Abstract

The stable isotopic composition of insoluble, refractory elements such as titanium (Ti) or zirconium (Zr), which are modified by magmatic differentiation but, *a priori,* are poorly affected by weathering or diagenesis, serve as powerful potential proxies to reconstruct the compositional evolution of the continental crust. Here we present the evolution of the Zr stable isotopic compositions ($\delta^{94/90}Zr_{IPGP-Zr}$, per mille

22 deviation of $^{94}Zr/^{90}Zr$ from IPGP-Zr standard) of the continental crust trough time,

23 using 38 sedimentary samples from the upper continental crust (UCC), including 12

24 Holocene loess from the Chinese Loess Plateau and Xinjiang, three oceanic sediments

25 from the sea floor outboard of the Lesser Antilles island arc and 23 glacial diamictite

26 composites with depositional ages ranging from ~ 2.9 Ga to 0.3 Ga from South

27 Africa, South America, Canada, USA and China. The samples show limited Zr

28 isotopic variations with $\delta^{94/90}Zr_{IPGP-Zr}$ values of 0.043‰ - 0.109‰ for loess; 0.069‰ -

29 0.083‰ for oceanic sediments and 0.031‰ - 0.118‰ for glacial diamictites; their Zr-

30 weighted average values are, 0.081± 0.044‰ (2SD, n = 12), 0.073 ± 0.015‰ (2SD, n

31 = 3) and 0.078 ± 0.047‰ (2SD, n = 23), respectively. The isotopic similarity among

32 loess, oceanic sediments and glacial diamictites, suggests that zircon enrichment

33 effects previously documented in some sedimentary samples have not biased the Zr

34 isotope compositions of these sedimentary rocks from their source rocks. Two groups

35 with or without Zr enrichment have similar average $\delta^{94/90}Zr_{IPGP-Zr}$ values (0.075 ±

36 0.040‰ and 0.080 ± 0.046‰). There is no correlation between Zr isotope

37 compositions and any proxy of chemical weathering (e.g., Al_2O_3/SiO_2, Fe_2O_3/SiO_2,

38 CIA, K_2O/Al_2O_3 and δ^7Li). The $\delta^{94/90}Zr_{IPGP-Zr}$ values are quite constant for these

39 sedimentary samples regardless of their depositional ages and locations. Therefore,

40 the UCC appears to have had a constant Zr isotopic composition between 3 Ga and

41 present, and is homogeneous at a large scale. Combining data for sedimentary

42 reference materials from the literature and the sedimentary rocks in this study, we

43   suggest a Zr-weighted $\delta^{94/90}Zr_{IPGP-Zr}$ value of 0.077 ± 0.058‰ (2SD, n = 44) for the

44   UCC, which is statistically distinct (t test, p value = 2.88×10^{-10}) and higher than that

45   of the mantle (0.040 ± 0.044‰, n = 72). Combining the $\delta^{94/90}Zr_{IPGP-Zr}$ values of

46   different terrestrial reservoirs, the $\delta^{94/90}Zr_{IPGP-Zr}$ of the BSE and bulk Earth is

47   constrained to be 0.041 ± 0.041‰.

48

49   Key words: zirconium isotopes, upper continental crust, BSE, glacial diamictites,

50   loess, oceanic sediments

51   **Introduction**

52   The Earth is the only terrestrial planet with plate tectonics, though the timing of its

53   initiation is still vigorously debated (Brown et al., 2020; Harrison, 2009; Korenaga,

54   2013). The production of the first felsic continental crust is usually taken as a proxy to

55   trace the initiation of subduction and, by extension, plate tectonics (Greber et al.,

56   2017; Tang et al., 2016). In particular, the concentrations of insoluble elements and

57   their ratios in terrigenous sedimentary rocks have been used to deduce the bulk

58   composition of the UCC over Earth history (Condie, 1993; Taylor and McLennan,

59   1985). Recently, based on the correlation between the stable Ti isotopic composition

60   of igneous rocks with their SiO_2 content, Ti isotope ratios in Archean shales have been

61   interpreted to reflect the presence of intermediate to felsic crust as early as 3.5 Ga

62   (Greber et al., 2017). However, later work demonstrated that tholeiitic and calc-

63   alkaline differentiation series produce different degrees of Ti isotope fractionation,

which could be interpreted as either a changing or constant UCC composition,

depending on which types of igneous rocks dominated at a particular time (Deng et

al., 2019; Hoare et al., 2020). Although not fully conclusive, the study of Ti isotope

composition of sediments highlights the strong potential of using novel stable isotope

tracers to shed new light on crustal evolution.

