Stochastic Optimal Prediction with Application to Averaged Euler Equations*

John Bell† Alexandre J. Chorin‡ William Crutchfield†

Abstract

Optimal prediction (OP) methods compensate for a lack of resolution in the numerical solution of complex problems through the use of an invariant measure as a prior measure in the Bayesian sense. In first-order OP, unresolved information is approximated by its conditional expectation with respect to the invariant measure. In higher-order OP, unresolved information is approximated by a stochastic estimator, leading to a system of random or stochastic differential equations.

We explain the ideas through a simple example, and then apply them to the solution of Averaged Euler equations in two space dimensions.

1 Introduction

Many problems in mechanics, in particular problems involving turbulence, cannot be properly resolved because the number of significant degrees of freedom is too large. The problem of making numerical predictions about the behavior of systems that have not been properly resolved has been addressed in [5, 6, 8, 10]; theoretical results can be found in [9, 10]; a general introduction to such methods can be found in [4]. When a system is underresolved, nothing much can be said without additional information; in the papers just quoted, it is assumed that the additional information consists of an invariant measure on the space of solutions; this gives rise to an optimal Markovian, deterministic, approximation. An invariant measure constitutes additional information because everything not explicitly known is assumed to be distributed according to the invariant measure; it functions like a prior measure in Bayesian statistics [1]. Unlike what happens in other areas of application of Bayesian statistics, nature often provides a rational choice of prior, invariant measure in the form of a canonical measure. The use of an invariant measure gives rise to approximations that are optimal in a sense that we shall specify below.

In many problems this optimal approximation is still not accurate enough, and a higher-order, stochastic, approximation can be derived. In the present paper we explain these constructions with the help of a simple example, and then apply them to the solution of Averaged Euler equations in two space dimensions. The main difficulty in higher-order prediction lies in finding estimators for stochastic processes whose temporal correlations are determined only empirically.

2 Optimal and stochastic prediction for Hamiltonian systems

We present properties associated with general, even infinite dimensional Hamiltonian systems, in the simple case of two oscillators, with position variables q_1, q_2 and momenta p_1, p_2, and the Hamiltonian:

$$H = H(q,p) = \frac{1}{2}\left(q_1^2 + q_2^2 + p_1^2 + p_2^2 + p_1^2 p_2^2\right) \tag{1}$$

(the "Hald system"). The equations of the motion of the system are:

$$\begin{array}{rcl} \frac{dq_1}{dt} &=& p_1 + p_1 p_2^2, \\ \frac{dp_1}{dt} &=& -q_1, \\ \frac{dq_2}{dt} &=& p_2 + p_2 p_1^2, \\ \frac{dp_2}{dt} &=& -q_2. \end{array} \tag{2}$$

We pretend that 4 equations in 4 unknowns are too difficult to solve on available computers but that 2 equations in 2 unknowns are accessible (A more realistic situation is one where one has to solve, say, 10^{20} equations and one can afford only 10^6). Alternately, suppose that for some reason at time $t = 0$ we only have values for q_1, p_1

but not for the two other variables. The question is, how does one write equations for q_1, p_1 without computing q_2, p_2.

In a standard, Galerkin, approach, one simply sets all the uncomputed variables to zero; this results in the system:

$$\frac{dq_1}{dt} = p_1, \quad \frac{dp_1}{dt} = -q_1,$$

which is not a very good approximation.

Suppose however that although the initial conditions for oscillator 2 are unknown, we do know that they are drawn from the canonical distribution:

$$\begin{aligned} P(x_1 \le q_1 < x_1 + dx_1, x_2 \le q_2 < x_2 + dx_2, \\ y_1 \le p_1 < y_1 + dy_1, y_2 \le p_2 < y_2 + dy_2) = \\ Z^{-1} \exp(-H(x,y)/T) dxdy, \end{aligned} \tag{3}$$

where P is the probability of the event in parentheses, Z is a normalization constant that ensures that the sum of all probabilities is 1, $dxdy = dx_1 dx_2 dy_1 dy_2$, T is a parameter that controls the variance of the samples and is known for physical reasons as the temperature, and $H(x,y)$ is the Hamiltonian function (1) with q_1 replaced by x_1, p_1 replaced by y_1, etc. Equation (3) is often written in the shorter symbolic form

$$P(q,p) = Z^{-1} \exp(-H(q,p)/T. \tag{4}$$

One can readily check that this probability distribution is invariant under the flow defined by (2), i.e., if the initial data are distributed as in (4), then the solutions $q_{1,2}, p_{1,2}$ have the same distribution at all later times. Nature likes this distribution, and reproduces it often (see any book on statistical mechanics).

