_{10} as $\beta = \ln(Q_{10})/10$, so that $\beta = 0.069$ for $Q_{10} = 2$ (Lloyd and Taylor
 20 1994). A mean soil temperature T_s was calculated as the average of data from 5 and 15 cm
 21 depths, under the assumption (supported by visual inspection of soil pits dug in all fields) that the
 22 0–15 cm depth interval contains a sufficient fraction of root biomass and soil organic matter to
 23 characterize soil respiration. We then estimated daytime soil respiration by applying measured

1 daytime soil temperatures in combination with the functional form and parameters of Equation
2 (2).

3

4 Following previous work of Gu et al. (2002), we estimated *GPP* as a simple rectangular
5 hyperbolic function of light:

$$6 \quad GPP = R_{eco}(T_s) - NEE_d = G_{max} \alpha Q / (G_{max} + \alpha Q), \quad (3)$$

7 where NEE_d is daytime measured NEE, G_{max} ($\mu\text{mol C m}^{-2} \text{s}^{-1}$) is the maximum rate of gross
8 assimilation, α ($\mu\text{mol C } \mu\text{mol}^{-1} \text{ photon}$) is the quantum efficiency, and Q ($\mu\text{mol photon m}^{-2} \text{s}^{-1}$) is
9 incident photosynthetically active radiation flux. Equations (1)–(3) were fit separately to the
10 NEE measured in each field to obtain estimates of R_0 , β , G_{max} , and α in 10-day intervals during
11 the active growing season and for 20-day intervals during dormant periods. We expect the
12 parameters to vary during the season as soil moisture and plant and microbial functions vary.

13

14 **3. Results**

15 3.1. Climate and Vegetation, 2001–2003

16 3.1.1. Temperature and Precipitation

17 A summary of surface climate for the sites is shown in Figure 2. A drought affecting much of the
18 central United States began in 2000, continued through the first half of 2002, and then abated in
19 late 2002 and early 2003 (Lawrimore and Stephens 2003). Mean air temperature in winter and
20 early spring 2002 was warmer than the corresponding period of 2003, while summer 2003 was
21 cooler than summer 2002. In this study, precipitation relevant for winter wheat (from previous
22 mid-June to current mid-May) was 380 mm in the 2002 harvest year and 810 mm in 2003. For

1 pasture and summer crops, the situation is different, in that the relevant period for accumulated
2 precipitation is shifted later into the summer, from about September to the following August. In
3 this study, summer crops and pasture received 760 mm for the 2002 harvest, significantly more
4 than the 580 mm received for 2003. In response, soil moisture was low during the wheat-
5 growing season in spring 2002 and again in the summer-crop season of summer 2003.

6 **3.1.2. Aboveground Biomass and Leaf Area**

7 The field with the highest maximum AGB was sorghum, while the field with the lowest
8 maximum AGB was the pasture (Table 1). Winter wheat AGB varied by ~10–20% across fields
9 within a given season, but the interannual variations were large. Maximum winter-wheat biomass
10 was 200 g C m⁻² in 2002, half as much as the 400 g C m⁻² in 2003. The large interannual
11 variation in biomass production is consistent with the large increase in precipitation between the
12 2002 and 2003 growth years. In contrast to winter wheat, peak pasture biomass (f21) was about
13 50% larger in 2002 than in 2003. As with winter wheat, the interannual variation in pasture
14 biomass production is positively related to the interannual variations in growth-year
15 precipitation.

16
17 Total LAI showed within-season and interannual variations similar to those observed for
18 aboveground biomass. Figure 3 shows the 2003 seasonal variations in LAI for winter wheat (f8
19 and f20), pasture (f21), and sorghum (f101) fields, while Table 1 reports LAI measured at the
20 time of near peak AGB for 2001, 2002 and 2003. Although winter wheat begins growth in the
21 fall preceding a given harvest year, the period of high photosynthesis lasts for only about 30 days
22 in the April to May period, with exact dates dependent on climate. Sorghum, which is a C₄ plant,
23 had a period of active growth that lasted from about mid-June to mid-July. For both winter wheat

1 and sorghum, LAI decreased rapidly at the end of the respective growing seasons. In contrast,
2 LAI persisted for nearly 90 days in pastures, because they contain a mix of C₃ and C₄ species.