Zirconium isotopes have the potential to further trace magmatic differentiation

and provide constraints on the formation and evolution of the continental crust (Guo

et al., 2020; Ibañez-Mejia and Tissot, 2019; Inglis et al., 2019). Zirconium, like Ti, is

a refractory (50% condensation temperature = 1741K; Lodders, 2003), incompatible,

and insoluble element. Ratios of similarly insoluble, incompatible, high field-strength

elements (HFSE) have been used to constrain mantle end members of intraplate

magmas, provide information on the genesis and eruptive environments of lavas, and

trace recycled crustal components in the mantle (Condie, 2005; Niu, 2004). Moreover,

zircon, the main host of Zr in most crustal rocks, is critical in studies of the temporal

evolution of both the crust and lithospheric mantle, due to its use for U-Th-Pb

geochronology, Lu-Hf, and O isotope measurements (Dhuime et al., 2012; Harrison et

al., 2005; Valley et al., 2005; Wilde et al., 2001).

Zirconium has five stable isotopes: ^{90}Zr (51.45%), ^{91}Zr (11.22%), ^{92}Zr (17.15%),

^{94}Zr (17.38%) and ^{96}Zr (2.8%), and fractionation of these isotopes is recorded using

delta notation ($\delta^{94/90}$Zr$_{IPGP-Zr}$). A strong covariation is observed between Zr contents

and Zr isotope compositions for lavas from the Hekla volcano, Iceland (Inglis et al.,

4

85 2019). For rocks with SiO_2 contents > ~66.8 wt.%, $\delta^{94/90}Zr_{IPGP-Zr}$ increases

86 significantly, together with a sharp decrease of the Zr concentrations. This is likely

87 caused by zircon fractionation from the residual melt (Inglis et al., 2019), creating an

88 overall range of $\delta^{94/90}Zr_{IPGP-Zr}$ of 0.582‰. Moreover, *in situ* Zr isotopic studies within

89 internally zoned zircons from the Gangdese arc, Tibet showed lighter isotope

90 compositions in the cores and heavier values toward the rims, with an overall range of

91 1.27 ‰ (Guo et al., 2020). This study demonstrated that lighter Zr isotopes are

92 preferentially incorporated into zircons, causing the residual melt to have heavier Zr

93 isotope composition. On the other hand, zircon and baddeleyite crystals from the

94 anorthositic gabbro GC-1 from the Duluth Complex were found to be enriched in the

95 heavier Zr isotopes (Ibañez-Mejia and Tissot, 2019; Zhang et al., 2019), with an

96 overall range of ~5 ‰. Recent *ab-initio* calculations suggested that while $\delta^{94/90}Zr_{IPGP-Zr}$

97 of zircon, in which Zr is in 8-fold coordination, should be lower than that of the

98 silicate melt, in which Zr is in 6-fold coordination, equilibrium fractionation is too

99 small to explain the fractionation observed in the Hekla, Duluth Complex, and

100 Gangdese igneous systems, and that part of the light isotope enrichment of zircons is

101 due to kinetic isotopic fractionation driven by diffusion (Chen et al., 2020; Méheut et

102 al., 2020). Whatever the mechanism driving these isotopic fractionations, the large Zr

103 isotopic variations due to magmatic differentiation suggest that Zr stable isotopes

104 could be used as a new proxy to constrain the chemical compositional evolution of

105   UCC. A first step in that direction is to evaluate the Zr isotope composition of UCC

106   over time.

107   Studies of the average composition of the UCC traditionally follow one of two

108   approaches: establishing weighted averages of the compositions of outcrops at the

109   surface via large-scale sampling, or weighted averaging of fine-grained clastic

110   sedimentary rocks (e.g., shale, loess and glacial diamictites) (Condie, 1993; Rudnick

111   and Gao, 2014; Taylor and McLennan, 1985). The former approach is the primary

112   source of estimates of the average abundance of major elements and a number of

113   soluble trace elements in the UCC. The latter approach is used to derive the average

114   composition of insoluble elements in the UCC, assuming that sedimentation processes

115   provide a natural sampling of large areas of the exposed crust and elements with low

116   solubility are not impacted by weathering. Furthermore, this approach could also be

117   used to investigate the secular evolution of the UCC by utilizing sedimentary rocks of

118   various depositional ages. In addition to the two methods noted above, Plank and

119   Langmuir (1998) generated a global subducting sediment (GLOSS) composition and

120   flux based on average global oceanic sediments, in order to assess the influence of

121   subducting sediments on arc volcanism and crust-mantle recycling, and re-evaluate

122   the chemical composition of the continental crust. They found that the HFSE

123   abundances are closely related to the presence of detrital phases and GLOSS is

124   dominated by terrigenous materials (76 wt.%). (Plank and Langmuir, 1998).