Suppose now that the missing initial conditions are drawn from the canonical distribution (4) conditioned by the known information q_1, p_1, i.e.,

$$P(x_2 \le q_2 < x_2 + dx_2, y_2 \le p_2 < y_2 + dy_2) = Z^{-1} \exp(-H_{q_1,p_1}(x_2, y_2)) dx_2 dy_2, \tag{5}$$

for some T, where H_{q_1,p_1} is H where the values of x_1, y_1 have been given the fixed, known values of these initial conditions. In the language of Bayesian estimation [1], the canonical distribution (4) is a prior distribution (what we believe the distribution to be before we have any data), and the conditional distribution (5) is a posterior distribution (the prior distribution modified by what we know in a special case). Averages with respect to the conditional distribution (5) are conditional averages, and denoted by $E[\cdot|q_1, p_1]$ (the information after the vertical line is what we know, and the prior distribution is implied). We now approximate equations (2) by the optimal prediction (OP) equations:

$$\frac{dq_1}{dt} = E[p_1 + p_1 p_2^2 | q_1, p_1] = p_1 + p_1 E[p_2^2 | q_1, p_1], \quad \frac{dp_1}{dt} = -q_1; \tag{6}$$

(clearly $E[p_1|p_1] = p_1$). In our particular case,

$$E[p_2^2|q_1, p_1] \quad = \quad E[p_2^2|p_1] =$$

$$\int\int p_2^2 \exp\left(-\frac{1}{2}\left(p_1^2+p_2^2+q_1^2+q_2^2+p_1^2p_2^2\right)\right) dq_2dp_2/$$
$$\int\int \exp(-(\cdots))dq_2dp_2;$$

(the argument of the exponential is the same in the denominator as in the numerator). After obvious cancellations,

$$E[p_2^2|p_1] = \int p_2^2 \exp(-p_2^2/2 - p_2^2p_1^2/2)dp_2/\int \exp(\cdots)dp_2 = \frac{1}{1+p_1^2},$$

(a function of p_1). A general theorem states that in the mean square with respect to the invariant canonical measure, $E[p_2^2|p_1]$ is the best of approximation of p_2^2 by a function of p_1. The error in this instance of OP is always smaller than in the Galerkin approximation above, though in this instance not by much (see [10]). One should think of the system (6) as producing the average of all solutions obtained by having initially values of q_1, p_1 and sampling the other variables from the conditioned canonical distribution. An important result due to Hald ([7]) states that first-order OP for a Hamiltonian system also forms a Hamiltonian system, with a renormalized Hamiltonian which is minus the logarithm of the original Hamiltonian averaged over all the "missing" variables.

First-order OP may be optimal in a mean square sense, but it may not be good enough in many situations, and we wish to do better. In particular, the mean solution of (2) decays, while the solution of the OP equations (6) does not.

This dichotomy can be understood in several equivalent ways. From irreversible statistical mechanics we know that the canonical measure represents thermal equilibrium and that the means of all quantities tend to their equilibrium values even when they are initially conditioned by partial information; the symmetry properties of the Hamiltonian (1) ensure that the asymptotic mean is zero. We will now present a second explanation of the decay of the mean which will motivate our approach to higher-order optimal prediction. Rewrite the OP equations in the form:

