Abstract

The conversion of aryl halides to primary arylamines with a convenient and inexpensive source of ammonia has been a long-standing synthetic challenge. Aqueous ammonia would be the most convenient and least expensive form of ammonia, but such a palladium-catalyzed amination reaction with a high concentration of water faces challenges concerning catalyst stability and

competing hydroxylation, and palladium-catalyzed reactions with this practical reagent are rare. Further, most reactions with ammonia to form primary amines are conducted with *tert*-butoxide base, but reactions with ammonium hydroxide would contain hydroxide as base. Thus, ammonia surrogates, ammonia in organic solvents, and ammonium salts have been used under anhydrous conditions instead with varying levels of selectivity for the primary amine. We report the palladium-catalyzed amination of aryl and heteroaryl chlorides and bromides with aqueous ammonia and a hydroxide base to form the primary arylamine with high selectivity. The palladium catalyst containing a new dialkyl biheteroaryl phosphine ligand (KPhos) suppresses both the formation of aryl alcohol and diarylamine side products. Mechanistic studies with a soluble hydroxide base revealed turnover-limiting reductive elimination of the arylamine and an equilibrium between arylpalladium amido and hydroxo complexes prior to the turnover-limiting step.

Graphical Abstract

INTRODUCTION

The coupling of nitrogen nucleophiles with aryl and heteroaryl halides with a transition-metal catalyst has become one of the most widely used reactions to synthesize arylamines in settings ranging from academic laboratories to agrochemical, pharmaceutical, and materials discovery and process groups.¹ A wide range of nitrogen nucleophiles form C–N bonds with the carbon at the site of C–X bonds (X = halogen or pseudohalogen) by this reaction.² While many reactions are conducted with complex nitrogen nucleophiles, the coupling with ammonia could be used to form arylamines on a large scale as intermediates to many amine, amide, sulfonamide, and heterocyclic end products. In this context, transition-metal-catalyzed C–N coupling with ammonia or its surrogates provides a route that is milder than classical sequences of nitration and reduction to form arylamines.

The synthesis of primary arylamines from aryl halides has been achieved by various research groups, including our own (Figure 1a),³ but these reactions have required toxic ammonia gas, ammonia solutions in organic solvents that are expensive and lose their ammonia over time, or ammonium salts that require excess base and generate an additional equivalent of halide (Figure 1b).⁴ Each process has required a *tert*-butoxide base. Protected or masked ammonia sources, such as benzophenone imine, bis(trimethylsilyl)amide, primary amides, *tert*-butyl carbamate, (di)allylamine, and benzylamine, have been used to form a single

C–N bond with aryl halides, but these reagents require deprotection after the reaction is completed.

These procedures were developed because no palladium system has been reported to catalyze the most preferable reaction: the coupling of aqueous ammonia with aryl halides and a simple hydroxide base (Figure 1c).⁵ Aqueous ammonia would be the ideal source because it is readily available, less expensive than organic solutions of ammonia, and easier to handle and store safely than anhydrous ammonia. However, the palladium-catalyzed amination of aryl halides with aqueous ammonia is difficult to achieve. Such a reaction must confront a series of potential side reactions, including the formation of aryl alcohol and diarylether, instead of the desired primary arylamine, potential catalyst decomposition through intermediate palladium hydroxo compounds,⁶ and the need for hydroxide as base that is rarely used for palladium-catalyzed aminations. Although several copper-catalyzed C–N bond-forming reactions occur with aqueous ammonia, the scope of aryl halide coupling partners is largely limited to aryl iodides and bromides, the reactions require high temperatures, and catalyst loadings are high, usually between 5 and 10 mol %.⁷ The narrow scope of aryl halide electrophiles and higher loadings of catalysts make the development of a more general and efficient amination method necessary.

We report the palladium-catalyzed amination of aryl and heteroaryl halides with aqueous ammonia and potassium hydroxide base enabled by the development of a new ligand (KPhos) based on a bipyrazole backbone (Figure 1d). The bipyrazole ligand suppresses formation of phenol, and appropriate substituents on the backbone and at phosphorus lead to the highest observed selectivities for formation of monoaryl- vs diarylamine products with a broad scope of aryl and heteroaryl halides. Mechanistic investigations, including kinetic analyses of the initial rates, show that reductive elimination of the arylamine is turnover-limiting and that an equilibrium between arylpalladium(II) amido and arylpalladium(II) hydroxo complexes occurs before this turnover-limiting step.

