Supporting Information

ABSTRACT: There is an increasing level of interest in the use of black TiO₂ prepared by thermal hydrogen treatments (H:TiO₂) due to the potential to enhance both the photocatalytic and the light-harvesting properties of TiO₂. Here, we examine oxygen-deficient H:TiO₂ nanotube arrays that have previously achieved very high solar-to-hydrogen (STH) efficiencies due to incident photon-to-current efficiency (IPCE) values of >90% for photoelectrochemical water splitting at only 0.4 V vs RHE under UV illumination. Our transient absorption (TA) mechanistic study provides strong evidence that the improved electrical properties of oxygen-deficient TiO₂ enables remarkably efficient spatial separation of electron–hole pairs on the submicrosecond time scale at moderate applied bias, and this coupled to effective suppression of microsecond to seconds charge carrier recombination is the primary factor behind the dramatically improved photoelectrochemical activity.

1. INTRODUCTION

Titanium dioxide has been studied as a photoanode material for water oxidation for over 40 years;^{1,2} however the large band gap energy of TiO₂ (3.0 eV, rutile) limits the maximum theoretical STH efficiency to 2.2%,³ which is well below the anticipated required STH of 10% needed for commercial viability.⁴ A further complication has been that typical achieved STH efficiencies of TiO₂ photoanodes have been well below the theoretical maximum, primarily because of the need for the application of large electrical biases to enable charge separation and minimize electron–hole recombination.⁵ Despite these drawbacks, TiO₂ remains an important model for mechanistic studies; furthermore, new efforts toward both narrowing the band gap and minimizing recombination losses offer hope that the STH efficiency can be significantly increased.

Approaches to extend the photoactivity of TiO₂ from UV to visible wavelengths have included elemental doping, dye-sensitization, and semiconductor sensitization,^{6–9} with the introduction of nonmetal dopants such as N, C, and S receiving particular attention.^{7,10–12} In 2011, Mao and co-workers reported a novel approach to obtaining TiO₂ with an extended absorption profile.¹³ Hydrogen treatments of TiO₂ nanoparticles at a moderate pressure (20 bar, 200 °C for 5 days) led to the formation of TiO₂ with highly disordered surfaces and crystalline cores. The surface disorder leads to band gap narrowing down to 1.0 eV, with a large shift in the valence band edge taking place.¹⁴ The black TiO₂ was found to exhibit remarkable photocatalytic activity for H₂ evolution in the

presence of a sacrificial electron donor, with a particularly high level of activity under UV illumination being a significant factor.^{13,15} DFT calculations indicate that the high photocatalytic efficiency can be attributed to the formation of localized midgap holes that are spatially separated from the conduction band electrons, limiting recombination losses.¹⁶

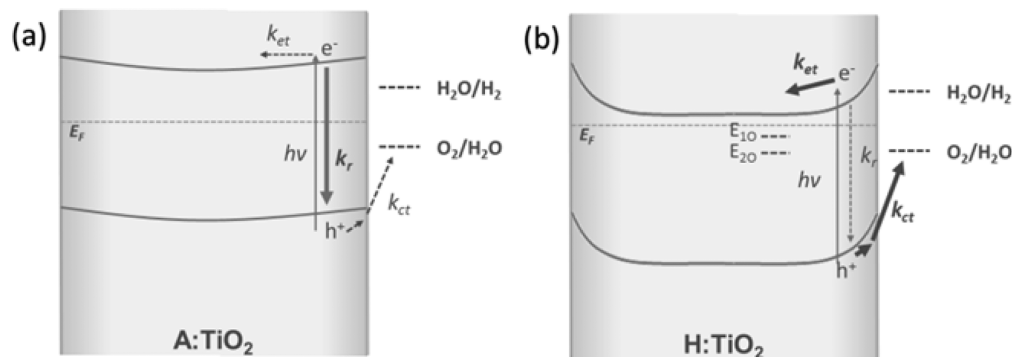

Li et al. have since explored the role of a lower pressure hydrogen treatment on TiO₂ photoanodes for water oxidation, leading in 2011 to a new benchmark STH efficiency of 1.1% for a TiO₂ photoanode.¹⁷ Rutile nanowires treated at 350 °C under a hydrogen atmosphere for 30 min (H:TiO₂) became yellow and showed very high photocurrents under simulated solar irradiation. Despite significant improvements in the visible light absorption properties, only a small increase in the visible light activity was observed. Instead, a very large increase in the IPCE values under UV illumination ($\geq 90\%$ H:TiO₂, $\sim 10\%$ air annealed TiO₂ (A:TiO₂), $\lambda = 300\text{--}375$ nm) at relatively low applied biases was found to be the primary cause of the high STH.