3 3.2. Ecosystem-Atmosphere Exchange

4 3.2.1. Fluxes of CO₂, Water, and Heat

5 The temporal patterns of NEE, LE, and H are shown for 2003 in Figure 4a. The largest variations
6 in NEE between fields were caused by the early growth of winter wheat versus the much-later
7 growth of pasture and sorghum. The similarity of fluxes in the wheat fields and differences with
8 other crops is highlighted in Figure 4b, which shows the ratios of NEE, LE, and H of different
9 fields to winter wheat field f8. Measurements made in 2001–2002 (not shown) exhibited similar
10 features, but had some differences. First, a sparse covering of Bermuda grass (LAI and AGB
11 were not measured) grew in the winter wheat field (f8), generating a small but measurable CO₂
12 uptake in July 2002. Second, although NEE differed by only ~10% between fields f8 and f20 in
13 2002, NEE in the third winter wheat field (f14) was 20% higher than the other fields.

14
15 Latent heat (like NEE) also exhibited the seasonality of the different crops, with the exception
16 that soil moisture evaporation continued into the summer after plant crops were harvested and
17 photosynthesis had stopped (Figures 4a and 4b). For example, LE increased briefly in the winter-
18 wheat fields near day 210 after a rain event (Figure 4b). Sensible heat did not exhibit as strong a
19 difference across the different fields. Sensible heat was small early in the season, when solar
20 input was small, and also during active growth, when LE was reasonably large, owing either to
21 plant transpiration or soil evaporation. The largest differences in H were observed between early
22 and late season crops during early summer, when winter wheat had been harvested, leaving bare,

1 dry soil and stubble while the summer crops were actively growing and generating large LE. H
2 was typically large and similar in magnitude for all three fields observed during late summer,
3 when plants had mostly senesced.

4 **3.2.3 Net Ecosystem Exchange, Gross CO₂ Uptake, and Ecosystem Respiration**

5 We separated measured NEE into estimates of GPP , R_{eco} , and NEE using Equation (1)–(3) and
6 measured PAR and T_s . Figure 5 shows that measured NEE is reasonably well represented by
7 predicted NEE for a representative 10-day period at the beginning of the active growing season
8 for winter wheat (f8) in 2003. For the 2003 year of winter wheat data, predicted NEE matched
9 measured NEE closely during periods with active photosynthesis, with $R^2 > 0.9$ and normally
10 distributed RMS residuals of 2-3 $\mu\text{mol m}^{-2} \text{s}^{-1}$ (about 10% of peak daytime fluxes). The
11 regression model captured a smaller fraction of the variance in NEE ($R^2 \sim 0.75$) during the
12 summer season, likely because of water stress, plant senescence, and respiration pulses following
13 rain events (Xu and Baldocchi 2004).

14
15 Estimates of GPP and R_{eco} for three winter wheat fields in 2002 and 2003 are compared in Figure
16 6. There is a strong positive correlation between GPP and R_{eco} when the data are separated into
17 an early period of active growth (before \sim Day 130) and a later period of seed production and
18 senescence. During the period of active growth, GPP was higher in 2003 than in 2002 for a
19 given value of R_{eco} , consistent with the greater photosynthetic uptake in 2003 than 2002.

20 However, the slope, $dGPP/dR_{eco}$, was similar in both years (3.0 ± 0.2) (Xu et al. 2004).

21
22 After Day 130, predicted R_{eco} increased by a constant amount independent of GPP . This increase
23 in respiration likely reflects increased autotrophic maintenance respiration necessary for

1 flowering and seed production (Baldocchi 1994). Comparisons of GPP and R_{eco} for the pasture
2 (f21) yielded an R_{eco} intercept and slope similar to that for actively growing winter wheat.
3 Sorghum also yielded an R intercept similar to that of wheat, but with a slope of 4.7 ± 0.8 .