125   Here we estimate the Zr isotopic composition of the UCC based on analyses of a

126   variety of sedimentary samples: twelve Holocene loess deposits, three oceanic

127   sediments and twenty-three glacial diamictite composites having depositional ages

128   spanning much of Earth history (~2.9 - 0.3 Ga). As Zr is an insoluble element, its

129   concentration and isotopic composition is not expected to be affected by chemical

130   weathering. Loess experiences limited chemical weathering during formation but may

131   have been affected by mineral sorting during transportation, such as zircon

132   enrichment (e.g., Taylor et al., 1983). The loess studied here are from Yimaguan,

133   Luochuan, and Nileke in China and have been previously well characterized (Gong et

134   al., 2017; Hao et al., 2012; Nan et al., 2018; Tsai et al., 2014). The oceanic sediments

135   have previously been characterized by Carpentier et al. (2008 and 2009). Their

136   composition is mainly controlled by detrital materials from the continental crust

137   (Carpentier et al., 2008). The glacial diamictite composites have been widely used to

138   study the chemical compositions of UCC (Chen et al., 2016; Gaschnig et al., 2014;

139   Gaschnig et al., 2016; Greaney et al., 2020; Johnson and Goldblatt, 2017; Li et al.,

140   2016; Mundl et al., 2018; Nan et al., 2018; Wang et al., 2019). By studying the Zr

141   isotope compositions of terrigenous sedimentary rocks we aim to constrain the Zr

142   isotope composition of the UCC, its secular evolution between 3 Ga and present, and

143   estimate whether mineralogical sorting and chemical weathering influences Zr isotope

144   compositions of terrigenous sediments.

145   **Methods and Samples**

146 **Loess**

147   Loess is fine, silt-sized aeolian sediment derived from glacial outwash plains or

148 from desert environments (Taylor et al., 1983). Pleistocene loess covers 10% of

149 Earth's surface (Taylor et al., 1983). Loess exhibits CIA values (CIA = molar

150 proportions $Al_2O_3 / (Al_2O_3 + K_2O + Na_2O + CaO^*)$, where CaO* is CaO amounts

151 contributed by silicate fraction of the whole sample) slightly above that of fresh

152 igneous rocks, and lower than typical CIA values of shales. The chemical weathering

153 signal in loess may also originate from glacially eroded bedrocks (Gallet et al., 1998).

154 Loess samples from around the world have similar rare earth element patterns, akin to

155 those seen in post-Archean shales (Taylor et al., 1983). As aeolian processing does

156 not seem to fractionate most incompatible and insoluble elements from lanthanum

157 except those affected by heavy mineral fractionation, loess is taken to provide a

158 robust estimate of the abundance of these elements in the UCC based on their ratios

159 with lanthanum (Taylor et al., 1983).

160   Eleven loess and one paleosol samples were collected from Yimaguan,

161 Luochuan, and Nileke, China (Table S1). The Yimaguan and Luochuan loess-paleosol

162 sections are representative of the Chinese Loess Plateau and was deposited over the

163 past 0.9 Ma. These samples comprise wind-rafted sediments from inland deserts in

164 northern and northwestern China and were previously used to determine the timing of

165 build-up of the northern hemisphere ice sheets (Hao et al., 2012) and to estimate the

166 Fe and Ba isotope compositions of the UCC (Gong et al., 2017; Nan et al., 2018).

8

167 Xinjiang is one of the most significant loess regions in China and Central Asia, and is

168 situated between the East Europe loess region and the well-studied Chinese Loess

169 Plateau. Xingjiang loess is mainly derived from adjacent deserts, transported via

170 northwesterly winds (Tsai et al., 2014). The Xinjiang loess samples in this study have

171 also been used to constrain the Ba isotopic composition of the UCC (Nan et al.,

172 2018).

173 **Oceanic sediments**

174 Oceanic sediments are primarily composed of products of erosion of the

175 continental crust, and biologically and chemically precipitated minerals (Carpentier et

176 al., 2009; Plank and Langmuir, 1998). The final composition of the sediments

177 depends on the distance to the detrital sources, biological productivity, carbonate

178 compensation depth and sedimentation rate (Carpentier et al., 2009). Plank and

179 Langmuir (1998) established the composition of global subducting sediment

180 (GLOSS) and found that GLOSS is dominated by terrigenous materials (76 wt.%

181 terrigenous, 7 wt.% calcium carbonate, 10 wt.% opal, 7 wt.% mineral-bound H_2O^+).

