Abstract

Background—Cardiovascular disease (CVD) is of increasing concern among breast cancer survivors. However the burden of this comorbidity in this group relative to the general population, and its temporal pattern, remains unknown.

Methods—We compared deaths due to CVD in a population-based sample of 1,413 women with incident breast cancer diagnosed in 1996-1997, and 1,411 age-matched women without breast cancer. Date and cause of death through December 31, 2009 were assessed through the National Death Index and covariate data was gathered through structured interviews and medical record abstraction. Hazard ratios and 95% confidence intervals (CI) were calculated using Cox regression for overall mortality (HR) and CVD-specific death (cause-specific HR). Subdistribution hazard ratios (sHR) for CVD death were estimated from the Fine-Gray model.

Results—Risk of death was greater among breast cancer survivors compared to women without breast cancer [HR: 1.8 (1.5, 2.1)]. An increase in CVD-related death among breast cancer survivors was evident only 7 years after diagnosis [years 0-7, cause-specific HR: 0.80 (0.53, 1.2), subdistribution HR: 0.59 (0.40, 0.87)]; years 7+, cause-specific HR: 1.8 (1.3, 2.5), subdistribution HR: 1.9 (1.4, 2.7); p-interaction: 0.001]. An increase in CVD-related mortality was observed among breast cancer survivors receiving chemotherapy.

Conclusions—Breast cancer survivors are at greater risk for CVD-related mortality compared to women without breast cancer and this increase in risk is manifest approximately 7 years after diagnosis. Efforts should be made to identify risk factors and interventions that can be employed during this brief window to reduce the excess burden of CVD in this vulnerable population.

Introduction

Breast cancer mortality among American women has decreased by more than 2% per year in the last decade¹, with nearly 90% of breast cancer patients currently surviving 5 years past their date of diagnosis.² In the United States there are nearly 3 million female breast cancer survivors³ many of whom die from conditions unrelated to their malignancy.^{4,5} This trend becomes more pronounced as age at diagnosis increases⁶ and among those with early stage disease.^{4,6}

Cardiovascular disease (CVD) is an important public health issue; among the general U.S. population it represents the leading cause of death among both men and women⁷ and is an issue of growing concern among cancer survivors.⁸⁻¹¹ For breast cancer survivors specifically, CVD represents the greatest single non-cancer cause of death, accounting for approximately 35% of non-breast cancer mortality for survivors 50 years of age and older.⁶ However, our current understanding of the etiology of CVD among breast cancer survivors is limited.^{10,12} Previous studies have examined risk factors for CVD-related mortality within cohorts of cancer survivors only, mostly focusing on breast cancer treatment.^{10,13} Although an increased risk of CVD has been documented in clinical studies, there have been few reports of the magnitude of this comorbidity in population-based cohorts of breast cancer survivors. Furthermore, the extent to which breast cancer survivors experience CVD related outcomes relative to women without breast cancer, and the time when any excess risk of CVD becomes manifest, has not been formally evaluated previously. This ambiguity limits the ability for clinicians to identify and provide accurate recommendations for CVD risk reduction strategies specific to breast cancer survivors, particularly with regard to the timing of the interventions.

The objective of this study was to estimate the relative burden of death due to CVD among a population-based sample of breast cancer survivors compared to an age-matched sample of women without breast cancer. We also explored whether rates of CVD death varied over time or according to cancer-related treatments.

Methods

This follow-up study uses resources from the population-based Long Island Breast Cancer Study Project (LIBCSP),¹⁴ which was approved by the Institutional Review Board of participating institutions.

Study Population

Women with breast cancer were English-speaking adults diagnosed with a first primary *in situ* or invasive breast cancer between August 1, 1996-July 31, 1997, and residents of Nassau or Suffolk counties, NY. Potentially eligible women with breast cancer were identified through all hospitals in the study catchment area, and patients' physicians were contacted to confirm the diagnosis and obtain permission to contact the women. Women without breast cancer were residents of the same two counties in NY, frequency matched to the expected distribution of survivors in 5-year age groups, and identified using random digit dialing for those under 65 years of age, and from Health Care Finance Rosters for those

age 65 or over. Baseline interview respondents included 1,508 women with (82.1% of eligible cases) and 1,556 without breast cancer (62.7% of eligible controls). Women ranged from 20 to 98 years of age at baseline, and 94% were white and 4% were African American. At baseline, 1,414 breast cancer survivors agreed to be re-contacted, and 1,033 ultimately participated in the follow-up interview.