RESULTS AND DISCUSSION

Reaction Development.

At the outset of our study to develop the selective monoarylation of ammonium hydroxide, we evaluated phosphine ligands with the G3 palladacyclic dimer (Figure 2a). Reactions with the catalyst generated from representative dialkyl arylphosphines showed that 1-chloro-4-fluorobenzene **1a** and aqueous ammonia form the desired aniline **2a** as a major product, but with side products comprising the corresponding diarylamine (**Ar₂NH**) from coupling of the product and aryl alcohol (**ArOH**) from coupling of the aryl halide with hydroxide. The biaryl substituent on phosphorus affected the selectivity for the formation of the phenol side product. Reactions with BrettPhos derivatives, which contain a sterically hindered biphenyl substituent, formed **ArOH** as the major side product,^{3g} whereas reactions conducted with *t*BuBippyPhos as ligand, which contains a bipyrazole backbone, formed no observable **ArOH**.^{3f,8}

With the result that the catalysts containing a bipyrazole ligand afford high selectivity for amination with ammonia over hydroxylation with water, we sought to further increase the

formation of the desired monoarylamine by suppressing the formation of the diarylamine side product. The reaction with the parent BippyPhos formed **Ar₂NH** as the major side product, generating a 2.9:1 ratio of **ArNH₂** to **Ar₂NH**. Bulkier alkyl substituents on the phosphorus of BippyPhos led to a slight improvement in the selectivity to form **2a** over **Ar₂NH** with AdBippyPhos giving a 5.8:1 ratio of **ArNH₂** to **Ar₂NH**.

To design an AdBippyPhos ligand that would lead to higher selectivity for the primary amine,⁹ we installed a methyl group on the C4 position adjacent to the C–P bond (Figure 2b). We followed the hypothesis that arylpalladium(II) complexes in the selectivity-determining step can adopt tetra- or tricoordinate isomers¹⁰ and proposed that the latter complex more readily coordinates the primary arylamine to provide the diarylamine side product. In this case, a new ligand with the methyl group in place of H could disfavor the tricoordinate complex, leading to a higher selectivity for the formation of primary arylamine. Furthermore, the methyl substituent should prevent metalation of the pyrazole C4 position that yields a palladacyclobutene complex, which would be an off-cycle species during the coupling reaction.^{11,12}

The new bipyrazole ligand, 4-methyl AdBippyPhos (KPhos), was generated on a gram scale in up to 70% isolated yield over four steps from a bipyrazole without the need for chromato-graphic purification (Figure 2c). Fomepizole, 1,3-diphenyl-1,3-propanedione, and phenylhydrazine were assembled by a three-step process in one pot to afford the bipyrazole core.¹³ The C5–H bond of the bipyrazole was then lithiated *in situ*, and the resulting bipyrazolyl lithium was quenched with di(1-adamantyl)bromophosphine.¹⁴ Purification of KPhos from the crude mixture was accomplished by the formation of KPhos·HBF₄, followed by filtration and neutralization.

Reactions catalyzed by the G3 palladacyclic dimer and KPhos under the same conditions as those with other dialkyl (bi)arylphosphine ligands occurred with exceptionally high yield and selectivity for the primary amine (Figure 2a). Comparison of the selectivity to that with the nonmethylated analog (AdBippyPhos) showed that the additional methyl group present in KPhos increased the selectivity of monoarylation over diarylation dramatically, from 5.8:1 for AdBippyPhos to 178:1 for KPhos. This increase in selectivity for amination was evaluated further by tracking the progress of amination reactions with KPhos and AdBippyPhos (Figure 2d). Under homogeneous conditions with arylpalladium(II) bromide complex **OA1** or **OA2** as the catalyst and the soluble base TBA(OH), the time courses of the reactions were recorded by ¹⁹F NMR spectroscopy, and the results are shown in Figure 2d. The catalyst containing KPhos reacted with higher turnovers and selectivity for the formation of monoarylamine **2a** over the corresponding diarylamine than did the catalyst containing AdBippyPhos. Although the KPhos-ligated palladium catalyst reacted more slowly than the AdBippyPhos-ligated analog, we used this new ligand for the rest of our studies because the selectivity for monoarylation and the turnover numbers were higher than with AdBippyPhos.¹⁵