In contrast to the materials prepared by Mao and co-workers,¹³ XPS measurements of the H:TiO₂ nanowires showed no change in the valence band edge. Instead, an increase in the concentration of oxygen vacancies (V_o) lying 0.75 and 1.18 eV below the conduction band edge occurs

^aUnder a positive applied bias at a distance away from the FTO interface showing the key kinetic processes occurring following absorption of UV light in which k_{ct} , k_r , and k_{et} correspond to the rates of charge transfer into solution, recombination, and electron transport and collection at the FTO Interface. E_{10} and E_{20} correspond to V_o at 0.75 and 1.2 eV below the conduction band edge. As described in the main text, A:TiO₂ is anticipated to be fully depleted at even moderate applied biases.

(scheme 1), which is in line with previous studies on single crystal rutile TiO₂ in which hydrogen treatment-induced V_o are known to lead to improved visible light absorption.^{18,19} In addition to changing the light-harvesting properties, it was proposed that the V_o act as electron donors, facilitating charge transport and separation, leading to the near unity IPCE values.¹⁷ The approach of introducing V_o into metal oxides to improve the electronic properties has since been further refined for TiO₂ electrodes²⁰ and extended to a range of other photoelectrodes for water splitting, including α -Fe₂O₃, WO₃ and ZnO.¹⁸ Furthermore, it has been shown that a synergistic effect can be achieved by combining both a hydrogen treatment with N-doping of TiO₂ nanowires²¹ or through visible light sensitization with gold nanoparticles²² to give improved photoactivity under visible light for the oxidation of water. In light of the remarkable photocatalytic activity of hydrogen-treated TiO₂, it is important that an improved understanding of the underlying mechanisms occurring on the most active materials is obtained.¹⁵ Herein, we present a study on the factors controlling the very high STH efficiencies for the oxygen-deficient rutile TiO₂ (H:TiO₂) nanowire arrays previously reported by some of us.¹⁷

Previous studies have proposed that the increased concentration of V_o decreases electron–hole recombination in hydrogen-treated TiO₂ nanoparticles. Numerous mechanisms have been invoked, including electron trapping by O₂ adsorbed at surface defects, electron trapping at V_o sites, and hole trapping at Ti³⁺ sites.^{23–25} In a photoelectrode under applied bias, the higher donor density of oxygen-deficient electrodes may also decrease recombination because the maximum voltage drop obtainable in the depletion layer of highly structured materials will be greater in materials with higher donor densities.¹⁸ Conversely, V_o centers have also been shown to act as recombination sites, lowering photocatalytic activity on several different types of TiO₂.^{26–28} A high photocatalytic efficiency can also be achieved through enhancement of the rate of surface reactions, either via the presence of localized surface V_o , leading to enhanced dissociative adsorption of water,²³ or through a change in the energy of the valence band edge.²⁹ It is therefore apparent that the rates of recombination, electron transport, and charge transfer can all be altered to differing degrees in oxygen-deficient TiO₂. To date, kinetic studies on oxygen-deficient TiO₂ have concentrated on nanoparticulate powders and suspensions; however, when assessing the factors

determining the high STH of H:TiO₂ photoanodes, it is also important that we consider how the applied potential will modify the rates of recombination, transport, and charge transfer.

Transient absorption (TA) spectroscopy has been used to measure the change in concentration of photoelectrons and holes with time in complete photoelectrochemical (PEC) cells using a range of photoelectrodes, including TiO₂,⁵ α -Fe₂O₃,^{30,31} WO₃,³² and ZnO,³³ providing important insights into the bias-dependent rates of charge carrier recombination, transport, and transfer. TiO₂ has been studied with TA spectroscopy for over 25 years,³⁴ and although slight differences in charge carrier spectra are observed, depending on the electrolyte, it is commonly accepted that on anatase TiO₂, trapped photoholes absorb light at $\lambda \sim 450$ –550 nm, trapped photoelectrons absorb at $\lambda \sim 800$ –900 nm, nontrapped photoelectrons have an absorption profile that increases in intensity with wavelength (>900 nm),^{35–37} and trapping of holes and electrons is known to occur within 500 ps of the laser flash.³⁸ Electron–hole recombination has been widely studied using TA spectroscopy across the picosecond-to-millisecond time scales, with kinetics being sensitive to the effective electron density,^{5,37} and recently, the required photohole lifetime for water oxidation, that is, the lifetime of hole transfer into solution during water oxidation, has also been measured and found to be ~ 0.03 –0.4 s, depending on the electrolyte pH.^{5,39} The potential of TA spectroscopy to provide insights into the role of trap states on recombination dynamics in hydrogen-treated metal oxide photoanodes has been demonstrated by a recent ultrafast study on hydrogen-treated ZnO;³³ however, to the best of our knowledge, no previous studies have been reported for H:TiO₂ photoanodes. In the following sections, we describe TA experiments on H:TiO₂ photoanodes in a complete PEC cell, allowing us to elucidate the factors behind the very high IPCE values and (i) identify the critical role of hydrogen treatment on electron–hole recombination dynamics; (ii) demonstrate that photoholes generated in H:TiO₂ require a lifetime for water oxidation similar to air-treated TiO₂, in line with expectations for an unmodified valence band edge; and (iii) examine the factors behind the low level of visible light activity on H:TiO₂.