Outcome Assessment

The National Death Index¹⁵ was used to establish vital status for all LIBCSP participants through 2009. We considered death from any cause (n=712; 268 women without breast cancer and 444 breast cancer survivors), as well as death from CVD (n=300; 129 and 171, respectively) if any of the following cardiovascular disease-related International Classification of Disease codes were listed as the primary cause of death: 394.9, 402.9, 410, 414.0, 427.5, I10, I11.9, I21.9, I25.1, I25.4 and I46.9. These codes were selected to include common cardiovascular disease outcomes, including myocardial infarction, cardiac arrest, hypertensive heart disease, coronary artery aneurysm and dissection. Women without a death record match in the NDI database were deemed alive as of December 31, 2009. Follow-up time ranged from 0.2 to 13.5 years.

Covariates

After signed informed consent was obtained, all participants completed the in-person baseline interview, which occurred within approximately 3 months of diagnosis for women with breast cancer. The baseline interview included assessment of history of comorbidities, menopausal status, education, income, first course of treatment for the first primary breast cancer diagnosis, and other factors. Only women with breast cancer were asked to complete the telephone follow-up interview, which occurred approximately 5 years later, to obtain more detailed information on full course of treatment for the first primary breast cancer.

Medical records were reviewed for information on tumor characteristics and treatment for 1,402 women with breast cancer who signed a medical record release form at baseline, and, again, for 598 women with breast cancer who signed a medical record release at the follow-up interview. Treatment data from the medical record agreed strongly with the data from the follow-up questionnaire¹⁶ (kappa coefficients: radiation therapy $\kappa=0.97$, chemotherapy $\kappa=0.96$ and hormone therapy $\kappa=0.92$), and thus the self-reported data are used in these analyses. Data on tumor size was collected from the New York State Cancer Registry.

Statistical Analysis

All statistical analyses were conducted using Stata 13 (College Station, TX). For overall mortality, Kaplan-Meier failure curves were calculated and Cox proportional hazards regression¹⁷ was used to estimate adjusted hazard ratios (HR) and 95% confidence intervals (CI). For CVD mortality we conducted a competing risks analysis¹⁸⁻²⁰ because other causes of death (e.g. breast cancer) may remove women from the risk set before the event of interest (CVD mortality) is observed. For CVD-related death we estimated the competing risks analog to the Kaplan-Meier failure function, the cumulative incidence function.²¹ For the competing risks analysis we estimated two measures of association: the cause-specific hazard ratio and the subdistribution hazard ratio.¹⁹ The cause-specific hazard ratio

represents the rate at which women with breast cancer experience CVD-related deaths relative to women without breast cancer among those still alive;^{22,23} this was estimated from a Cox model with all non-CVD causes of death treated as censored. The subdistribution hazard ratios indicate the relative difference in the cumulative incidence of CVD deaths between women with and without breast cancer,^{18,19} and were estimated using the Fine-Gray model.²² The subdistribution hazard ratio accounts for the influence of other causes of death (e.g. breast cancer) that would render subjects incapable of experiencing the death of interest (CVD), and therefore reflects the relative risk of experiencing a CVD-related death.^{22,23}