4 **3.2.4 Estimated Model Parameters**

5 Model parameters (G_{max} , α , β , and R_0) were estimated for each 10- or 20-day interval. The
6 seasonal variations in G_{max} and α showed smooth increases in maximum values at periods of
7 peak growth, followed by decreases toward senescence, as observed previously for crops and
8 grasslands (Gilmanov et al. 2003; Xu et al. 2004). We summarize the parameter values obtained
9 during periods of peak uptake for several of the different fields in Table 2, noting that the period
10 of peak uptake varied between years.

11
12 Mean light use efficiency in wheat, pasture, and sorghum were 0.04 ± 0.01 , 0.03 ± 0.008 , and
13 0.05 ± 0.004 mol C/ mol photosynthetically active photons, respectively. These values are
14 approximately consistent with previous estimates for similar plant types (Gilmanov et al. 2003;
15 Xu et al. 2004).

16
17 Peak growing season values of G_{max} for winter wheat were $20\text{--}30 \mu\text{mol C m}^{-2} \text{s}^{-1}$ in 2002 and
18 $40\text{--}50 \mu\text{mol C m}^{-2} \text{s}^{-1}$ in 2003, consistent with the interannual difference in LAI. Because G_{max}
19 scaled approximately linearly with LAI, we estimated a maximum uptake rate per unit leaf area,
20 A_{max} ($\mu\text{mol C m}^{-2} \text{s}^{-1}$). Interestingly, A_{max} and α did not vary significantly between years for the
21 winter-wheat fields. Weighted averages of A_{max} for winter wheat, pasture, and sorghum were 16
22 ± 4 , 17 ± 6 , and $23 \pm 3 \mu\text{mol C m}^{-2} \text{s}^{-1}$, respectively. The respiration coefficients R_0 and β appear
23 to have been greater in 2002 than 2003 for all fields. The temperature dependence of respiration

1 was indistinguishable between the three cover types, with mean values for β in wheat, pasture,
2 and sorghum of 0.066 ± 0.015 , 0.069 ± 0.015 , and 0.08 ± 0.02 , respectively (corresponding to
3 Q_{10} values near 2).

4 **3.2.5 Effect of Moisture Stress**

5 For several periods during the summer with clear-sky conditions, carbon uptake in the afternoon
6 was significantly lower than uptake in the morning. Figure 7 shows a typical example, in which
7 C uptake in the 2003 sorghum crop decreased by a factor of two from mid-morning to mid-
8 afternoon. In these cases, the best fit GPP and R_0 sum to a predicted NEE that is consistently
9 larger than measured NEE. This discrepancy could be caused by some combination of a
10 limitation to afternoon uptake or an increase in afternoon respiration not captured by Equations
11 (1)–(3). An increase in afternoon respiration is unlikely, because modeled afternoon R_{eco} was
12 already quite large (see Figure 7), and because afternoon R_{eco} would also likely be limited by
13 diurnal afternoon reductions in soil moisture (Norman et al. 1992; Mielnick et al. 2000). The
14 most likely explanation for the decrease in net uptake and model-measurement mismatch is that
15 the simple expression GPP from Equation (2) does not include parameterizations for water
16 stress. Although beyond the scope of this study, this problem requires more detailed modeling.
17 Possible modifications to the model might include parameterizations for stomatal and
18 nonstomatal (e.g., enzyme) impacts of water stress (Colello et al. 1998; Griffiths and Parry
19 2002).

20

21 **4. Discussion**

22 Here we discuss how the results described above provide insight into the importance of land
23 cover and moisture availability for spatial and temporal variations in carbon, water, and energy

1 fluxes. To broaden the geographic scope of our findings, we also explore the relationship
2 between moisture and winter wheat production across the Southern Great Plains, using a
3 statistical analysis of historical climate and agricultural data.