2. EXPERIMENTAL SECTION

2.1. TiO₂ Film Preparation. Rutile TiO₂ nanoarrays with nanowire bundles of 100–200 nm diameter consisting of individual 10–20 nm diameter elements with typical lengths of 2–3 μm were prepared on fluorine-doped tin oxide (FTO) glass as previously reported.¹⁷ Samples were annealed in air at 550 °C for 3 h. Air-annealed samples (A:TiO₂) were used without further modification. H:TiO₂ samples were then annealed under hydrogen at 350 °C for 30 min.

2.2. Electrochemical Measurements. The working electrode was the TiO₂ photoanode illuminated from the electrolyte–electrode (EE) side. The cell also contains a platinum gauze (99.9%) counter electrode and a 3 M KCl Ag/AgCl reference electrode (SSE, Bioanalytical Systems Ltd.), and all potentials are quoted versus this electrode unless otherwise stated. To prevent degradation of the reference electrode during long measurements, a double junction was employed, with the intermediate solution being 0.5 M NaClO₄. The electrolyte in the main cell was 1 M NaOH (Aldrich) prepared with Milli-Q water (Millipore Corp, 18.2 MΩ cm at 25 °C). TiO₂ samples were UV-cleaned (75 W Xe lamp) prior to experiments for a minimum of 20 min in the electrolyte. The electrolyte was then replaced following cleaning, and Argon gas was bubbled for at least 30 min through the electrolyte before experiments.

2.3. Transient Measurements. The TA apparatus has been described elsewhere.³⁷ Briefly, the third harmonic of a Nd:YAG laser (Continuum, Surelite I-10, 355 nm, 4–6 ns pulse width) operating at 0.33 Hz was the UV excitation source. Visible light was obtained using an OPO (Continuum, Surelite OPO plus) pumped by 355 nm from the Nd:YAG. The repetition rate was chosen to ensure that all charge carriers had fully decayed prior to the next excitation event. The laser intensity employed was 70 μJ cm⁻² at 355 nm and 250 μJ cm⁻² at 575 nm, and this energy refers to that incident on the TiO₂ sample with corrections for losses from the cell accounted for. A stabilized 75 W Xe lamp (OBB Corp.) coupled to a monochromator (OBB Corp., set to 4 nm resolution) acted as the probe light, and light transmitted through the photoanode was measured using a monochromator coupled to a Si photodiode and homemade amplification system. Typical experiments consisted of ~300 laser shots per wavelength studied for data in the spectra and ~600 laser shots for lower noise kinetic traces. All TA experiments were carried out on the complete PEC cells described in section 2.2 under potentiostatic control (Thomson, Ministat).

3. RESULTS AND DISCUSSION

The photocurrent voltage plots for both a H:TiO₂ and A:TiO₂ photoanodes in a 1 M NaOH electrolyte are shown in Figure 1. In agreement with the previous report, the H:TiO₂ electrode is significantly more active for water oxidation under UV illumination, with both an earlier onset potential and a higher plateau photocurrent, and we observe an ~10-fold enhancement of the photocurrent between A:TiO₂ and H:TiO₂ at -0.6 V vs Ag/AgCl.¹⁷

TA Spectra of Rutile TiO₂ Photoanodes. TA spectra of both H:TiO₂ and A:TiO₂ PEC cells under operating conditions at a range of applied potentials are shown in Figure 2. In light of the previous TA studies on anatase TiO₂,^{36,38} we assign the TA signals between 425 and 550 nm on our rutile TiO₂ samples to trapped photoholes. The TA spectrum of holes on