Confounders included variables that may affect both breast cancer incidence and cardiovascular disease mortality: age (at reference date=date of diagnosis for women with breast cancer or date of identification for women without breast cancer; restricted cubic spline with 5 knots at equally spaced percentiles), menopausal status (pre-/post-menopausal), previous use of hormone replacement therapy (HRT, yes/no), cigarette smoking history (never, passive exposure only, active smoker only, both active smoker and passive exposure), average lifetime alcohol intake (non-drinkers, <15 g/day, 15-30 g/day, 30 or more g/day), body mass index (BMI, kg/m²) the year before reference date and self-reported history of the following comorbidities at reference date: diabetes, dyslipidemia, myocardial infarction, hypertension, or stroke. All confounders were ascertained relative to the study participant's reference date. We additionally considered adjustment for additional factors that could be related to access to care, health care utilization and health behavior (income and education) and cardiovascular disease risk (cholesterol-lowering medications and aspirin use), but adjustment for these factors did not materially change the estimates and thus we did not include them in the final models. The proportional hazards assumption was assessed using a Wald test for the interaction between follow-up time and each covariate. Violations of this assumption were noted for history of myocardial infarction and hypertension for overall mortality, and for history of diabetes for CVD mortality, therefore the final respective models included interactions between these terms and follow-up time. Breast cancer status also violated this assumption in all models, and so the overall association is interpreted as an average effect over the entire follow-up period;²³ we additionally report this association separated by duration of follow-up, described below.

We evaluated the potential for the association with breast cancer status to vary over time by exploring interactions with follow-up time categorized as before and after 6 years of follow-up (e.g. follow-up time ≤ 6 years vs. > 6 years) for overall mortality, and 7 years for CVD mortality, determined to be the most meaningful cutpoints based on empirical results and visual inspection of Kaplan-Meier failure curves and cumulative incidence function plots. Significance in this interaction was determined at the 5% level. We additionally explored heterogeneity of the association among breast cancer survivors by classifying them according to treatment (chemotherapy, hormone therapy, radiation therapy). Small numbers for these subgroup analyses precluded categorization of breast cancer survivors into more detailed treatment types or combinations.

Final Analytic Sample Size

Small amounts of missing data were noted for baseline menopausal status (30 cases/63 controls), history of HRT (4 cases/1 control), smoking (37 cases/42 controls), BMI (17 cases/28 controls), or any CVD-related comorbidity (9 cases/13 controls) yielding a sample of 1,413 women with, and 1,411 women without, breast cancer for the primary analyses.

Results

At the reference date the mean age of women in our sample was 57 years for women without breast cancer and 59 years for women with breast cancer. In our population-based sample of 1,413 women diagnosed with a first primary breast cancer in 1996-1997 the number of deaths through 2009 was higher for all-cause and CVD-related mortality (415 and 133, respectively) than among the 1,411 age-matched population-based women without breast cancer (242 and 105, respectively) (Table 1). When considering the six pre-existing CVD-related risk factors (history of myocardial infarction, history of stroke, pre-existing diabetes, hypertension or high cholesterol, or $BMI \geq 30 \text{ kg/m}^2$), we noted that the average number of risk factors was slightly higher among women with breast cancer (mean: 1.03) than among women without breast cancer (0.97).

As shown in Figure 1, risk of death from all causes was greater among breast cancer survivors compared to the population-based sample without breast cancer [adjusted HR (95% CI): 1.8 (1.5, 2.1)]. Breast cancer was also associated with greater rate of CVD-related death across the entire follow-up [adjusted cause-specific HR: 1.3 (1.0, 1.7); subdistribution HR: 1.2 (0.89, 1.5)].

CVD-related mortality among the breast cancer survivors appeared to increase sharply after approximately year 5. Analyses that considered heterogeneity of these relationships over the follow-up showed a significant difference in the association between mortality and breast cancer status over time (Table 2). As expected, within the first 6 years the overall mortality rate was much greater among breast cancer survivors than women without breast cancer [within years 0-6, HR: 2.2 (1.7, 2.8); after year 6, HR: 1.5 (1.3, 1.9), p-interaction: 0.04], largely driven by the greater number of breast cancer-related deaths among survivors in the years immediately following diagnosis. However, the rate of CVD death was greater among longer-term breast cancer survivors compared to the women without breast cancer after 7 years of follow-up [csHR: 1.8 (1.3, 2.5)]. In contrast, there was a trend towards an inverse association of breast cancer status with CVD-related death within the first 7 years [cause-specific HR: 0.80 (0.53, 1.2), p-interaction: 0.004]. After year 7, breast cancer survivors had nearly twice the risk of CVD mortality compared to those without breast cancer [sHR: 1.9 (1.4, 2.7)], while the risk of CVD death was lower among breast cancer survivors in the early years [years 0-7, subdistribution HR: 0.59 (0.40, 0.87), p-interaction <0.001]. This reduction in incident CVD mortality among survivors in the short term most likely reflects the influence of the major competing risk in this group (breast cancer-related death).