$$\frac{dq_1}{dt} = p_1 + p_1z(t), \quad \frac{dp_1}{dt} = -q_1, \tag{7}$$

(where $z(t)$ is of course p_2^2). In equations (6) the random function $z(t)$ is approximated by its conditional mean. However, in truth $z(t)$ varies from realization to realization of the initial data, and we are averaging over systems in which $z(t)$ has a mean value and a fluctuation around this mean value. If one thinks of each copy of the system, which conserves energy, as moving on some constant energy surface, the surfaces are slightly different for different copies of the system and the systems move on their surfaces at different rates. The constant energy surfaces are sphere-like, the means of these dispersed systems fall ever closer to the common center of these surfaces, which is the origin in qp space. To capture this effect we need to take into account the variability of $z(t)$; the system (7) with the initial data q_1, p_1 can be viewed as a random or stochastic differential equation; the problem is that we have yet to figure out what $z(t)$ looks like, as a function of t and as a random variable (the randomness coming from the initial conditions). As we now explain, the existence of an invariant measure places

constraints on $z(t)$ but also helps in modeling it. This modeling has to rely on the specific properties of the system under consideration; some of the elegant generality of first-order optimal prediction will be lost. We shall give below an example of how a term such as $z(t)$ can be estimated.

3 The Langevin equation and fluctuation / dissipation theorems

Consider a single particle interacting with a thermal sea of other particles, the whole being presumably described in detail by some inaccessibly complicated Hamiltonian system. We wish to describe the evolution of the single particle's velocity without explicitly calculating the evolution of the sea of particles. The Langevin equation is a standard approximation of this system:

$$\frac{du}{dt} = -\gamma u + n(t), \tag{8}$$

where $u = u(t)$ is the unknown particle velocity, $n(t)$ is white noise with zero mean and γ is a constant. The noise $n(t)$ repesents the fluctuating force exerted by the sea of particles, while the first term on the right hand side represents the mean force exerted by the sea which opposes the motion of the particle. The Langevin equation is a standard example that shows how an invariant measure constrains the random forcing term in a stochastic or random differential equation. This equation can be solved by elementary means [2, 4]. If one thinks of u as the velocity of a particle of mass 1, then one should require that asymptotically, as $t \to \infty$, the distribution of u converge to the canonical distribution with density $Z^{-1} \exp(-u^2/2T)$; this is achieved if $\gamma = 2/T$; this is a "fluctuation/dissipation" result [2, 4]. One can understand it as follows: suppose $\gamma = 0$; then the variance of u increases with time t (indeed it is proportional to t). If there is no white noise, the initial variability of u decreases because the term in γ is damping. When the fluctuation/dissipation relation holds, the damping and the fluctuations imposed by the white noise balance asymptotically so that the invariant distribution is reached. Application of the fluctuation/dissipation theorems allows the prediction of the magnitude and direction of the mean force from the invariant measure and the statistical properties of the random force. The formula connecting the damping γ to the temperature is based on the assumption that the autocorrelation of the noise is a delta function, as it is in white noise; more general fluctuation/dissipation theorems [7, 14, 16] will not be used in the present paper.

4 The Averaged Euler equations

As an example of the application of these ideas, we consider the Averaged Euler equations [13, 15] in two space dimensions. We choose these equations because an analysis of the three-dimensional Euler equations presupposes an extensive discussion of turbulence, while the statistical mechanics of the usual two-dimensional Euler equations leads

to negative temperature states and other unusual phenomena. The two-dimensional Averaged Euler equations describe certain temporal averages of the Euler equations as well as certain viscoelastic flows, and their statistical mechanics is compatible with the machinery we have described.

We introduce the operator

$$A = (1 - a^2\Delta)^s,$$

where Δ is the Laplace operator, a is a real constant, and s is a positive number. If s is not an integer, A is a pseudo-differential operator. The Averaged Euler equations are:

$$\frac{\partial A\mathbf{u}}{\partial t} + (\mathbf{u}\cdot\nabla)A\mathbf{u} + (\nabla\mathbf{u})^T\cdot A\mathbf{u} = -\nabla p, \quad \nabla\cdot\mathbf{u} = 0, \tag{9}$$