To understand the origin of the high selectivity with the KPhos ligand, the geometry of arylpalladium(II) bromide complex **OA1** was determined by single-crystal X-ray diffraction (Figure 3a). The geometry of **OA1** at the palladium atom is distorted square planar

($\angle\text{C26-Pd1-C14} = 168.95^\circ$), with the phosphine ligand coordinated in a bidentate fashion through phosphorus and C4 of the distal pyrazole ring. The distortion of the bond angles results from steric interactions between the adamantyl groups on phosphorus and the aryl group bound to the palladium. As shown in Figure 3b, the distances between one of the hydrogens in the methyl substituent and the hydrogens of the adamantyl groups are 2.156 and 2.124 Å respectively, implying that rotation of the C–P bond of **OA1** to provide the three-coordinate intermediate in Figure 2b is restricted. In addition, the distances between the *ortho*-hydrogens of the aryl group to palladium and the hydrogens of the adamantyl groups (~2.3 Å) are shorter than the 1,3-diaxial distances between adamantyl hydrogens (~2.5 Å, Figure 3c). This feature limits the scope of the amination of *ortho*-substituted aryl halides and is discussed later in this paper.

Scope of Aryl Halides that React with Aqueous Ammonia.

A diverse set of aryl chlorides and bromides undergo catalytic coupling with aqueous ammonia to give aniline products (Table 1). The reactions of aryl halides containing electron-donating *para*-substituents resulted in the formation of primary arylamines **2a–g** in good yields. Electron deficient aryl halides bearing trifluoromethoxy (**2h**), trifluoromethyl (**2i**), acyl (**2j–l**), carbamoyl (**2m**), cyano (**2p**), nitro (**2q**), sulfonyl (**2t**), or sulfamoyl (**2u**) groups also underwent the reaction to furnish the corresponding aniline derivatives. We did not observe defluorinated side products derived from $\text{S}_{\text{N}}\text{Ar}$ processes with aryl chlorides or bromides containing an aryl fluoride. Aminojulolidine product **2g** was synthesized on 3 mmol scale from the corresponding aryl bromide, demonstrating the high activity of the palladium catalyst derived from KPhos and Pd-G3 dimer in >1.0 mmol scale reactions.

Aryl halides derived from carbonyl derivatives, such as alkyl aryl ketones, a diaryl ketone, and an *N,N*-disubstituted benzamide, converted to the corresponding primary arylamines (**2j–m**) in good yields without side reactions, such as hydration, hydrolysis, or condensation. However, methyl and *tert*-butyl 4-chlorobenzoates underwent saponification under the reaction conditions, yielding the corresponding 4-amino- and 4-chloro-benzoic acids. An aryl chloride bearing a secondary benzylic alcohol underwent the catalytic amination, providing **2n** without the formation of aryl alkyl ether or 4-aminoacetophenone that would arise from reaction of an arylpalladium(II) alkoxo complex. It is remarkable that 4-chloroaniline, which possesses a primary arylamine moiety, afforded 1,4-phenylenediamine **2o** as the sole product, underscoring the high selectivity for monoarylation. Reactions involving functional groups on the aryl halide that have been detrimental to previously reported palladium catalyst systems gave the corresponding anilines in good yields (**2p–s**). *Meta*-substituted aryl halides and 2-chloronaphthalene participated in the amination reaction to afford primary arylamines **2l** and **2v–y**.