The CVD-specific mortality rate was elevated among those who received chemotherapy [cause-specific HR: 1.7 (1.1, 2.6)] but not those not receiving chemotherapy [cause-specific HR: 1.1 (0.82, 1.6)] (Table 3). Similar increases were observed regardless of receipt of

hormone therapy, while a more pronounced, but non-significant increase was seen among those not receiving radiation therapy [without radiation therapy cause-specific HR: 1.5 (1.0, 2.2); with radiation therapy cause-specific HR: 1.2 (0.82, 1.7)]. Associations with the cumulative incidence of CVD death (sHRs) followed similar patterns, but were attenuated. Given that adjuvant chemotherapy is associated with early menopause, which may impact CVD risk, we conducted an exploratory analysis where we examined the relationship with chemotherapy treatment among women who were pre-menopausal at diagnosis (n=466 women with breast cancer and 485 women without) and found more pronounced associations with chemotherapy in this subgroup than we observed in the overall population [cause-specific HR: 2.8 (1.3, 6.3), sHR: 2.5 (1.1, 5.7) among women receiving chemotherapy vs. women without breast cancer; cause-specific HR: 1.4 (0.43, 4.3), subdistribution HR: 1.4 (0.43, 4.2) among women not receiving chemotherapy vs. women without breast cancer] (data not in table).

Discussion

We are the first, to our knowledge, to determine that death due to CVD is higher among a population-based cohort of breast cancer survivors than a comparable group of women without breast cancer. We were also able to identify at which point after diagnosis—approximately year 7—CVD becomes a disproportionate cause of death for cancer survivors. The increase in CVD-related mortality among breast cancer survivors, compared to other women, appeared to be strongest among survivors who received chemotherapy for their first primary breast cancer. Our finding that breast cancer survivors are at greater risk for CVD than women without breast cancer has important clinical implications for these women who are already older at diagnosis, and the long-term survivors who continue to age.

The most noteworthy finding of our study is that the increased risk of CVD-related death among breast cancer survivors does not become apparent until several years after diagnosis. The near-null cause-specific HR for CVD mortality observed within the first 7 years reflects the fact that near diagnosis the rate of CVD mortality is similar between breast cancer survivors and women without breast cancer, however the significant inverse subdistribution HR suggests that the cumulative incidence of CVD-related death is lower among breast cancer survivors during this time since breast cancer survivors are more likely to experience the competing risk of breast cancer-related death. However, this dynamic appears to change around year 7, when not only does the influence of the competing risk decrease, but the association of breast cancer diagnosis with rate of CVD death increases sharply. These two factors combine to yield a nearly twofold increase in the incidence of CVD for these long-term survivors (shown by the subdistribution HR in years 7+). The current paradigm that suggests survivorship 5 years after diagnosis is a meaningful threshold for cancer survivors²⁴ does not account for the substantial increase in risk of non-cancer related death that occurs after this point. Instead, it over-emphasizes improvements in short-term survival attributable to improvements in treatment, while ignoring the sizeable late effects of such treatment on risk of potentially fatal comorbidities, in particular cardiovascular disease.