182 Therefore, GLOSS is similar to the UCC in composition (Plank and Langmuir, 1998).

183 Three oceanic sediment samples, which were collected from DSDP 14 Site 144

184 (at 2960 m water depth) on the Demerara Rise, and DSDP 78A Site 543 (at 5630 m

185 water depth), located to the east of Dominica Island, were analyzed for their Zr

186 isotope composition. Site 144 is situated southeast of the Lesser Antilles island arc,

187 closer to the South American continent (340 km) compared to Site 543 (860 km)

188   (Carpentier et al., 2008; Carpentier et al., 2009). Some Site 144 sediments exhibit

189   remarkable Zr and Hf enrichments, which are attributed to enrichment of zircons in

190   coarse detrital fractions (Carpentier et al., 2009), including the two samples selected

191   for this study. By contrast, the sediments from site DSDP 543 are enriched in finer

192   clay-rich fractions devoid of zircon (Carpentier et al., 2009). These samples have been

193   well characterized for trace elements and Sr-Nd-Pb-Hf, Li and Mo isotope

194   compositions (Carpentier et al., 2008; Carpentier et al., 2009; Gaschnig et al., 2017;

195   Tang et al., 2014). Overall, the sediments from Site 144 and 543 are dominated by

196   input from old detrital continental materials that have different compositions. For the

197   samples studied here, the two from site 144 show the effects of detrital quartz and

198   zircon enrichment, while the one from site 543 is dominated by detrital clays. The

199   CIA values of the three samples vary from 61 to 66, which is slightly higher than

200   those of the loess samples in this study (from 57 to 64 with an average of 60).

201   **Glacial diamictites**

202   Goldschmidt (1933) first noted that glacial loam may provide a means of

203   determining the average composition of the UCC. Nevertheless, it took nearly 80

204   years for geoscientists to begin to explore these deposits for this purpose (Gaschnig et

205   al., 2014). Glaciers mechanically erode the soil and bedrock that they traverse,

206   producing comminuted sediments that approximate the average of the soils and rocks

207   underlying the glaciers. When the glaciers melt, their sedimentary load is deposited as

208   glacial till, which is later lithified. These deposits may occur on land or in the shallow

209   marine environment (Gaschnig et al., 2014). Minimal chemical weathering is

210   expected to have occurred during erosion, transport and deposition due to the low

211   temperatures and the rapid deposition of the diamctites. Compared to loess and shales,

212   glacial diamictites are not reworked by wind or water (Gaschnig et al., 2014; Rudnick

213   and Gao, 2014; Taylor and McLennan, 1985). Twenty-three glacial diamictite

214   composites comprised of more than 100 individual samples with depositional ages

215   ranging from 2.9 Ga to 0.3 Ga from South Africa, South America, Canada, USA and

216   China, were analyzed for their Zr isotopic composition (Table S2). The glacial

217   diamictites have been previously well characterized for their chemical compositions

218   (Chen et al., 2016; Gaschnig et al., 2014; Gaschnig et al., 2016), and a wide range of

219   isotopic compositions (Li, N, O, Mo, Nd, Hf-W, Ba, and Ni; Gaschnig et al., 2016;

220   Greaney et al., 2020; Johnson and Goldblatt, 2017; Li et al., 2016; Mundl et al., 2018;

221   Nan et al., 2018; Wang et al., 2019). Most of the composites have elevated CIA

222   values relative to the values of fresh igneous rocks (Nesbitt and Young, 1982) and are

223   depleted in Sr, reflecting the influence of chemical weathering. Li et al. (2016) used

224   lithium isotopes and Pb isotopes, along with chemical, petrographic, and outcrop data

225   to evaluate the origin of this weathered signature. They concluded that the signatures

226   are mainly inherited from the UCC traversed by the glaciers rather than during syn- or

227   post- depositional weathering.