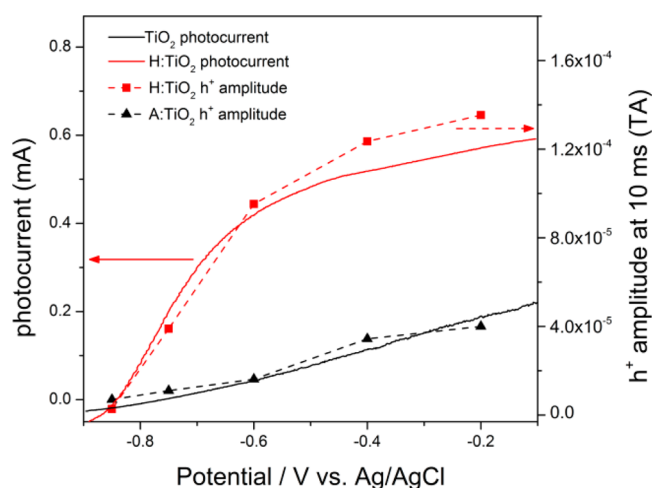

Figure 1. (Solid lines, left axis) Linear sweep voltammogram recorded at a scan rate of 50 mV s⁻¹, sweeping from negative to positive potentials, of A:TiO₂ (black) and H:TiO₂ films (red) in 1 M NaOH_(aq) under UV illumination ($\lambda = 355$ nm). (Dashed lines, right axis) Overlay of the relative photohole concentration 10 ms after pulsed laser (355 nm) excitation of A:TiO₂ and H:TiO₂ at the bias indicated measured by TA spectroscopy (500 nm probe).

anatase TiO₂ has previously been assigned to transitions between surface and subsurface O⁻ centers,⁴⁰ and DFT calculations on rutile TiO₂ have also indicated that hole trapping also occurs on similar oxygen lattice sites.⁴¹ The TA features from 750 to 900 nm in Figure 2 are assigned to trapped photoelectrons, also in agreement with the previous literature.³⁷ It has been previously shown that TA measurements of the yield of long-lived photoholes, those which are sufficiently long-lived to participate in water oxidation, provide a quantitative measure of the level of charge separation.^{30,42} In Figure 1, we observe an excellent correlation between the amplitude of the TA signal measured at 500 nm, at 10 ms after the laser flash, and the measured photocurrent under continuous illumination. This further reinforces the assignment of the TA signals in the 425–550 nm region to trapped holes on rutile TiO₂, and it also indicates that our transient measurements with a pulsed excitation source are a reasonable model for the same photoelectrochemical cell under continuous irradiation.

Figures 1 and 2 show that the yield of long-lived photoholes on H:TiO₂ sharply increases between -0.85 and -0.6 V prior to leveling slightly at potentials greater than -0.6 V (figure 1), and it is clear that the overall level of electron–hole recombination in H:TiO₂ is very sensitive to the applied electrical bias between -0.85 and -0.6 V. In contrast, on A:TiO₂, we observe only a gradual increase in the yield of long-lived holes with applied bias across the whole potential window studied (-0.85 to -0.2 V vs Ag/AgCl), and a far greater electrical energy input is needed to drive charge separation, with the yield of long-lived holes on A:TiO₂ at -0.2 V at 10 ms matching that achieved with 0.55 V less bias on H:TiO₂. To rationalize the dramatic effect of the applied bias between -0.85 and -0.6 V on H:TiO₂, we now examine the potential dependence of the photohole and electron kinetics in detail.

Role of Applied Bias on Charge Carrier Recombination Dynamics. At -0.85 V, minimal photocurrent is measured on both A:TiO₂ and H:TiO₂ under illumination from the Xe lamp (Figure 1). TA experiments at this potential show only weak and short-lived signals, with the decay kinetics