Several potential mechanisms could play a role in these associations. Cancer survivors have been reported to have a higher prevalence of CVD risk factors compared to the general

population,²⁵ although this difference was not pronounced in our cohort when we compared the average number of risk factors between women in these two groups. Additionally, the cardiotoxic effects of breast cancer treatments, specifically radiotherapy and chemotherapy, are well documented.^{10,13,26} Anthracycline-related cardiotoxicity is especially established,^{26,27} however this agent is predominantly related to congestive heart failure and cardiomyopathy,^{26,27} which were not included in our definition of CVD-related death. Therefore, the observed increase in CVD-related deaths among women receiving chemotherapy could be attributed to a number of other agents with effects that act on the cardiovascular system.²⁶ In addition to any direct effects of chemotherapy on CVD risk, there may be indirect mechanisms linked with early menopause,²⁸ which is associated with unfavorable changes in lipid levels²⁹ and hemostasis factors³⁰ that may increase risk of cardiovascular events.³¹ This is consistent with our observation of a more pronounced association for chemotherapy treatment among pre-menopausal women. Our overall finding of an increased risk of CVD-related death among breast cancer patients who underwent chemotherapy is consistent with these previous studies, yet we are the first to quantify the magnitude of this increase compared to women without breast cancer. We did note a modest decrease in the rate of CVD-related death among women with breast cancer in the first several years after diagnosis, which could be consistent with a previously noted reduction in death due to myocardial infarction associated with tamoxifen.³² However, a limited number of events in the years shortly after diagnosis limited our ability to examine treatment-by-time interactions in this analysis.

Although our finding of no increase in CVD mortality among those receiving radiation therapy was in agreement with some previous studies,^{33,34} this result lies in contrast to others.^{9,35-39} Radiation therapy, in particular to the left side of the chest wall, may increase CVD risk through injury to cardiac muscle or the surrounding vasculature.⁴⁰ However, several recent studies have failed to observe a difference in cardiac events between women receiving radiation therapy for left- vs. right-sided tumors.^{34,42,43} A potential explanation for these recent null findings, including ours, is that current radiotherapy techniques are more targeted and less cardiotoxic than older regimens.^{41,42} It is also possible that the severity or form of radiation-induced CVD is less fatal than chemotherapy-induced disease, as our outcome was mortality rather than incident disease. Alternatively, radiation-induced CVD could take longer to manifest than we have available follow-up, as studies have found an increase in risk of morbidity or mortality more than 15 years³⁶ to 20 years^{37,39} after treatment, a time period several years past what we had available. Other reports have found a synergistic effect between radiotherapy and other systemic therapies¹³ that we did not have the study power to examine here.

A major strength of our study includes the innovative focus on a population-based sample of women with and without breast cancer. We are the first, to our knowledge, to compare risk for non-cancer mortality between a cohort of breast cancer survivors and a sample of women without breast cancer from the same source population. This study design offers a unique opportunity to identify differences in the risk of health outcomes between breast cancer survivors and a comparable group of women without breast cancer. Nearly all of the previous epidemiologic studies of cancer survivors have been limited to identification of risk factors among survivors alone. Our novel design allows us to identify unique patterns of risk

in this subgroup, in particular the time at which risk between these two groups diverges. Our findings suggest that breast cancer survivors should be closely monitored for development of cardiovascular abnormalities and CVD risk factors beginning in the years immediately following diagnosis and treatment. Importantly, our population-based design strengthens the interpretation of our findings—since the study participants with and without breast cancer were both representative of the same source population from which they are drawn.

Although this study has noteworthy strengths, our conclusions must be interpreted in light of potential limitations. The women from this cohort are predominantly white, and these findings may not be generalizable to other racial and ethnic groups. Although we controlled for pre-existing comorbid conditions that may be related to CVD-mortality (and potentially breast cancer treatment choices), there is the potential for residual confounding by the degree to which the comorbid conditions are controlled or confounding by indication for analysis of treatment-specific effects. Data on cause of death was determined through the National Death Index (NDI), a reliable source for determination of all-cause mortality.¹⁵ The NDI uses death certificate information to establish cause of death, which is a potential source of misclassification. However, our conclusions that the rate of overall mortality between those with and without breast cancer tended to converge over time, while the CVD-related mortality rate was initially identical, then diverged, suggests that classification of death was accurate, or at least that any misclassification would be nondifferential. Such misclassification would result in either bias toward the null, or in certain circumstances, no bias.⁴⁴ Another potential concern is our use of self-reported data for pre-existing CVD-related comorbidities. Yet self-reported comorbidities such as those considered here have been demonstrated to be associated with mortality in similar cohorts.^{45,46} Additionally, given the size of our study, we were only able to evaluate treatment modalities broadly and not by specific agents. Subsequent studies would be improved by a larger sample size, which would facilitate more detailed analyses, such as death from specific CVD-related conditions, or due to specific chemotherapy agents or combinations of treatments.