228   **Other samples**

229   In addition to the terrigenous sedimentary rocks described above, we evaluate Zr

230   isotopic data of sedimentary reference materials including shales, river, or lake

231   sediments to derive an estimate of the Zr isotope composition of the UCC and the

232   BSE. They are: stream sediments JSD-1and JSD-2, lake sediments JLK-1, and shales

233   SCo-1, SBC-1 and SGR-1 (Table S3).

234   **Analytical methods**

235   The loess and oceanic sediment samples (Carpentier et al., 2008) were hand

236   crushed to powders in an agate mortar. The preparation of the glacial diamictite

237   composites was described in detail in Gaschnig et al. (2016). The powders were

238   digested using 2 mL mixture of 27 M HF and 16 M HNO_3 at a 5:1 ratio within PTFE

239   vials. These vials were placed within spring-loaded screw-top steel vessels obtained

240   from Parr Instruments® (typically referred to as Parr bombs). After heating at 160 ℃

241   for five days the sample solutions were evaporated to dryness and treated with 2 mL

242   6M HCl on a hot plate at 140 ℃ for two days for fluoride decomposition.

243   An aliquot containing ~1 μg Zr obtained from each solution was dried down,

244   brought back into solution in 2 mL of 4 M HF and spiked with a ^{91}Zr-^{96}Zr double-

245   spike (51.4% ^{91}Zr and 48.6% ^{96}Zr) at an optimal spike to sample ratio of 43:57.

246   Before chemical separation, the spiked solutions were heated at 120 ℃ for at least 12

247   hours to equilibrate the samples and double spike. Zirconium separation was achieved

248   using a procedure described in Tian et al. (2020a), which is modified after the

249   approach reported in Inglis et al. (2018). Because 4 M HF could not re-dissolve the

12

250 samples completely, before loading on the first column, which is packed with 2 mL

251 anion exchange resin (Bio-Rad AG1-X8 200–400 mesh), the sample solutions with

252 precipitates were placed in an ultrasonic bath for 1 h, then centrifuged. The

253 supernatant was carefully taken up and loaded onto the column. Except for HFSE,

254 most matrix elements are removed with 32 mL (4×8 mL) of 4 M HF. During the

255 second stage, matrices were eluted with 12 mL of 12 M HNO_3 and 12 mL 3 M HNO_3

256 on the column with DGA resin. Finally, Zr was collected in 10 mL 3 M HNO_3 + 0.2

257 M HF. Recovery yields for Zr were higher than 90%. After evaporating to dryness, 16

258 M HNO_3 was added to the sample and then heated at 120 °C for 2 h to remove any

259 organic residues possibly coming from the resin. Then the samples were dried down

260 and dissolved in 0.5 M HNO_3 + 0.1 M HF in preparation for measurements on the

261 mass spectrometer.

262   Zirconium isotopic compositions were measured via the double spike method on

263 a *Thermo Fisher* Neptune Plus MC-ICP-MS at IPGP. Measurement details are

264 provided in Tian et al. (2020a, 2020b). Briefly, inert sample introduction kits,

265 including a Savillex™ PFA cyclonic spray chamber (CSC) and a Savillex™ sapphire

266 torch injector were used because the carrier acid has 0.1 M HF. $^{90}Zr^+$, $^{91}Zr^+$, $^{92}Zr^+$,

267 $^{94}Zr^+$, $^{95}Mo^+$ and $^{96}Zr^+$ were monitored simultaneously using Faraday cups with 10^{11}

268 Ω resistors. $^{91}Zr^+/^{90}Zr^+$, $^{94}Zr^+/^{90}Zr^+$ and $^{96}Zr^+/^{90}Zr^+$ were used for double spike data

269 processing, which was done by the *IsoSpike* add-on in the software package Iolite

270 (Creech and Paul, 2015). Before calculation, $^{95}Mo^+$ was used to correct interferences

271 from $^{94}Mo^+$ and $^{96}Mo^+$ on corresponding isobaric Zr ions. The data are reported

272 against the IPGP-Zr standard; a calibration against other standards (e.g., zircon G1,

273 NIST SRM 3169, 'NIST') can be found in Tian et al. (2020a). Total procedure blanks

274 were <1 ng for Zr.

275 **Results**

276 The $\delta^{94/90}Zr_{IPGP-Zr}$ values we determined for BHVO-2 and GA are 0.048 ±

277 0.017‰ (2SD, n=4) and 0.13 ± 0.013‰ (2SD, n=7), respectively (Table S1), which

278 agree well with data from the literature (Inglis et al., 2018; Tian et al., 2020a),

279 confirming the accuracy of our data. Overall, the Zr isotope compositions of

280 sedimentary rocks in this study are quite homogenous, ranging from 0.031 to 0.118‰

281 with an average $\delta^{94/90}Zr_{IPGP-Zr}$ of 0.078 ± 0.044‰ (2SD, n= 38), with a Zr-weighted