4 4.1. Spatial Variation: Importance of Land Cover

5 Spatial variations in the magnitude and timing of carbon, water, and heat fluxes across the
6 landscape were controlled primarily by land-cover type, and to a lesser extent, by climate and
7 management. In particular, the largest spatial differences at any time in fluxes are associated with
8 different phenologies of winter wheat versus summer crop or pasture. However, even comparing
9 sorghum (a summer crop) with pasture (a late spring to summer mix), fluxes differ by up to
10 100% at any time, resulting from differences in plant phenology and management practices such
11 as planting and harvest dates. The pasture growing season was 2–3 months longer than that of
12 the single species crops, because they include cool season C_3 grasses (dominant early in the
13 spring) and hot-dry adapted C_4 grasses (dominant later in the summer) (Still et al. 2003).

14
15 These land-cover controls on surface fluxes can impact regional climate. For example, a
16 modeling analysis of the SGP found that spatially coherent differences in the timing of the wheat
17 harvest raise surface temperatures by as much as 5°C, by changing the balance between latent
18 and sensible heat fluxes (Cooley et al. 2005). For most areas of the Great Plains and globally,
19 there are no readily available maps or data products for land cover or land use that match the
20 temporal resolution of regional model applications (i.e., that are accurate for the modeled
21 period). While it is widely recognized that improved maps specific to season will significantly
22 improve predictions of surface exchanges, we also suggest that they will improve prediction of
23 atmospheric processes such as convection and cloud formation.

1

2 As illustrated in Figure 4a, the issue of scaling is expected to be particularly difficult in this
3 highly heterogeneous region. Because of the very different phenological timing of different land
4 cover types, regional estimates of NEE, H, and LE will most likely be multipeaked with very
5 complex shapes. Further, each land-cover type contributing to the overall convolution must be
6 weighted in accordance to its relative abundance. These weighting factors themselves will vary
7 on an annual basis, as individual farmers make decisions about what crops to plant.

8 4.2. Interannual Variations: Importance of Moisture

9 The large difference in both growing-season precipitation and winter-wheat productivity from
10 2002 to 2003 emphasizes the importance of interannual variations in soil moisture. As shown in
11 Figure 8, there was a close correspondence between interannual variation in winter wheat AGB,
12 cumulative growing-season NEE, and growing-season-averaged root-zone soil moisture in 2002
13 and 2003. In 2002, the near-surface soil moisture was systematically lower than in 2003. Our
14 conclusion that moisture is limiting to NEE in the Southern Great Plains is supported by previous
15 studies in SGP prairies, which found that while NEE in years with average precipitation showed
16 net uptake (approximately $100 \text{ g C m}^{-2} \text{ yr}^{-1}$), years with drought resulted in a net carbon release
17 of comparable magnitude (Meyers 2001; Suyker et al. 2003).

18

19 Finally, we consider how the results of the current study could be used to improve model
20 prediction of NEE in response to varied moisture limitation in individual agricultural plots and
21 the factors that should be considered to capture variations at the landscape-scale. Although the
22 first order factors include the amount and timing of precipitation interacting with crop type and
23 planting date, additional factors include water and residue management, because all of these

1 factors are expected to affect both plant physiology and soil respiration (Gervois et al. 2004;
2 Hanan et al. 2005). Although in our study, the dominant effect was caused by a large interannual
3 variation in precipitation, timing of planting relative to precipitation can be important, because
4 fields need to receive moderate precipitation soon after planting, but heavy precipitation soon
5 after germination can damage small plants. Capturing the effect of management is a challenge at
6 the landscape scale, largely because data on management is not (to our knowledge) collected in a
7 systematic fashion. For example, farmers may attempt to increase soil-water retention before an
8 anticipated drought through alternative tillage or boost production with increased fertilizer
9 application during a year with ample moisture. Although only an anecdotal example, we note
10 that f14 was tilled (according to a private communication with the farmer) in summer 2001 to
11 conserve moisture (by reducing runoff), and subsequently experienced higher soil moisture and
12 greater productivity in 2002. In this study, we could not address the question of differences in
13 fertilizer application. Of the winter-wheat fields that were observed, only f8 in 2002 received a
14 significantly different nitrogen treatment, roughly half of the fertilizer applied to other fields and
15 or years, while both fields f8 and f20 yielded roughly comparable AGB and accumulated NEE in
16 2002 (a drought year) and 2003 (a nondrought year). In summary, we suggest that a study (or
17 multistudy synthesis) including data covering many years of measurements in fields of different
18 cover types and management strategies, would be valuable for characterizing the response of
19 NEE to varied moisture and management.