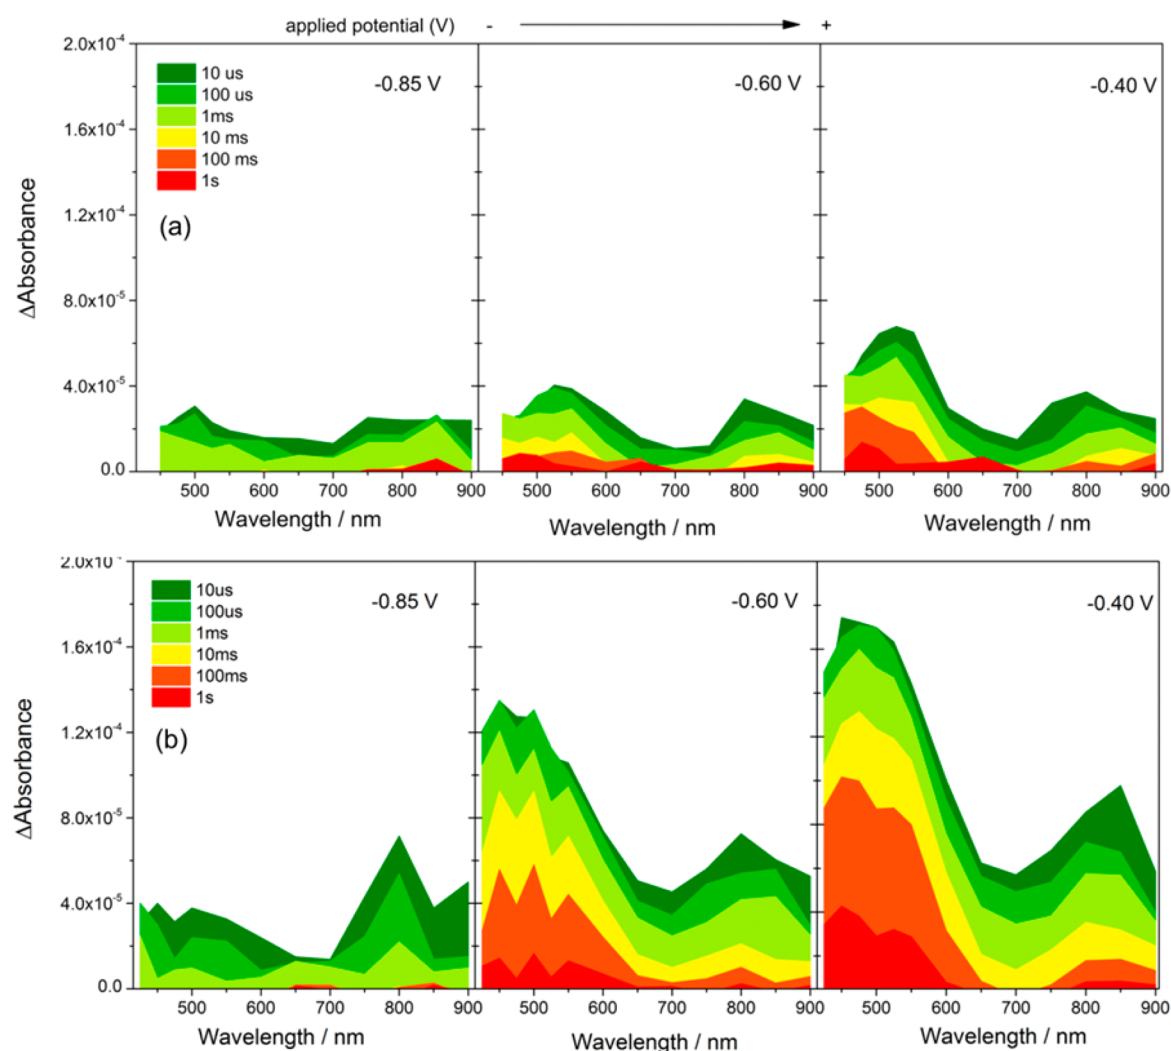

Figure 2. TA spectra recorded after excitation of (a) A:TiO₂ and (b) H:TiO₂ in 1 M NaOH_(aq) at the bias indicated (vs Ag/AgCl), 355 nm excitation, 70 μJ cm⁻², 0.33 Hz laser repetition rate.

of the photoelectrons and holes at -0.85 V being indistinguishable on the microseconds–seconds time scale, indicating a common decay mechanism, namely, recombination (Supporting Information Figure S1). The recombination kinetics at -0.85 V are well fitted to a power law decay function,⁴³ and power law recombination kinetics have been reported for a number of different semiconductor materials with a high density of trap states in which nongeminate recombination occurs via multiple trapping–detrapping steps.⁴⁴ As the applied bias is made more positive than -0.85 V, we note (i) a large increase in the electron–hole yield at the earliest times studied on H:TiO₂ (1 – 10 μs, Figure 2a) and (ii) a decrease and decoupling of the rate of decay of the electron and hole TA signals on the microseconds–seconds time scales.

The increased yield of electrons and holes at 10 μs indicates retardation of fast (submicrosecond) recombination upon the application of the anodic potential. TA spectroscopy can be used to derive the concentration of photogenerated charge carriers in a material if the extinction coefficient is known, allowing us to estimate the relative charge carrier yields at 10 μs after laser excitation.⁴² Photoelectrons in single crystal rutile TiO₂ have been reported to have $\epsilon = 600$ M⁻¹ cm⁻¹ at 850 nm,⁴⁵ and we estimate a maximum $\Delta A_{850\text{ nm}} \sim 1.2 \times 10^{-4}$ when 100% of absorbed photons lead to the generation of trapped

electrons. We therefore approximate that 30%, 55%, and 75% of photoelectrons remain in the H:TiO₂ film at -0.85 , -0.6 , and -0.4 V, respectively, 10 μs after the laser flash.⁴⁶

In contrast, using A:TiO₂, only a minimal change in initial photoelectron yield is measured as the applied bias is varied (Figure 2b, 10 μs): between -0.85 and -0.6 V, the yield changes from 20% to 25%, and even at -0.4 V, a yield of only 30% achieved. It is noteworthy that the yield of the photogenerated charge carriers in H:TiO₂ at 10 μs is much more sensitive to the applied bias than A:TiO₂, and this effective initial fast charge separation is a significant factor behind the enhanced activity of the H:TiO₂.