Our results show that years after diagnosis and treatment long-term breast cancer survivors are at increased risk of death due to cardiovascular disease compared to women from the general population. In future, larger studies are needed to confirm our findings and identify the forms of CVD that are most common in this group, as well as including incident CVD as well as CVD-related mortality. Identification of potential mechanisms through which the breast cancer survivorship experience influences CVD etiology will help identify potential targets for intervention in this high-risk population.

Figure 1.

Unadjusted Kaplan-Meier failure curves and adjusted hazard ratios (HR) for overall mortality (first panel) and cumulative incidence function, cause-specific HR (csHR) and subdistribution HR (sHR) for CVD-related mortality (second panel) among a population-based sample of breast cancer survivors and age-matched women without breast cancer. The Long Island Breast Cancer Study, 1996-2009.

*HRs adjusted for age at reference date (age at diagnosis for breast cancer survivors and date of identification for women without breast cancer), menopausal status, previous use of hormone replacement therapy, smoking history, average lifetime alcohol intake, body mass index the year before reference date, income, education, and history of the following cardiovascular disease risk factors: diabetes, myocardial infarction, hypertension, dyslipidemia or stroke. Model for overall mortality included interaction between follow-up time and history of hypertension and myocardial infarction and models for CVD mortality included interaction between follow-up time and history of diabetes.

Table 1

Baseline characteristics, and vital status as of December 31, 2009, among a population-based sample of 1,413 breast cancer survivors and 1,411 women without breast cancer frequency matched by age. Long Island Breast Cancer Study Project, 1996-2009.

	Women without Breast Cancer (n=1,411)	Breast Cancer Survivors (n=1,413)
Deaths from any cause	242	415
Deaths from CVD ^a	105	133
Deaths from Breast Cancer ^a	2	135
Menopausal status		
Premenopausal, No. (%)	485 (34)	466 (33)
Postmenopausal, No. (%)	926 (66)	947 (67)
Ever used hormone replacement therapy		
No	1,073 (76)	1,033 (73)
Yes	338 (24)	408 (27)
Smoking		
Never	177 (13)	161 (11)
Passive exposure only	465 (33)	464 (33)
Ever active smoker only	132 (9.4)	133 (9.4)
Both active and passive	637 (45)	655 (46)
Alcohol intake, Lifetime average g/day		
Non-drinker	551 (39)	550 (39)
0-15	672 (48)	651 (46)
15-30	107 (7.6)	142 (10)
>=30	81 (5.7)	70 (4.9)
BMI ^b (kg/m ²) in year before reference date ^b		
<18.5	31 (2.2)	25 (1.8)
18.5-24.9	662 (47)	629 (44)
25.0-29.9	415 (29)	450 (32)
30.0	303 (22)	309 (22)
Hypertension		
No	946 (67)	925 (65)
Yes	465 (33)	488 (34)
Diabetes		
No	1,313 (93)	1,285 (91)
Yes	98 (6.9)	128 (9.1)
High Cholesterol		
No	980 (69)	988 (70)
Yes	431 (30)	425 (30)
Myocardial Infarction		

		Women without Breast Cancer (n=1,411)	Breast Cancer Survivors (n=1,413)
Stroke	No	1,367 (97)	1,356 (96)
	Yes	44 (3.1)	57 (4.0)
Chemotherapy	No	1,387 (98)	1,372 (97)
	Yes	24 (1.7)	41 (2.9)
Radiation Therapy	No	N/A	561 (58)
	Yes	N/A	400 (42)
Hormone Therapy	No	N/A	375 (39)
	Yes	N/A	590 (61)
Tumor size	No	N/A	369 (39)
	Yes	N/A	580 (61)
	<2cm	N/A	781 (76)
	>=2cm	N/A	248 (24)
	Missing	N/A	479

^aCVD: cardiovascular disease. According to primary cause of death field from National Death Index data.