The reactions of 1-chloronaphthalene or aryl chlorides possessing *ortho*-substituents proceeded to lower conversion under standard reaction conditions than those lacking *ortho*-substituents, presumably due to the steric demand of the KPhos ligand from the increased size of the adamantyl substituents at phosphorus and the *ortho*-substituent of aryl halides caused by the methyl group on the ligand, as illustrated in the ORTEP diagram of **OA1** (Figure 3c). However, reactions of such *ortho*-substituted aryl chlorides with

aqueous ammonia conducted with AdBippyPhos in place of KPhos as the ligand formed the corresponding primary arylamines in good yields (**2z–aa**) with high selectivity for monoarylation that results from the steric properties of the substrate.

A wide range of heteroaryl chlorides and bromides also reacted to afford primary arylamines. Aryl halides containing 5-membered heterocycles such as 1,3-benzodioxole, indole, indazole, pyrrole, benzothiazole, and benzothiophene provided the corresponding products in good yields (**2ab–ah**). In addition, various aminopyridines (**2ai–ak**), quinolines (**2al–ao**), and quinoxaline (**2ap**) formed under the reaction conditions. The selectivity between the formation of mono- and diarylamine consistently exceeded 20:1 under the reaction conditions for all substrates included in Table 1 by the analysis of the crude reaction mixture by ¹H NMR spectroscopy. While the vast majority of substrates tested reacted to form the arylamine product, a few examples of substrates that decomposed or were unreactive are provided in the Supporting Information.

We also investigated the effect of the ratio of ligand to catalyst and Pd(0) source on the yield of primary arylamine. The reaction to form **2ae** with a 1:1 ratio of KPhos to **Pd-G3** dimer instead of the standard 2:1 ratio formed **2ae** in 83% isolated yield. Moreover, product **2ae** was isolated in quantitative yield when 0.5 mol % Pd₂(dba)₃ was used instead of 0.5 mol % Pd-G3 dimer. These results demonstrate the high activity of the catalyst system generated *in situ* from KPhos and a Pd(0) source.

Investigation of the Reaction Mechanism.

The major phosphine-ligated palladium species during initial rate measurements was determined by ¹⁹F and ³¹P NMR spectroscopy to be the KPhos-ligated arylpalladium(II) hydroxo complex [(KPhos)Pd(Ar)(OH)] (**Pd-(Ar)OH**, Ar = 4-fluorophenyl) under conditions of the kinetic studies with the soluble base (Figure 4). This species was independently generated by combining (KPhos)Pd(4-F-C₆H₄)Cl (**OA3**) and TBA(OH)·30H₂O in the presence of excess 1-chloro-4-fluorobenzene (see Supporting Information). We were unable to isolate **Pd-(Ar)OH** because it reacts to form the corresponding phenol and biaryl products in the absence of ammonia, and attempts to generate **Pd-(Ar)OH** from **OA3** in the absence of the added aryl halide led to nonspecific decomposition and formation of palladium black. The resting state of the catalytic reaction with KOH as base is more complex than that with TBA(OH)·30H₂O. We propose an arylpalladium complex lacking a phosphine ligand is the major species, but the lack of reactivity without ligand shows that the small amount of ligated palladium is the active catalyst (see Supporting Information).¹⁶

To reveal the effects of the atypical, monophasic, organic-aqueous solvent, and hydroxide base and the effect of the new structure of the phosphine on the mechanism of this process, we analyzed initial rates of the reactions depicted in Figure 5a with varied concentrations of the reagents, catalysts, and aniline product, and we monitored the evolution of the palladium catalyst by NMR spectroscopy. The initial rates were measured by ¹⁹F NMR spectroscopy with TBA(OH) base instead of KOH, so that the reaction is homogeneous, and with **OA1** as the catalyst instead of **Pd-G3**, to minimize the induction period leading to the active catalyst.