The decoupling of the electron and hole kinetics to give nonidentical decay traces on the microseconds–seconds time scales at potentials ≥ -0.6 V on A:TiO₂ and H:TiO₂ is significant because it indicates that processes apart from direct electron–hole recombination are able to occur. In Figure 3a, the TA signal of the photoelectrons in H:TiO₂ at -0.6 V decays by more than 50% between 10 μs and 1 ms, whereas the photohole (500 nm) concentration remains largely unchanged. The photoelectron decay is reasonably well fitted to either a power law or the tail of stretched exponential type function ($\tau \sim 1.4 \times 10^{-4}$ s), and because the lack of hole decay on this time scale precludes this being due to direct electron–hole

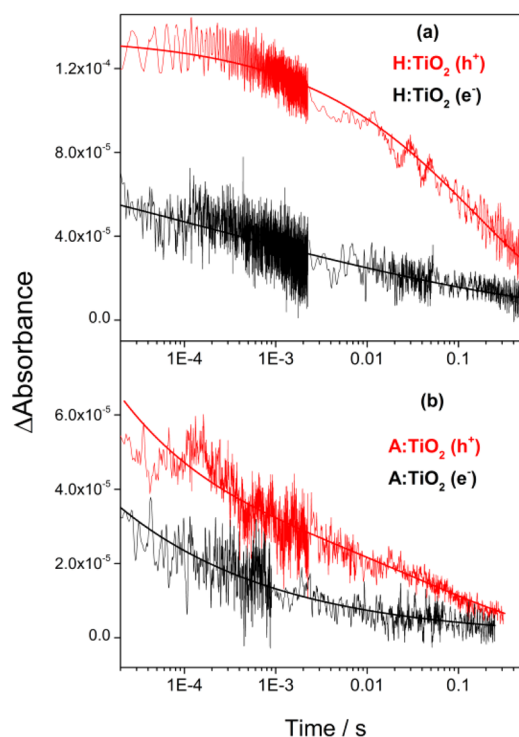

Figure 3. TA decay traces of photoholes ($\lambda = 500$ nm, red traces) and electrons ($\lambda = 800$ nm, black traces) recorded after excitation of (a) H:TiO₂ and (b) A:TiO₂ in 1 M NaOH_(aq) at -0.6 V (vs Ag/AgCl), 355 nm excitation, $70 \mu\text{J cm}^{-2}$, 0.33 Hz laser repetition rate. The functions employed to give the solid fit lines are described in the main text.⁴³

recombination, we tentatively assign the electron kinetics in Figure 3a to electron transport to the external circuit. The kinetics of the hole signal on H:TiO₂ in Figure 3a are fitted to a single stretched exponential function with a lifetime of 0.15 ± 0.03 s.⁴³ It is expected that terminal charge transfer into solution will be the slowest photohole process measured, and we have previously found that water oxidation on anatase TiO₂ photoelectrodes requires holes with a lifetime of between 0.03 and 0.4 s.³⁹ Here, we also assign the slow decay of the 500 nm TA signal on H:TiO₂ to hole transfer into solution. The decay of the photohole signal by this single pathway is striking because it indicates electron–hole recombination has been effectively blocked on H:TiO₂ on the microseconds–seconds time scales at a relatively low applied potential (-0.6 V vs Ag/AgCl, $+0.4$ V vs RHE).

In contrast, on A:TiO₂, we observe high levels of electron–hole recombination on the microseconds–seconds time scale. At -0.6 V, the hole trace on A:TiO₂ can be fitted to a combination of both a stretched exponential function and a power law type decay, indicating that at least two different kinetic pathways are operating (Figure 3b). The power law decay ($b = 0.35$) is assigned to electron–hole recombination, whereas the slow (~ 0.1 s) exponential decay component is assigned to the hole transfer into solution. The small magnitude of the component assigned to hole transfer ($A_1 = 2.6 \times 10^{-5}$) is due to kinetic competition with electron–hole recombination and is in line with the low ($\sim 15\%$) IPCEs achieved previously.¹⁷ The photoelectron signal at -0.6 V on A:TiO₂ is relatively weak, limiting our ability to accurately fit the data; however, it would be anticipated to be dominated by the electron–hole recombination, and the rate of decay of the 800

nm signal, which is similar to that of the hole at 500 nm, does indicate that this is the case.