20

21 **5. Conclusions**

22 Based on our surface flux and biomass measurements, land cover dominates the timing and
23 spatial variability of carbon uptake in the Southern Great Plains, because of the distinct and

1 punctuated growing seasons for winter wheat, summer crops, and to a lesser extent, pasture.
2 Within a land-cover type, temporal variability, in the form of interannual differences in
3 productivity correlated with large interannual differences in rainfall, was much larger than spatial
4 variability across fields. Water availability limits carbon uptake and ecosystem respiration for the
5 region in the crop systems we studied. Absorption of solar radiation and the partitioning of net
6 radiation between latent and sensible heat are also strongly influenced by cover type and
7 moisture level. This is largely because they are directly affected by soil moisture, but also
8 because plant cover and transpiration control these fluxes. Because current models do not
9 accurately predict variations in surface exchanges during periods of moisture limitation (Gervois
10 et al. 2004; Hanan et al. 2005), we consider these results motivation for further model
11 development and experimental testing. Providing accurate predictions of regional land-surface
12 exchange is increasingly important for informed policy decisions, because large scale
13 modifications of land cover have the potential to generate ecological feedbacks to climate and
14 affect other environmental services. This will become increasingly relevant as societies consider
15 changes to the balance of agricultural land used for production of food, fiber, and energy.

16

17 **Acknowledgments**

18 We thank Dennis Baldocchi, Shashi Verma, and the late Marvin Wesley for useful advice in
19 conducting this project, the LBNL Earth Sciences Division shop for assistance with instrument
20 fabrication, Edward Dumas of NOAA-ATDD and Joesph Verfallie of CSU San Diego for
21 sharing data collection software, and Pat Dowell and the ARM-SGP staff for assistance in site
22 acquisition, instrument deployment, maintenance, and LAI measurements and soil sampling. We
23 also thank Xiaozhong Liu and Dafeng Hui at the University of Oklahoma for performing the

1 measurements of LAI and aboveground biomass in 2001, Asmeret Asefaw Berhe and Heather
2 Cooley for performing the soil analysis and identifying soil associations, respectively, and Alice
3 Ciallela at the ARM External Data Center at Brookhaven National Laboratory for providing the
4 image used in Figure 1. This work was supported by the Atmospheric Radiation Measurement
5 Program, Office of Science, U.S. Department of Energy under Contract No. DE-AC02-
6 05CH11231.

Figure 1. Aerial view of the fields that were measured during the period 2001–2003. Inset map marks the location of the ARM Central Facility (CF) in North Central Oklahoma. The view shows the field conditions in July 2001, with harvested wheat fields (white to beige) and growing summer crops and pastures (green).

Figure 2. Interannual variation in surface climate for sites near ARM Central Facility, 2001–2003. The upper panel shows minimum and maximum (dots), and mean daily (line) air temperature. The middle panel shows the cumulative daily (lines) and monthly precipitation (boxes). The bottom panel shows vapor-pressure deficit and soil moisture at 5 and 25 cm depths. Vertical lines mark the main growth periods for winter wheat (W) and summer crops (S) and pastures.

Figure 3. Leaf area index measured in winter wheat (f8), pasture (f21), and sorghum (f101) fields in 2003 showing the distinct seasonality in LAI for different land-cover types.

Figure 4a. Seasonal variations in daily averaged net ecosystem CO₂ exchange (NEE), latent heat (LE), and sensible heat (H) across fields with different land cover in 2003. Fields are winter wheat (black =f8, green = f20), pasture (red= f21), and sorghum (blue=f101).

Figure 4b. Ratio of fluxes in different fields to the flux measured in field f8. Color scheme is the same as in Figure 4a.