where $\mathbf{u}$ is a vector with components $u_\alpha, \alpha = 1, 2$. As $a \to 0$, these equations formally converge to the Euler equations. We consider a periodic domain, and expand the u_α in Fourier series: $u_\alpha = \sum \hat{u}_{\alpha,\mathbf{k}} e^{i\mathbf{k}\cdot\mathbf{x}}$, where $\mathbf{x} = (x_1, x_2), \mathbf{k} = (k_1, k_2)$, and $\cdot$ denotes an inner product. Substitution into equation (9) yields the following equations of motion for the Fourier coefficients:

$$\frac{d}{dt}A(\mathbf{k})\hat{u}_{\alpha,\mathbf{k}} = -i\sum_{\beta\gamma\mathbf{k}'} P_{\alpha\beta}(\mathbf{k})(k'_\gamma A(\mathbf{k})u_{\gamma,\mathbf{k}-\mathbf{k}'}u_{\beta,\mathbf{k}'} + k'_\beta A(\mathbf{k}-\mathbf{k}')u_{\gamma,\mathbf{k}'}u_{\beta,\mathbf{k}-\mathbf{k}'}) \tag{10}$$

where $P_{\alpha\beta}(\mathbf{k}) = \delta_{\alpha\beta} - \frac{k_\alpha k_\beta}{k^2}$, with δ=Kronecker delta, $k^2 = k_1^2 + k_2^2$, is the Fourier space projection on the space of divergence-free vectors ($k_1u_{1,\mathbf{k}} + k_2u_{2,\mathbf{k}} = 0$,), β, γ are component indices and $A(\mathbf{k}) = (1 + a^2k^2)^s$ is the Fourier transform of the operator A defined above. (This is the straightforward Fourier series of the right-hand side of the projection form of equation 9, with the zero-divergence condition built-in and the pressure eliminated).

Equation (9) conserves an energy, $(\mathbf{u}, A\mathbf{u})$, where the inner product is the standard L_2 inner product, and an "enstrophy", $(A\xi, A\xi)$, where ξ is the vorticity $\xi = \nabla\times\mathbf{u}$. Each of these invariants, as well as any of their linear combinations with positive coefficients, gives rise to an invariant measure with density of the form $Z^{-1}\exp(-C/T)$, where C is a suitable linear combination. However, one can see from general considerations ([3]) that the energy is irrelevant: if there is no enstrophy in the expression for the measure the resulting measure is not ergodic, while if the enstrophy is present the energy makes little difference. Thus we consider a measure with density $Z^{-1}\exp(-(A\xi, A\xi)/T)$, in Fourier variables; (a detailed example of such a construction is given in [8]). The measure is carried by divergence-free vectors (all vectors whose divergence is not zero have probability 0), and up to the normalizing factor Z has the density

$$\exp(-\sum k^2(1 + a^2k^2)^{2s}|\hat{\mathbf{u}}_\mathbf{k}|^2/T), \tag{11}$$

(For simplicity, we are assuming for the rest of the paper that $s = 1$ in the operator A). This expression shows why the negative temperatures of the usual Euler equations do not appear here: they are necessary in the Euler case to keep the enstrophy finite [3]; here, for large k, $\hat{\mathbf{u}}_\mathbf{k} \sim k^{-3}$, which makes the enstrophy $\sum k^2|\hat{\mathbf{u}}|^2$ finite even when the temperature T is positive.

With this measure, one can see by a simple calculation that if all velocities are divergence-free, then

$$E[\hat{u}^*_{\alpha,\mathbf{k}}\hat{u}_{\beta,\mathbf{k}'}] = \frac{T\delta_{\mathbf{k},\mathbf{k}'}P_{\alpha\beta}(\mathbf{k})}{k^2(1+a^2k^2)^2} \quad . \tag{12}$$