Our TA experiments clearly demonstrate that initial charge separation (submicroseconds) and suppression of recombination on the microseconds–seconds time scale at -0.6 V is far more effective on H:TiO₂ than A:TiO₂. The large differences in the recombination kinetics with applied bias may be interpreted through a model in which effective spatial separation of charges occurs as a result of the presence of localized hole or electron traps following the thermal hydrogen treatment.¹⁶ Although we do not rule this out as a contributing mechanism, the general similarities of the electron and hole TA spectra on both A:TiO₂ and H:TiO₂ indicate that the nature of the trap states in both materials is similar. Alternatively, the differences in the role of the applied potential on the recombination kinetics can be interpreted within the context of the model developed by Gartner⁴⁷ and Gerischer,^{48,49} in which electron–hole pair separation is driven by the presence of a depletion layer that drives holes toward the semiconductor–liquid junction (SCLJ) and electrons away from the interface.

In the band-bending model, the application of a positive bias increases the width and depth of the space–charge layer in the TiO₂, leading to enhanced charge separation yields. The maximum possible radial field (depletion layer) depth depends upon the donor density, the dielectric constant, the radius of the nanowire, and the distance from the substrate contact.^{50,51} In highly nanostructured materials, it is common for the radial dimensions to be significantly smaller than the width of the space charge layer at a given applied potential, leading to complete depletion and limiting the degree of band bending achievable.⁵² Following a previous methodology, we estimate that for the air-annealed rutile TiO₂ with 10–20 nm feature sizes studied here, the maximum voltage drop obtainable at axial distances more than a few tens of nanometers away from the substrate is ~ 0.03 – 0.11 V (calculations are shown in the Supporting Information).⁵⁰ In contrast, the numerous V_0 in H:TiO₂ act as electron donors, leading to a measured $N_d \sim 10^{22} \text{ cm}^{-3}$, much greater than that of A:TiO₂ ($\sim 10^{18} \text{ cm}^{-3}$).¹⁷ The higher N_d of H:TiO₂ dramatically decreases the width of the space charge layer, making the individual nanowires more than thick enough to support a sufficiently large radial electric field for effective spatial charge separation, leading to both the high initial charge carrier yields and the suppression of slow ($> \mu\text{s}$) recombination (Scheme 1b).

In A:TiO₂, the inability to maintain a significantly large radial electrical field leads to higher levels of recombination losses and lower IPCE values (Scheme 1a). We still do observe a clear, albeit weaker, bias dependence of the TA data for A:TiO₂. This is interpreted through a previously invoked model for highly nanostructured photoanodes in which the primary effect of the application of a positive potential is to lower the Fermi level of the TiO₂ and, hence, the background electron density, decreasing the rate of bimolecular electron–hole recombination.^{5,30} As the rate of recombination is decreased with the applied potential, electron transport and hole transfer into solution become viable pathways.

Hole Transfer Kinetics. To assess the possible contribution of modified hole transfer kinetics to the activity of H:TiO₂, we have examined the slow hole kinetics of both H:TiO₂ and A:TiO₂ in detail (Figure 4). In the previous section, we assigned the slow decay at 500 nm on H:TiO₂ at -0.6 V ($\tau = 0.15 \pm 0.03$ s) to the transfer of holes into solution. Analysis of the hole decay at -0.4 V on H:TiO₂ also gives a very similar

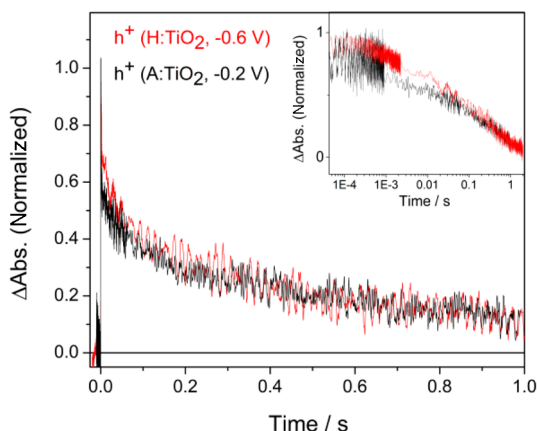

Figure 4. TA decay traces of photoholes ($\lambda = 500$ nm) on H:TiO₂ at -0.6 V (red trace) and A:TiO₂ at -0.2 V (black trace) following UV excitation (355 nm, 0.33 Hz). The inset shows the same data on a logarithmic time scale.

lifetime ($\tau = 0.13 \pm 0.04$ s), indicating that under the conditions employed here, the average rate of hole transfer is not very sensitive to the applied bias. An approximate lifetime of ~ 0.1 s was also found for the hole transfer on A:TiO₂ at -0.6 V vs Ag/AgCl; however, overlapping electron–hole recombination kinetics limited the accuracy of this lifetime measurement.