Kinetic measurements on the reaction with TBA(OH)·30H₂O as base showed that the reaction with KPhos is zeroth-order in the concentrations of aryl chloride, added ligand, base, and added product aniline (Figure 5b).¹⁷ The reaction was first-order in the Pd/KPhos catalyst. Measurements of initial rates with varied concentrations of TBA(OH)·30H₂O or aqueous ammonia without maintaining a constant [H₂O] led to a partial negative order in the concentration of TBA(OH)·30H₂O and to partial positive and negative orders in ammonia at lower and higher concentrations, respectively. These results implied that the amount of water affects the rate, and qualitative studies showed that additional water inhibits the reaction.¹⁸ Thus, we also measured the initial rates with varied concentrations of TBA(OH)·30H₂O or aqueous ammonia at a constant concentration of water. Under these conditions, the initial rates as a function of ammonia concentration were first-order in the concentrations of ammonia up to 0.31 M, which is the concentration of the synthetic studies.^{19,20}

The zeroth-order dependence of the initial rate on the concentration of ligand for reactions with TBA(OH)·30H₂O suggests that the displacement by ammonia is effectively irreversible during these rate measurements, but the accumulation of primary amine selectively at long reaction times implies that a small concentration of phosphine-ligated species catalyzes the amination once the system reaches steady state. Consistent with this assertion, the reaction of **1a** and aqueous ammonia with KOH as base catalyzed by a 1:1 ratio of KPhos/OA1 converted 43% of **1a** to the corresponding monoarylamine **2a** at 90 min, but the reaction catalyzed by a 3:1 ratio of KPhos/OA1 quantitatively converted **1a** to **2a** after the same 90 min reaction time.

To determine if the proton transfer step could be rate limiting, the kinetic isotope effect was measured for reactions with the combination of NH₄·OH and KOH and the combination of ND₄·OD and KOD. The two reactions in parallel under the standard conditions gave a KIE of 1.03 ± 0.16 (Scheme 1). This small value indicates that the proton transfer step is not turnover-limiting. However, this value is consistent with a potential equilibrium between Pd-(Ar)OH and the arylpalladium(II) amido complex [(KPhos)Pd(Ar)-(NH₂)] (Pd-(Ar)NH₂) prior to turnover-limiting reductive elimination, particularly because of the similarity in $\nu_{\text{N-H}}$ and $\nu_{\text{O-H}}$ values.

To gain information on whether reductive elimination could be rate limiting, a linear free energy relationship between the initial rates of amination and *para*-substituents on the aryl chloride was investigated (Figure 5c).²¹ A Hammett plot of the initial rate versus σ_p was nonlinear with $R^2 = 0.77$. A Swain–Lupton plot with σ_p values created by varying the field and resonance contributions of the substituents was linear ($R^2 = 0.97$) with the optimized field and resonance parameters of $\sigma_p = 0.37F + 0.63R^-$.²² The positive ρ value (+2.48) of the optimized Swain–Lupton plot and larger resonance than the field effect is consistent with values from prior studies varying substituents on the palladium-bound aryl group on reductive eliminations to form carbon–nitrogen bonds and, thereby, further supports turnover-limiting reductive elimination. Thus, our kinetic data are consistent with turnover-limiting reductive elimination of the primary arylamine from the parent arylpalladium(II) amido complex generated by the reversible reaction of ammonia with the arylpalladium hydroxo resting state.

To understand the origin of selectivity for the formation of aniline, we conducted density functional theory (DFT) calculations of putative reaction intermediates. However, the reaction conditions that include hydrated dioxane as solvent with dissolved NH_3 , varying ionicity from dissolved KOH and KCl, and need for explicit binding of solvent to the K^+ and hydrogen bonding to the OH and NH_2 ligands and anions, precluded accurate absolute energies. Yet, our calculations did offer some insight into the experimental selectivity.

The calculations were conducted with dioxane and water as solvents using the SMD model to assess differences in energies resulting from differences in the bulk solvent dielectric constants. These calculations were consistent with our experimental finding that **Pd-(Ar')OH** (with $\text{Ar}' = \text{Ph}$) is the resting state of the catalyst and that reaction of this species with ammonia to generate the reactive complex **Pd-(Ar')NH₂** lies uphill (by approximately 4.3 kcal/mol in dioxane and 6.2 kcal/mol in water). These thermodynamic differences in energy corroborate the observation of **Pd-(Ar)OH** as the resting state and account for the lack of observation of **Pd-(Ar)NH₂** prior to turnover-limiting reductive elimination.