We want to model the evolution of a small number of Fourier coefficients, those that satisfy $|\mathbf{k}|_\infty = \max(|k_1|, |k_2|) \leq m$, which we shall call the "resolved modes". We will refer to the remaining modes as "sampled modes". We rewrite the evolution equations for the resolved modes as sums of terms that depend only on the resolved modes plus terms that also involve the sampled modes. For this purpose we take advantage of the fact that the right hand side of equation (10) is quadratic in $\mathbf{u}$ so that its Fourier transform is a convolution of the form

$$\sum \phi_{\alpha\beta}(\mathbf{k}, \mathbf{k}')\hat{u}_{\alpha,\mathbf{k}'}\hat{u}_{\beta,\mathbf{k}-\mathbf{k}'}, \tag{13}$$

where the function $\phi_{\alpha\beta}$ consists of expressions that guarantee incompressibility and perform the several differentiations; it depends only on the wave numbers but not on the amplitudes of the Fourier coefficients. The terms in the evolution of the resolved modes can be divided into three groups:

1. Those where both $|\mathbf{k}-\mathbf{k}'|_\infty \leq m$ and $|\mathbf{k}'|_\infty \leq m$ (i.e, both are in the resolved range); we denote their sum by G^1.
2. Those where one factor belongs to the resolved range and one does not; the structure of the convolution is such that the factor in the sampled range has a wave number such that $|\mathbf{k}|_\infty \leq 2m$. In other words, resolved modes cannot interact with sampled modes further away. If we can model this subset of the sampled range, we have all the input we need to follow the dynamics of the resolved range. We call their sum G^2.
3. Those where neither factor belongs to the resolved range; their sum is G^3.

Thus the Fourier-space evolution equation (10) takes the form:

$$\frac{d}{dt}\hat{u}_{\alpha,\mathbf{k}} = G^1_{\alpha,\mathbf{k}} + G^2_{\alpha,\mathbf{k}} + G^3_{\alpha,\mathbf{k}} \quad . \tag{14}$$

In first-order optimal prediction $G^2 + G^3$ would be approximated by its conditional expectation given the values of the Fourier components in the resolved range. The Averaged Euler equations share with the usual Euler equations the remarkable property that when the measure is Gaussian and based on energy and/or enstrophy, this conditional expectation is zero provided $\hat{\mathbf{u}}_0 = 0$. If $\hat{\mathbf{u}}_0 \neq 0$ the conditional expectation takes a simple form, that we shall not specify here because it will not be needed.

5 Monte Carlo simulations

The system of equations (10) is simple enough so that we can find its mean solution when we have partial data and the remaining data are drawn from a given distribution,

by sampling the distribution $N_{ensemble}$ times, evolving the system in time, and averaging. The system is also simple enough that we can determine the statistical properties of the modes, in particular their time covariances. The evolution equations are evolved with a fourth-order Runge-Kutta ODE solver with adaptive time-step control. A typical simulation requires $10^2 - 10^3$ runs for reasonable accuracy because Monte Carlo methods exhibit errors proportional to $1/\sqrt{N_{ensemble}}$.

Our Monte Carlo simulation lead us to the following observations. First, the simulation results are only weakly dependent on the size of the sampled region as long as it includes $\{\mathbf{k}|\ |\mathbf{k}|_\infty \leq 2m\}$. The evidence for this observation will be presented elsewhere.

In the rest of this paper the time correlation function

$$C(\alpha, \mathbf{k_1}, t_1; \beta, \mathbf{k_2}, t_2) =< (u_{\alpha,\mathbf{k_1}}(t_1) - \overline{u_{\alpha,\mathbf{k_1}}(t_1)})^*(u_{\beta,\mathbf{k_2}}(t_2) - \overline{u_{\beta,\mathbf{k_2}}(t_2)}) > \tag{15}$$

of the sampled modes plays an important role. Our numerical simulations lead us to the following observations about the correlation function: At time $t = 0$, when the probability distribution is known, the various Fourier components are independent. We observe that, to a very good approximation, this remains true for $t > 0$, and the time-correlation function is diagonal in $\mathbf{k}$. We may therefore restrict consideration to the autocorrelation functions of the sampled modes. The spatial index structure of the autocorrelation is determined by the requirement that the velocity fields be divergence free. We make two further observations about the correlation functions:

- The autocorrelation functions are well approximated in time as Gaussians whose width is a function of $\mathbf{k}$.
- The peak height of the Gaussian is well approximated by the magnitude of the correlation function in the invariant measure (12). Certainly this must be true asymptotically as $t \to \infty$. Our numerical calculations indicate that this is approximately true at all times.