282 average of 0.079 ± 0.044‰ (2SD, n=38). The $\delta^{94/90}Zr_{IPGP-Zr}$ values of Yimaguan,

283 Luochuan, and Nileke loess range from 0.043 to 0.109‰, with an overall Zr-weighted

284 average of 0.081 ± 0.044‰ (2SD, n = 12) and with individual weighted averages of

285 0.089 ± 0.028‰ (2SD, n = 6), 0.067± 0.043‰ (2SD, n = 3) and 0.082 ± 0.071‰

286 (2SD, n = 3), respectively. The three oceanic sediments from the DSDP sites outboard

287 of the Lesser Antilles arc display a weighted average of $\delta^{94/90}Zr_{IPGP-Zr}$ of 0.073 ±

288 0.015‰ (2SD, n = 3). Glacial diamictites have similar Zr isotope compositions as

289 those of the loess and oceanic sediments (Table S2 and S1). The $\delta^{94/90}Zr_{IPGP-Zr}$ values

290 of 23 individual glacial diamictite composites vary from 0.031 to 0.118‰, with a Zr-

291 weighted average of 0.078 ± 0.047‰ (2SD, n = 23). The Zr-weighted average

292 $\delta^{94/90}Zr_{IPGP-Zr}$ values of Mesoarchean, Paleoproterozoic, Neoproterozoic and Paleozoic

293 diamictite composites are 0.084 ± 0.033‰ (2SD, n = 4), 0.070 ± 0.052‰ (2SD, n =

294 6), 0.077 ± 0.055‰ (2SD, n = 10) and 0.090 ± 0.030‰ (2SD, n = 3), respectively.

295 **Discussion**

296 The different types of sedimentary samples analyzed here have relatively

297 homogenous Zr isotope compositions, reflecting limited Zr isotope fractionation

298 during the diverse geological processes by which these samples formed. Nevertheless,

299 we first consider the possible effects of mineral sorting and chemical weathering on

300 the Zr isotope compositions of these sedimentary samples, and then use the data to

301 calculate the average Zr isotope compositions of the UCC, BSE and bulk Earth.

302 1. **Zircon sorting has negligible effect on the Zr isotope compositions of**

303 **sedimentary samples**

304 On average, coarse-grained sedimentary samples show higher Zr and Hf

305 concentrations compared to fine-grained samples, which is usually interpreted to be

306 due to an enrichment of heavy minerals such as zircon and rutile via hydrodynamic

307 mineral sorting (Carpentier et al., 2009; Taylor and McLennan, 1985). Early studies

308 suggested that loess was enriched in Zr and Hf relative to the estimated average

309 composition of the UCC, reflecting concentration of zircon by aeolian processes

310 (Gallet et al., 1998; Taylor et al., 1983). Chauvel et al. (2014) argued that periglacial

311 loess samples had a large excess of Zr and Hf owing to the enrichment of zircons, but

312 that Chinese, Tajikistan, Argentinian and Sahara loess deposits do not show a zircon

15

313 excess effect, as evidenced by their $\Delta\varepsilon_{Hf}$ (Hf isotopic deviation from the terrestrial

314 array defined by Carpentier et al., 2009) and Nd/Hf ratio relationship, that is, low

315 Nd/Hf and negative $\Delta\varepsilon_{Hf}$ (Chauvel et al., 2014), even though most of these loess

316 samples have higher Zr/Al_2O_3 (12.3 ~ 26.0, data from Chauvel et al., 2014) ratios

317 compared to the UCC (12.5, Rudnick and Gao, 2014). It is worth noting that the

318 Western European loess samples studied in Chauvel et al. (2014), which showed a

319 zircon excess effect have some of the highest Zr/Al_2O_3 ratios: from 20.7 to 68.7.

320 Because zircons can have different Zr isotopic composition than their melts

321 (Chen et al., 2020; Guo et al., 2020; Inglis et al., 2019; Méheut et al., 2020; Tian et

322 al., 2020a; Zhang et al., 2019), zircon-enriched sedimentary samples may be

323 isotopically different. To quantify zircon enrichment, we first divided the oceanic

324 sediments and glacial diamictite composites into two groups according whether they

325 show higher Nd/Hf ratios relative to UCC . The samples whose Nd/Hf ratio is lower

326 than 5.1 are classified as having excess zircon. The Nd and Hf concentration of the

327 Chinese loess samples were not available, but considering that their Zr/Al_2O_3 ratios

328 (from 16.6 to 24.8) are comparable to those of Chinese loess samples in Chauvel et al.