The computed barriers to reductive elimination to form the C–N bond in the aniline product ($G_{\text{Aniline}}^\ddagger$) from **Pd-(Ar')NH₂** without any explicit hydrogen bonding of the medium to the amido group were 10.8 kcal/mol in dioxane and 10.9 kcal/mol in water. The combination of these barriers and the 4.3 or 6.2 kcal/mol endothermicity for formation of **Pd-(Ar')NH₂** from the resting state are lower than the values that would correspond to the experimentally observed initial rates for formation of 4-fluoroaniline of 9.3×10^{-5} M/s at 73 °C ($G^\ddagger = \text{ca. } 27$ kcal/mol). However, this computed barrier is lower in free energy than that computed for the formation of the C–O bond in the corresponding phenol by approximately 1.8 kcal/mol in dioxane. These relative energies of the transition states are consistent with the high selectivity for formation of aniline over the phenol.

Finally, the computed free energy of the arylpalladium(II) anilido complex **Pd-(Ar')NHPH** and free ammonia was approximately 7.6 kcal/mol lower than that of the **Pd-(Ar')NH₂** complex and free aniline. In addition, the computed barrier to reductive elimination to form diarylamine from **Pd-(Ar')NHPH** was only about 12 kcal/mol, suggesting that the diarylamine product would readily form under the reaction conditions if the hydroxo or parent amido complex were to react with aniline to form the arylpalladium(II) anilido complex in the catalytic system. Because diarylamine is less than 1% of the product, we hypothesize that the barrier to formation of the arylpalladium(II) anilido complex is kinetically inaccessible from either of these two complexes. Consistent with this assertion and the assumption that the exchange of the hydroxo ligand with an arylamido ligand would be preceded by binding of aniline, the computed free energy for binding of aniline to **Pd-(Ar')OH** is 5 kcal/mol higher than binding of ammonia to the free hydroxo complex **Pd-(Ar')OH** (see Supporting Information for further discussion on the interpretation and limitations of computational methods).

The kinetic and spectroscopic studies are all consistent with the proposed catalytic cycle for the palladium-catalyzed amination of aryl chlorides with aqueous ammonia and a hydroxide base depicted in Figure 5d. The observation of the first-order dependence

on the concentration of the palladium catalyst and the zeroth-order dependence on the concentration of aryl chloride, excess ligand, and base without the product inhibition supports turnover-limiting reductive elimination of the primary arylamine. The positive slope ($\rho = +2.48$) of the linear free energy relationship with the optimized Swain–Lupton parameters is further consistent with the proposed mechanism. The inhibitory effects of water on the initial rate, the first-order dependence on lower concentration of ammonia, and the KIE of 1.03 ± 0.16 imply that the arylpalladium(II) amido complex equilibrates with an arylpalladium(II) hydroxo complex and that reductive elimination of aniline is turnover-limiting. These conclusions are consistent with the arylpalladium(II) hydroxo complex being the sole or major resting state of the catalyst depending on the concentration of ammonia.

The lack of effect of added aniline on the rate or selectivity for monoarylamine product, together with DFT calculations indicating that reductive elimination to form the diarylamine product would occur with a barrier lower than that for reductive elimination to form the monoarylamine product, suggests that arylpalladium(II) anilido complexes **Pd-(Ar)-NHPH** do not form in the catalytic system.

This mechanism can be compared to that of a prior system with anhydrous ammonia and dimethoxyethane (DME) or dioxane solvent, NaOtBu as base, and the large, chelating bisphosphine ligand CyPFtBu.^{3a,c,23} The resting state and origin of selectivity of the two systems are clearly distinct and result from the difference in the reaction medium and ligand. Studies on this prior system showed that the arylpalladium(II) amido complex was the resting state, implying that reductive elimination of the primary arylamine was also the turnover-limiting step. However, in this prior system with the hindered alkoxide base NaOtBu, the resting state contained the Pd–N bond to an amido ligand instead of the Pd–O bond to the alkoxo or hydroxo ligand. For the prior system, reductive elimination of aniline was computed to be faster than reductive elimination of primary arylamine from the parent amido complex, so the selectivity to form the primary arylamine resulted from the thermodynamically favored formation of the parent amido complex over the anilido complex due to the steric properties of the bisphosphine. In our current system, the selectivity for primary amine over secondary amine appears to result from the kinetic selectivity for the formation of the parent amido complex. The selectivity for formation of arylamine over phenol must result from the low barrier to reductive elimination that forms the C–N bond, considering that **Pd(Ar)NH₂** is less thermodynamically stable than the hydroxo complex **Pd(Ar)OH** and that the hydroxo complex accumulates in the catalytic system.