These observations allow us to describe the correlation functions with a single parameter $\sigma(\mathbf{k})$:

$$C(\alpha, \mathbf{k}, t_1; \beta, \mathbf{p}, t_2) \sim \delta_{\mathbf{k},\mathbf{p}} \frac{T}{k^2(1 + a^2k^2)^2} P_{\alpha,\beta}\ e^{(t_1-t_2)^2/\sigma(\mathbf{k})^2} \tag{16}$$

In general, $\sigma(\mathbf{k})$ will be a function of the direction and magnitude of the momentum vector $\mathbf{k}$, time t, as well as the initial value of the resolved components. However, in practical application, it will be advantageous to approximate $\sigma(\mathbf{k})$ by a function of the magnitude of $\mathbf{k}$ only. A reasonable approach to this would be to Monte Carlo simulate the correlation function C with all $u_{\alpha,\mathbf{k}}$ chosen from the invariant measure (i.e. no resolved modes). This produces the correlation functions of the invariant measure, which can only be a function of $|\mathbf{k}|$. Figure 1 compares $\sigma(\mathbf{k})$ at equilibrium, i.e., with all the modes sampled, to $\sigma(\mathbf{k})$ calculated when the initial measure has specified resolved modes in the wave-number region $[-5, 5] \times [-5, 5]$.

Having determined the autocorrelation functions in the prior distribution, we shall now use them to approximate specific initial value problems with prescribed partial data, thus pushing the general methodology of OP to a higher order in the statistics.

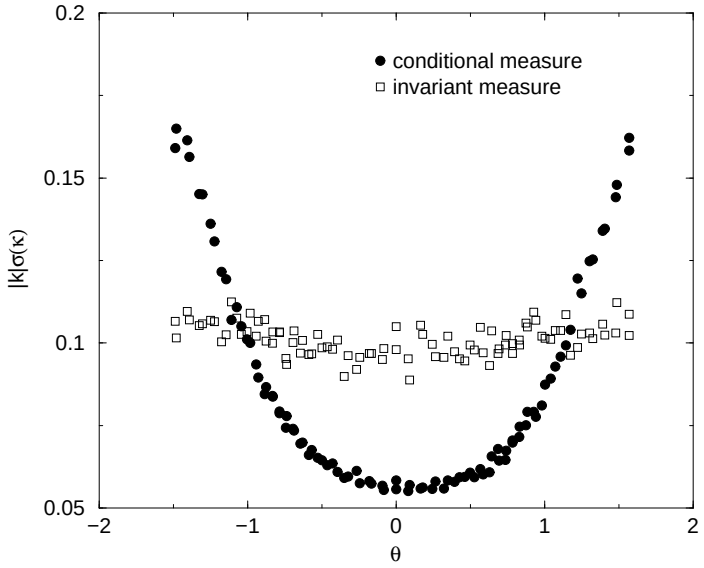

Figure 1: Comparison of autocorrelation widths $\sigma(\mathbf{k})$ in the invariant measure and in a specific run with prescribed partial data. Widths are scaled by multiplying by the magnitude of $\mathbf{k}$.

In particular, $\sigma(\mathbf{k})$ will henceforth be modeled as a constant divided by the magnitude of $\mathbf{k}$, where the constant is determined by the invariant measure, as suggested by Figure 1.

6 Approximation of an underresolved system by a stochastic differential equation

Equation (14) shows that the resolved modes interact with the sampled modes only through the terms G^2 and G^3. We shall ignore G^3 since it is higher order in the sampled modes and hence suppressed by factors of $1/k^3$. In the following, we shall use $\hat{u}_{\alpha,\mathbf{k}}$ to refer only to the resolved modes, and $\hat{v}_{\alpha,\mathbf{k}}$ to refer to the sampled modes. The sampled modes may be written as a mean plus a fluctuation: $\hat{\mathbf{v}}_\mathbf{k} = \overline{\hat{\mathbf{v}}_\mathbf{k}} + \delta\hat{\mathbf{v}}_\mathbf{k}$. Because G^2 is linear in the sampled modes, we may write it as $L(\hat{\mathbf{u}})(\overline{\hat{\mathbf{v}}} + \delta\hat{\mathbf{v}})$. The evolution equation for the resolved modes may now be written as