329 (2014), and that the Yimaguan and Luochuan loess samples belong to the same loess

330 deposit as the one reported by Chauvel et al. (2014), these samples probably do not

331 record a zircon excess. The Xinjiang loess samples derive from a desert region, not

332 periglacial, so they are similar to other Chinese loess from Chinese Loess Plateau and

333 are also considered to not show a zircon excess effect. The two groups of samples

334   with or without zircon enrichment display average $\delta^{94/90}Zr_{IPGP-Zr}$ values of 0.075 ±

335   0.040‰ (2SD, n = 9) and 0.080 ± 0.046‰ (2SD, n = 29), respectively, which are

336   statistically indistinguishable (t test, p value = 0.55). In addition, there is no

337   correlation between $\delta^{94/90}Zr_{IPGP-Zr}$ values and Nd/Hf ratios (Fig. 2a, $R^2 = 0.01$), or

338   Zr/Al_2O_3 ratios (Fig. 2b, $R^2 = 9.6\times10^{-7}$). The similarity of the Zr isotope composition

339   between these two groups and the absence of correlation between $\delta^{94/90}Zr_{IPGP-Zr}$ Nd/Hf

340   and Zr/Al_2O_3 illustrate that zircon addition or subtraction has not affected the Zr

341   isotope composition of the sedimentary samples to a measurable extent.

342   2. **No measurable Zr isotope fractionation due to chemical weathering**

343   There has not yet been a study of Zr isotope behavior during chemical

344   weathering. Nevertheless, the data for sedimentary samples reported here provide

345   some insights. Terrigenous sedimentary rocks are the product of chemical weathering

346   of preexisting rocks (Taylor and McLennan, 1985), and loess and most of the glacial

347   diamictites studied here carry a chemical weathering signature (Gaschnig et al., 2014;

348   Gaschnig et al., 2016; Sauzéat et al., 2015; Taylor et al., 1983).

349   As chemical weathering progresses, clay fractions increasingly dominate over

350   primary minerals, and this is accompanied by a progressive increase of Al_2O_3 and

351   Fe_2O_3 (T) but a decrease of SiO_2, Na_2O, K_2O, and CaO contents. Higher Al_2O_3/SiO_2,

352   Fe_2O_3/SiO_2, CIA values and lower K_2O/Al_2O_3 values are common indicators of the

353   degree of chemical weathering (Gallet et al., 1998; Gaschnig et al., 2014; Huang et

354   al., 2020).

355   The Zr isotopic values of sedimentary samples analyzed in this study do not

356   correlate with any of these weathering proxies (Fig. 3), suggesting that chemical

357   weathering does not produce measurable Zr isotope fractionation. Additionally, the

358   average $\delta^{94/90}Zr_{IPGP-Zr}$ values of glacial diamictite composites, loess and oceanic

359   sediments plot within analytical error of each other, even though the oceanic

360   sediments recorded more extensive chemical weathering, and fluid-rock exchange

361   during transport and deposition compared to loess. Finally, there is no correlation

362   between the δ^7Li and $\delta^{94/90}Zr_{IPGP-Zr}$ values of the glacial diamictite composites and

363   oceanic sediments (Fig. 4), further indicating that chemical weathering has not

364   affected Zr isotope compositions of these samples.

365   **3. No evidence for Zr isotope fractionation of the UCC through space and**

366   **time**

367   The glacial diamictites studied here record evidence for a secular change in the

368   composition of the UCC between the Archean and post-Archean, with Archean

369   samples systematically enriched in platinum group elements (Chen et al., 2016), Cr,

370   Ni, Co, (Gaschnig et al., 2016) and other transition metals such as Cu (Chen et al.,

371   2019) relative to post-Archean diamictites.

372   These changes have been interpreted as reflecting a transition from a more mafic

373   UCC to one similar to the present-day at the end of the Archean. A similar transition

374   in UCC composition was earlier documented on the basis of the geochemistry of

375   shales (Taylor and McLennan, 1983; Condie, 1993). However, this transition from

mafic to felsic UCC has been disputed, and a mostly felsic Hadean or early Archean

377 crust has been proposed based on various geochemical lines of evidence, including

378 the reinterpretation of the chemical composition of the terrigenous sediments (Greber

379 and Dauphas, 2019; Ptáček et al., 2020), the Ti isotopic composition of shales (Greber

380 et al., 2017) and Hf-O isotope compositions of the Hadean zircons (Harrison, 2009).

381 Here, the Zr isotope composition of the diamictite composites show no secular trend

382 (Fig. 5a), suggesting that the Zr isotopic composition of UCC has been constant since

383 at least the Mesoarchean.