Application of a significantly more positive bias to A:TiO₂ further lowers the level of electron–hole recombination, and at -0.2 V, we find that the hole transfer kinetics can be accurately fitted to a single stretched exponential with $\tau = 0.13 \pm 0.02$ s, which is the same, within the error, as that observed on H:TiO₂ at -0.6 V. The insensitivity of the TA spectrum (Figure 2) and surface kinetics of the trapped photoholes to hydrogen treatment is in line with previous XPS studies, which showed no shift in the valence band edge in this particular form of H:TiO₂. However, we do note that a limitation of our TA experiment is that we measure the average hole transfer rate over 300–600 shots, and changes induced in the rates of individual steps which occur on the H:TiO₂ photoelectrodes will be hard to identify in these experiments. Nonetheless, our TA experiments do clearly show that the average rate of hole transfer into solution on H:TiO₂ is not sufficiently different from that of A:TiO₂ to account for the approximate 10-fold increase in IPCE under UV illumination. This further confirms that suppression of recombination and not enhanced surface reaction kinetics is the key factor for the improved photocatalytic activity of the H:TiO₂.

Role of Visible Light with H:TiO₂. Figure 5 shows TA spectra of H:TiO₂ recorded following both the UV (355 nm) and visible light (575 nm, 2.2 eV) excitation at -0.6 V. In this experiment, the 575 nm laser light has been employed because this wavelength showed the highest IPCE in the visible region in the previous report.¹⁷ The intensity of the laser has been adjusted so that the number of photons absorbed is equivalent to that in the 355 nm experiment. Despite H:TiO₂ absorbing light effectively at this wavelength (Supporting Information Figure S2), we observe no long-lived photohole or photoelectron signals following visible light excitation, in line with previously very low reported IPCE yields at $\lambda > 400$ nm, indicating that any electron–hole pairs that are generated are rapidly recombining. Oxygen vacancies in rutile TiO₂ are localized at 0.75 and 1.2 eV below the conduction band edge,¹⁹

Figure 5. TA spectra recorded at the time scales indicated after UV (355 nm, $70 \mu\text{J cm}^{-2}$, black traces) and visible light (575 nm, $250 \mu\text{J cm}^{-2}$, red traces) excitation of H:TiO₂ in 1 M NaOH_(aq) at -0.6 V, 0.33 Hz laser repetition rate.

and charge carriers generated following photoexcitation to and from the E₁₀ and E₂₀ states (Scheme 1) have been proposed to be inactive as a result of their decreased energy and mobility. Here, our mechanistic study of the factors controlling the very high STH for the oxygen-deficient rutile TiO₂ nanowire arrays provides strong evidence to support the hypothesis that the improved electrical properties of H:TiO₂ enables efficient charge separation under an applied bias.¹⁷ The TA experiments demonstrate that near complete suppression of electron–hole recombination can be achieved at only -0.6 V vs Ag/AgCl on H:TiO₂ following UV excitation. We also rule out a significant change in surface kinetics being an important factor behind the improved IPCE. Given that recent improvements in STH have also been achieved with a wider range of oxygen-deficient photoelectrodes, including α -Fe₂O₃ and WO₃,¹⁸ it is apparent that the introduction of V_o for improved charge separation yields is a common design rule, making it probable that a similar mechanism of enhancement is also occurring in these materials, and further experiments to explore this hypothesis are now underway.

4. CONCLUSIONS

In light of the increased interest in hydrogen-treated TiO₂ for a range of applications, including photocatalysis, DSSC, and supercapacitors,¹⁸ it is essential that an improved understanding of the fundamental mechanisms occurring is achieved. Here, our mechanistic study of the factors controlling the very high STH for the oxygen-deficient rutile TiO₂ nanowire arrays provides strong evidence to support the hypothesis that the improved electrical properties of H:TiO₂ enables efficient charge separation under an applied bias.¹⁷ The TA experiments demonstrate that near complete suppression of electron–hole recombination can be achieved at only -0.6 V vs Ag/AgCl on H:TiO₂ following UV excitation. We also rule out a significant change in surface kinetics being an important factor behind the improved IPCE. Given that recent improvements in STH have also been achieved with a wider range of oxygen-deficient photoelectrodes, including α -Fe₂O₃ and WO₃,¹⁸ it is apparent that the introduction of V_o for improved charge separation yields is a common design rule, making it probable that a similar mechanism of enhancement is also occurring in these materials, and further experiments to explore this hypothesis are now underway.

(46) Details are given in the SI. The absolute yields do have potentially large errors due to the potential errors associated with the extinction coefficient employed; however, this does not affect our analysis of the trends in photoelectron yields.