$$\frac{d}{dt}\hat{u}_{\alpha,\mathbf{k}} = G^1_{\alpha,\mathbf{k}}(\hat{\mathbf{u}}) + L_{\alpha,\mathbf{k};\beta,\mathbf{p}}\overline{\hat{v}_{\beta,\mathbf{p}}} + L_{\alpha,\mathbf{k};\beta,\mathbf{p}}\delta\hat{v}_{\beta,\mathbf{p}} \tag{17}$$

We will view the fluctuating part of the sampled Fourier modes, $\delta\hat{\mathbf{v}}$, not as a dynamically evolving function of a random initial configuration, but rather as a random variable with specific statistical properties, just like $z(t)$ in section 2. By construction $\delta\hat{\mathbf{v}}$ has zero mean. The results of the previous section require $\delta\hat{\mathbf{v}}_\mathbf{k}$ to be uncorrelated with any mode with different $\mathbf{k}$, and that its autocorrelation have the form of equation (16). We shall not specify any higher order statistics.

The evolution equation above also involves the mean value $\overline{\hat{\mathbf{v}}}$. We have not presented any empirical observations about $\overline{\hat{\mathbf{v}}}$. However, by analogy to the Langevin equation, we can see that the average effect of the $\overline{\hat{\mathbf{v}}}$ term in the evolution equation is to provide a dissipation that counteracts the fluctuating $\delta\hat{\mathbf{v}}$ term. We thus write the evolution equation as

$$\frac{d}{dt}\hat{u}_{\alpha,\mathbf{k}} = G^1_{\alpha,\mathbf{k}}(\hat{\mathbf{u}}) - \gamma_{\alpha,\mathbf{k};\beta,\mathbf{p}}\hat{u}_{\beta,\mathbf{p}} + L_{\alpha,\mathbf{k};\beta,\mathbf{p}}\delta\hat{v}_{\beta,\mathbf{p}} \tag{18}$$

We can use the fluctuation-dissipation theorem to estimate the dissipation matrix γ. Because the matrix γ is dominated by the diagonal elements, in numerical computations we will only use the diagonal element:

$$\gamma_{\mathbf{k},\mathbf{k}} = \sum_{\mathbf{k}=\mathbf{p}+\mathbf{q}} \frac{T\sqrt{\pi}\sigma(\mathbf{k})(\mathbf{q}^\perp\cdot\mathbf{p})(A(\mathbf{p})p^2 - A(\mathbf{q})q^2)^2|\hat{\mathbf{u}}_\mathbf{p}|^2}{q^4A(\mathbf{q})^2p^2k^2A(\mathbf{k})^2} \tag{19}$$

where $q^\perp = (q_2, -q_1)$ and q runs over the sampled modes while p runs over the resolved modes.

The new evolution equation is now a stochastic differential equation driven by random inputs $\delta\mathbf{v}$. The only Fourier modes that are evolved by the equations are the resolved modes; the sampled modes are not evolved. The statistics of the sampled modes represent the effect of the unresolved modes.

The numerical algorithm described in section 5 can be modified for the stochastic differential equation. First, only the resolved modes are evolved. The Fourier amplitudes $\hat{u}_{\alpha,\mathbf{k}}$ in the sampled region are chosen randomly from a population with the correct autocorrelation function (16). This correctly models the $L(\hat{\mathbf{u}})\delta\hat{\mathbf{v}}$ term in equation (18). Third, a dissipation term (19) is introduced on the right hand side to model the γu term in (18); this extracts from the noise the main part of its mean. Unlike what we saw in the Langevin equation of section 3 which has purely additive noise, we have no guarantee here that the fluctuation/dissipation formula will take into account all of the dissipation. In the evaluation of the dissipation term, we assume that the autocorrelation of each mode is a constant times a delta function, with the constant equal to the integral of the autocorrelation. What we have done is tranform a problem with random initial data into a stochastic differential equation.