384   In addition, post-Archean diamictites, loess and oceanic sediments display

385 indistinguishable Zr isotope compositions regardless of their geographic settings (Fig.

386 5b). Thus, it appears that the UCC is spatially homogenous when it comes to Zr

387 isotopes.

388   **4. Zr isotope composition of UCC and BSE**

389   As demonstrated above, zircon enrichment or depletion, chemical weathering,

390 and fluid-rock exchange processes, bulk UCC composition and geographic setting do

391 not appear to have influenced the Zr isotopes of these sedimentary samples to any

392 measurable extent. These samples can therefore be used to estimate the Zr isotope

393 composition of the UCC.

394 Combining the data of sedimentary reference materials from the literature and Zr

395 isotopic values of sedimentary samples reported in this study, we obtain a Zr-

396 weighted UCC average $\delta^{94/90}Zr_{IPGP-Zr}$ of $0.077 \pm 0.058‰$ (2SD, n = 44) (Fig. 6a). This

397   value falls between the $\delta^{94/90}Zr_{IPGP-Zr}$ of the mantle (0.040 ± 0.044‰, n = 72), based

398   on oceanic basalts (Inglis et al., 2019) and komatiites (Tian et al. 2020b), and evolved

399   igneous rocks, which have higher $\delta^{94/90}Zr_{IPGP-Zr}$, showing a wide range from 0.053 to

400   0.475‰ based on the $\delta^{94/90}Zr_{IPGP-Zr}$ of granitoid reference materials (Fig. 6a and 6b,

401   Table S3). The distinct and higher $\delta^{94/90}Zr_{IPGP-Zr}$ value of the UCC compared to the

402   mantle (t test with a p value 2.88×10^{-10}, Fig. 6a) likely reflects a large-scale mixing of

403   isotopically heavy felsic igneous rocks with isotopically light mantle-like mafic

404   igneous rocks within the UCC.

405   The mass fractions of the main terrestrial reservoirs and their Zr abundances are

406   presented in Table 1. Zirconium concentration is highest in the UCC (193ppm)

407   (Rudnick and Gao, 2014), which is about two times that of the deep (middle and

408   lower) crust (98 ppm) (Rudnick and Gao, 2014) and the oceanic sediments (82 ppm)

409   (Jenner and O'Neill, 2012), and twenty times that of the mantle (9.8 ppm)

410   (McDonough and Sun, 1995). However, the mantle still contains 92.38% of the Zr of

411   the Earth, while the Zr fractions contributed by the UCC, deep continental crust and

412   oceanic crust are only 3.34%, 3.02% and 1.26%, respectively. The Zr isotope

413   composition of the deep continental crust is unknown. Considering its more mafic

414   composition, it can be assumed that the lower continental crust has a similar Zr

415   isotope composition to that of the mantle, as is the case for the oceanic crust.

416   Therefore, the UCC is apparently the only isotopically fractionated reservoir within

417   the BSE. Accordingly, the updated estimate of the BSE $\delta^{94/90}Zr_{IPGP-Zr}$ value is 0.041 ±

418   0.041‰ (Table 1). Given that the Earth's core does not likely contain any Zr (Li and

419   Fei, 2014), and that the Zr content of the hydrosphere is also negligible (1.84×10^{-7} %),

420   we infer that the bulk Earth has a $\delta^{94/90}Zr_{IPGP-Zr}$ of 0.041 ± 0.041‰.

421   **Conclusions**

422   Terrigenous and oceanic sedimentary samples that represent the UCC, with

423   depositional ages ranging from the Archean to the present have been analyzed in

424   order to estimate the Zr isotope composition of the UCC. Glacial diamictite

425   composites, loess and oceanic sediments display a restricted range of $\delta^{94/90}Zr_{IPGP-Zr}$,

426   which is systematically higher than $\delta^{94/90}Zr_{IPGP-Zr}$ of the mantle. The $\delta^{94/90}Zr_{IPGP-Zr}$ of

427   the sedimentary samples are constant regardless of their depositional ages, enrichment

428   or depletion of zircon, degree of chemical weathering and geographical locations,

429   reflecting a conservative Zr isotope composition of the UCC globally through time.

430   Combined with the $\delta^{94/90}Zr_{IPGP-Zr}$ values of sedimentary reference materials reported

431   in the literature, we derive a $\delta^{94/90}Zr_{IPGP-Zr}$ of the UCC of 0.077 ± 0.058‰ (2SD, n =

432   44).