CONCLUSIONS

We have developed a catalyst for highly selective and broadly applicable palladium-catalyzed amination of aryl chlorides and bromides with aqueous ammonia and a hydroxide base. The selective formation of primary arylamines was achieved by developing KPhos, a ligand that contains a methyl substituent on the AdBippyPhos ligand. This small modification to C4 of the bipyrazole adjacent to the C–P bond dramatically improved the selectivity for monoarylation over diarylation, and the palladium catalyst containing bipyrazole ligands are selective for amination over hydroxylation with aqueous ammonia. The reaction occurred with a broad range of aryl halides to provide the primary arylamines

with at least 20:1 selectivity for the formation of the monoarylamine over the diarylamine. Mechanistic investigations under the reaction conditions with a soluble hydroxide base or KOH base have demonstrated that reductive elimination from the arylpalladium(II) amido complex, which is in equilibrium with the resting arylpalladium(II) hydroxo complex, is turnover-limiting. Studies exploring the applicability of the KPhos ligand for other catalytic cross-coupling reactions, in which nucleophiles may be delivered in aqueous solution and a hydroxide base may be used, are being conducted in our laboratory.

- (14). Bipyrazolyl lithium did not undergo phosphinylation reaction to provide KPhos when commercially available di(1-adamantyl) chlorophosphine was used.
- (15). We did not observe any traces of palladacyclopentene complexes in ³¹P NMR spectra during and after the reactions with KPhos.
- (16). We were unable to determine the major phosphine-ligated palladium complex in the reactions with AdBippyPhos and AdBrettPhos as ligand in place of KPhos.
- (17). We assessed qualitatively the effect of added aniline on the rate and selectivity of the reactions with AdBrettPhos and AdBippyPhos as ligand. When 1 equiv. of exogeneous aniline was added to the reaction of AdBrettPhos, the rate of consumption of aryl chloride was indistinguishable from that without added aniline and the ratio of primary to secondary amine decreased to 1:1.36. When exogeneous aniline was added to the reaction of AdBippyPhos, the rate was higher but the diarylamine became the major product with a ratio of 1:12.7. See Supporting Information for details.
- (18). For details, see Supporting Information.
- (19). At higher concentrations, the rate saturated, and the curve of rate vs [NH₃] fit the values $V_{\max} = 6.8 \times 10^{-5} \text{ M}\cdot\text{s}^{-1}$, $K_M = 1.22 \text{ M}$. For details, see Supporting Information.
- (20). Kinetic studies under the standard reaction conditions with KOH did not provide consistent results due to the heterogeneity of the reaction. For the preliminary studies including the quantitative ICP-MS analysis of the palladium in the aqueous phase, see Supporting Information for details.

Table 1.

Scope of Aryl Halides for the Amination with Aqueous Ammonia^a

^a Standard reaction conditions: Aryl halide (1.00 mmol), Pd-precatalyst (5.00 μ mol), KPhos (20.0 μ mol), aq NH₃ (3.00 mmol), and KOH (3.00 mmol) in 1,4-dioxane (10.0 mL) at 100 °C for 24 h.

^b Isolated yields.

^c Ratio was determined by ¹H NMR spectroscopy of the crude mixture.

^d Isolated as *N*-Boc protected amine.

^e Pd-precatalyst (10.0 μ mol) and KPhos (40.0 μ mol) were used.

^f 1.5 equiv KOH was used. ^gPd-precatalyst (15.0 μ mol) and KPhos (60.0 μ mol) were used.

^h AdBippyPhos was used instead of KPhos. Five equiv aq NH₃ was used.

ⁱ Pd-precatalyst (25.0 μ mol) and KPhos (100 μ mol) were used.

^j 1.2 equiv aq NH₃ was used.

^k 2,6-Diaminopyridine was formed in 18% yield. ^lReactions for 48 h.