^bBMI: body mass index.

Table 2

Overall and CVD mortality among a population-based sample of breast cancer survivors and women without breast cancer stratified by time since the beginning of follow-up. The Long Island Breast Cancer Study Project, 1996-2009.

Overall Mortality				
HR ^a (95% CI)				
Time since beginning of follow-up	Women without Breast Cancer (235 deaths)	Breast Cancer Survivors (407 deaths)		p ^b
0-6 years	1.0	2.2 (1.7, 2.8)		0.04
>6 years	1.0	1.5 (1.3, 1.9)		
CVD Mortality				
Time since beginning of follow-up	Women without Breast Cancer (114 deaths)	Breast Cancer Survivors (155 deaths)		
Cause-specific HR ^{a,c} (95% CI)				
0-7 years	1.0	0.80 (0.53, 1.2)		0.004
>7 years	1.0	1.8 (1.3, 2.5)		
Subdistribution HR ^{a,d} (95% CI)				
0-7 years	1.0	0.59 (0.40, 0.87)		<0.001
>7 years	1.0	1.9 (1.4, 2.7)		

^a Models adjusted for age at reference date (date of diagnosis for breast cancer survivors and date of identification for women without breast cancer), menopausal status, previous use of hormone replacement therapy, smoking history, average lifetime alcohol intake, body mass index the year before reference date, income, education, and history of the following cardiovascular disease risk factors: diabetes, myocardial infarction, hypertension, dyslipidemia or stroke. Model for overall mortality included interaction between follow-up time and history of hypertension and myocardial infarction and models for CVD mortality included interaction between follow-up time and history of diabetes.

^b P-value for likelihood ratio test of interaction between breast cancer status and time.

^c Cause-specific hazard ratio estimates relative rate of CVD mortality between women with and without breast cancer, not accounting for competing causes of death.

^d Subdistribution hazard ratio reflects association between breast cancer diagnosis and incidence of CVD death.

Table 3

CVD mortality by treatment regimen for a population-based sample of breast cancer survivors and women without breast cancer. Long Island Breast Cancer Study Project, 1996-2009.

Cause-specific HR ^{a,b} (95% CI)			
Treatment	Women without Breast Cancer	Breast Cancer Survivors without Treatment	Breast Cancer Survivors with Treatment
Chemotherapy	1.0	1.1 (0.82, 1.6)	1.7 (1.1, 2.6)
Hormone Therapy	1.0	1.3 (0.82, 1.9)	1.3 (0.93, 1.8)
Radiation Therapy	1.0	1.5 (1.0, 2.2)	1.2 (0.82, 1.7)
Subdistribution HR ^{a,c} (95% CI)			
Treatment	Women without Breast Cancer	Breast Cancer Survivors without Treatment	Breast Cancer Survivors with Treatment
Chemotherapy	1.0	1.1 (0.77, 1.5)	1.4 (0.95, 2.2)
Hormone Therapy	1.0	1.2 (0.77, 1.8)	1.2 (0.86, 1.7)
Radiation Therapy	1.0	1.3 (0.89, 2.0)	1.1 (0.77, 1.6)

^aModels adjusted for age at reference date (date of diagnosis for breast cancer survivors and date of identification for women without breast cancer), menopausal status, previous use of hormone replacement therapy, smoking history, average lifetime alcohol intake, body mass index the year before reference date, income, education, and history of the following cardiovascular disease risk factors: diabetes, myocardial infarction, hypertension, dyslipidemia or stroke. Models also included interaction between follow-up time and history of diabetes.

^bCause-specific hazard ratio estimates relative rate of CVD mortality between women with and without breast cancer, not accounting for competing causes of death.

^cSubdistribution hazard ratio reflects association between breast cancer diagnosis and incidence of CVD death.