An initial test of the stochastic differential equation approach consists in computing a norm of the average solution as a function of time. We choose as norm the A-enstrophy of the solution:

$$A_enstrophy(\mathbf{u}) = \sum_\mathbf{k} k^2(1+a^2k^2)^2|\hat{\mathbf{u}}_\mathbf{k}|^2. \tag{20}$$

This norm gives an equal weighting to all the modes. The A-enstrophy is, of course, conserved in time in each realisation of the system, but not on the average (see the discussion in section 2).

Figure 2 shows the decay of the A-enstrophy of the average solution. One curve shows the true result obtained from many Monte Carlo samples of the full equations. The second curve results from the stochastic differential equation. Clearly the decay characteristics are accurately modeled by the stochastic differential equation. This

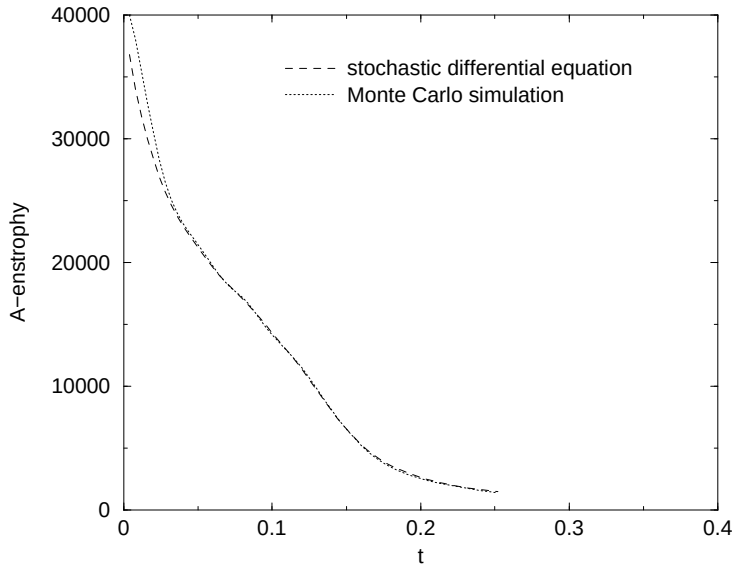

Figure 2: Comparison of decay of the mean A-enstrophy. The physical domain is $[0, 2\pi] \times [0, 2\pi]$. The resolved region in wave-number space is $[-5, 5] \times [-5, 5]$. The parameter a in the Average Euler equation was taken to be 1. First curve is the true decay as calculated by Monte Carlo. Second curve results from approximating system as stochastic differential equation.

is an important improvement over first order optimal prediction whose evolution is governed by a renormalized Hamiltonian as noted above, and hence is not dissipative.

7 Conclusions

We have used the ideas of optimal prediction to reduce an underresolved problem to a stochastic differential equation. This stochastic differential equation has fewer modes than the full equation, and requires only partial information about the initial state. On the other hand, it does require prior knowledge about the statistics of the solution, as we expect in OP methods. The full power of higher-order, stochastic OP will appear when we create effective variance-reduction techniques for the stochastic differential equation. The real test of the ideas will come when we attempt to solve Euler and Navier-Stokes equations in three space dimensions; the outstanding problem is the formulation of a reasonable invariant measure in those cases. The OP approach transfers the onus of modeling turbulence from trying to guess relations between moments to trying to guess the relevant invariant measures (and awaiting a mathematical derivation of such measures). We also expect that the OP machinery will find important uses in other problems dominated by complexity, for example in molecular dynamics (see e.g.[12]).

Note that Figure 2 illustrates a major principle that is often overlooked: an underresolved conservative system behaves on the average as a dissipative system. The

importance of this fact for the understanding of turbulence cannot be overstated.

8 Acknowledgements

We would like to thank Prof. G.I. Barenblatt, Prof. O. Hald, Dr. A. Kast, Prof. R. Kupferman, Prof. D. Levy, Mr. P. Okunev, and Prof. B. Turkington, for helpful discussions and for providing much of the mathematical machinery upon which this work is based.
